Decreased intravascular volume	Orthostatic hypotension, dehydration
Sensitivity to hypokalemia	Arrhythmia, muscle weakness
Decreased renal and hepatic function	Drug accumulation
Polypharmacy	Drug interaction
Central nervous system changes	Depression, confusion

even greater protective effects in diabetic than nondiabetic persons,[24] [32] including those with nephropathy.[169]

HYPERTENSIVE PATIENTS WITH IMPOTENCE.

Erectile dysfunction is common in hypertensive patients, even more so in those who are also diabetic.[170] The problem may be exacerbated by diuretic therapy, even in appropriately low doses.[100] Fortunately, sildenafil usually returns erectile ability, but caution is advised with antihypertensive drugs.[171] The potential for hypotension, well recognized with concomitant nitrate therapy, may also appear with other vasodilators, although to a lesser degree.

HYPERTENSION WITH CONGESTIVE HEART FAILURE.

Cardiac output may fall so markedly in hypertensive patients who are in heart failure with systolic dysfunction that their blood pressure is reduced, obscuring the degree of hypertension; often, however, the DBP is raised by intense vasoconstriction while the systolic pressure falls as a result of the reduced stroke volume. Lowering the blood pressure may, by itself, relieve the heart failure. Chronic unloading has been most efficiently accomplished with ACE inhibitors, and beta blockers have been shown to further reduce morbidity and mortality in ACE inhibitor-treated patients in heart failure.[172] Caution is needed for those elderly hypertensive patients with diastolic dysfunction related to marked left ventricular hypertrophy, because unloaders may worsen their status, whereas beta blockers or calcium antagonists may be beneficial.

As noted in Chapter 28 , left ventricular hypertrophy is frequently found by echocardiography, even in patients with mild hypertension. All antihypertensive drugs except direct vasodilators have been shown to regress left ventricular hypertrophy and regression may continue for as long as 5 years of treatment.[173]

HYPERTENSION WITH ISCHEMIC HEART DISEASE.

The coexistence of ischemic heart disease makes antihypertensive therapy even more essential, because relief of the hypertension may ameliorate the coronary disease. Beta blockers and calcium antagonists are particularly useful if angina or arrhythmias are present. Caution is needed to avoid decreased coronary perfusion that may be responsible for the J curve seen in several trials[32] (see p. 975).

The often markedly high levels of blood pressure during the early phase of an acute myocardial infarction may reflect sympathetic nervous hyperreactivity to pain. Antihypertensive drugs that do not decrease cardiac output may be cautiously utilized in the immediate postinfarction period, whereas beta blockers[174] and ACE inhibitors[175] have been shown to provide long-term benefit.

THERAPY FOR HYPERTENSIVE CRISES

When DBP exceeds 140 mm Hg, rapidly progressive damage to the arterial vasculature is demonstrable experimentally, and a surge of cerebral blood flow may rapidly lead to encephalopathy (p. 966). If such high pressures persist or if there are any signs of encephalopathy, the pressures should be lowered using parenteral agents in those patients considered to be in immediate danger or with oral agents in those who are alert and in no other acute distress.

A number of drugs for this purpose are currently available (Table 29-12) . If diastolic pressure exceeds 140 mm Hg and the patient has any complications, such as an aortic dissection, a constant infusion of nitroprusside is most effective and almost always lowers the pressure to the desired level. Constant monitoring with an intraarterial line is mandatory because a slightly excessive dose may lower the pressure abruptly to levels that induce shock. The potency and rapidity of action of nitroprusside have made it the treatment of choice for life-threatening hypertension. However, nitroprusside acts as a venous and arteriolar dilator, so that venous return and cardiac output are lowered and intracranial pressures may increase. Therefore, other parenteral agents are being more widely used. These include labetalol and the calcium antagonist nicardipine.[165]

With any of these agents, intravenous furosemide is often needed to lower the blood pressure further and prevent retention of salt and water. Diuretics should not be given if volume depletion is initially present.

For patients in less immediate danger, oral therapy may be used. Almost every drug has been used and most will, with repeated doses, reduce high pressures. The prior preference for liquid nifedipine by mouth or sublingually has been deflated because of occasional ischemic complications from too rapid reduction in blood pressure.[137] Oral doses of other short-acting formulations may be used, including furosemide, propranolol, captopril, or felodipine. A safer course for any patients, particularly if their current high pressures are simply a reflection of stopping previously effective oral medication and they are asymptomatic, is simply to restart that medication and monitor their response

TABLE 29-12 -- PARENTERAL DRUGS FOR TREATMENT OF HYPERTENSIVE EMERGENCY (IN ORDER OF RAPIDITY OF ACTION)

DRUG	DOSAGE	ONSET OF ACTION	ADVERSE EFFECTS
Vasodilators			
Nitroprusside (Nipride, Nitropress)	0.25-10 mug/kg/min as IV infusion	Instantaneous	Nausea, vomiting, muscle twitching, sweating, thiocyanate intoxication
Nitroglycerin	5-100 mug/min as IV infusion	2-5 min	Tachycardia, flushing, headache, vomiting, methemoglobinemia
Nicardipine (Cardene)	5-15 mg/hr IV	5-10 min	Tachycardia, headache, flushing, local phlebitis
Hydralazine (Apresoline)	10-20 mg IV 10-50 mg IM	10-20 min 20-30 min	Tachycardia, flushing, headache, vomiting, aggravation of angina
Enalapril (Vasotec IV)	1.25-5 mg q 6 hr	15 min	Precipitous fall in blood pressure in high renin states; response variable
Fenoldopam (Corlopam)	0.1-0.3 mug/kg/min	<5 min	Tachycardia, headache, nausea, flushing
Adrenergic inhibitors			
Phentolamine (Regitine)	5-15 mg IV	1-2 min	Tachycardia, flushing
Esmolol (Brevibloc)	500 mug/kg/min for 4 min, then 150-300 mug/kg/min IV	1-2 min	Hypotension

Labetalol (Normodyne, Trandate)	20-80 mg IV bolus every 10 min 2 mg/min IV infusion	5-10 min	Vomiting, scalp tingling, burning in throat, postural hypotension, dizziness, nausea

closely. If their nonadherence to therapy was caused by side effects, appropriate changes should be made.

Most centers are seeing fewer patients in hypertensive crisis, presumably because more patients are diagnosed and treated before the disease enters this malignant course. The continued successful treatment of many more hypertensive persons will prevent the more frequent long-range cardiovascular complications of hypertension.

Chapter 30 - The Vascular Biology of Atherosclerosis

PETER LIBBY

A remarkable evolution in concepts concerning the pathogenesis of atherosclerosis occurred in the 20th century. This disease has a venerable history, having left traces in the arteries of Egyptian mummies.[1] Apparently uncommon in antiquity, atherosclerosis became epidemic as populations increasingly survived early mortality caused by infectious diseases and as many societies adopted dietary habits that may promote atherosclerosis.

At the end of the 19th century, the first edition of Osler's *Textbook of Medicine* articulated a rather fatalistic view of atheroma as an inevitable degenerative process that affected arteries, which were structures viewed by many of his contemporaries as mere conduits: "In the make-up of the machine bad material was used in the tubing."[2] Indeed, until very recently internists and cardiologists generally viewed arteries as inanimate tubes rather than living, dynamic tissue. Over 100 years ago, Virchow recognized the participation of cells in atherogenesis. A controversy raged between Virchow, who viewed atheroma as a proliferative disease,[3] and Rokitansky, who believed that atheroma derived from healing and resorption of thrombi.[4] In the early part of the 20th century, Anitschkow and Chalatow used dietary modulation to produce fatty lesions in the arteries of rabbits and ultimately identified cholesterol as the culprit.[5] These observations, followed by the characterization of human lipoprotein particles at mid century, promoted the concept of insudation of lipids as a cause for atherosclerosis. At the beginning of the new millennium, we have learned enough about atherosclerosis to recognize that elements of all of these pathogenic theories participate in atherogenesis. This chapter summarizes evidence from human studies, animal experimentation, and in vitro work, and highlights a synoptic view of atherogenesis, taking into account advances in vascular biology that have enabled us to achieve a deeper understanding of the process.

Acquaintance with the vascular biology of atherosclerosis should prove useful to the practitioner. Our daily contact with this common disease lulls us into a complacent belief that we understand it better than we actually do. For example, we are just beginning to learn why atherosclerosis affects certain regions of the arterial tree preferentially and why its clinical manifestations occur only at certain times. Atherosclerosis can involve both large and medium-sized arteries diffusely. Postmortem and intravascular ultrasound studies have revealed widespread intimal thickening in patients with atherosclerosis and, indeed, in many asymptomatic human adults.[6] At the same time, atherosclerosis is a focal disease that constricts some areas of affected vessels much more than others. Understanding of the biological basis of the predilection of certain sites to develop atheroma is just beginning to emerge.[7]

Atherosclerosis also displays heterogeneity in time, being a disease with both chronic and acute manifestations. Few human diseases have a longer "incubation" period than atherosclerosis, which begins to affect arteries of many North Americans in the second and third decades of life (Fig. 30-1) .[7] Yet typically, symptoms of atherosclerosis do not occur until several decades later, characteristically occurring even later in women. Despite this indolent time course and prolonged period of clinical inactivity, the dreaded complications of atheroma such as myocardial infarction, unstable angina, or stroke typically occur suddenly.

Another poorly understood aspect of atherogenesis is its role in causing narrowing, or stenosis, of some vessels and ectasia of others. Typically, we fear stenoses in coronary atherosclerosis. However, aneurysm is a common manifestation of this disease in other vessels, including the aorta. Even in the life history of a single atherosclerotic lesion, a phase of ectasia known as positive remodeling, or compensatory enlargement, precedes the formation of stenotic lesions.[8] [9] Contemporary vascular biology is beginning to shed light on some of these apparent contradictions, or paradoxes, in understanding atherosclerosis.

STRUCTURE OF THE NORMAL ARTERY

The Intima

Understanding the pathogenesis of atherosclerosis first requires knowledge of the structure and biology of the normal artery and its indigenous cell types. Normal arteries have a well-developed trilaminar structure (Fig. 30-2) . The innermost layer, the tunica intima, is thin at birth in humans and many nonhuman species. Although often depicted as a monolayer of endothelial cells abutting directly on a basal lamina, the structure of the adult human intima is actually much more complex and heterogeneous. The endothelial cell of the arterial intima constitutes the crucial contact surface with blood. Arterial endothelial cells possess many highly regulated mechanisms of capital importance in vascular homeostasis that often go awry during the pathogenesis of arterial diseases.

Figure 30-1 A schematic life history of an atherosclerotic lesion. In westernized societies, and increasingly in developing countries, atherogenesis begins in early life. Lesion evolution usually occurs slowly over decades, often progressing in a asymptomatic manner or eventually causing stable symptoms related to embarrassment of flow, such as angina pectoris or intermittent claudication. For the first part of the life history of the lesion, growth proceeds abluminally, in an outward direction preserving the lumen (compensatory enlargement or "positive remodeling"). A minority of lesions will produce thrombotic complications, leading to clinical manifestations such as the unstable coronary syndromes, thrombotic stroke, or critical limb ischemia.

Figure 30-2 The structures of normal arteries. *A,* Elastic artery. Note the concentric laminae of elastic tissue that form sandwiches with successive layers of smooth muscle cells. Each level of the elastic arterial tree has a characteristic number of elastic laminae. *B,* Muscular artery. The smooth muscle cells are surrounded by a collagenous matrix but lack the concentric rings of well-organized elastic tissue character istic of the larger arteries.

Figure 30-3 The endothelial thrombotic balance. This diagram depicts the anticoagulant profibrinolytic functions of the endothelial cell *(left)* and certain procoagulant and antifibrinolytic functions *(right).* t-PA=tissue type plasminogen activator; PGI_2 =prostacyclin; PA_i =plasminogen activator inhibitor; vWf= von Willebrand factor.

For example, the endothelial cell provides one of the only surfaces, either natural or synthetic, that can maintain blood in a liquid state during protracted contact (Fig. 30-3). This remarkable blood compatibility derives in part from the expression of heparan sulfate proteoglycan molecules on the surface of the endothelial cell. These molecules, like heparin, serve as a cofactor for antithrombin III, causing a conformational change that allows this inhibitor to bind to and inactivate thrombin. The surface of the endothelial cell also contains thrombomodulin, which binds thrombin molecules and can exert antithrombotic properties by activating proteins S and C. Should a thrombus begin to form, the normal endothelial cell possesses potent fibrinolytic mechanisms associated with its surface. In this regard, the endothelial cell

can produce both tissue and urokinase type plasminogen activators. These enzymes catalyze the activation of plasminogen to form plasmin, a fibrinolytic enzyme. (For a complete discussion of the role of endothelium in hemostasis and fibrinolysis, see Chap. 62.)

The endothelial monolayer rests upon a basement membrane containing nonfibrillar collagen types, such as type IV collagen, laminin, fibronectin, and other extracellular matrix molecules.[10] With aging, human arteries develop a more complex intima containing arterial smooth muscle cells and fibrillar forms of interstitial collagen (types I and III). The smooth muscle cell produces these extracellular matrix constituents of the arterial intima. The presence of a more complex intima, known by pathologists as diffuse intimal thickening, characterizes most adult human arteries. Some locales in the arterial tree tend to develop thicker intimas than other regions, even in the absence of atherosclerosis.[11] For example, the proximal left anterior descending coronary artery often contains an intimal cushion of smooth muscle cells more fully developed than that in typical arteries. (See also Chap. 41.) The diffuse intimal thickening process does not necessarily go hand in hand with lipid accumulation and may occur in individuals without substantial burdens of atheroma. The internal elastic membrane bounds the tunica intima abluminally and serves as the border between the intimal layer and the underlying tunica media.

The Tunica Media

The tunica media lies under the media and internal elastic lamina. The media of elastic arteries such as the aorta have well-developed concentric layers of smooth muscle cells, interleaved with layers of elastin-rich extracellular matrix (see Fig. 30-2 *A*). This structure appears well adapted to the storage of the kinetic energy of left ventricular systole by the walls of great arteries. The lamellar structure also doubtless contributes to the structural integrity of the arterial trunks. The media of smaller muscular arteries usually have a less-stereotyped organization (see Fig. 30-2 *B*). Smooth muscle cells in these smaller arteries generally reside within the surrounding matrix in a more continuous than lamellar array. The smooth muscle cells in normal arteries are generally quiescent from the standpoint of growth control. That is, rates of cell division and cell death are quite low.[12] In the normal artery, a state of homeostasis of extracellular matrix also typically prevails. Because extracellular matrix neither accumulates nor atrophies, rates of matrix synthesis and dissolution must balance each other under normal conditions. The external elastic lamina bounds the tunica media abluminally, forming the border with the adventitial layer.

The Adventitia

The adventitia of arteries has typically received little attention, although appreciation of its potential roles in arterial homeostasis and pathology has recently increased. The adventitia contains collagen fibrils in a looser array than usually encountered in the intima. Vasa vasorum and nerve endings localize in this outermost layer of the arterial wall. The cellular population in the adventitia is more sparse than in other arterial layers. Cells encountered in this layer include fibroblasts and mast cells (see Fig. 30-2) .

INITIATION OF ATHEROSCLEROSIS

Extracellular Lipid Accumulation

The first steps in atherogenesis in humans remain largely conjectural. However, integration of observations of tissues obtained from young humans with the results of experimental studies of atherogenesis in animals provides hints in this regard. On initiation of an atherogenic diet rich in cholesterol and saturated fat, one of the first ultrastructural alterations is an accumulation of small lipoprotein particles in the intima (Fig. 30-4 ,*1*).[13] These lipoprotein particles appear to decorate the proteoglycan of the arterial intima and tend to coalesce into aggregates (Fig. 30-5) .[14] [15] Detailed kinetic studies of labeled lipoprotein particles indi

Figure 30-4 Schematic of the evolution of the atherosclerotic plaque. *1,* Accumulation of lipoprotein particles in the intima. The modification of these lipoproteins is depicted by the darker color. Modifica tions include oxidation and glycation. *2,* Oxidative stress including products found in modified lipopro teins can induce local cytokine elaboration. *3,* The cytokines thus induce increased expression of adhesion molecules for leukocytes that cause their attachment and chemoattractant molecules that direct their migration into the intima. *4,* Blood monocytes, on entering the artery wall in response to chemoattractant cytokines such as monocyte chemoattractant protein 1 (MCP-1), encounter stimuli such as macrophage colony stimulating factor (M-CSF) that can augment their expression of scavenger receptors. *5,* Scavenger receptors mediate the uptake of modified lipoprotein particles and promote the development of foam cells. Macrophage foam cells are a source of mediators such as further cytokines and effector molecules such as hypochlorous acid, superoxide anion (O_2 -), and matrix metalloproteinases. *6,* Smooth muscle cells in the intima divide, and other smooth muscle cells migrate into the intima from the media. *7,* Smooth muscle cells can then divide and elaborate extracellular matrix, promoting extracellular matrix accumulation in the growing atherosclerotic plaque. In this manner, the fatty streak can evolve into a fibrofatty lesion. *8,* In later stages, calcification can occur (not depicted) and fibrosis continues, sometimes accompanied by smooth muscle cell death (including programmed cell death, or apoptosis), yielding a relatively acellular fibrous capsule surrounding a lipid-rich core that may also contain dying or dead cells and their detritus. LDL\m4\low-density lipoprotein; IL-1 = interleukin-1.

Figure 30-5 Scanning electron micrograph of a freeze etch preparation of rabbit aorta that received an intravenous injection of human low-density lipoprotein (LDL). Round LDL particles decorate the strands of proteoglycan found in the subendothelial region of the intima. By binding LDL particles, proteoglycan molecules can retard their traversal of the intima and promote their accumulation. Proteoglycan-associated LDL appears particularly susceptible to oxidative modification. Accumulation of extracellular lipoprotein particles is one of the first morphological changes noted after initiation of an atherogenic diet in experimental animals. (From Nievelstein PF, Fogelman AM, Mottino G, et al: Lipid accumulation in rabbit aortic intima 2 hours after bolus infusion of low density lipoprotein: A deep-etch and immunolocalization study of ultrarapidly frozen tissue. Arterioscler Thromb Vasc Biol 11:1795-1805, 1991.)

cate that a prolonged residence time characterizes sites of early lesion formation in rabbits. [16] [17] The binding of lipoproteins to proteoglycan in the intima captures and retains these particles, accounting for their prolonged residence time.[15] Lipoprotein particles bound to proteoglycan appear to exhibit increased susceptibility to oxidative or other chemical modifications, considered by many to be an important component of the pathogenesis of early atherosclerosis (see Fig. 30-4 ,*2*).[15] [19] [21] Other studies suggest that permeability of the endothelial monolayer increases at sites of lesion predilection to low-density lipoprotein (LDL).[22] Contributors to oxidative stress in the nascent atheroma could include the nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate-dependent oxidases expressed by vascular cells[23] and lipoxygenases expressed by infiltrating leukocytes.[24] In addition to oxidation, aggregation, enzymatic processing due to sphingomyelinase, and glycation (see Chap. 63) can modify LDL in the intima.

Leukocyte Recruitment

The second morphologically definable event in the initiation of atheroma is leukocyte recruitment and accumulation (see Fig. 30-4 ,*3*). The normal endothelial cell generally resists adhesive interactions with leukocytes. Even in inflamed tissues, most recruitment and trafficking of leukocytes occurs in postcapillary venules, not in arteries. However, very early after initiation of hypercholesterolemia, leukocytes adhere to the endothelium and diapedese between endothelial cell junctions to enter the intima, where they begin to accumulate lipids and transform into foam cells (Fig. 30-6) .[25] In addition to the monocyte, T lymphocytes also tend to accumulate in early human and animal atherosclerotic lesions.[26] [27]

The expression of certain leukocyte adhesion molecules on the surface of the endothelial cell regulates the adherence of monocytes and T cells to the endothelium. Two broad categories of leukocyte adhesion molecules exist (Table 30-1) . [28] Members of the immunoglobulin superfamily include structures such as vascular cell adhesion molecule-1 (VCAM-1).[29] [32] This adhesion molecule has particular interest in the context of early atherogenesis because it interacts with an integrin (very late antigen-4 [VLA-4]) characteristically expressed by only those classes of leukocytes that accumulate in nascent atheroma, monocytes, and T cells. Moreover, studies in rabbits and mice have shown expression of VCAM-1 on endothelial cells overlying very early atheromatous lesions.[30] Another member of the immunoglobulin superfamily of leukocyte adhesion molecules is intercellular adhesion molecule-1.[33] [34] This molecule is more promiscuous, both in the types of leukocytes it binds and because of its wide and constitutive expression at low levels by endothelial cells in many parts of the circulation.

Selectins constitute the other broad category of leukocyte adhesion molecules. The prototypical selectin, E-selectin (E for "endothelial," the cell type that selectively expresses this particular family member), probably has little to do with early atherogenesis. E-selectin preferentially recruits polymorphonuclear leukocytes, a cell type seldom found in early atheroma (but an essential protagonist in acute inflammation and host defenses against bacterial pathogens). Moreover, endothelial cells overlying atheroma do not express high levels of this adhesion molecule. Other members of this family, including P-selectin (P for "platelet," the original source of this adhesion molecule), may play a greater role in leukocyte recruitment in atheroma, because endothelial cells overlying human atheroma do express this adhesion molecule.[34] [36] Selectins tend to promote saltatory or rolling locomotion of leukocytes over the endothelium. Adhesion molecules belonging to the immunoglobulin superfamily tend to promote tighter adhesive interactions and immobilization of leukocytes.[28]

Figure 30-6 Electron microscopy of leukocyte interactions with the artery wall in hypercholesterolemic nonhuman primates. *A* and *B,* Scanning electron micrographs that demonstrate the adhesion of mononuclear phagocytes to the intact endothelium 12 days after initiating a hypercholesterolemic diet in rabbits. *C* and *D,* Transmission electron micrographs. Note the abundant interdigitations and intimate association of the monocyte with the endothelium in *C.* In *D,* a monocyte appears to diapedese between two endothelial cells to enter the intima. (From Faggiotto A, Ross R, Harker L: Studies of hypercholesterolemia in the nonhuman primate: I. Changes that lead to fatty streak formation. Arteriosclerosis 4:323-340, 1984.)

Once adherent to the endothelium, leukocytes must receive a signal to penetrate the endothelial and enter the arterial wall (see Figs. 30-4 , *4* and 30-6 *C*). The current concept of directed migration of leukocytes involves the action of protein molecules known as chemoattractant cytokines, or chemokines.[37] Two groups of chemokines have particular interest in recruiting the mononuclear cells characteristic of the early atheroma. One such molecule, known

TABLE 30-1 -- EXAMPLES OF ENDOTHELIAL-LEUKOCYTE ADHESION MOLECULES

NAME	ABBREVIATION	COGNATE LIGAND	LEUKOCYTES BOUND
Vascular cell adhesion molecule-1	VCAM-1	VLA-4 integrin	Monocytes Lymphocytes
Intercellular adhesion molecule-1	ICAM-1	CD11a integrin (LFA-1) CD11b integrin (Mac-1)	Many classes
E-selectin	Formerly ELAM-1	Sialyl-Lewis x	Granulocytes>monocytes>memory T cells
P-selectin	Formerly GMP-140	PSGL-1	Monocytes; lymphocytes; granulocytes
L-selectin		PSGL-1; mucosal vascular addressin (MAdCAM-1)	Expressed on the leukocytes

as monocyte chemoattractant protein-1 (MCP-1), is produced by the endothelium in response to oxidized lipoprotein and other stimuli. Cells intrinsic to the normal artery, including endothelium and smooth muscle, can produce this chemokine when stimulated by inflammatory mediators, as do many other cell types.[38] , [39] MCP-1 selectively promotes the directed migration, or chemotaxis, of monocytes. Studies conducted with genetically modified mice lacking MCP-1 or its receptor CCR-2 have delayed and attenuated atheroma formation when placed on an atherosclerosis-prone, hyperlipidemic genetic background.[40] , [41] Human atherosclerotic lesions express increased levels of MCP-1 compared with uninvolved vessels.[42] Thus, MCP-1 appears causally related to monocyte recruitment during atherogenesis in vivo. Another group of chemoattractant cytokines may heighten lymphocyte accumulation in plaques. Atheromas express a trio of lymphocyte-selective chemokines (interferon-inducible protein 10 [IP-10], interferon-inducible T-cell alpha chemoattractant [I-TAC], monokine induced by interferon-gamma [MIG]).[43] Interferon gamma, a cytokine known to be present in atheromatous plaques, induces the genes encoding this family of T cell chemoattractants.

The Focality of Lesion Formation

The spatial heterogeneity of atherosclerosis has proven challenging to explain in mechanistic terms. Equal concentrations of blood-borne risk factors such as lipoproteins bathe the endothelium throughout the vasculature. It is difficult to envisage how injury due to inhaling cigarette smoke could produce any local rather than global effect on arteries. Yet, atheroma typically form focally, as revealed by studies of morphology, lipid accumulation, and adhesion molecule expression. Some have invoked a multicentric origin hypothesis of atherogenesis, positing that atheromas arise as benign leiomyomas of the artery wall.[44] The monotypia of various molecular markers such as glucose-6-phosphate dehydrogenase isoforms in individual atheroma supports this "monoclonal hypothesis" of atherogenesis.[45] However, the location of sites of lesion predilection at proximal portions of arteries after branch points or bifurcations at flow dividers suggests a hydrodynamic basis for early lesion development. Arteries without many branches (e.g., the internal mammary or radial arteries) tend not to develop atherosclerosis. (See also Chap. 41.)

Two concepts that can help understand how local flow disturbances might render certain foci sites of lesion predilection. Locally disturbed flow could induce alterations that promote the steps of early atherogenesis. Alternatively, the laminar flow that usually prevails at sites that do *not* tend to develop early lesions may elicit antiatherogenic homeostatic mechanisms (atheroprotective functions).[7] The endothelial cell experiences the laminar shear stress of normal flow and the disturbed flow (usually yielding decreased shear stress) at predilected sites. In vitro data suggest that laminar shear stress can augment the expression of genes that may protect against atherosclerosis, including forms of the enzymes superoxide dismutase or nitric oxide synthase.[46] Superoxide dismutase can reduce oxidative stress by catabolizing the reactive and injurious superoxide anion. Endothelial nitric oxide synthase produces the well-known endogenous vasodilator nitric oxide (NO). However, beyond its vasodilating actions,
NO can resist inflammatory activation of endothelial functions such as expression of the adhesion molecule VCAM-1.[47] Nitric oxide appears to exert this antiinflammatory action at the level of gene expression by interfering with the transcriptional regulator nuclear factor kappa B (NFkappaB). Nitric oxide actually increases the production of an intracellular inhibitor (IkappaBalpha) of this important transcription factor.[48] The NFkappaB system regulates numerous genes involved in inflammatory responses in general, and in atherogenesis in particular.[49] These examples show how basic vascular biology is beginning to yield insight into previously obscure yet important aspects of atherogenesis. Future study of the molecular regulation of vascular cell function by mechanical stimuli promises to clarify further the mechanisms of lesion formation at particular sites in the circulation.

Likewise, study of vascular developmental biology may aid understanding of the tendency of certain arteries to develop atherosclerosis at different rates and in different ways. Smooth muscle cells vary in embryological origin in different regions.[50] For example, upper body arteries can recruit smooth muscle from neurectoderm, whereas in the lower body smooth muscle cells derive principally from mesoderm. Coronary artery smooth muscle cells arise from an Anlage known as the proepicardial organ.[51] How this heterogeneity in the origin of smooth muscle cells might impact human atherosclerosis and may help explain some of the poorly understood issues regarding dispersion of atheroma in time and space remains intriguing yet speculative. (See also Chap. 41.)

Intracellular Lipid Accumulation: Foam Cell Formation

The monocyte, once recruited to the arterial intima, can there imbibe lipid and become a foam cell, or lipid-laden macrophage (see Fig. 30-4 ,*5*). Whereas most cells can express the classical cell surface receptor for LDL, that receptor does not mediate foam cell formation. This is evident clinically, because patients lacking functional LDL receptors (familial hypercholesterolemia homozygotes) still develop tendinous xanthomas filled with foamy macrophages. The LDL receptor does not mediate foam cell formation because of its exquisite regulation by cholesterol. As soon as a cell collects enough cholesterol from LDL capture for its metabolic needs, an elegant transcriptional control mechanism quenches expression of the receptor (see also Chap. 31) .

Instead of the classical LDL receptor, various molecules known as "scavenger" receptors appear to mediate the excessive lipid uptake characteristic of foam cell formation.[52] , [53] The longest studied of these receptors belong to the scavenger receptor-A family. These surface molecules bind modified rather than native lipoproteins and apparently participate in their internalization. Atherosclerosis-prone mice with mutations that delete functional scavenger receptor-A have less exuberant fatty lesion formation than those with functional scavenger receptor-A molecules.[54] Other receptors that bind modified lipoprotein and that may participate in foam cell formation include CD36 and macrosialin, the latter exhibiting preferential binding specificity for oxidized forms of LDL (see Table 31-3) .

Once macrophages have taken up residence in the intima and become foam cells, they not infrequently replicate. The factors that trigger macrophage cell division in the atherosclerotic plaque likely include macrophage colony-stimulating factor (M-CSF). This co-mitogen and survival factor for mononuclear phagocytes exists in human and experimental atheromatous lesions. Atherosclerosis-prone mice lacking functional M-CSF have retarded fatty lesion development.[55] , [56] Other candidates for macrophage mitogens or co-mitogens include interleukin-3 and granulocyte-macrophage colony-stimulating factor.

Thus far, the scenario of the evolving atheroma has invoked only leukocytes, principally the macrophage. The precursor lesion, known as the fatty streak, consists mainly of accumulations of such lipid-engorged leukocytes. Fatty streaks may occur in children and in societies less affected by the atherosclerosis pandemic than the developed Western nations. Moreover, in experimental animals, withdrawal of the atherogenic diet or treatment with drugs that lower lipoprotein levels in plasma can reduce the extent of established lesions. Thus, fatty streaks composed primarily of macrophages are likely reversible, at least to some extent.

THE EVOLUTION OF ATHEROMA

Smooth Muscle Cell Migration and Proliferation

Whereas the early events in atheroma initiation involve primarily altered endothelial function and recruitment and accumulation of leukocytes, the subsequent evolution of atheroma into more complex plaques involves smooth muscle cells as well (see Fig. 30-4 ,*6* and *7*).[57] Smooth muscle cells in the normal arterial tunica media differ considerably from those in the intima of an evolving atheroma. Although some smooth muscle cells likely arrive in the arterial intima early in life, others that accumulate in advancing atheroma likely arise from cells that have migrated from the underlying media into the intima.[11] , [57] The chemoattractants for smooth muscle cells likely include molecules such as platelet-derived growth factor (PDGF), a potent smooth muscle cell chemoattractant secreted by activated macrophages and overexpressed in human atherosclerosis.[58] These smooth muscle cells in the atherosclerotic intima can also multiply by cell division. Estimated rates of division of smooth muscle cells in the human atherosclerotic lesion are on the order of less than 1 percent.[59] However, considerable smooth muscle cell accumulation may occur over the decades of lesion evolution.

Smooth muscle cells in the atherosclerotic intima appear to exhibit a less mature phenotype than the quiescent smooth muscle cells in the normal arterial medial layer. Instead of expressing primarily isoforms of smooth muscle myosin characteristic of adult smooth muscle cells, those in the intima have higher levels of the embryonic isoform of smooth muscle myosin.[60] Thus, smooth muscle cells in the intima seem to recapitulate an embryonic phenotype. These intimal smooth muscle cells in atheroma appear morphologically distinct as well. They contain more rough endoplasmic reticulum and fewer contractile fibers than do normal medial smooth muscle cells.

Although replication of smooth muscle cells in the steady state appears indolent in mature human atheroma, bursts of smooth muscle cell replication may occur during the life history of a given atheromatous lesion. For example, and as will be discussed in considerable detail later, episodes of plaque disruption with thrombosis may expose smooth muscle cells to potent mitogens, including the coagulation factor thrombin itself. Thus, accumulation of smooth muscle cells during atherosclerosis and growth of the intima may not occur in a continuous and linear fashion. Rather, "crises" may punctuate the history of an atheroma, during which bursts of smooth muscle replication and/or migration may occur (Fig. 30-7) .

Smooth Muscle Cell Death During Atherogenesis

In addition to smooth muscle cell replication, death of these cells may also participate in complication of the atherosclerotic plaque (see Fig. 30-4 ,*8*). At least some smooth muscle cells in advanced human atheroma exhibit fragmentation of their nuclear DNA characteristic of programmed cell death, or apoptosis.[61] [63] Apoptosis may occur in response to inflammatory cytokines known to be present in the evolving atheroma.[64] In addition to soluble cytokines that may trigger programmed cell death, the T cells in atheroma may participate in eliminating some smooth muscle cells. In particular, certain T cell populations known to accumulate in plaques can express *fas* ligand on their surface. *Fas* ligand can engage *fas* on the surface of smooth muscle cells and, in conjunction with soluble proinflammatory cytokines, lead to death of the smooth muscle cell.[65]

Thus, smooth muscle cell accumulation in the growing atherosclerotic plaque probably results from a tug-of-war between cell replication and cell death. Contemporary cell and molecular biological research has identified candidates

Figure 30-7 The time course of atherosclerosis. Traditional teaching held that atheroma formation followed an inexorably progressive course with age, depicted in the curve in the left panel. Current thinking suggests an alternative model, a step function rather than a monotonically upward course of lesion evolution in time (curve in right panel). According to this latter model, "crises" can punctuate periods of relative quiescence during the life history of a lesion. Such crises might follow an episode of plaque disruption, with mural thrombosis, and healing, yielding a spurt in smooth muscle proliferation and matrix deposition. Intraplaque hemorrhage due to rupture of a friable microvessel might produce a similar scenario. Such episodes might usually be clinically inapparent. Extravascular events such as an intercurrent infection with systemic cytokinemia or endotoxemia could elicit an "echo" at the level of the artery wall, evoking a round of local cytokine gene expression by "professional" inflammatory leukocytes resident in the lesion. The episodic model of plaque progression shown on the right fits human angiographic data better than the continuous function depicted on the left.

for mediating both the replication and attrition of smooth muscle cells, a concept that originated from the careful morphological observations of Virchow almost a century and a half ago.[3] Referring to the smooth muscle cells in the intima, Virchow noted that early atherogenesis involves a "multiplication of their nuclei." However, he recognized that cells in lesions can "hurry on to their own destruction" because of death of smooth muscle cells.

The Arterial Extracellular Matrix

Extracellular matrix rather than cells themselves makes up much of the volume of an advanced atherosclerotic plaque. Thus, extracellular constituents of plaque also require consideration. The major extracellular matrix macromolecules that accumulate in atheromas include interstitial collagens (types I and III) and proteoglycans such as versican, biglycan, aggrecan, and decorin.[10] Elastin fibers may also accumulate in atherosclerotic plaques. The vascular smooth muscle cell produces these matrix molecules in disease, just as it does during development and maintenance of the normal artery (see Fig. 30-4 ,*7*). Stimuli for excessive collagen production by smooth muscle cells include PDGF and transforming growth factor-beta (TGF-beta), both constituents of platelet granules and products of many cell types found in lesions.[66]

Much like the accumulation of smooth muscle cells, extracellular matrix secretion also depends on a balance. In this case, the biosynthesis of the extracellular matrix molecules counters breakdown catalyzed in part by catabolic enzymes known as matrix metalloproteinases (MMPs).[67] , [68] Dissolution of extracellular matrix macromolecules undoubtedly plays a role in migration of smooth muscle cells as they penetrate into the intima from the media through a dense extracellular matrix, traversing the elastin-rich internal elastic lamina. In injured arteries, overexpression of inhibitors of such proteinases (known as tissue inhibitors of metalloproteinases [TIMPs]) can delay smooth muscle accumulation in the intima.[69]

Extracellular matrix dissolution also likely plays a role in arterial remodeling that accompanies lesion growth. During the first part of the life history of an atheromatous lesion, growth of the plaque is outward, in an abluminal direction, rather than inward in a way that would lead to luminal stenosis[8] , [9] (see Fig. 30-1). This outward growth of the intima leads to an increase in caliber of the entire artery. This so-called positive remodeling or compensatory enlargement must involve turnover of extracellular matrix molecules to accommodate the circumferential growth of the artery. Luminal stenosis tends to occur only after the plaque burden exceeds some 40 percent of the cross-sectional area of the artery.[8]

Angiogenesis in Plaques

The smooth muscle cell is not alone in its proliferation and migration within the evolving atherosclerotic plaque. Endothelial migration and replication also occur as plaques develop in microcirculation, characterized by plexuses of newly formed vessels.[70] Such plaque neovessels usually require special stains for visualization. However, histological examination with appropriate markers for endothelial cells reveals a rich neovascularization in evolving plaques. These microvessels likely form in response to angiogenic peptides overexpressed in atheroma. These angiogenesis factors include acidic and basic fibroblast growth factors (human BGFs I and II),[71] vascular endothelial growth factor (VEGF),[72] , [73] and oncostatin M.[74]

These microvessels within plaques probably have considerable functional significance. For example, the abundant microvessels in plaques provide a relatively large surface area for the trafficking of leukocytes, which could include both entry and exit of leukocytes. Indeed, in the advanced human atherosclerotic plaque, microvascular endothelium displays the mononuclear-selective adhesion molecules such as VCAM-1 much more prominently than does the macrovascular endothelium overlying the plaque.[75] The microvascularization of plaques may also allow growth of the plaque overcoming diffusion limitations on oxygen and nutrient supply, in analogy with the concept of tumor angiogenic factors and growth of malignant lesions. Consistent with this view, administration of inhibitors of angiogenesis to mice with experimentally induced atheromas limits lesion expansion.[76] Finally, the plaque microvessels may be friable and prone to rupture like the neovessels in the diabetic retina. Hemorrhage and thrombosis in situ could promote a local round of smooth muscle cell proliferation and matrix accumulation in the area immediately adjacent to the microvascular disruption. This scenario illustrates a special case of one of the "crises" described earlier in the evolution of the atheromatous plaque (see Fig. 30-7) . Attempts to augment myocardial perfusion by enhancing new vessel growth by transfer of angiogenic proteins or their genes might have adverse effects on lesion growth or clinical complications of atheroma by these mechanisms.

Plaque Mineralization

Plaques often develop areas of calcification as they evolve. Indeed, both Virchow and Rokitansky recognized morphological features of bone formation in atherosclerotic plaques in early microscopic descriptions of atherosclerosis.[3] [4] In recent years, understanding of the mechanism of mineralization during evolution of atherosclerotic plaques has advanced.[77] Some subpopulations of smooth muscle cells may foster calcification by enhanced secretion of cytokines such as bone morphogenetic proteins, homologues of TGF-beta. Atheromatous plaques may also contain proteins with gamma carboxylated glutamic acid residues specialized in sequestering calcium and thus promoting mineralization.

COMPLICATIONS OF ATHEROSCLEROSIS

Arterial Stenoses and Their Clinical Implications

The process of initiation and evolution of the atherosclerotic plaque generally takes place over many years, during which the affected person often has no symptoms. After the plaque burden exceeds the capacity of the artery to remodel outward, encroachment on the arterial lumen begins. Eventually the stenoses may progress to a degree that impedes blood flow through the artery. Lesions that produce stenoses of greater than some 60 percent can cause flow limitations under conditions of increased demand. In the coronary tree such obstructive lesions may cause symptoms such as angina pectoris. Thus, the symptomatic phase of atherosclerosis usually occurs many decades after lesion initiation (see Fig. 30-1). The development of chronic stable angina pectoris or intermittent claudication on increased demand is a common presentation of this type of atherosclerotic disease. During this chronic asymptomatic or stable phase of lesion evolution, growth probably occurs discontinuously, with periods of relative quiescence punctuated by episodes of rapid progression (see Fig. 30-7). Human angiographic studies support this discontinuous growth of coronary artery stenoses.[78] [79]

However, in many cases of myocardial infarction no history of prior stable angina heralds the acute event. In some cases, this mode of transition from the chronic stable or asymptomatic phase of coronary atherosclerosis may result from progressive intimal growth and critical narrowing of the vessel due to a high-grade stenosis. Several kinds of clinical observation over the last several years, however, suggest that most myocardial infarctions result not from

critical blockages but from lesions that produce stenoses that do not limit flow. For example, in individuals who have undergone coronary arteriography in the months preceding myocardial infarction, the culprit lesion most often shows less than 50 percent stenosis. In a compilation of four such serial angiographic studies, only approximately 15 percent of acute myocardial infarctions arose from lesions with degrees of stenosis greater than 60 percent on an antecedent angiogram.[80] [81]

Instead of progressive growth of the intimal lesion to a critical stenosis, we now recognize that thrombosis, complicating a not necessarily occlusive plaque, most often causes episodes of unstable angina or acute myocardial infarction. Angiographic studies performed in individuals undergoing thrombolysis support this view. In one such study, almost half of patients undergoing thrombolysis for a first myocardial infarction had an underlying stenosis of less than 50 percent once the acute thrombus was lysed.[82]

It is a misconception, however, that small atheromas cause most myocardial infarction. Indeed, culprit lesions of acute myocardial infarction actually may be sizable. However, they may not produce a critical luminal narrowing because of the phenomenon of compensatory enlargement. Studies using intravascular ultrasonography, a cross-sectional imaging modality, to examine culprit lesions of acute myocardial infarction support this concept[83] (see also Chap. 12) . Of course, critical stenoses do cause myocardial infarctions. In fact, the high-grade stenoses are more likely to cause acute myocardial infarction than nonocclusive lesions.[80] However, because the noncritical stenoses by far outnumber the tight focal lesions in a given coronary tree, the lesser stenoses cause more infarctions even though their individual probability of causing a myocardial infarction is less than that of the high-grade stenoses.

Thrombosis and Atheroma Complication

This evolution in our view of the pathogenesis of the acute coronary syndromes places new emphasis on thrombosis as the critical mechanism of transition from chronic to acute atherosclerosis. In the past decade we have seen considerable progress in our understanding of the mechanisms of coronary thrombosis. We now appreciate that a physical disruption of the atherosclerotic plaque commonly causes acute thrombosis.[68] [80] [84] Two major modes of plaque disruption provoke most coronary thrombi. The first mechanism, accounting for some two thirds of acute myocardial infarctions, involves a fracture of the plaque's fibrous cap (Fig. 30-8 *A*).[80] The second mode involves a superficial erosion of the intima (see Fig. 30-8 *B*), accounting for up to a fourth of acute myocardial infarctions in highly selected referral cases from medical examiners who have studied individuals who succumbed to sudden cardiac death.[85] Superficial erosion appears more frequently in women than in men as a mechanism of coronary sudden death.[86] [87]

Plaque Rupture and Thrombosis

The rupture of the plaque's fibrous cap probably reflects an imbalance between the forces that impinge on the plaque's cap and the mechanical strength of the fibrous cap.[88] Interstitial forms of collagen provide most of the biomechanical resistance to disruption to the fibrous cap. Hence, the metabolism of collagen probably participates in regulating the propensity of a plaque to rupture. Factors that decrease collagen synthesis by smooth muscle cells can impair their ability to repair and maintain the plaque's fibrous cap. For example, the T cell-derived cytokine interferon gamma po

Figure 30-8 Mechanisms of plaque disruption. Advanced atherosclerotic plaques can promote thrombosis by disruption. Fracture of the plaque's protective fibrous cap accounts for three fourths of fatal coronary thromboses. *A,* When the fibrous cap ruptures, blood with its coagulation factors can contact the tissue factor within the plaque, notably associated with plaque macrophages, although also found as acellular particles and on smooth muscle cells. *B,* The remainder of fatal coronary plaque disruptions appear to occur because of a superficial erosion of the endothelial layer exposing the blood and platelets to the subendothelial basement membrane containing collagen platelet activation and thrombosis.

Figure 30-9 A schematic relating extracellular matrix metabolism to intimal inflammation during athero genesis. The lymphocyte can elaborate gamma interferon (IFN-gamma) that inhibits smooth muscle cell collagen production. The lymphocyte can also signal either by elaboration of soluble mediators or by contact activation of macrophages. Other cytokines produced in response to products of oxidized lipoproteins, among other stimuli, can further activate the macrophage. The activated phagocyte can release collagen- degrading matrix metalloproteinases and elastolytic enzymes, including certain nonmetalloenzymes such as cathepsins S and K. These enzymes promote matrix catabolism. Thus, in states characterized by heightened intimal inflammation, the extracellular matrix that confers biomechanical strength to the plaque's fibrous cap is under double attack: decreased synthesis and increased degradation. This results in a weakening and thinning of the fibrous cap, features associated in pathological studies with fatal atheromatous plaque disruptions and thrombosis. TNF-alpha = tumor necrosis factor-alpha; M-CSF = macrophage colony stimulat ing factor; MCP-1 = monocyte chemoattractant protein-1. (After Libby P: The molecular bases of the acute coronary syndromes. Circulation 91:2844-2850, 1995. Copyright 1995, American Heart Association.)

tently inhibits smooth muscle cell collagen synthesis (Fig. 30-9) .[66] On the other hand, as already noted, certain mediators released from degranulating platelets can increase smooth muscle cell collagen synthesis, tending to reinforce the plaque's fibrous structure. Such mediators include TGF-beta and PDGF contained in platelet granules.[66]

In addition to reduced de novo collagen synthesis by smooth muscle cells, increased catabolism of the extracellular matrix macromolecules that comprise the fibrous cap can also contribute to weakening this structure and rendering it susceptible to rupture, and hence thrombosis. The same matrix-degrading enzymes thought to contribute to smooth muscle migration and arterial remodeling may contribute to weakening of the fibrous cap as well (see Fig. 30-9) . [67] [68] , Macrophages in advanced human atheromas overexpress matrix metalloproteinases and elastolytic cathepsins that can break down the collagen and elastin of the arterial extracellular matrix.[89] [91] Thus, the strength of the plaque's fibrous cap is under dynamic regulation, linking the inflammatory response in the intima with the molecular determinants of plaque stability and, hence, the thrombotic complications of atheroma. The thinning of the plaque's fibrous cap, a result of reduced collagen synthesis and increased degradation, probably explains why pathological studies have shown that a thin fibrous cap characterizes atherosclerotic plaques that have ruptured and caused fatal myocardial infarction.[92] [93]

Another feature of the so-called vulnerable atherosclerotic plaque defined by pathological analysis is a relative lack of smooth muscle cells.[94] As explained earlier, inflammatory mediators both soluble and associated with the surface of T lymphocytes can provoke programmed cell death of smooth muscle cells. "Dropout" of smooth muscle cells from regions of local inflammation within plaques probably contributes to the relative lack of smooth muscle cells at places where plaques rupture.[63] Because these cells are the source of the newly synthesized collagen needed to repair and maintain the matrix of the fibrous cap, the lack of smooth muscle

cells may contribute to weakening of the fibrous cap and, hence, the propensity of that plaque to rupture.[68]

A prominent accumulation of macrophages and a large lipid pool is a third microanatomical feature of the so-called vulnerable atherosclerotic plaque.[94] From a strictly biomechanical viewpoint, a large lipid pool can serve to concentrate biomechanical forces on the shoulder regions of plaques, which are common sites of rupture of the fibrous cap.[95] [96] From a metabolic standpoint, the activated macrophage characteristic of the plaque's core region produces the proinflammatory cytokines and the matrix-degrading enzymes thought to regulate aspects of matrix catabolism and smooth muscle cell apoptosis in turn.[97] The success of lipid-lowering therapy in reducing the incidence of acute myocardial infarction or unstable angina in patients at risk may result from a reduced accumulation of lipid and decrease in inflammation. Recent animal studies and monitoring of peripheral markers of inflammation in humans support this concept. (See also Chap. 31.)

Thrombosis Due to Superficial Erosion of Plaques

The foregoing section discusses the pathophysiology of rupture of the plaque's fibrous cap. The pathobiology of superficial erosion is much less well understood. In experimental atherosclerosis in the nonhuman primate areas of endothelial loss and platelet deposition occur in the more advanced plaques (Fig. 30-10) . In humans, superficial erosion appears

more likely to cause fatal acute myocardial infarction in women and in individuals with hypertriglyceridemia and diabetes mellitus.[85] [87] However, the underlying molecular mechanisms remain obscure. Apoptosis of endothelial cells could contribute to desquamation of endothelial cells in areas of superficial erosion. Likewise, matrix metalloproteinases such as certain gelatinases specialized in degrading the nonfibrillar collagen found in the basement membrane (e.g., collagen type IV) might also sever the tetherings of the endothelial cell to the subjacent basal lamina and promote their desquamation.

Most plaque disruptions do not give rise to clinically apparent coronary events. Careful pathoanatomical examination of hearts obtained from individuals who have succumbed to noncardiac death have shown a surprisingly high incidence of focal plaque disruptions with limited mural thrombi. Moreover, hearts fixed immediately after explantation from individuals with severe but chronic stable coronary atherosclerosis and who had undergone transplantation for ischemic cardiomyopathy show similarly evidence for ongoing but asymptomatic plaque disruption.[84] Experimentally, in atherosclerotic nonhuman primates, mural

Figure 30-10 Superficial erosion of experimental atherosclerotic lesions shown by scanning electron microscopy. *A,* In the low-power view, the rent in endothelium is evident. Leukocytes have adhered to the subendothelium, which is beginning to be covered with a carpet of platelets. *B,* The high-power view shows a field selected from the center of *A* that shows the leukocytes and platelets adherent to the subendothelium. (From Faggiotto A, Ross R: Studies of hypercholesterolemia in the nonhuman primate: II. Fatty streak conversion to fibrous plaque. Arteriosclerosis 4:341-356, 1984.)

Figure 30-11 Platelet thrombus complicating a plaque disruption in experimental atherosclerosis. This transmission electron micrograph shows a cross section of macrophage studded with platelets that have clumped to form a microscopic thrombus. (From Faggiotto A, Ross R, Harker L: Studies of hypercholesterolemia in the nonhuman primate: I. Changes that lead to fatty streak formation. Arteriosclerosis 4:323-340, 1984.)

platelet thrombi can complicate plaque erosions without causing arterial occlusion (Fig. 30-11) .[102] Therefore, repetitive cycles of plaque disruption, thrombosis in situ, and healing probably contribute to lesion evolution and plaque growth. Such episodes of thrombosis and healing constitute one type of "crisis" in the history of a plaque that may cause a burst of smooth muscle cell proliferation, migration, and matrix synthesis. The TGF-beta and PDGF released from platelet granules stimulate collagen synthesis by smooth muscle cells.[66] Thrombin, generated at sites of mural thrombosis, potently stimulates smooth muscle cell proliferation.[103] The late stage or "burned out" fibrous and calcific atheroma may represent a late stage of a plaque previously rich in lipid and vulnerable but now rendered fibrous and hypocellular owing to a wound-healing response mediated by the products of thrombosis.

SPECIAL CASES OF ARTERIOSCLEROSIS

Restenosis after Arterial Intervention (See also Chap. 38)

The problem of restenosis after percutaneous arterial intervention represents a special case of arteriosclerosis. After balloon angioplasty, luminal narrowing recurs in approximately one third of cases within 6 months (see also Chap. 38) . Initially, work on the pathophysiology of restenosis after angioplasty focused on smooth muscle proliferation.[104] A good deal of the thinking regarding the pathobiology of restenosis depended on extension to the human situation of the results of withdrawal of an overinflated balloon in a previously normal rat carotid artery. Study of this very well standardized preparation promoted precise understanding of the kinetics of intimal thickening after this type of injury. Furthermore, these studies identified a role for PDGF in stimulating smooth muscle cell migration and basic fibroblast growth factor in triggering smooth muscle cell proliferation in the rat carotid artery after injury.[105] [107] However, the attempts to transfer this information to human restenosis met with considerable frustration. This disparity between the balloon withdrawal injury of animals arteries and human restenosis is not surprising. The substrate of the animal studies was usually a normal rather than atherosclerotic artery, with all the attendant cellular and molecular differences highlighted earlier. Moreover, a high-pressure inflation of an angioplasty balloon only vaguely resembles the overinflated balloon withdrawal injury commonly practiced in rats.

Although smooth muscle cell proliferation appears prominent in the simple experimental models of intimal thickening, observations on human specimens showed relatively low rates of smooth muscle cell proliferation and called into question therapeutic targeting of this process. Moreover, intravascular ultrasound studies in humans, and considerable evidence from animal experimentation, suggested that a substantial proportion of the loss of luminal caliber after balloon angioplasty resulted from a constriction of the vessel from the adventitial side ("negative remodeling").[108] These observations renewed interest in adventitial inflammation with scar formation and wound contraction as a mechanism of arterial constriction after balloon angioplasty.[109] [110]

The widespread introduction of stents has changed the face of the restenosis problem. The process of in-stent stenosis, in contrast to restenosis after balloon angioplasty, depends uniquely on intimal thickening, as opposed to "negative remodeling." The stent provides a firm scaffold that prevents constriction from the adventitia. Histological analyses reveal that a great deal of the volume of the in-stent restenotic lesion is made up of "myxomatous" tissue, comprising occasional stellate smooth muscle cells embedded in a loose and highly hydrated extracellular matrix.

The introduction of stents has reduced the clinical impact of restenosis because of the very effective increase in luminal diameter achieved by this technique. Even if a considerable degree of lumen loss occurs due to intimal thickening, the luminal caliber remains sufficient to alleviate the patient's symptoms because of the excellent dilatation achieved. Currently, radiation treatment, presumably targeting smooth muscle proliferation and matrix synthesis, is under evaluation as a therapeutic approach to limiting in-stent stenosis (see Chap. 38).

Accelerated Arteriosclerosis after Transplantation (See also Chap. 20)

Since the advent of effective immunosuppressive therapy such as cyclosporine, the major limitation to long-term survival

of cardiac allografts is the development of an accelerated form of arterial hyperplastic disease (see also Chap. 20.)

Figure 30-12 Comparison of usual atherosclerosis and transplantation arteriosclerosis. Usual atherosclerosis *(left panel)* characteristically forms an eccentric lesion with a lipid core and fibrous capsule. In contrast, the lesion of transplantation-associated accelerated arteriosclerosis *(right panel)* characteristically has a concentric intimal expansion without a clear central lipid core.

I favor the term *arteriosclerosis* (hardening of the arteries) rather than *atherosclerosis* (gruel-hardening) to describe this process because of the inconstant association with lipids (the "gruel" in atherosclerosis). [111] This form of arterial disease often presents a diagnostic challenge. The patient may not experience typical anginal symptoms due to the interruption of cardiac denervation after transplantation. In addition, graft coronary disease is concentric and diffuse, not only affecting the proximal epicardial coronary vessels but also penetrating smaller intramyocardial branches (Fig. 30-12) . [112] For this reason, the angiogram, well suited to visualize focal and eccentric stenoses, consistently underestimates the degree of transplantation arteriosclerosis.[113]

In most centers, a majority of patients undergoing transplantation have atherosclerotic disease and ischemic cardiomyopathy. However, a sizable minority undergo heart transplantation for idiopathic dilated cardiomyopathy and may have few risk factors for atherosclerosis. Even in the absence of traditional risk factors, this latter group of individuals shares the risk of developing accelerated arteriosclerosis. This observation suggests that the pathophysiology of this form of accelerated arteriosclerosis differs from that of usual atherosclerosis.

The selective involvement of the engrafted vessels with sparing of the host's native arteries suggests that accelerated arteriopathy does not merely result from the immunosuppressive therapy or other systemic factors in the transplantation recipient. Rather, these observations suggest that the immunological differences between the host and the recipient vessels might contribute to the pathogenesis of this disease. Considerable evidence from both human and experimental studies currently supports this viewpoint. Endothelial cells in the transplanted coronary arteries express histocompatibility antigens that can engender an allogeneic immune response from host T cells.[114] The activated T cells can secrete cytokines (e.g., interferon gamma) that can augment histocompatibility gene expression, recruit leukocytes by induction of adhesion molecules, and activate macrophages to produce smooth muscle cell chemoattractants and growth factors. Interruption of interferon gamma signaling can prevent experimental graft coronary disease in mice.[115] This disease appears to occur despite cyclosporine therapy, because this immunosuppressant is relatively ineffective as a suppressor of the endothelial allogeneic response. These observations hold out the hope that combinations of cyclosporine with other immunosuppressive agents that more effectively suppress the endothelial allogeneic response may prove an effective therapy to retard or prevent graft arteriosclerosis.

The data just summarized suggest that graft arteriosclerosis represents an extreme case of immunologically driven arterial hyperplasia (Fig. 30-13) that can happen in the absence of other risk factors.[111] On the other extreme, patients with homozygous familial hypercholesterolemia can develop fatal atherosclerosis in the first decade of life due solely to an elevation in LDL. The vast majority of patients with atherosclerosis fall somewhere between these two extremes. Analysis of usual atherosclerotic lesions shows evidence for a chronic immune response and lipid accumulation. Therefore, by studying the extreme cases, such as transplantation arteriopathy and familial hypercholesterolemia, one can gain insight into elements of the pathophysiology that contribute to the multifactorial form of atherosclerosis that affects the majority of patients.

Figure 30-13 A multifactorial view of the pathogenesis of atherosclerosis. This diagram depicts two extreme cases of atherosclerosis. One *(far left side)* represents accelerated arteriosclerosis that can occur in the transplanted heart in the absence of traditional coronary risk factors. This disease likely represents primarily immune-mediated arterial intimal disease. The other extreme *(far right side)* depicts the case of a child who may succumb to rampant atherosclerosis in the first decade of life due solely to an elevated low density lipoprotein (LDL) caused by a mutation in the LDL receptor (homozygous familial hypercholesterolemia). Between these two extremes lie the vast majority of patients with atherosclerosis, probably involving various mixtures of immune and inflammatory and/or lipoprotein-mediated disease. One can further consider that this diagram extends to a third dimension that would involve other candidate risk factors such as homocysteine, lipoprotein(a), infection, tobacco abuse, and so on.

Aneurysmal Disease (See also Chap. 40)

Atherosclerosis produces not only stenoses but also aneurysmal disease. Why does a single disease process manifest itself in directionally opposite manner, for example, most commonly producing stenoses in the coronary arteries but causing ectasia of the abdominal aorta? In particular, aneurysmal disease characteristically affects the infrarenal abdominal aorta. This region is highly prone to the development of atherosclerosis. Data from the Pathobiological Determinants of Atherosclerosis In Youth Study (PDAY) show that the dorsal surface of the infrarenal abdominal aorta has a particular predilection for development of fatty streaks and raised lesions in Americans younger than age 35 who succumbed for noncardiac reasons.[116] [118] Because of the absence of vasa vasorum the relative lack of blood supply to the tunica media in this portion of the abdominal aorta might explain the regional susceptibility of this portion of the arterial tree to aneurysm formation. In addition, the lumbar lordosis of the biped human may alter the hydrodynamics of blood flow in the distal aorta, yielding flow disturbances that may promote lesion formation.

Histological examination shows considerable distinction between occlusive atherosclerotic disease and aneurysmal disease. In typical coronary artery atherosclerosis, expansion of the intimal lesion produces stenotic lesions. The tunica media underlying the expanded intima is often thinned, but its general structure remains relatively well preserved. In contrast, transmural destruction of the arterial architecture occurs in aneurysmal disease. In particular, the usually well-defined laminar structure of the normal tunica media disappears with loss of the elastic laminae. The medial smooth muscle cells, usually well preserved in typical stenotic lesions, are notable for their paucity in the media of advanced aortic aneurysms.

Study of the pathophysiology that underlies these anatomical pathological findings has proven frustrating. Informative animal models are not available. The human specimens obtainable for analysis generally represent the late stages of this disease. Nonetheless, recent work has

identified several mechanisms that may underlie the peculiar pathology of aneurysmal disease. Widespread destruction of the elastic laminae suggests a role for degradation of elastin, collagen, and other constituents of the arterial extracellular matrix. Many studies have documented overexpression of matrix-degrading proteinases including matrix metalloproteinases in human aortic aneurysm specimens.[119] [121]

Thus, heightened elastolysis may explain the breakdown of the usually ordered structure of the tunica media in this disease. In addition, aortic aneurysms show evidence for considerable inflammation, particularly in the adventitia.[122] The lymphocytes that characteristically abound on the adventitial side of aneurysmal tissue suggest that apoptosis of smooth muscle cells triggered by inflammatory mediators including soluble cytokines and *fas* ligand, elaborated by these inflammatory cells, may contribute to smooth muscle cell destruction, and promote aneurysm formation.[123] Although extracellular matrix degradation and smooth muscle cell death also occur in sites where atherosclerosis causes stenosis, they appear to predominate in regions of aneurysm formation and to affect the tunica media much more extensively, for reasons that remain obscure.

Infection and Atherosclerosis

Recently, interest has increased in the possibility that infections may cause atherosclerosis. A considerable body of seroepidemiological evidence supports a role for certain bacteria, notably *Chlamydia pneumoniae*, and certain viruses, notably *cytomegalovirus* (CMV), in the etiology of atherosclerosis.[124] [125] The seroepidemiological studies have spurred a number of in vivo and in vitro experiments that lend varying degrees of support to this concept. In evaluation of the seroepidemiological evidence, several caveats apply. First, confounding factors should be carefully considered.[126] For example, smokers may have a higher incidence of bronchitis due to *C. pneumoniae*. Therefore, evidence for infection with *C. pneumoniae* may merely serve as a marker for tobacco use, a known risk factor for atherosclerotic events. Additionally, a strong bias favors publication of positive studies as opposed to negative studies. Thus, meta-analyses of seroepidemiological studies may be slanted toward the positive merely because of underreporting of negative studies. Finally, atherosclerosis is a common and virtually ubiquitous disease in developed countries. In most societies, many adults have serological evidence of prior infections with Herpesviridae, such as CMV, and respiratory pathogens, such as *C. pneumoniae*. It is difficult to sort out coincidence from causality when the majority of the population studied has evidence of both infection and atherosclerosis. (See also Chap. 31.)

Although proof that bacteria or viruses can cause atherosclerosis remains elusive, it is quite plausible that infections may potentiate the action of traditional risk factors, such as hypercholesterolemia. Based on the vascular biology of atherosclerosis discussed in this chapter, a number of scenarios might apply. First, cells within the atheroma itself may be a site for infection. For example, macrophages existing in an established atherosclerotic lesion might become infected with *C. pneumoniae*, which could spur their activation and accelerate the inflammatory pathways that are currently believed to operate within the atherosclerotic intima. Specific microbial products such as lipopolysaccharides, heat-shock proteins, or other virulence factors might act locally at the level of the artery wall to potentiate atherosclerosis in infected lesions.[127] [133]

Extravascular infection might also influence the development of atheromatous lesions and provoke their complication. For example, circulating endotoxin or cytokines produced in response to a remote infection can act locally at the level of the artery wall to promote the activation of vascular cells and of leukocytes in preexisting lesions, producing an "echo" at the level of the artery wall of a remote infection.[134] Also, the acute phase response to an infection in a nonvascular site might affect the incidence of thrombotic complications of atherosclerosis by increasing fibrinogen or plasminogen activator inhibitor-1 (PAI-1) or otherwise altering the balance between coagulation and fibrinolysis. Such disturbance in the prevailing prothrombotic, fibrinolytic balance may critically influence whether a given plaque disruption will produce a clinically inapparent transient or nonocclusive thrombus or sustained and occlusive thrombi that could cause an acute coronary event.

Acute infections might also produce hemodynamic alterations that could trigger coronary events. For example, the tachycardia and increased metabolic demands of fever could augment the oxygen requirements of the heart, precipitating ischemia in an otherwise compensated individual. These various scenarios illustrate how infectious processes, either local in the atheroma or extravascular, might aggravate atherogenesis, particularly in preexisting lesions or in concert with traditional risk factors. Currently, a number of well-designed trials are critically testing the hypothesis that treatment with antibiotics can reduce recurrent coronary events in survivors of myocardial infarction. The results of such studies will be forthcoming in the next several years. However, even if these studies were positive, they would not establish a role for a particular infectious agent, nor could they prove that the antibiotic effect of the agents tested, rather than some other action not related to their antimicrobial effect, could produce benefit.

Acknowledgment

This chapter is dedicated to the memory of Dr. Russell Ross, author of the chapter on atherosclerosis in the last three editions of this text. Dr. Ross died unexpectedly in March of 1999 and was thus unable to participate in authoring this chapter, as had been planned.

Chapter 31 - Risk Factors for Atherosclerotic Disease

PAUL M RIDKER
JACQUES GENEST
PETER LIBBY

Cardiovascular disease is the single most common cause of death in the developed world and accounts for almost 1 million fatalities in the United States alone each year. Of these cardiovascular deaths, nearly half result directly from coronary artery disease and another 20 percent from stroke (see Chap. 1) . Given our current understanding of the pathophysiology of atherothrombosis (see Chap. 30) , it is historically surprising that the conceptual basis for considering specific "cardiovascular risk factors" did not formally exist until the initial findings of the Framingham Heart Study began to appear in the early 1960s.[1] [2]

From an epidemiological perspective, a "risk factor" is a characteristic or feature of an individual or population that is present early in life and is associated with an increased risk of developing future disease. The risk factor of interest may be a behavior (e.g., smoking), an inherited trait (e.g., family history), or a laboratory measurement (e.g., cholesterol). For a risk factor to be considered causal, the marker of interest must predate the onset of disease and must have biological plausibility. Most risk factors used in daily practice have demonstrated a consistent graded-response effect and are substantiated by a large series of consistent prospective studies in broad population groups. Several risk factors such as hyperlipidemia and hypertension are modifiable, and trials have demonstrated that lowering these factors reduces vascular risk.

This chapter reviews the epidemiological evidence underlying the conventional atherosclerotic risk factors of hyperlipidemia, smoking, hypertension, insulin resistance and diabetes, physical activity, obesity, and hormone status, as well as general strategies for reducing risk related to these factors. However, it has become increasingly clear that not all coronary events occur in individuals with traditional risk factors and that in some individuals isolated abnormalities of hemostasis and thrombosis appear to play critical roles.[3] In particular, nearly half of all instances of myocardial infarction in the United States occur among individuals without overt hyperlipidemia.[4] Thus, this chapter also reviews in detail a series of novel atherosclerotic risk factors, including homocysteine, fibrinogen, and lipoprotein(a) (Lp[a]), as well as indices of fibrinolytic function (e.g., tissue-type plasminogen activator [t-PA] and plasminogen activator inhibitor 1 [PAI-1]) and markers of inflammation (e.g., high-sensitivity C-reactive protein (hs-CRP). Strategies for reducing coronary risk, often through modification of the factors outlined here, are provided in Chapter 32 and the pharmacotherapy of lipid disorders is dealt with more specifically in Chapter 33 .

Despite recent advances,[5] coronary artery disease will continue to play a major role well into the 21st century[6] (see also Chap. 1) . Thus, risk prediction algorithms such as those developed in the Framingham Heart Study or by the European Consortium[1] will remain important for patient care (see Chap. 32) . However, risk reduction strategies targeted solely at high-risk individuals are not the only viable approach to coronary prevention. For a disease as common as atherosclerosis, population-based strategies can also be highly effective, particularly for primary prevention. To date, population-wide reductions in cigarette consumption, hyperlipidemia, and blood pressure have been reported for the United States.[7] [8] Determining whether similar programs to increase physical activity, reduce the prevalence of hyperinsulinemia, or directly target novel risk factors for atherosclerosis can further reduce coronary heart disease rates presents a major challenge for the future.[8A] [8B] [8C]

DYSLIPIDEMIA

The Lipid Hypothesis (See also Chap. 30)

HISTORICAL CONSIDERATIONS.

The role of cholesterol in the pathogenesis of atherosclerotic heart disease remained controversial until surprisingly recently.[9] Early experiments by Anitschow on cholesterol-fed animals and the later identification of cholesterol as an important constituent of the plaque furnished landmark clues in the case against cholesterol in the pathogenesis of cardiovascular diseases.[10] As early mortality due to communicable diseases subsided, chronic diseases, especially atherosclerosis, became the most important causes of mortality and disability[11] in the latter part of the 20th century (see Chaps. 1 and 32) . The importance of serum (or plasma) cholesterol emerged not only from the large epidemiological studies conducted after World War II but also from a large body of epidemiological data that include the Seven Country Study, the Ni-Hon-San study, the Northwick Park study, and, more recently, the Prospective Cardiovascular Munster (PROCAM) study.[9] [12] Further refinements in analytical methodologies, especially the use of the ultracentrifuge (which allows separation of plasma lipoproteins), provided important data on the relationship between low-density lipoproteins (LDL) and possibly very low-density lipoproteins (VLDL) and coronary artery disease.[13] The role of high-density lipoproteins (HDL) as a protective fraction also emerged.[14] Despite these results, until recently, enthusiasm for treating patients with drugs to lower cholesterol lagged for two reasons: (1) the drugs themselves had undesired effects and (2) little direct evidence actually demonstrated reduced morbidity and mortality.

Data regarding the role of diet in cardiovascular diseases only added to the confusion. The Seven Country Study[15] provided compelling data that plasma cholesterol levels correlated much more with saturated fat intake than with dietary cholesterol. Furthermore, there was a strong and graded relationship between saturated fat intake,

serum cholesterol, and the incidence of coronary heart disease. Dietary cholesterol had a much weaker correlation with coronary heart disease, an often overlooked but important point. Many intervention studies with earlier generations of lipid-lowering drugs showed a reduction of coronary events, but no change in total mortality and a tendency toward increased noncardiovascular deaths (see Chap. 33 for an extensive discussion of clinical trials of lipid lowering). These findings led to a sober reevaluation of the lipid hypothesis. However, recent trials, notably those using hydroxymethylglutaryl coenzyme A (HMG CoA) reductase inhibitors, have established beyond a doubt that lipid-lowering therapy in high-risk or even moderate-risk subjects reduces cardiovascular morbidity and mortality.

We advocate use of the more general term *dyslipoproteinemia* in place of hyperlipidemia to describe disorders of the lipid and lipoprotein transport pathways. Dyslipidemia encompasses disorders that include low HDL but average total plasma cholesterol levels, very commonly encountered in clinical practice. Despite their prevalence, most dyslipoproteinemias have few, if any, symptoms and only rarely cause clinical signs evident on physical examination. Proper recognition and management of dyslipidemia thus requires a working knowledge of elements of lipid metabolism.

The Lipid Transport System

Plasma Lipids

The lipid transport system has evolved to ferry hydrophobic molecules (fat) from sites of synthesis to sites of utilization. Not surprisingly, the proteins (apolipoproteins) that mediate this process are remarkably well conserved throughout evolution. Most apolipoproteins probably derive from an ancestral gene and contain alpha-helical domains with an amphipathic structure allowing the interface between the aqueous environment of plasma and the phospholipid constituents of the lipoprotein.[16] Four major types of lipids circulate in plasma: cholesterol and cholesteryl esters, phospholipids, and triglycerides.

CHOLESTEROL.

This is a polycyclic molecule that is waxy and water insoluble. It is an essential component of mammalian cell membranes and serves as the substrate for synthesis of corticosteroid hormones and bile acids. All cells require cholesterol for their membranes and tightly regulate its production. Most cholesterol in plasma circulates in the form of cholesteryl esters, with a fatty acid moiety linked to its weakly polar hydroxyl group.

TRIGLYCERIDES.

These are composed of glycerol (a 3-carbon alcohol), covalently linked to three fatty acids chains. The fatty acids vary in both chain length and presence of single (monounsaturated) or multiple (polyunsaturated) double bonds. Triglyceride molecules are nonpolar and hydrophobic.

PHOSPHOLIPIDS.

All cellular membranes contain phospholipids and glycerol molecules, with two of its hydroxyl groups esterified with fatty acids of various chain length and saturation. The third carbon is attached to a phosphate group, which is linked to one of four molecules: choline (phosphatidyl choline--or lecithin), ethanolamine (phosphatidylethanolamine), serine (phosphatidyl serine), or inositol (phosphatidylinositol). A related phospholipid, sphingomyelin, is a critical component of the plasma membrane and functions in the formation of membrane microdomains. Phospholipids also participate in signal transduction pathways after hydrolysis by membrane-associated phospholipases.

Lipoproteins

Lipoprotein particles provide water-soluble packages of hydrophobic lipids permitting their transport in blood. Lipoproteins contain an envelope of phospholipids and some free cholesterol, as well as a core of triglycerides or cholesteryl esters (Fig. 31-1). Lipoproteins vary in origin, size, density in an aqueous environment (plasma), lipid, and apolipoprotein content (Fig. 31-2 , Table 31-1) .[17] Ultracentrifugation separates lipoproteins according to their density in plasma (density 1.006 gm/ml). The triglyceride-rich lipoproteins consisting of chylomicrons and VLDL float in the ultracentrifuge (density < 1.006 gm/ml). The rest of the ultracentrifuged plasma contains LDL, HDL and Lp(a). More convenient methods of separation have now replaced ultracentrifugation for many practical purposes.[13] [18]

Apolipoproteins, Receptors, and Processing Proteins

The protein moieties of lipoproteins known as apolipoproteins (Table 31-2) have four major roles: (1) they assemble and secrete the lipoprotein (apo B_{100} and B_{48}); (2) they provide structural integrity to the lipoprotein (apo B, apo E, apo AI, apo AII); (3) they act as co-activators of enzymes (apo AI, CII, CIII) (Table 31-3) ; and (4) they bind or dock to specific receptors and proteins for cellular uptake (apo AI, B_{100} , E). The role of several apolipoproteins (AIV, D, and J) remains incompletely understood.

Identification and characterization of proteins that regulate the synthesis, secretion, and metabolic fate of lipoproteins has allowed crucial understanding of cellular biology and provided targets for drug

Figure 31-1 Structure of lipoproteins. Phospholipids are oriented with their polar head toward the aqueous environment of plasma. Free cholesterol is inserted within the phospholipid layer. The core of the lipoprotein is made up of cholesteryl esters and triglycerides. Apolipoproteins provide structural integrity to the lipoprotein and act as cofactors for enzymes or as ligands for various receptors. (From Grundy SM: Cholesterol and Atherosclerosis: Diagnosis and Treatment. Philadelphia, JB Lippincott, 1990.)

Figure 31-2 Relative size of plasma lipoproteins according to their hydrated density.

development. The discovery of the LDL receptor (LDL-R) constituted a landmark in understanding how cells take up complex molecules by receptor-mediated endocytosis.[19] The level of LDL-R expression depends exquisitely on cellular cholesterol content, decreasing when supplies are sufficient. The discovery of the LDL-R set the stage for molecular characterization of several other lipoprotein receptors. We now recognize several receptors for VLDL that bind to specific epitopes on VLDL but not on LDL.[20] [21] Apo E is the apparent preferred ligand for the LDL receptor-related peptide (LRP), which mediates the uptake of chylomicron remnants and VLDL.[22] LRP interacts with hepatic lipase. In addition, a novel receptor, the lipolysis-stimulated receptor (LSR), is expressed in response to free fatty acids.[23]

Macrophages can express receptors that bind modified (especially oxidized) lipoproteins. Such scavenger receptors mediate the uptake of oxidized LDL into macrophages (see also Chap. 30) .[24] This mechanism contributes to the removal of modified lipoproteins from the arterial intimal layer, where they can provoke an inflammatory reaction. Lipid-laden macrophages may exit the artery wall and become engulfed in the reticuloendothelial system. In contrast to the LDL-R, cellular cholesterol sufficiency does not suppress scavenger receptors. Therefore, macrophages can rapidly become lipid-laden foam cells under conditions of cholesterol excess and form fatty streaks.[25] Endothelial cells can also take up modified lipoproteins through specific receptors such as Lox-1.[26] Receptors for HDL have engendered

TABLE 31-1 -- PLASMA LIPOPROTEIN COMPOSITION

Cubilin	Apo AI receptor	Renal HDL clearance	

considerable debate. Of the receptors that have been postulated, several are strong candidates. The only HDL receptor clearly identified is a protein of the scavenger receptor class B, SR-B1.[27] SR-B1 binds HDL (and LDL and VLDL as well, but with less affinity). Animal data show that SR-B1 mediates the selective uptake of HDL cholesteryl esters in steroidogenic tissues (Fig. 31-3 *A*). Recent work has characterized other putative HDL receptors.[28] For example, cubilin, probably in concert with megalin (both of which are proteins expressed by resorptive epithelial cells), appears to mediate renal clearance of HDL.[28A] [28B]

Physiology of Lipoprotein Transport

The lipid transport system has two predominant roles: (1) the efficient transport of triglycerides from the gut and the liver to sites of utilization or storage (fat tissue or muscle) and (2) the transport of the cholesterol molecule to peripheral tissues, for membrane synthesis, for steroid hormone production, or to the liver for bile acid synthesis (Fig. 31-4) . Lipoproteins also deliver essential fatty acids that the human body must derive from dietary sources.

THE FATE OF DIETARY FAT.

Most dietary fat consists of triglycerides. For an individual consuming 2000 Kcal/day, with 30 percent in the form of fat, this represents approximately 66 gm of triglycerides per day and the intake of cholesterol is approximately 250 mg. On ingestion, fats are emulsified in the bowel by bile salts and form micelles before being hydrolyzed by pancreatic lipases into free fatty acids and monoglycerides or diglycerides. The fatty acids are reassembled into very large lipoproteins, the chylomicron, inside the intestinal cell and then secreted in the portal circulation (see Fig. 31-4 ,*1*).

Chylomicrons contain apo B48, which is the amino-terminal component of apo B100. In the intestine, the apo B gene is modified during transcription into messenger RNA with a substitution of a uracil for a cytosine by an apo B48-editing enzyme. This mechanism, which involves the deamination of cytosine, leads to a termination codon at residue 2153 and a truncated form of apo B.[29] Only intestinal cells contain this apo B-editing complex (apoBec). Chylomicrons rapidly enter the plasma compartment in the postprandial phase. In capillaries of adipose tissue or muscle cells, chylomicrons in the peripheral circulation encounter lipoprotein lipase (LPL), an enzyme attached to heparan sulfate on the luminal side of endothelial cells (see Fig. 31-4 ,*2*).

LPL activity is modulated by apo CII (an activator of LPL) and by apo CIII (an inhibitor). LPL has broad specificity for triglycerides; it cleaves all fatty acyl residues attached to glycerol, generating three molecules of free fatty acid for each molecule of glycerol. The fatty acids are rapidly taken up by muscle cells for energy utilization, a process requiring insulin, or by adipose cells for storage. Fatty acids can also bind to fatty acid-binding proteins and reach the liver, where they will be repackaged in VLDL. Peripheral resistance to insulin may therefore increase the flux of free fatty acids to the liver, with a consequent increase in VLDL secretion and increased apo B particles in plasma. As discussed later, this is one of the consequences of insulin resistance syndrome. The chylomicron remnants contain apo E and are taken up by the liver for degradation and reutilization of its core constituents (see Fig. 31-4 ,*3*).

HEPATIC LIPOPROTEIN SYNTHESIS: AN ALTERNATIVE SOURCE OF FAT FOR ENERGY SUPPLY.

Food is not always available and dietary fat content is not always constant. The body, therefore, must ensure readily available triglyceride molecules for energy

demands. This is done by hepatic secretion of triglyceride-rich VLDL particles that contain apo B100 as their main lipoprotein (see Figs. 31-2 and 31-4 ,*4;* Table 31-1) . Apo B48 lacks the domain recognized by the LDL-R present in apo B100. VLDL particles undergo the same catabolic pathway as chylomicrons by lipoprotein lipase (see Fig. 31-4 ,*2*).

REMODELING OF TRIGLYCERIDE-RICH LIPOPROTEIN: A ROLE IN REVERSE CHOLESTEROL TRANSPORT.

Whether derived from diet or hepatic synthesis, triglyceride-rich lipoproteins undergo hydrolysis by LPL. At this stage, an exchange of proteins and lipids takes place: VLDL particles (and chylomicrons) acquire apo Cs and apo E, in part, from HDL particles. A cholesterol ester transfer protein (CETP) mediates net exchange of VLDL triglycerides for cholesteryl esters from HDL (see Fig. 31-4 ,*6* and *9*). Such bidirectional transfer of constituents between lipoproteins serves several purposes. It allows lipoproteins to acquire specific apolipoproteins that will dictate their metabolic fate. It also allows the transfer of cholesterol from HDL to VLDL remnants so it can be metabolized in the liver. Both of these roles contribute to reverse cholesterol transport, a pathway that can promote export of cholesterol from the vessel wall.

FORMATION OF LDL FROM VLDL

Lipoprotein lipase partly depletes VLDL of triglycerides, and the exchanges just discussed enrich the particles in cholesterol and apo E while they shed several other apolipoproteins (especially the C apolipoproteins). The resultant VLDL remnants are called intermediate-density lipoproteins (IDL) and can be either taken up by the liver by means of its apo E moiety (see Fig. 31-4 ,*3*) or be further delipidated by hepatic lipase to form an LDL particle (see Fig. 31-4 ,*6*). There are at least four receptors for triglyceride-rich lipoproteins: the VLDL receptor, the remnant receptor, the LDL-R (also called the apo B/E receptor), and the LDL-related protein (LRP).[22] A common feature of most hepatic receptors is their recognition of apo E, which mediates uptake of several classes of lipoproteins, including VLDL and IDL. The interaction of apo E with its ligand is complex and involves the "docking" of triglyceride-rich lipoproteins on heparan sulfate proteoglycans (HSPG) before presentation of the ligand to its receptor.[30] LDL particles contain mostly cholesterol and apo B100. Normally, LDL particles contain only 4 to 8 percent of their mass as triglycerides. Under certain circumstances, especially in conditions of elevated levels of triglycerides, LDL particles can be enriched in triglycerides and depleted in core cholesteryl esters, making them smaller and denser.

Cells can either make the cholesterol they require from acetate (a pathway with at least 33 steps) or capture it from LDL particles using the LDL-R (see Fig. 31-3 *A*). The LDL-R localizes in a region of the plasma membrane rich in the protein clathrin (clathrin-coated pits) (see Figs. 31-3 *B* and 31-4,*7*). After binding of LDL to the receptor, clathrin polymerizes and forms an endosome that contains LDL

Figure 31-3 Cellular cholesterol homeostasis in various tissues. *A,* Selective uptake of cholesterol. Examples of steroidogenic tissues include the adrenal cortex and the gonads. *B,* LDL-receptor pathway (hepatic cell). *C,* Cellular cholesterol efflux (peripheral cell). *D,* Adipocyte. ASP = acylation stimulating protein; SER = smooth endoplasmic reticulum; RER = rough endoplasmic reticulum; Lys = lysosome; CERP = cholesterol efflux regulatory protein (product of the ABC 1 gene); HMG CoA Red = hydroxylmethylglutaryl coenzyme A reductase; LDL-R = LDL receptor; Apo = apolipoprotein; ACAT = Acyl coenzyme A: cholesterol acyl transferase.

bound to its receptor, a portion of the plasma membrane, and clathrin. This internalized particle then fuses with a lysosome containing cholesteryl ester hydrolase, which releases free cholesterol and proteinases that degrade apo B. The unbound LDL-R then recycles to the plasma membrane.[19] The disorder familial hypercholesterolemia (FH) results from mutations of the LDL-R gene.

REGULATION OF INTRACELLULAR CHOLESTEROL METABOLISM.

Several mechanisms closely control cellular cholesterol content. Cholesterol synthesis in the smooth endoplasmic reticulum (by means of HMG CoA reductase) and receptor-mediated endocytosis of LDL or selective free cholesterol uptake from LDL are controlled transcriptionally by a factor known as the steroid-responsive element-binding protein (SREBP).[31] Other regulatory mechanisms include cholesterol efflux from plasma membrane to cholesterol acceptor particles (predominantly HDL) and intracellular cholesterol esterification through the enzyme acyl-CoA:cholesteryl acyltransferase (ACAT) (see Fig. 31-3 *B*). The cholesterol content in membranes regulates the amount of ACAT at the protein level. (Humans have two forms of ACAT: ACAT1 probably mediates cellular cholesterol esterification for storage in the cytosolic compartment, whereas ACAT2 appears to mediate cholesterol esterification in the endoplasmic reticular lumen for lipoprotein assembly and secretion.[32]) The cholesterol efflux pathway appears to be regulated through the adenosine triphosphate (ATP) binding cassette 1 (*ABC1*) gene, which produces cholesterol efflux regulatory protein (CERP) (see Fig. 31-3 *C*). [33] [34] [35] In conditions of cellular cholesterol excess, the cell can decrease its input of cholesterol by reducing the de novo synthesis

Figure 31-4 Schematic diagram of the lipid transport system. Apo = apolipoprotein; LPL = lipoprotein lipase; HL = hepatic lipase; CETP = cholesteryl ester transfer protein; LCAT = lecithin cholesterol acyl transferase; FFA = free fatty acids; numbers are keyed to explanations in the text.

of cholesterol and decrease the amount that enters the cell by means of the LDL-R, thus decreasing the amount stored as cholesteryl esters. The cell can also promote the removal of cholesterol by increasing the movement of cholesterol to the plasma membrane for efflux by means of the ATP-1 gene product.[36]

HDL AND REVERSE CHOLESTEROL TRANSPORT.

Plasma levels of HDL-C correlate inversely with the presence of coronary artery disease. Several mechanisms may underlie HDL's atheroprotective effects, including reverse cholesterol transport and limiting lipoprotein oxidation.[37] [38] HDL metabolism is complex and only partly understood.

The components of HDL derive from several sources and undergo metabolism at different sites. Both the intestine and the liver produce the main protein of HDL, apo AI. Apo AI acquires phospholipids from cell membranes and from phospholipids shed during hydrolysis of triglyceride-rich lipoproteins. Because these nascent HDL particles contain little or no cholesterol, they have no central lipophilic core, are discoid, and are not currently measured by standard laboratory tests, although they can mediate reverse cholesterol transport. On reaching a cell membrane, these nascent HDL particles can capture membrane-associated cholesterol and promote the efflux of free cholesterol onto other HDL particles (see Fig. 31-4 ,*8*). The free cholesterol will then be esterified by the plasma enzyme lecithin:cholesterol acyl transferase (LCAT), an enzyme activated by apo AI (see Fig. 31-4 ,*8*). LCAT transfers an acyl chain (a fatty acid) from the R2 position of a phospholipid to the 3 OH residue of cholesterol, resulting in the formation of a cholesteryl ester. Because cholesteryl esters are hydrophobic, they move to the core of the lipoprotein, whereby the HDL particle now assumes a spherical configuration. This particle is an HDL_3 . With further cholesterol esterification, the HDL increases in size to become an HDL_2 , which is more buoyant than an HDL_3 . Cholesterol within HDL particles can be exchanged with triglyceride-rich lipoproteins by means of CETP, which mediates an equimolar exchange of cholesterol from HDL to triglyceride-rich lipoproteins and triglyceride movement from triglyceride-rich lipoproteins onto HDL (see Fig. 31-4 ,*9*). Such triglyceride-enriched HDL particles are denoted HDL_{2b} . Hepatic lipase can hydrolyze triglycerides within these HDL_{2b} , converting them back to HDL_3 particles. One mechanism of reverse cholesterol transport involves the uptake by HDL of cellular cholesterol, its esterification by LCAT, its transport by large HDL particles, and its exchange for one triglyceride molecule from a triglyceride-rich lipoprotein by CETP. The cholesterol molecule, originally on an HDL particle and now on a triglyceride-rich lipoprotein or LDL particle, can then be taken up by hepatic receptors that recognize apo E. Therefore, HDL particles act as a shuttle between tissue cholesterol, triglyceride-rich lipoproteins, and the liver.

Classification of Lipoprotein Disorders

Because time and new knowledge having brought necessary changes, there are several classifications of lipoprotein disorders. The prototypical classification of lipoprotein relied on the measurement of total plasma cholesterol and triglycerides and on analysis of lipoprotein patterns after separation by electrophoresis. This classification recognized elevations of chylomicrons (type I), VLDL or pre-beta lipoproteins (type IV), "broad beta" disease (or type III hyperlipoproteinemia), beta lipoproteins (LDL) (type II), and elevations of both chylomicrons and VLDL (type V). In addition, the combined elevations in pre-beta (VLDL) and beta (LDL) lipoproteins were recognized as type IIb hyperlipoproteinemia. Although it still provides a useful conceptual framework after nearly 40 years, this classification has some drawbacks. It does not include HDL cholesterol nor does it differentiate severe monogenic lipoprotein disorders from the more common polygenic disorders. Subsequently, the World Health Organization, the European Atherosclerosis Society, and, more recently, the National Cholesterol Education Program have classified

lipoprotein disorders on the basis of arbitrary cut-points. Most guidelines specify that lipid profiles should be measured after an overnight fast. However, postprandial dyslipidemia may contribute to coronary risk and is not assessed under these conditions.[39]

A clinically practical approach describes the lipoprotein disorder by the absolute plasma levels of lipids (cholesterol and triglycerides) and lipoprotein cholesterol levels (LDL-C and HDL-C). This biochemical characterization provides a context for the clinical manifestations. For example, a young patient presenting with eruptive xanthomas and a plasma triglyceride level of 11.3 mmol/liter (1000 mg/dl) is likely to have familial hyperchylomicronemia. An obese,

hypertensive middle-aged man with a cholesterol of 6.4 mmol/liter (247 mg/dl), triglycerides of 3.1 mmol/liter (274 mg/dl), a HDL-C level of 0.8 mmol/liter (31 mg/ml), and a calculated LDL of 4.2 mmol/liter (162 mg/dl) is very likely to have the metabolic syndrome with insulin resistance. This finding suggests concomitant clinical disorders such as hypertension and hyperglycemia. Current evidence does not establish that measurement of apolipoproteins AI and B or of LDL particle size adds substantial information to that provided by the conventional lipid profile. Taken as a single measurement, the apo B level provides information on the number of potentially atherogenic particles. Similarly, LDL particle size correlates highly with readily measured plasma HDL-C and triglyceride levels and does not appear to be an independent cardiovascular risk factor.[40] The presence of small, dense LDL particles may be related to features of the "metabolic syndrome," characterized by the presence of abdominal obesity, peripheral insulin resistance, high blood pressure, and a dyslipoproteinemia with elevated plasma triglycerides and reduced HDL-C levels. In some studies, improvement in LDL particle size has correlated with angiographic improvement of coronary artery disease. It remains to be determined whether in addition to LDL particle number reduction, a change in LDL particle size will bring further clinical benefit.

Genetic Lipoprotein Disorders

Knowledge of the genetics of lipoprotein metabolism is rapidly expanding. Monogenic disorders tend to be infrequent or very rare, with the exception of FH. Disorders that appear heritable on careful family study may be difficult to characterize unambiguously because of age, gender, gene-gene, and environmental interactions. Most lipoprotein disorders encountered clinically result from the interaction of increasing age, lack of physical exercise, weight gain, inadequate diet, and genetic makeup of the individual. A useful resource for the identification of genes related to heart disease is the Online Mendelian Inheritance in Man web site, OMIM, from the Johns Hopkins University in Baltimore, Maryland (MIM: #144250:1994). The web site can be accessed at http://www.ncbi.nlm.nih.gov/omim/ (see also Chap. 56) .

For clinical purposes, this discussion will divide genetic lipoprotein disorders into those that affect LDL, Lp(a), remnant lipoproteins, triglyceride-rich lipoproteins (chylomicrons and VLDL), and HDL (Table 31-4) . Within each of these, genetic disorders can cause an excess or a deficiency of a specific class of lipoprotein. The genes involved in these genetic lipoprotein disorders are identified in Table 31-4 .

GENETIC DISORDERS OF LOW-DENSITY LIPOPROTEINS (TYPE II HYPERLIPIDEMIA).

Familial hypercholesterolemia is the most thoroughly studied lipoprotein disorder.[19] Affected subjects present with an elevated LDL-C level greater than the 95th percentile for age and gender. In adulthood, clinical manifestations include corneal arcus, tendinous xanthomas over the extensor tendons (metacarpophalangeal joints, Achilles tendons), and xanthelasmas. The transmission is autosomal codominant, and the prevalence of FH is estimated at approximately 1:500, although this prevalence is higher in populations with founder effects (see Chap. 56) . Men with heterozygous FH usually develop clinical coronary artery disease by the third to fourth decade, whereas it occurs in women 8 to 10 years later. Elevated plasma LDL-C, the presence of a family history of premature coronary artery disease, and the presence of xanthomas establish the diagnosis clinically. Molecular diagnosis is sometimes required. Defects at the LDL-R gene that alter the function of the LDL-R protein and its function cause FH (see Fig. 31-4, *7*) by allowing accumulation of LDL particles

TABLE 31-4 -- GENETIC LIPOPROTEIN DISORDERS

in plasma. There are five classes of LDL-R defects at the cellular level, including lack of RNA synthesis (large LDL-R gene truncations), unstable RNA synthesis, abnormal protein folding and intracellular degradation, recycling defective protein, and decreased binding affinity to its ligands. To date, well over 200 mutations of the LDL-R gene have been identified see http://www.umd.necker.fr and http://www.ud.ac.uk/fh/.[41]

ABNORMAL APOLIPOPROTEIN B.

Mutations within the apo B gene, leading to an abnormal ligand-receptor interaction, can cause a form of FH clinically indistinguishable from FH. This disorder, called familial defective apo B 100 (FDB), results from several mutations at the postulated binding site to the LDL-R (see Fig. 31-4 ,*7*). [42] These consist of apo $B_{Arg3500Gln}$, apo $B_{Arg3500Trp}$, and apo $B_{Arg3531Cys}$. The apo $B_{Arg3500Gln}$ results from a G
A substitution at nucleotide 3500 within exon 26 of the apo B gene. The defective apo B has a reduced affinity (20 to 30 percent of control) for the LDL-R.[43] LDL particles with the defective apo B have a plasma half-life threefold to fourfold longer than normal LDL and may thus undergo oxidative modifications that can enhance their atherogenic potential. Affected subjects usually have elevated LDL-C levels, up to 400 mg/dl (10.4 mmol/liter), but they may also have normal levels. The reasons for the variability of plasma LDL-C levels remain unexplained. The prevalence of FDB is about the same as for FH (1/500). In subjects with the classic presentation of FH, the prevalence of FDB is reported to be 1/50 to 1/20. Mutations within the apo B gene may lead to truncations of the mature apo B_{100} peptide. Many such mutations cause a syndrome of reduced LDL-C and VLDL-C, but with little or no clinical manifestations and no known risk of cardiovascular disease. Truncation of the apo B moiety close to its amino terminus impairs the ability of the truncated apo B moiety to bind lipids, leading to a syndrome similar to abetalipoproteinemia.

ABETALIPOPROTEINEMIA.

Abetalipoproteinemia is a rare recessive lipoprotein disorder of infancy characterized by mental retardation and growth abnormalities. It is caused by a mutation in gene encoding the microsomal triglyceride transfer protein (MTP), which is required for assembly of apo B-containing lipoproteins in the liver and

the intestine. [44] As a result of such mutations, no apo B-containing lipoproteins are found in plasma, with a resulting marked deficiency of fat-soluble vitamins (A, D, E, and K) that circulate in lipoproteins.

PHYTOSTEROLEMIA.

A rare condition of increased intestinal absorption and decreased excretion of plant sterols (sitosterol and campesterol) can mimic clinical features of severe FH, with extensive xanthoma formation and premature atherosclerosis.[45] However, patients with phytosterolemia have normal or reduced plasma cholesterol and triglyceride levels. The diagnosis requires specialized analysis of plasma sterols, revealing an elevation in sitosterol, campesterol, cholestanol, sitostanol, and campestanol. Although the molecular defect remains unknown, positional cloning techniques have localized the defect to chromosome 2p21.[46]

LIPOPROTEIN (a).

Lipoprotein(a)--Lp(a), pronounced "lp little a" to distinguish it from apolipoprotein A--consists of an LDL particle covalently linked to one molecule of apo (a).[47] The apo (a) moiety has a high degree of homology with plasminogen. There are multiple repeats of one of the kringle motifs (kringle IV) within the apo (a) gene, varying in number from 12 to over 40 in each individual. Plasma Lp(a) levels correlate inversely with the number of kringle repeats and, therefore, with the molecular weight of apo (a). Prospective epidemiological studies have yielded controversial data on the association between Lp(a) and coronary artery disease, as discussed in more detail later.

TRIGLYCERIDE-RICH LIPOPROTEINS.

Elevation of plasma triglyceride levels is most often seen in the presence of obesity and of a diet rich in calories, sugars, and saturated fats in diabetic subjects; it is a component of the metabolic syndrome. Severe elevation of plasma triglyceride levels results from genetic disorders of the processing enzymes or apolipoproteins.

FAMILIAL HYPERTRIGLYCERIDEMIA.

Familial hypertriglyceridemia (type IV hyperlipoproteinemia) is not associated with clinical signs such as corneal arcus, xanthoma, and xanthelasmas. Plasma levels of triglycerides and of VLDL-C and VLDL triglycerides are moderately to markedly elevated; the LDL-C is usually low, and the HDL-C is also reduced. The total cholesterol value is normal or elevated, depending on VLDL-C levels. Fasting plasma concentrations of triglycerides are in the range of 2.3 to 5.7 mmol/liter (200-500 mg/dl). After a meal, plasma triglyceride levels may exceed 11.3 mmol/liter (1000 mg/dl). The disorder is found in first-degree relatives, but phenotypic variability is related to gender, age, hormone use (especially estrogens), and diet. Alcohol intake is a potent stimulus for hypertriglyceridemia in these subjects, as is caloric and carbohydrate intake. The relationship with coronary artery disease is not as strong or as consistent as with familial combined hyperlipidemia. Depending on the criteria used, the prevalence of familial hypertriglyceridemia ranges from 1:100 to 1:50. The disorder is highly heterogeneous and likely results from several genes, with a strong environmental influence.[48] Familial glycerolemia, an unrelated chromosome X-linked genetic disorder, may mimic familial hypertriglyceridemia because most measurement techniques for triglycerides use the measurement of glycerol after enzymatic hydrolysis of triglyceride.[49] The diagnosis of familial hyperglycerolemia therefore requires ultracentrifugation of plasma and analysis of glycerol.

The metabolic defect in familial hypertriglyceridemia causes hepatic overproduction of VLDL (see Fig. 31-4 ,*4*); the catabolism (uptake) of VLDL particles may be normal or reduced. Lipolysis by LPL does not appear to be a limiting factor, although the triglyceride load, especially in the postprandial state, may limit processing of VLDL particles. The genetic basis of familial hypertriglyceridemia is unknown, and the candidate gene approach to find the gene(s) involved (apo B, LDL, apo CIII) has been unfruitful. Treatment is based first on lifestyle modifications, including withdrawal of hormones (estrogens and progesterone), limiting alcohol intake, reducing caloric intake, and increasing exercise. The decision to treat this disorder with medications depends on global cardiovascular risk.

TYPE V HYPERLIPIDEMIA

An infrequent disorder characterized by severe elevation in plasma triglyceride levels (both VLDL and chylomicrons) is associated with a fat-rich diet, obesity, and poorly controlled diabetes. Recognized as type V hyperlipidemia, the pathogenesis is multifactorial and results from overproduction of both VLDL and chylomicrons and decreased catabolism of these particles.

FAMILIAL HYPERCHYLOMICRONEMIA

In this rare disorder, also know as type I hyperlipidemia, severe hypertriglyceridemia occurs with elevations in fasting plasma levels of triglycerides greater than 11.3 mmol/liter (>1000 mg/dl). Affected individuals do not necessarily have increased coronary risk, but they do have recurrent bouts of pancreatitis and eruptive xanthomas. Interestingly, severe hypertriglyceridemia may also be associated with xerostomia and xerophthalmia and with abnormalities in behavior. The hyperchylomicronemia results from a markedly reduced or absent LPL activity or, more rarely, by the absence of its activator, apo CII (see Table 31-3 , Fig. 31-4 ,*2*). [50] [51] These deficiencies lead to a lack of hydrolysis of chylomicrons and VLDL and to accumulation of these lipoproteins in plasma, especially in the postprandial phase. Extreme elevations of plasma triglycerides of more than 11.3 mmol/liter (>10,000 mg/dl) can occur. The plasma from a patient with very high triglyceride levels is milky white; and after a specimen stands overnight in a refrigerator, a clear band of chylomicrons appears at its top. The prevalence of mutations at the *LPL* gene locus are relatively frequent in populations with a founder effect (see also Chap. 56) . Multiple mutations at the *LPL* gene locus have been identified, with LPL_{188} , $LPL_{Asn291Ser}$, and LPL_{207} being frequently associated with hyperchylomicronemia. There are at least 60 LPL mutations that cause LPL deficiency.[52] Heterozygotes for the disorder tend to have an increase in fasting plasma triglyceride levels and smaller, denser LDL particles. Many patients with complete LPL deficiency present in childhood with failure to thrive and recurrent bouts of pancreatitis. Consistent with the importance of the role of LPL, mice deficient in this enzyme have a lethal phenotype.[53]

Treatment of acute pancreatitis in patients with familial hyperchylomicronemia consists of intravenous hydration and avoidance of fat in the diet (including in parenteral nutrition). Rarely, plasma filtration may be required. Chronic treatment includes avoidance of alcohol and dietary fats. The use of short-chain fatty acids (which are not incorporated in chylomicrons) can make the diet more palatable.

TYPE III HYPERLIPOPROTEINEMIA

Type III hyperlipoproteinemia, also referred to as dysbetalipoproteinemia or "broad beta disease," is a rare genetic lipoprotein disorder characterized by an accumulation in plasma of remnant lipoprotein particles.[54] Agarose gel electrophoresis of the lipoproteins yields a typical pattern of a broad band between the pre-beta (VLDL) and beta (LDL) lipoproteins, hence its name. Affected individuals clearly have increased cardiovascular risk. Clinical features include tuberous xanthomas and palmar striated xanthomas, which are pathognomonic of the disease. The total plasma cholesterol level is increased, as are triglyceride levels; the HDL-C value is reduced. Remnant lipoproteins (partly catabolized chylomicrons and VLDL) accumulate in plasma and are enriched in cholesterol esters. The defect is due to abnormal apo E that does not bind to hepatic receptors using apo E as a ligand, initially the LDL receptor (see Fig. 31-4 ,*3*). Patients with type III hyperlipoproteinemia have increased ratio of VLDL-C to triglycerides, normally less than 0.7 in mmol/liter (< 0.30 in mg/dl), owing to cholesteryl ester enrichment of remnant particles. The diagnosis includes plasma ultracentrifugation for lipoprotein separation, lipoprotein electrophoresis, and apo E phenotyping or genotyping.

There are three common alleles for apo E: apo E2, E3, and E4. Patients with type III hyperlipoproteinemia have the apo E2/2 phenotype or genotype. The apo E2 allele has markedly decreased binding to the apo B:E (LDL) receptor. Normal populations have a prevalence of the apo E2/2 genotype of 0.7 to 1.0 percent. Type III hyperlipoproteinemia is only seen in approximately 1 percent of subjects bearing the apo E2/2 phenotype. The reasons for the relative rarity of type III dyslipoproteinemia (or low penetrance of the E2/2 genotype) are not fully understood. A second "hit" may enable the full expression of the disorder. Other rare mutations of the apo E gene can also cause type III hyperlipoproteinemia.[55] Apo E-deficient mice currently serve as one useful model for the study of atherosclerosis. Type III dyslipoproteinemia generally responds well to dietary therapy and to correction of other metabolic abnormalities (diabetes, obesity). In some cases it requires

drug therapy, such as with fibric acid derivatives or statins.

FAMILIAL COMBINED HYPERLIPIDEMIA.

One of the most common familial lipoprotein disorders is familial combined hyperlipoproteinemia (FCH). Described initially in survivors of myocardial infarction,[56] FCH has undergone several definitions since its original description. The presence in several members of the same family of elevated total cholesterol and/or triglycerides based on arbitrary cut-points defines FCH. The disorder must be identified in at least one first-degree relative for a diagnosis of FCH. The biochemical abnormalities include the elevation of plasma total and LDL-C (> 90th or 95th percentile), and/or an elevation of plasma triglycerides (> 90th to 95th percentile), a type IIb lipoprotein phenotype, a reduction in HDL-C, and elevation in apo B levels; small, dense LDL particles are frequently seen. Measurement of LDL-C and, in some cases, apo B levels can further characterize this disorder. Because of the lack of a clear-cut clinical or biochemical marker, there is considerable overlap between FCH, familial dyslipidemic hypertension, the insulin-resistance metabolic syndrome, and hyperapobetalipoproteinemia.

There are few clinical features of FCH; corneal arcus, xanthomas, and xanthelasmas occur infrequently. The underlying metabolic disorder appears to be hepatic overproduction of apo B-containing lipoproteins, delayed postprandial triglyceride-rich lipoprotein clearance, and increased flux of free fatty acids (FFA) to the liver. Experimental data have shown that hepatic apo B secretion is substrate driven, the most important substrates being FFA and cholesteryl esters. The increased delivery of FFA to the liver that occurs in states of insulin resistance augments hepatic apo B secretion.

Genetic heterogeneity probably underlies FCH. The prevalence of FCH is reported at approximately 1:50 and accounts for 10 to 20 percent of patients with premature coronary artery disease.[57] FCH has complex genetics. Initially considered to be an autosomal codominant trait, a more complex mode of inheritance may pertain. Phenotypical expression of the disease varies with gender, age, diet, and comorbid states such as obesity and lack of exercise. Initial reports of linkage with the apo AI-CIII-AIV and LPL genes have not been substantiated. A novel locus on chromosome 1 in Finnish families appears promising in the identification of genes related to FCH.[58]

Recent reports of the acylation stimulating protein (ASP) pathway suggests that abnormal peripheral uptake of FFA may underlie some cases of FCH and the insulin-resistance metabolic syndrome (see Fig. 31-3 *D*). ASP regulates FFA uptake by tissues. According to this scheme, increased flux of FFAs to the liver caused by this decreased uptake and utilization at the periphery drives hepatic apo B-containing lipoprotein assembly and secretion.[59]

Abnormalities of HDL Metabolism

Observational studies have consistently linked a reduced plasma level of HDL-C to the development or presence of coronary artery disease. Most cases of reduced HDL-C result secondarily from elevated plasma triglycerides or apo B levels. These abnormalities often cluster with other features of the insulin-resistant metabolic syndrome (see also Chap. 63) . Familial hyperchylomicronemia, familial hypertriglyceridemia, and FCH are all associated with reduced HDL-C levels. Primary forms of low HDL-C, although less common, also are associated with premature coronary artery disease. Close study of these abnormalities has shed new light on the complex metabolism of HDL particles. Genetic disorders can cause either decreased production of HDL or abnormal maturation and increased catabolism of HDL or its primary apoprotein, AI.

Primary defects affecting production of HDL particles consist predominantly in apo AI-CIII-AIV gene defects. There are approximately a dozen reported mutations affecting the structure of apo AI[38] [60] with a marked reduction in HDL-C levels. Not all these defects cause premature cardiovascular disease. Clinical presentations can vary from extensive, atypical xanthomatosis and corneal infiltration of lipids to no manifestations. The treatment of these apo AI gene defects is generally unsuccessful in raising HDL-C levels. Other mutations of apo AI accelerate apo AI catabolism and may not be linked with cardiovascular disease. One such mutation, apo AI_{Milano} (apo $AI_{Arg173Cys}$), may be associated with longevity.[60] Genetic defects in the HDL-processing enzymes give rise to interesting phenotypes. Deficiencies of LCAT, which catalyzes the formation of cholesteryl esters in plasma, cause corneal infiltration of neutral lipids and hematological abnormalities because of abnormal constitution of red blood cell membranes. LCAT deficiency can cause an entity called "fish eye disease" because of the characteristic pattern of corneal infiltration observed in affected individuals.[61]

Patients with absent CETP have very elevated HDL-C levels, enriched in cholesteryl esters.[62] Because CETP facilitates the transfer of HDL cholesteryl esters into triglyceride-rich lipoproteins, a deficiency of this enzyme causes accumulation of cholesteryl esters within HDL particles. Despite the high HDL levels, CETP may not afford protection against coronary artery disease.[63]

A rare disorder of HDL deficiency was first identified in a proband from the island of Tangier in the Chesapeake Bay in the United States. The proband has markedly enlarged yellow tonsils and a near absence of HDL-C. His sister was also affected, and the entity was named Tangier disease.[64] Since then, at least 50 cases have been reported worldwide.[65] The cellular defect in Tangier disease has been identified as a reduced cellular cholesterol efflux in skin fibroblasts from affected subjects.[36] A more common entity, familial HDL deficiency, also results from decreased cellular cholesterol efflux. The genetic defect in Tangier disease and in familial HDL deficiency has been identified as a result of mutations of *ABC1,* which encodes CERP (see Fig. 31-3 *C*). [33] [34] [35]

OTHER CHOLESTEROL TRANSPORT DEFECTS

Niemann-Pick disease type C is a disorder of lysosomal cholesterol transport. Mental retardation and neurological manifestations occur frequently in patients with Niemann-Pick disease type C. The cellular phenotype includes markedly decreased (acid) sphingomyelinase activity, reduced cholesterol esterification, and a cellular cholesterol transport defect involving the Golgi apparatus. Unlike Tangier disease/familial HDL deficiency, the cellular defect in Niemann-Pick disease type C appears therefore to be proximal to the transport of cholesterol to the plasma membrane. The gene for Niemann-Pick disease type C (*NPC1*), mapped to the chromosomal location 18q21, encodes a 1278-amino acid protein of as yet unknown function. The *NPC1* gene product shares homology with the morphogen receptor "patched" and the SREBP cleavage activating protein (SCAP).[66] [67]

Secondary Causes of Dyslipidemia

Several clinical disorders secondarily alter lipoprotein status (Table 31-5) .[68]

HORMONAL CAUSES OF DYSLIPIDEMIA (see also Chap. 64) .

Hypothyroidism often causes elevated levels of LDL-C, triglycerides, or both. An elevated thyroid stimulating hormone (TSH) value is key to the diagnosis, and the lipoprotein abnormalities often revert to normal once the thyroid status is corrected. Rarely, hypothyroidism may uncover a genetic lipoprotein disorder such as type III hyperlipidemia. A TSH level should be obtained on all patients with unexplained elevations in triglyceride levels.

Estrogens can increase plasma triglyceride levels and HDL-C owing to increases in hepatic VLDL secretion and apo AI secretion (see also Chap. 58) . In postmenopausal women, estrogens may reduce LDL-C by 0-15%. Rarely, pregnancy, in a woman with LPL deficiency, severely increases plasma triglyceride levels. Such cases present a serious threat to mother and child and must be referred to specialized centers. Male sex hormones and anabolic steroids may increase hepatic lipase activity and have been used in the treatment of hypertriglyceridemia in men. Growth hormone use reduces LDL-C and increases

METABOLIC CAUSES OF DYSLIPIDEMIA.

The constellation of metabolic abnormalities seen in the insulin-resistance metabolic syndrome currently constitutes the most frequent secondary cause of dyslipidemia (see also Chap. 63) . The findings of increased visceral fat (abdominal obesity), elevated blood pressure, and peripheral insulin resistance frequently cluster with increased plasma triglyceride levels and a reduced HDL-C level. Elevated plasma triglyceride levels and a low HDL-C value often accompany overt diabetes, especially type II adult-onset diabetes.[69] These abnormalities have prognostic implications in patients with type II diabetes. Although type II diabetics often do not have marked elevations in LDL-C levels, those with coronary artery disease benefit from lipid-lowering therapy with a statin.[70] One recent angiographic trial (Flu Diabetes Atherosclerosis Intervention Study [DAIS]) showed slowed progression in diabetic patients treated with a fibric acid derivative, fenofibrate, which lowered triglyceride levels and raised HDL-C levels.[71] Poorly controlled diabetes, obesity, and moderate to severe hyperglycemia can yield severe hypertriglyceridemia with chylomicronemia and increased VLDL. Subjects with juvenile diabetes may also present with severe hypertriglyceridemia when the diabetes is poorly controlled. Familial lipodystrophy (complete or partial) may be associated with increased VLDL secretion. In glycogen storage disorders, elevated plasma triglyceride levels are often encountered.

RENAL DISORDERS AND DYSLIPIDEMIA.

Glomerulonephritis or protein-losing nephropathies can cause a marked increase in secretion of hepatic lipoproteins, elevating LDL-C levels, which may approach the levels seen in FH.[72] [73] In contrast, patients with chronic renal failure have a pattern of hypertriglyceridemia with reduced HDL-C. Patients on hemodialysis or chronic ambulatory peritoneal dialysis also exhibit similar lipoprotein changes. Many hemodialysis patients have elevations in Lp(a). After organ transplantation, the immunosuppressive regimen (glucocorticoids and systemic immunosuppressive drugs) can contribute to elevation in triglyceride levels and a reduced HDL-C level.

LIVER DISEASE AND DYSLIPIDEMIA.

Obstructive liver disease, especially primary biliary cirrhosis, may lead to the formation of an abnormal lipoprotein termed lipoprotein-x (Lp-x).[74] This type of lipoprotein is found in LCAT deficiency and consists of an LDL-like particle, but with a marked reduction in cholesteryl esters. Extensive xanthoma formation on the face and palmar areas can result from accumulation of Lp-x.

DYSLIPIDEMIA ASSOCIATED WITH THERAPY FOR ACQUIRED IMMUNODEFICIENCY SYNDROME (See alsoChap. 68) .

The introduction of inhibitors of a major protease of human immunodeficiency virus-1 (HIV-1) has markedly prolonged the survival of infected individuals.[75] Although HIV protease inhibitors have emerged as the cornerstone of highly active antiretroviral therapy (HAART), these agents can cause secondary dyslipidemia.[76] [77] Treatment with HAART results in increased levels of triglyceride-rich lipoprotein particles, such as VLDL.[78] In addition to the rise in total cholesterol and triglyceride levels, HAART causes a concomitant decrease in HDL levels. Reminiscent of the diabetic dyslipidemic syndrome, these changes in lipoprotein profile go hand in hand with hyperinsulinemia and insulin resistance.[79] Moreover, there is a striking and prevalent association of HAART with lipodystrophy. Specifically, patients receiving HAART often have a decreased peripheral accumulation of adipose tissue, while central adiposity increases. Although in most instances, the lipodystrophy is mild to moderate, more striking alterations can occur, including development of a "buffalo hump."[80] Potential clinical consequences of HAART-associated dyslipidemia may include premature atherosclerosis and pancreatitis due to hypertriglyceridemia.

The mechanism of HAART-associated dyslipidemia remains obscure. Recent metabolic studies have shown maintained levels of LPL but decreased levels of hepatic lipase, and evidence for increased production of VLDL. Interestingly, the HIV protease active site has homology to two receptors involved in lipid metabolism.[81] The lipoprotein-related receptor has regions of approximately 60 percent sequence similarity with the HIV protease. Thus, HIV protease inhibitors might interfere with the function of this remnant receptor involved in clearing certain triglyceride-rich lipoprotein particles. The HIV protease also shares sequence similarity with regions of a retinoid binding protein known as CRAB1.[81] [82] By binding to CRAB1, HIV protease inhibitors might interfere with the synthesis of *cis*-9-retinoic acid. The retinoic acids are, of course, classic ligands for the retinoid X receptor (RXR). When liganded RXR pairs with another nuclear receptor, PPAR gamma, and forms an active transcription factor known to control adipocyte differentiation and insulin sensitivity.[83] Thus, the HIV protease inhibitors might interfere with the activation of these transcription factors and contribute to the lipodystrophy and insulin resistance.

Management.

The treatment of HAART-associated dyslipidemia requires control of triglyceride levels, particularly in patients with or at risk for pancreatitis. Treatment with fibric acid derivatives may help in this regard. No systematic information exists yet regarding the effect of lipid-lowering therapy on outcomes in individuals with HAART-associated dyslipidemia. However, reports of management of this dyslipidemia with fibric acid derivatives alone, or in combination with HMG CoA reductase inhibitors, have appeared. Because agents included in HAART can interfere with the metabolism of concomitantly administered drugs due to changes in cytochrome p450 isoform function, addition of lipid-lowering agents to HAART requires careful consideration of potential drug interactions.

OTHER MEDICATIONS.

Several medications commonly cause alterations in lipoproteins.[68] Thiazide diuretics can increase plasma triglyceride levels. Beta blockers, especially the non-$beta_1$-selective agents, increase triglycerides and lower HDL-C levels. Retinoic acid can increase triglyceride levels, sometimes dramatically. Corticosteroids and immunosuppressive agents can increase plasma triglyceride levels.[84] Because transplantation recipients and patients on this class of drugs generally have an increase in cardiovascular risk, this secondary hyperlipidemia may warrant treatment (see also Chap. 30) .[85] Estrogens can increase plasma HDL-C significantly and may also increase triglyceride concentrations, sometimes substantially.[86] [87]

LIFESTYLE FACTORS CONTRIBUTING TO DYSLIPIDEMIA.

Factors contributing to obesity, such as an imbalance between caloric intake and energy expenditure, lack of physical activity, and a diet rich in saturated fats and refined sugars, contribute in large part to the lipid and lipoprotein lipid levels within a population. In clinical practice, many dyslipoproteinemias other than the genetic

forms mentioned earlier share important environmental components. Lifestyle changes (diet, exercise, reduction of abdominal obesity) remain the cornerstone of the treatment of most dyslipidemias. (See later and Chap. 32 for more information on exercise and obesity.) The effects of marked alterations in lifestyle,[88] reduction in dietary fats, especially saturated fats,[89] and exercise[90] can improve cardiovascular prognosis (see later and Chap. 32) . Translating these findings into practice, however, has been more difficult. For instance, dietary manipulations as performed in a physician's office lead to relatively small reductions in plasma lipid and lipoprotein cholesterol levels.[91]

Management of Lipoprotein Disorders

GENERAL APPROACHES.

Cardiologists must consider evaluation and management of dyslipidemia an integral part of their practice. Two major questions confront the

clinician treating patients with lipoprotein disorders. First, are there secondary causes for the dyslipoproteinemia and, second, what risk does this disorder have for the patient's health? The clinical evaluation should include a thorough history, including a complete family history that may reveal clues about genetic etiology and genetic susceptibility to cardiovascular disease. Most patients with dyslipoproteinemias have few symptoms. Exceptions include those with severe hypertriglyceridemia, who may present with acute pancreatitis, and those with familial lipoprotein disorders, who have cutaneous manifestations (xanthomas, xanthelasmas). Other risk factors should be sought (cigarette smoking, diabetes) along with secondary causes (diet, physical activity, alcohol intake). Concomitant medication use should be investigated; alternative treatments should be considered that avoid alterations in the lipid profile.

The physical examination should include a search for xanthomas (in extensor tendons, including hands, elbows, knees, Achilles' tendons, as well as palmar xanthomas), the presence of xanthelasmas, and corneal arcus, corneal opacifications. Blood pressure, waist circumference, weight, and height should be recorded, and signs of vascular compromise must be carefully examined. A complete cardiovascular examination must be performed. The diagnosis of lipoprotein disorders is based on laboratory measurements (Table 31-6) . The lipid profile generally suffices for most lipoprotein disorders, and specialized laboratories can refine the diagnosis and provide expertise for extreme cases. Additional tests (e.g., measurement of apolipoprotein levels or of LDL particle size) increase cost and may not add predictive power beyond that of the lipid profile but may help to refine the diagnosis. It is advisable to stop all lipid-lowering therapy for 1 month before measuring a lipid profile during initial evaluation. Except in severe hypertriglyceridemia, this measure is unlikely to have a clinically significant adverse effect.

At least two lipid profiles should be obtained, and secondary causes should be explored by the measurement of TSH and glucose. Baseline aspartate and alanine aminotransferases and creatinine kinase should also be obtained in candidates for drug therapy.

SPECIFIC TREATMENTS.

The therapeutic options consist of lifestyle modifications, treatment of secondary causes, if possible, diet, and medications (see Chap. 33 for an extensive discussion of pharmacotherapy). The diet should have three objectives: (1) it should allow the patient to reach and maintain ideal body weight; (2) it should provide a well-balanced diet with fruits, vegetables, and grains; and (3) it should be restricted in saturated fats and refined carbohydrates.[92] The services of a professional dietitian prove valuable in this regard. Present guidelines recommend a diet in which protein intake represents 15 to 20 percent of calories and fats represent 25 to 30 percent (with only one third from saturated fats).[93] The remaining calories are obtained from carbohydrates. Cholesterol intake is limited to less than 300 mg/d. Alcohol is not part of the current recommendations, although up to 2 drinks per day is associated with decreased cardiovascular deaths in many studies. The high cost of alcohol-related accidents, violent deaths, and liver disease, however, makes any recommendation regarding alcohol intake controversial. Although dietary changes should be instituted in most if not all the clinically relevant dyslipidemias, medications should be concomitantly initiated along with dietary changes in high-risk subjects, because in many cases the patient's diet may be insufficient to reach target levels.

Chapter 33 reviews in detail the evidence base supporting the use of lipid-lowering interventions (pharmacological and nonpharmacological) in clinical trials. This section is provided as a "how to" guide to the use of currently available lipid-lowering agents.[68]

RESINS.

The bile acid-binding resins act to interrupt the enterohepatic circulation of bile acids by inhibiting their reabsorbtion in the intestine (bile acids that contain cholesterol are more than 90 percent reabsorbed through this pathway). Their main indication is as adjunctive therapy in patients with severe hypercholesterolemia due to increased LDL-C. Because bile acid binding resins are not absorbed systemically (they remain in the intestine and are eliminated in the stool), they are considered safe in children. Cholestyramine (Questran) is used in 9-gm unit doses (containing 4 grams of anhydrous resin) as powder, and colestipol (Colestid) is used in 5-gm unit doses; a 1-gm tablet of colestipol is available. Effective doses range from two to six unit doses per day, always taken with meals. The side effects are predominantly gastrointestinal, with constipation, a sensation of fullness, and gastrointestinal discomfort being the most important ones. Hypertriglyceridemia can result from the use of these drugs. Decreased drug absorption dictates careful scheduling of medications 1 hour before or 3 hours after taking bile acid-binding resins. Bile acid-binding resins can be used in combination with statins in cases of severe hypercholesterolemia.

HMG CoA REDUCTASE INHIBITORS (STATINS).

The development of the statins has led to a further validation of the lipid hypothesis. Their target is the rate-limiting enzyme for cholesterol synthesis. Under treatment, maintenance of cellular cholesterol homeostasis involves increased expression of the LDL-R and decreased rate of cholesteryl ester formation. These changes increase LDL-C clearance from plasma and decrease hepatic production of VLDL and LDL. The statins are generally very well tolerated; side effects include hepatotoxicity and myositis, which necessitate discontinuation of the drug in approximately 1 percent of patients. The currently available drugs include fluvastatin (Lescol), 20 to 80 mg/d; lovastatin (Mevacor), 20 to 80 mg/d; pravastatin (Pravachol), 20 to 40 mg/day; simvastatin (Zocor) 10 to 80 mg/d; atorvastatin (Lipitor) 10 to 80 mg/d; and cerivastatin (Baycol), 0.2 to 0.4 mg/d. There is considerable debate regarding the degree to which these drugs exert beneficial effects on cellular function independent from their effects on cholesterol

TABLE 31-6 -- LABORATORY TESTS FOR THE DIAGNOSIS OF LIPOPROTEIN DISORDERS

LIPID PROFILE	MAY HELP IN DIAGNOSIS	SPECIALIZED CENTERS	RESEARCH TOOLS
Cholesterol	Lipoprotein separation by UTC	LDL particle size	Molecular diagnosis
Triglycerides	Apo B	LPL assay	
HDL-C	Apo AI	LCAT assay	
LDL-C*	Apo E genotype/phenotype	Apo E levels	
	Lp(a)	Apolipoprotein separation by PAGE	
		LDL-R assay	
		Apo CII, CIII	

PAGE=polyacrylamide gel electrophoresis.

Ultracentrifugation.
*Calculated as LDL-C=Cholesterol - (Triglycerides/2.2+HDL-C) in mmol/liter (or triglycerides divided by 5 in mg/dl); valid for triglycerides < 4.5 mmol/liter (<400 mg/dl). LDL-C can also be directly measured in plasma.

homeostasis. Concomitant therapy with drugs that interfere with the metabolism of statins by inhibiting cytochromes P-450, 3A4, or 2C9 can increase plasma

concentrations of statins. Such agents include certain antibiotics, antifungal medications, antiviral drugs, grapefruit juice, amiodarone, and several others.[68]

FIBRIC ACID DERIVATIVES (FIBRATES).

There are currently three derivatives of fibric acid available in the United States and two more in Canada and Europe. Gemfibrozil (Lopid) is used at a standard dose of 600 mg twice daily and is indicated in hypertriglyceridemia and in the secondary prevention of cardiovascular diseases in patients with a low HDL-C. These latter recommendations are based on the Veterans Administration HDL Intervention Trial (VA-HIT). Fenofibrate (Tricor, Lipidil Micro) is used to treat hypertriglyceridemia and combined hyperlipoproteinemia. The dose is 200 mg/d, and a new formulation is available to vary the dose from 67 mg (especially in renal failure) to 200 mg/d. Clofibrate (Atromid) is still available in some centers, although its use has declined since the introduction of newer molecules. Ciprofibrate (Lypanthyl, Lipanor) and bezafibrate (Bezalip) are more widely used in Europe. The main indication for the use of fibrates is hypertriglyceridemia when diet and lifestyle changes are not sufficient. Another indication is the prevention of cardiovascular diseases in patients with elevated plasma triglycerides and low HDL-C. The mechanism of action results in part from their interaction with the nuclear transcription factor peroxisome proliferator-activated receptor-alpha (PPARalpha) that regulates the transcription of the LPL, apo CII, and apo AI genes and may also have direct antiinflammatory effects at the level of the artery wall.[94] The undesired effects of fibrates include cutaneous manifestations, gastrointestinal effects (abdominal discomfort, increased bile lithogenicity), erectile dysfunction, elevated serum aminotransferases, interaction with oral anticoagulants and elevated plasma homocysteine, especially with fenofibrate and, to a lesser extent, with bezafibrate.[95] Because fibrates increase apoB transcription, a consequent rise in LDL-C levels often occurs in patients with hypertriglyceridemia treated with this class of medications.

NICOTINIC ACID (NIACIN).

Niacin has been used for decades for the treatment of dyslipidemias and is particularly effective in increasing HDL-C and lowering triglyceride levels. The effect of niacin on LDL-C is more modest. Effective doses of niacin are in the range of 3000 mg/d, in three separate doses. It is preferable to use an escalating dose schedule to reach the full dose in 2 to 3 weeks rather than starting with the full dose. Aspirin may ameliorate niacin-induced skin flushing. Niacin decreases the hepatic secretion of VLDL from the liver and decreased FFA mobilization for the periphery. Although niacin has been shown in the long-term follow-up of the Coronary Drug Project to decrease mortality at 15 years,[96] important and sometimes life-threatening side effects and now the development of statins have hampered use of niacin. Side effects of niacin include flushing, hyperuricemia, hyperglycemia, hepatotoxicity, acanthosis nigricans, and gastritis. Long-acting niacin has the advantage of a once- or twice-daily dosing schedule, but older preparations of slow-release niacin were potentially more hepatotoxic.

FISH OILS.

Fish oils are rich in polyunsaturated fatty acids with the first double bond in the omega-3 position, such as eicosapentaenoic acid or docosahexaenoic acid. These fatty acids have been found to lower plasma triglyceride levels and to have antithrombotic and perhaps antiinflammatory properties.[97] [98] Although they have been used in the treatment of hypertriglyceridemia, their use is reserved in cases of severe hypertriglyceridemia refractory to conventional therapy. Fish oils decrease VLDL synthesis and decrease VLDL apo B. The response to fish oils depends on dose. A significant benefit on plasma triglyceride levels requires a daily intake of 10 to 15 gm of eicosapentaenoic acid or docosahexaenoic acid.

MONITORING.

After initiation of medical therapy, the response should be checked within the first 3 months, along with transaminases and creatinine kinase. Thereafter, clinical judgment should dictate the interval between follow-up visits. Although frequent visits are probably not useful in the detection of serious side effects, they serve to encourage compliance, adherence to diet, and lifestyle changes.

OTHER MEDICATIONS.

Probucol has modest effects on plasma lipoprotein levels and antioxidant properties. The lack of conclusive evidence that probucol has beneficial effects led to its withdrawal. Recent studies indicate that it may have a role in the prevention of restenosis after coronary angioplasty if used before the procedure.[99] In the absence of documented hypothyroidism, thyroxine has no role as a lipid modulator.

DIETARY SUPPLEMENTS ("NUTRACEUTICALS").

The armamentarium for lipid-lowering intervention now includes products available directly to the public as food or dietary supplements. Many patients will ask their physicians about these so-called "neutraceuticals" learned of in the lay press, by word-of-mouth, or advertising. Such products currently marketed in the United States include Benechol and Take Control, formulated as margarine-like spreads, in salad dressings, and in snack bars. These products contain plant sterols (phytosterols) that interfere with intestinal absorption of cholesterol.[100] [101] The typical adult daily diet includes about 0.1 percent phytosterols. Consumption of 2 to 3 gm/d of plant sterols can lower LDL-C 10 to 15 percent with few untoward effects.[100] [101] [102] Combination of these products with statins may help some patients achieve an LDL-C goal.[103] However, the formulations are high calorie and would be best substituted for butter or margarine already included in the patient's diet. The suggested intake of three servings a day, especially if used on bread, might increase body weight. Also, phytosterol-enriched foods containing *trans*-fatty acids or saturated fat (sometimes included in the salad dressings and snack bars) might have a less salubrious effect on the lipid profile.

Other dietary products patients may take or ask about include psyllium, folate (commonly found enriched in food), natural phytoestrogens, soy, green tea, and synthetic fat substitutes (olean).[104] Cholestin, a controversial over-the-counter dietary supplement, contains a biologically active statin derived from a red yeast found on rice.[105] When devising treatment plans and counseling patients, the physician should bear in mind that scant clinical trial evidence currently shows cardiovascular event reduction with neutraceuticals. Patients should not supplant indicated lipid-lowering medications of proven cardiovascular benefit with untested dietary supplements.

AGGRESSIVE MEASURES FOR TREATING REFRACTORY ELEVATION OF LDL.

Cases of severe hypercholesterolemia, especially in homozygous hypercholesterolemia, can only be treated by an extracorporeal LDL elimination technique. These techniques are based on selective filtration, adsorption, or precipitation of LDL (or apo B-containing particles) after plasma apheresis. Such techniques are only available in highly specialized centers but may dramatically reduce the risk of developing cardiovascular disease and improve survival.[106]

GENE THERAPY: A FUTURE APPROACH TO DYSLIPIDEMIA?

Severe, homozygous monogenic disorders will eventually be treated by gene therapy. The initial trials of gene therapy in homozygous FH have not led to a major improvement and have largely been abandoned.[107] However, the lifelong burden of these rare disorders and the potential for cure makes this approach very appealing. Other diseases, such as abetalipoproteinemia, LPL deficiency, Niemann-Pick disease type C, phytosterolemia, and Tangier disease, may become therapeutic targets for gene therapy. If

the approach to correct these disorders is successful, the more widely spread application of gene-based therapies to reduce potential cardiovascular risk will become a daunting medical, social, and ethical problem.

DRUG DEVELOPMENT AND FUTURE DIRECTIONS

Novel proteins that regulate the synthesis of lipids have become therapeutic targets for drug development. A good example has been the development of competitive inhibitors of HMG CoA reductase leading to statins. These drugs have an important impact on cardiovascular morbidity and mortality reduction in high-risk individuals (see Chap. 33) . Inhibitors of pancreatic lipases are currently used to treat obesity. Future potential drug targets might include inhibition of apo B secretion by inhibiting the microsomal triglyceride transfer protein (MTP), which is crucial in the assembly of apo B-containing lipoproteins.[44] [108] Reports of hepatic steatosis in animal studies may limit the use of this approach in humans. Selective inhibition of ACAT may also provide a therapeutic target to inhibit cholesterol absorption through the intestinal wall and reduce apo B-containing lipoprotein secretion from the liver.[109] Drugs that increase cellular cholesterol efflux to increase HDL-C levels may also prove useful in the treatment of dyslipoproteinemias.

The development of novel pharmaceutical agents for the treatment of lipoprotein disorders will likely continue because cardiovascular disease due to atherosclerosis represents the largest burden of disease for the near future.[6] [11] Better targeting of high-risk individuals[93] will allow optimization of expensive therapies. We may

witness the development of new "nutraceuticals" to aid the dietary management of dyslipidemia. The "genomics revolution" will foster the burgeoning field of pharmacogenetics and might soon permit treatment of patients tailored to their genetic make-up.[110] Genetic screening will become a useful clinical tool as technology improves and rapid genotyping for diagnostic and prognostic purposes becomes available for clinicians. Beyond issues of cost, the ethics of screening for genetic predisposition to disease and access to information present daunting challenges. The discovery that the apo E4 allele confers risk of early-onset Alzheimer's disease illustrates the kind of complexity we will encounter more frequently in the postgenomic era.[111]

SMOKING

Cigarette consumption constitutes the single most important modifiable risk factor for coronary artery disease and the leading preventable cause of death in the United States, where it accounts for over 400,000 deaths annually.[112] Despite the relative stability in prevalence of current smokers in the United States at 25 percent,[113] rates of tobacco use are increasing among adolescents and young adults.[114] Close to 1 million young Americans begin smoking each year.[115] Although increased recognition of the hazards of smoking might be hoped to slow these trends, nearly 1 billion individuals now smoke worldwide.[116] Smoking has a particularly staggering impact in the Third World: almost one-half billion individuals worldwide will eventually die of smoking-related complications.[117] Even among nonsmokers, we now recognize that inhaled smoke, whether from passive exposure or from cigar and pipe consumption, also greatly increases coronary risk.[118] [119]

Landmark studies in the early 1950s first reported strong positive associations between cigarette exposure and coronary heart disease. Over the next 40 years, an exceptionally consistent series of prospective studies have clearly documented

Figure 31-5 Relative risks of death due to coronary artery disease *(top)* and stroke *(bottom)* according to level of daily cigarette consumption. (Adapted from The Health Benefits of Smoking Cessation: A Report from the Surgeon General, 1990.)

the effects of smoking on coronary risk. These studies suggest that, compared with nonsmokers, those who consume 20 or more cigarettes daily have a twofold to threefold increase in total coronary heart disease. Moreover, these effects depend on dose; consumption of as few as one to four cigarettes daily increases coronary artery disease risk.[120] Smoking acts synergistically with oral contraceptive agents, placing younger women at even higher relative risk. In addition to myocardial infarction, cigarette consumption directly relates to increased rates of sudden death, aortic aneurysm formation, symptomatic peripheral vascular disease, and ischemic stroke. As for coronary disease, the risk of stroke directly increases with the number of cigarettes consumed.[121] (Fig. 31-5) .

Smoking affects atherothrombosis by several mechanisms. In addition to accelerating atherosclerotic progression,[122] long-term smoking may enhance oxidation of LDL-C and reduce levels of HDL-C.[123] [124] Smoking also impairs endothelium-dependent coronary artery vasodilation[125] [126] ; has multiple adverse hemostatic effects[127] ; increases inflammatory markers such as CRP, soluble intercellular adhesion molecule-1 (ICAM-1), and fibrinogen[128] [129] ; causes spontaneous platelet aggregation [130] ; and increases monocyte adhesion to endothelial cells.[131] Compared with nonsmokers, smokers have an increased prevalence of coronary spasm[132] and may have reduced thresholds for ventricular arrhythmia.

SMOKING CESSATION (see also Chap. 32) .

Cessation of cigarette consumption constitutes the single most important intervention in preventive cardiology. Smoking cessation

alone reduces the risk of a first heart attack by nearly 65 percent.[133] Trials of nicotine replacement therapy using either transdermal nicotine[134] [135] or nicotine chewing gum have both proven to greatly increase abstention rates after cessation. Such pharmacological programs, as well as physician-guided counseling, are cost effective and should be provided as a standard prevention service.[136] Patients need to recognize that "low yield" cigarettes do not appear to reduce risks of myocardial infarction.[137] Unfortunately, although the elevated cardiovascular risks associated with smoking decrease significantly after cessation, the risks of cancer of the lungs, pancreas, and stomach persist for more than a decade, as do the risks of developing chronic obstructive pulmonary disease. Thus, primary prevention remains the most important population-based component of any smoking reduction strategy.

HYPERTENSION (See also Chaps. 28 , 29 , and 32)

In contrast to cigarette consumption, hypertension is often a silent cardiovascular risk factor. Of the estimated 50 million Americans with high blood pressure, almost a third evade diagnosis and only a fourth receive effective treatment.[138] Elevated levels of blood pressure consistently correlate with elevated risks of stroke and myocardial infarction (see Fig. 28-6). An early meta-analysis that evaluated over 5500 cardiovascular events found a 27 percent increase in risk of coronary heart disease and a 42 percent increase in risk of ischemic stroke for every 7 mm Hg elevation of diastolic blood pressure.[139] Although hypertension often clusters with insulin resistance and obesity, the risk imposed by hypertension increases in the presence of other cardiovascular risk factors.

Even among individuals without diastolic hypertension, isolated increases in systolic pressure are a risk factor. Isolated systolic hypertension markedly increases risk for nonfatal myocardial infarction and cardiovascular death among both general population samples[140] and apparently low-risk groups.[141] Pulse pressure, a potential surrogate for vascular wall stiffness, also potently predicts both first and recurrent myocardial infarction.[142] Interestingly, both isolated systolic hypertension and pulse pressure independently predict coronary risk.

The pathophysiology and treatment of hypertension are discussed at length in Chapters 28 and 29 . In regard to treatment, blood pressure reduction greatly reduces risk, even among individuals with mild to moderate hypertension. In overview analyses, pharmacological reductions in diastolic blood pressure of 5 to 6 mm Hg appear to reduce the risk of stroke by over 40 percent, the risk of vascular mortality by 21 percent, and the risk of coronary heart disease by 14 percent.[143] In the elderly, randomized trial data have also indicated the efficacy of treating isolated systolic hypertension.[144] [145] Among compliant patients, sodium reduction and weight loss can be effective.[146] However, not all patients respond to such measures, and the long-term success of non-pharmacologic approaches to hypertension control has often proven disappointing. Thus, although the most recent report from the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure continues to stress weight loss, alcohol reduction, increased physical activity, and sodium restriction as first-line approaches, the proportion of hypertensive patients being treated pharmacologically will continue to increase. As with smoking cessation, programs of blood pressure control have consistently been found cost effective.[147]

INSULIN RESISTANCE AND DIABETES (See also Chap. 63)

Three fourths of all deaths among diabetic patients result from coronary heart disease.[148] Compared to unaffected individuals, diabetic patients have a greater atherosclerotic burden both in the major arteries and in the microvascular circulation. Not surprisingly, diabetic patients have substantially increased rates of atherosclerotic complications both in the settings of primary prevention and after coronary interventional procedures.[149] Thus, insulin resistance and diabetes rank among the major cardiovascular risk factors.

Patients with diabetes have threefold to fivefold increased rates of future cardiovascular events,[150] with even higher rates reported among diabetic women.[151] The risk of coronary disease among premenopausal diabetic women resembles that of nondiabetic men, indicating that diabetes largely mitigates the protective effects of female gender.[152] However, although hyperglycemia is associated closely with microvascular disease, insulin resistance itself promotes atherosclerosis even before it produces frank diabetes.[153] Recent studies corroborate the role of insulin resistance as an independent risk factor for atherothrombosis.[154] This finding has prompted recommendations for increased surveillance for the insulin resistance syndrome, a cluster of glucose intolerance and hyperinsulinemia accompanied by hypertriglyceridemia, low HDL levels, and a predominance of small dense LDL particles. Insulin resistance also produces a prothrombotic state due to increased levels of PAI-1 and fibrinogen.[155] [156] [157]

In addition to these systemic metabolic abnormalities, hyperglycemia causes accumulation of advanced glycation end products inculpated in vascular damage[158] (see Chap. 63) . Furthermore, diabetic patients have markedly impaired endothelial and smooth muscle function[159] [160] and appear to have increased leukocyte adhesion to vascular endothelium, a critical early step in atherogenesis. Diabetic nephropathy, detected by microalbuminuria, accelerates these adverse processes. Among individuals with non-insulin-dependent diabetes, microalbuminuria predicts both cardiovascular and all cause mortality.[161] [161A]

Despite evidence concerning pathophysiological abnormalities associated with diabetes and epidemiological data describing increased hazards associated with hyperglycemia, few clinical trials have evaluated whether improved glycemic control improves cardiovascular risk. The Diabetes Complications and Control Trial of strict glycemic control among insulin-dependent diabetics reported benefits on microvascular endpoints but did not find significant benefits on coronary event rates.[162] Similarly, the United Kingdom Prospective Diabetes Study found only marginal benefit for improved glycemic control among non-insulin-dependent diabetics.[163] Thus,

as outlined later, exercise, diet, avoidance of obesity, and aggressive control of other risk factors remain primary targets for risk reduction in type II diabetic populations.[163A]

EXERCISE AND OBESITY

Regular physical exercise reduces myocardial oxygen demand and increases exercise capacity, both of which are associated with lower levels of coronary risk[164] (see also Chap. 39) . A consistent series of prospective studies have demonstrated an association between levels of physical activity and reduced rates of cardiovascular morbidity and all-cause mortality[90] [165] [166] [167] [167A] [167B] [167C] [167D] (Fig. 31-6) . For example, in a prospective evaluation of Harvard alumni initially free of apparent cardiovascular disease, those men with the highest

Figure 31-6 Prospective studies of physical activity and the risk of subsequent cardiovascular mortality. (From Pate RR, Pratt M, Blair SN, et al: Physical activity and public health: A recommendation from the Centers for Disease Control and Prevention and the American College of Sports Medicine. JAMA 273:402-407, 1995. Copyright 1995, American Medical Association.)

levels of activity at baseline had a 40 percent reduction in nonfatal cardiovascular events and a 24 percent reduction in cardiovascular death compared with those with sedentary lifestyles.[165] Whereas the level of exercise in early life predicts long-term exercise pattern, significant reductions in subsequent risk also applied to individuals who were initially sedentary but later increased exercise levels.[90] Thus, increasing exercise levels even in mid to late life reduces coronary risk in men[168] and women.[169] Rates of stroke also decline among those with life-long exercise habits, independent of hypertension.[170] [171]

Mortality data suggest that over 200,000 deaths result from physical inactivity annually in the United States.[172] Thus, a recent joint statement from the Centers for Disease Control and Prevention and the American College of Sports Medicine recommends that every American should accumulate at least 30 minutes of moderate-intensity physical activity daily.[173] Similarly, the American Heart Association has recommended an exercise energy expenditure approaching 2000 calories each week, a level of exercise that can be achieved with modest daily exertion.[174] Regrettably, only 25 percent of the American population achieve this level of activity and another 25 percent participate in no leisure-time physical activity at all.[175] Thus, recommendations from physicians to increase exercise levels play an important role in coronary risk reduction, particularly among the elderly, women, and those of lower socioeconomic status whose exercise rates tend to be lower.

The mechanisms by which exercise lowers cardiovascular risk remain uncertain but likely include favorable effects on blood pressure,[176] weight control, lipid profiles,[177] and improved glucose tolerance.[178] [179] Exercise also improves endothelial function, enhances fibrinolysis, reduces platelet reactivity, and reduces propensity for in situ thrombosis.[180] [181] [182]

Weight reduction programs should include exercise as a critical component, a particularly effective measure when combined with dietary restriction.[183] It is important to recognize that obesity itself is associated with substantially increased cardiovascular risk, regardless of activity levels. For example, the Nurses Health Study revealed a direct linear relation between body mass index and subsequent risk of coronary heart disease.[184] Modest weight gain in mid to late adulthood also increases risks of coronary disease among both men and women,[185] [186] as does the distribution of body fat. Recent studies indicate that the waist-to-hip ratio, a surrogate for centripetal or abdominal obesity, is an independent marker of vascular risk both in women and older men.[187] [188]

Controversy remains as to whether obesity itself is a true risk factor for cardiovascular disease or whether its impact on vascular risk is mediated solely through interrelations with glucose intolerance, insulin resistance, hypertension, physical inactivity, and dyslipidemia. Nonetheless, obesity is epidemic in the United States and weight control must play a fundamental role in all preventive cardiology practices, preferably in conjunction with advice regarding diet and exercise.[92] [189]

MENTAL STRESS AND CARDIOVASCULAR RISK

The adrenergic stimulation of mental stress can clearly augment myocardial oxygen requirements and aggravate myocardial ischemia. Mental stress can cause coronary vasoconstiction, particularly in atherosclerotic coronary arteries, and hence can influence myocardial oxygen supply as well.[190] Myocardial ischemia provokable by mental stress can predict future coronary events.[191] [192] Catecholamines can also promote alterations in thrombosis and coagulation that might favor clot formation and stability. These factors may well trigger complications of preexisiting atherosclerotic lesions. The increase in coronary death documented during missile attacks or natural disasters such as earthquakes support this concept.[193]

What remains less certain is the effect of mental stress per se on the development of atherosclerosis.[194] Studies in this regard have proven challenging because the metrics for mental stress lend themselves less well to controlled clinical trials than other more readily quantified risk factors. Behavioral interventions, often combined with dietary changes, have proven in some studies to decrease atherosclerosis or its manifestations.[194] Ongoing studies such as the Enhancing Recovery in Coronary Heart Disease (ENRICHD) study, which include specific interventions that target psychosocial factors, should shed light on this elusive but potentially important contributor to cardiovascular risk.[195]

ESTROGEN STATUS (See also Chap. 58)

Before menopause, women have lower age-adjusted incidence and mortality rates for coronary heart disease than men. Gender-specific incidence rates converge after menopause, suggesting a major role for estrogen in delaying progression of atherosclerosis. Much of this effect results from beneficial actions of estrogen on lipid fractions. In studies of exogenous oral estrogen replacement therapy such as the Postmenopausal Estrogen/Progestin Intervention (PEPI) Trial, estrogen reduces LDL-C by 10 to 15 percent while increasing HDL-C, apo A1, and triglycerides.[86] The mechanism of this effect from oral estrogen results partly from a first-pass action in the liver that augments LDL catabolism while reducing activity of hepatic lipase with subsequent promotion of hepatic HDL uptake.[196]

The lipid effects of estrogen, however, explain only part of the apparent cardiovascular benefits enjoyed by premenopausal women and women taking hormone replacement therapy.[197] In observational studies, even women without dyslipidemia appear to benefit from hormone replacement therapy.[198] Estrogen must therefore have other potentially beneficial effects.[199] These likely include direct vascular mechanisms such as improved endothelial-dependent vasomotion,[200] [201] reduced LDL oxidation,[202] altered adhesion molecule levels,[203] increased fibrinolytic capacity,[204] and enhanced glucose metabolism.[205]

Despite these data, exogenous estrogen use among young women as a form of oral contraception is associated with increased rates of intravascular thrombosis, including deep vein thrombosis and pulmonary embolism as well as myocardial infarction and stroke. These effects are particularly prominent among smokers such that women who continue to smoke should use alternative forms of contraception.[206] Although low-dose oral contraceptive preparations may have an improved toxicity profile,[207] the incidence of pathological thrombosis remains high among smokers using low-dose oral contraceptives.[208] [209]

By contrast, among postmenopausal women using hormone replacement therapy, prospective observational studies suggest that estrogen use reduces cardiovascular risk by 35 to 45 percent.[210] [211] In one study, estrogen users had an adjusted relative risk of coronary heart disease 40 percent lower than that of nonusers[212] as well as reduced rates of all-cause mortality.[213] However, the clinical utility of estrogen replacement therapy remains controversial for several reasons: (1) observational studies are prone to bias and it remains possible that estrogen use is a marker for improved access to health care or differences in socioeconomic and educational levels, which in turn result in lowered rates of cardiovascular disease[214] ; (2) the potential risks of estrogen use including endometrial cancer, gallstones, venous thrombosis, and possibly breast cancer[215] require patient-specific decisions concerning this therapy[216] ; (3) data from the randomized, double-blind Heart and Estrogen/progestin Replacement Study (HERS) of women with preexisting coronary disease found no evidence of a difference in risk for nonfatal myocardial infarction or cardiovascular death between women assigned to combined hormone replacement or to placebo (relative risk = 0.99).[217] In that study, time-trend subgroup analyses suggest a possible early hazard with hormone initiation as well as later benefits, although these observed differences may well be due to chance effects. Post-hoc analysis of the HERS suggests that women with elevated Lp(a) levels at the outset of the study may have derived benefit from the hormone therapy.[218] Thus, at least in this secondary prevention setting, data from available randomized trials are at apparent odds with observational evidence and thus underscore the need for successful completion of the federally funded Women's Health Initiative randomized trial. Randomized trials of selective estrogen receptor modulators (SERMS)[219] [220] in the secondary prevention of cardiovascular disease are also underway (see Chap. 58) .

NOVEL ATHEROSCLEROTIC RISK FACTORS

Despite the importance of blood lipids, half of all myocardial infarctions occur among individuals without overt hyperlipidemia. [221] Several novel markers of atherothrombotic risk have emerged from epidemiological studies and might prove useful clincially. However, when considering adoption of screening for any new cardiovascular risk factor, clinicians need to consider[222] whether there is a standardized and reproducible assay for the marker of interest[223] ; whether there is a consistent series of prospective studies demonstrating that baseline elevations of a given parameter predict future risk; and whether the novel marker adds to the predictive value of lipid screening.[224] This section applies these basic epidemiological requirements to five promising novel markers of cardiovascular risk: total plasma homocysteine, fibrinogen, Lp(a), fibrinolytic function as ascertained by t-PA or PAI-1 antigens, and markers of low-grade inflammation such as hs-CRP (Fig. 31-7) , Table 31-7) . Physicians should also consider the relative magnitude of novel markers in terms of risk prediction, particularly in comparison to lipid screening. Figure 31-7 shows data describing the relative efficacy of several variables measured at baseline in one cohort of middle-aged men, the Physicians' Health Study.

Homocysteine

Homocysteine is a sulfhydryl-containing amino acid derived from the demethylation of dietary methionine. Patients with rare inherited defects of methionine metabolism can develop severe hyperhomocystinemia (plasma levels > 100 mumol/liter) and can have premature atherothrombosis. The mechanisms that account for these effects remain uncertain but may include endothelial toxicity, accelerated oxidation of LDL-C, impairment of endothelial-derived relaxing factor, and reduced flow-mediated arterial vasodilation.[225] [226] [227] [228]

In contrast to severe hyperhomocystinemia, mild to moderate elevations of homocysteine (plasma levels > 15 mumol/liter) are common in general populations, primarily due to insufficient dietary intake of folic acid.[229] Other patient groups that tend to have elevated homocysteine levels include those with common polymorphisms in the methylene tetrahydrofolate reductase gene (*MTHFR*), those receiving folate antagonists such as methotrexate and carbamazepine, and those with impaired homocysteine metabolism due to hypothyroidism or to renal insufficiency.[230] [231]

In most clinical settings, total plasma homocysteine (the combination of free homocysteine, bound homocystine, and mixed disulfides) is measured by high-performance liquid chromatography, although reliable and less expensive immunoassay

Figure 31-7 Relative risks of future myocardial infarction among apparently healthy middle aged men according to baseline levels of lipoprotein(a) (Lp[a]), D -dimer, total plasma homocysteine (tHCY), total cholesterol (TC), fibrinogen, soluble intercellular adhesion molecule type-1 (sICAM-1), tissue type plasminogen activator antigen (tPA:ag), the total to HDL cholesterol ratio (TC:HDLC), interleukin-6 (IL-6), high sensitivity C reactive protein (hs-CRP), and the combination of hs-CRP and the TC:HDLC ratio. For consistency, risks are computed for those in the top quartile compared with the bottom quartile. (From Ridker PM: Novel risk factors and markers for coronary disease. Adv Intern Med 45:391-418, 2000.)

TABLE 31-7 -- ASSESSMENT OF THE CLINICAL UTILITY OF NOVEL MARKERS OF CARDIOVASCULAR RISK

MARKER	ASSAY CONDITIONS STANDARDIZED?	PROSPECTIVE STUDIES CONSISTENT?	ADDITIVE TO TOTAL AND HIGH-DENSITY LIPOPROTEIN CHOLESTEROL?
Lipoprotein(a)	No	Yes/no	Yes/no
Total homocysteine	Yes	Yes/no	Yes/no
Tissue-type plasminogen activator and plasminogen activator inhibitor	Yes/no	Yes	Yes/no
Fibrinogen	Yes/no	Yes	Yes
High-sensitivity C-reactive protein	Yes	Yes	Yes

techniques now exist. Although a nonfasting evaluation of total plasma homocysteine suffices for most clinical purposes, measurement of homocysteine levels 2 to 6 hours after ingestion of an oral methionine load (0.1 gm/kg body mass) can identify individuals with impaired homocysteine metabolism despite normal fasting levels.

A large series of cross-sectional and retrospective studies indicate a positive relationship between mild to moderate hyperhomocystinemia and atherosclerosis; on average, those with plasma levels above 15 mumol/liter appear to have a relative risk one and one-half to two times higher than individuals with lower levels.[232] [233] However, because homocysteine levels increase after myocardial infarction and stroke,[234] [235] such data cannot be used to establish a cause-and-effect relationship.

By contrast, prospective epidemiological studies (where homocysteine levels are ascertained before the onset of cardiovascular events) have provided mixed data. For example, although positive prospective studies have been reported among apparently healthy middle-aged men[236] [237] [238] and women[239] [240] as well as among those with known coronary atherosclerosis,[241] it is important to recognize that several high-quality prospective studies have found no relationship between baseline homocysteine levels and subsequent vascular risk.[242] [243] [244] Furthermore, although some studies have found positive associations both among those taking and not taking multivitamins,[239] this effect lacks consistency. Finally, in some of the "positive" cohort studies, no evidence of association was seen with longer-term follow-up.[245] Thus, prospective studies of hyperhomocystinemia do not provide consistent evidence of association (Fig. 31-8). Moreover, the width of the 95 percent confidence intervals in these studies indicates a modest magnitude of any true increase in risk associated with homocysteine, perhaps limited to those individuals with markedly elevated levels. Due in part to this lack of compelling epidemiological data, current recommendations from both the American Heart Association and the American College of Cardiology do not recommend population-based screening for homocysteine.[230] The observation that mutation in the *MTHFR* gene leads to hyperhomocysteinemia but not to increased vascular risk also reduces enthusiasm for screening, at least from a genetic perspective. [246]

Recent fortification of the United States food supply with folate to reduce the risk of neural tube defects[247] also complicates clinical issues in terms of screening for hyperhomocystinemia. Since its initiation in 1992, the addition

Figure 31-8 Prospective studies of homocysteine as a risk factor for future cardiovascular events in populations free of clinical disease. PHS = Physicians' Health Study; MRFIT = Multiple Risk Factor Intervention Trial; BUPA = British United Provident Association; ARIC = Atherosclerosis Risk in Communities; WHS = Women's Health Study. (From Ridker PM: Novel risk factors and markers for coronary disease. Adv Intern Med 45:391-418, 2000.)

of small amounts of folic acid to enriched flour and grain products has resulted in a 9 to 10 percent drop in mean population homocysteine levels and an almost 50 percent drop in the number of individuals with homocysteine levels within the moderately elevated range.[248] Thus, the number of individuals potentially identifiable by general screening has decreased considerably over just a few years.

In some patient groups, such as those with premature atherosclerosis, an absence of other risk factors or in the setting of renal failure, homocysteine screening may have increased utility. Folic acid, given in doses of up to 400 mug/d, can be expected to reduce homocysteine levels approximately 25 percent, whereas the addition of vitamin B_{12} will likely reduce levels another 7 percent.[249] Because this therapy is inexpensive and has low toxicity in the absence of vitamin B_{12} deficiency, vitamin supplementation may be a more cost-effective approach for high-risk groups than screening.[230] No randomized trial data are available that demonstrate that reducing homocysteine levels reduces coronary risk.

Fibrinogen

Plasma fibrinogen critically influences platelet aggregation and blood viscosity, interacts with plasminogen binding, and in combination with thrombin mediates the final step in clot formation.[250] In addition, fibrinogen associates positively with age, obesity, smoking, diabetes, and LDL-C and inversely with HDL-C, alcohol use, physical

activity, and exercise level.[251] [252]

Given these relationships, it is not surprising that fibrinogen was among the first "novel" risk factors to be evaluated in epidemiological studies. Early reports from the Gothenburg,[253] Northwick Park,[254] and Framingham[255] heart studies all found significant positive associations between fibrinogen and future risk of cardiovascular events. A series of prospective studies have since confirmed these results,[256] [257] [258] [259] [260] [261] and a recent meta-analysis indicates that the relative risk of future cardiovascular events is 1.8 times higher for individuals in the top as compared with the bottom tertile of baseline fibrinogen concentration.[262] Women may have higher risks, although confounding by the effects of hormone replacement therapy limit interpretation of available studies.[263] Plasma viscosity, determined in part by fibrinogen level, also predicts cardiovascular risk.[264] [265]

Due to the consistency of these data, many consider fibrinogen an independent marker of risk for coronary heart disease.[266] However, two issues have limited clinical screening for fibinogen to improve risk prediction: (1) inadequate standardization between competing laboratory techniques and (2) wide intraindividual variation in plasma levels over time.[267] In addition, because smoking and estrogen replacement therapy appear to have opposite effects on fibrinogen levels,[127] [268] [269] care must be taken when interpreting results for these subgroups. Furthermore, the magnitude to which fibrinogen assessment improves coronary risk prediction models has varied widely in different studies[270] [271]

Despite major genetic determinants of fibrinogen concentration,[272] [273] substantial variation in plasma levels results from environmental factors. Smoking cessation, increased exercise, and weight loss can reduce fibrinogen concentration. Fibric acid derivatives also reduce fibrinogen, apparently through a PPAR-alpha mechanism.[274] [275] However, results of the Bezafibrate Infarction Prevention Trial do not show a significant decrease in vascular risk despite an overall 9 percent reduction in fibrinogen due to drug administration.[276] Furthermore, although hormone replacement therapy also reduces fibrinogen levels, this effect did not translate into a net clinical benefit among participants in HERS.[217]

Fibrinogen elevation occurs as part of the acute-phase response and may thus be associated with risk owing to its role as a marker of systemic inflammation. However, as is reviewed later in this chapter, other markers of inflammation such as hs-CRP appear to be more powerful than fibrinogen in terms of risk prediction

Lipoprotein(a)

As described on page 1017 , Lp(a) consists of an LDL particle with its apo B-100 component linked by a disulfide bridge to apo(a), a variable length protein that has sequence homology to plasminogen.[47] The apo(a) component of Lp(a) is a complex molecule composed in part of varying numbers of cysteine-rich kringle repeats that result in great heterogeneity. Plasma Lp(a) concentrations vary inversely with apo(a) isoform size but may vary even within isoform size based on differential levels of production.[277] Underlying its molecular complexity, more than 25 heritable isoforms of Lp(a) exist.[47] This molecular variability has clinical import because Lp(a) levels vary widely across ethnic groups.

Although the normal function of Lp(a) is unknown, the close homology between Lp(a) and plasminogen has raised the possibility that this unusual lipoprotein may inhibit endogenous fibrinolysis by competing with plasminogen for binding on the endothelial surface.[278] More recent data demonstrate accumulation of Lp(a) and co-localization with fibrin within atherosclerotic lesions, both in stable patients and among those with unstable angina pectoris.[279] [280] Apo(a) may also induce monocyte chemotactic activity in the vascular endothelium,[281] whereas Lp(a) may increase release of PAI.[282] Thus, several mechanisms may contribute to a role for Lp(a) in atherothrombosis.

Many retrospective and cross-sectional studies suggest a positive association between Lp(a) and vascular risk. However, as in the case of homocysteine, levels of Lp(a) increase after acute ischemia and such studies cannot reliably determine causality. Prospective studies of Lp(a) avoid this bias but have not always found consistent evidence of association. For example, although several prospective studies employing plasma based assays for either apo(a) or for Lp(a) mass concentration have reported a positive, graded association,[258] [283] [284] [285] several other well-designed prospective studies have not demonstrated these effects.[286] [287] [288] [289] Electrophoretic detection of pre-beta-lipoprotein, a surrogate for Lp(a), has also been associated with increased vascular risk.[290] [291] However, these studies reported inconsistent data between men and women and between the endpoints of myocardial infarction and stroke. Thus, available prospective studies do not establish the importance of Lp (a) as a marker for all future cardiovascular events or whether any increased risk is restricted to those with the highest levels or an absence of other traditional risk factors.

Beyond these considerations, several practical issues limit the utility of Lp (a) screening. First, commercially available tests for Lp(a) lack sufficient standardization and there remains no consensus among clinical chemists on how best to measure this highly polymorphic molecule. This issue hampers reproducibility between laboratories, greatly reducing clinical efficacy.[292] Second, Lp(a) levels vary widely among different racial groups, with the African-American population tending to have more individuals in the higher range.[293] Scant evidence establishes the predictive value of Lp(a) for many ethnic groups, including African-Americans.[294] Similarly, the predictive value of Lp(a) in women is controversial.[295] Third, even in the positive studies of Lp(a), it is unclear whether evaluation of this lipoprotein adds to the predictive value of total and HDL-C. Indeed, LDL reduction markedly reduces any adverse hazard associated with Lp(a).[296]

Whereas niacin can modestly reduce Lp(a) levels, specific Lp(a)-lowering therapies are not available. For all of these reasons, most authorities do not recommend general Lp(a) screening.[297] However, as with homocysteine, special situations may warrant Lp(a) evaluation, such as young individuals who have suffered infarction yet who appear to lack other traditional risk factors.

Markers of Fibrinolytic Function (PAI-1, t-PA, Clot Lysis, and D

-Dimer)Impaired fibrinolysis can result from an imbalance between the clot-dissolving enyzmes tissue-type plasminogen activator (t-PA) or urokinase-type plasminogen activator (u-PA) and their endogenous inhibitors, primarily PAI-1. Plasma levels of PAI-1 peak in the morning whereas concentrations of t-PA demonstrate a less prominent circadian variation.[298] On this basis, a relative hypofibrinolytic state may prevail in the morning that, along with increased platelet reactivity, may contribute to the increased risk of myocardial infarction seen in this time period.[299] Visceral obesity yields enhanced PAI-1 production from adipocytes, and thus impaired fibrinolysis may help explain how weight gain and obesity influence atherothrombosis.[300] [301] [302] Individuals with the insulin resistance syndrome commonly have impaired fibrinolysis.[303] [304]

Clinically, patients with isolated PAI-1 deficiencies have excess rates of hemorrhage whereas animals with genetically mediated PAI-1 excess may develop spontaneous thrombosis.[305] [305A] However, a role for either t-PA or PAI-1 in the development of venous thrombosis remains controversial because retrospective studies may fail to account for acute-phase effects[306] and available prospective studies have not provided consistent evidence of association.[307]

By contrast, a highly consistent series of prospective studies have linked abnormalities of fibrinolysis to increased risk of arterial thrombosis. For example, prospective associations exist between PAI-1 antigen and activity levels and the risk of first and recurrent myocardial infarction.[251] [271] [308] [309] Perhaps paradoxically, individuals at risk for future coronary as well as cerebral thrombosis consistently have elevated levels of circulating t-PA antigen.[304] [310] [311] [312] [313] These latter effects may represent evidence of underlying endothelial dysfunction among individuals at risk or of direct relationships between t-PA and PAI-1, or they may represent a biological response to impaired fibrinolysis. In this regard, reduced clot lysis time, an overall indicator of net fibrinolytic function, also predicts coronary risk.[314] Finally, several studies indicate that levels of D-dimer, a peptide released by plasmin's action on fibrin, also predict myocardial infraction, peripheral atherothrombosis, and recurrent coronary events.[315] [316] [317]

Despite these data, the clinical use of fibrinolytic markers to determine coronary risk may offer little marginal value. Direct measurement of PAI-1 activity is difficult in clinical settings and requires special anticoagulants and precise phlebotomy techniques to avoid degranulation of platelets, a rich source of PAI-1. In addition, these markers, particularly PAI-1, have wide circadian variation. Furthermore, few data indicate that assessment of fibrinolytic markers adds substantially to clinical risk prediction models.[3]

The recognition that fibrinolytic function contributes to atherothrombotic risk has nonetheless yielded several practical clinical applications. For example, PAI-1-resistant thrombolytic agents may provide a means to increase the efficacy of fibrinolytic therapy for acute myocardial infarction. Furthermore, the renin-angiotensin system plays an important role in the regulation of fibrinolysis, and at least two randomized trials have shown the ability of angiotensin-converting enzyme inhibitors to influence favorably the balance between t-PA and PAI-1.[318] [319] Finally, genetic polymorphism in the promoter of the PAI-1 gene appears to be associated with elevated levels of PAI-1 expression,[320] [321] although whether this increases risk of myocardial infarction remains uncertain.[322] [323]

Markers of Inflammation (hs-CRP, ICAM-1, and IL-6)

INFLAMMATION CHARACTERIZES ALL PHASES OF ATHEROSCLEROSIS.

As reviewed in Chapter 30 , inflammation characterizes all phases of atherosclerosis.[324] [325] Formation of the fatty streak, the earliest phase of atherogenesis, involves recruitment of leukocytes due to expression of leukocyte adhesion molecules on endothelial cells in turn triggered by primary proinflammatory cytokines such as interleukin (IL)-1 or tumor necrosis factor-alpha. Subsequent migration of inflammatory cells into the subendothelial space requires chemotaxis controlled by chemokines induced by the primary cytokines.[326] Mononuclear cells within this initial infiltrate as well as intrinsic vascular cells subsequently release growth factors that stimulate proliferation of the smooth muscle cells and hence the progression of plaques. Finally, the thrombotic complications of plaques often involve physical disruption, usually associated with signs of inflammation.[327] [328] Other proinflammatory cytokines such as CD154 (CD40 ligand) can induce tissue factor procoagulant expression and promote thrombus

Figure 31-9 Pathways by which vascular and extravascular sources of inflammation result in circulating levels of inflammatory markers associated with atherothrombosis. formation.[329] Thus, the inflammatory response participates in every stage of atherothrombosis.

The primary proinflammatory cytokines IL-1 and tumor necrosis factor-alpha induce, in turn, the expression of another cytokine, IL-6. We have dubbed IL-6 a "messenger" cytokine because it can act remotely to change the program of protein synthesis in the liver from "housekeeping" proteins (e.g., albumin) to a family of proteins known collectively as acute-phase reactants. In this manner, local inflammation (in this case, the artery wall) can produce a reflection in the peripheral blood. We envisage this cytokine cascade orchestrating the expression of effector molecules (e.g., the adhesion molecules) as a biochemical pathway, similar to those encountered in intermediary metabolism (Fig. 31-9) .

MARKERS OF INFLAMMATION PREDICT FUTURE RISK OF VASCULAR EVENTS.

Given this underlying pathophysiology, it is not surprising that several markers of low-grade systemic inflammation have also proven useful for cardiovascular risk prediction.[330] [331] These markers include nonspecific acute-phase reactants such as hs-CRP, adhesion molecules such as ICAM-1, which are involved in mononuclear cell attachment to the vascular endothelium, and cytokines such as IL-6 and tumor necrosis factor. Each of these inflammatory markers can be measured in plasma and may thus provide a window on the inflammatory processes at the level of the arterial wall.

It remains unclear to what extent the acute-phase reactants serve merely as markers or themselves act as effectors of pathological responses. A large body of consistent evidence validates the use of acute-phase reactants such as CRP and serum amyloid A as markers of risk (see later). The evidence regarding their roles as direct mediators of pathology remains much more speculative. Nonetheless, CRP may activate complement and thus participate in sustaining inflammation. Serum amyloid A can bind to HDL particles, perhaps rendering them less protective against vascular inflammation.[332] Fibrinogen, another acute-phase protein, clearly can participate in coagulation, as discussed earlier.

Among the inflammatory markers, hs-CRP will likely prove the most clinically useful because it is easy and inexpensive to measure with commercial assays.[333] CRP has proven to have strong predictive value both among currently healthy men[334] [334A] [334B] and women[331] [335] as well as among the elderly,[336] high-risk smokers,[337] those with stable[338] and unstable angina pectoris,[339] [340] and those with prior myocardial infarction.[341] In these studies, individuals with hs-CRP levels in the upper quartile had relative risks of future vascular events three to four times higher than individuals with lower levels, effects that were independent of all other traditional cardiovascular risk factors (Fig. 31-10) (Figure Not Available) . Moreover, plasma levels of hs-CRP appear to add to the predictive value of plasma lipid measurements, and thus may provide an improved method to determine future vascular risk[342] (Fig. 31-11) .

In one recent large-scale prospective evaluation of 12 different inflammatory and lipid markers of risk, hs-CRP proved to be the single best predictor of future vascular thrombosis.[331] Moreover, in multivariate analysis, only hs-CRP or the total cholesterol:HDL-C ratio independently predicted risk. Importantly, levels of hs-CRP as well as the

Figure 31-11 Relative risks for future myocardial infarction among currently healthy men according to baseline tertile of the total to HDL-cholesterol ratio and to baseline tertile of hs-CRP. From Ridker PM, Glynn R, Hennekens CH: C-reactive protein adds to the predictive value of total and HDL cholesterol in determining risk of first myocardial infarction. Circulation 97:2007-2011, 1998. Copyright 1998, American Heart Association.)

inflammatory markers serum amyloid A, soluble ICAM-1, and IL-6 all predicted future vascular risk. Interestingly, these variables establish increased risk even among those with LDL-C levels below 130 mg/dl, the threshold for pharmacotherapy mandated by National Cholesterol Education Program (NCEP) Adult Treatment Program-2 (ATP-2) guidelines (Fig. 31-12) . [331] Thus, the clinical use of inflammatory markers may help to identify individuals at higher risk for myocardial infarction despite not meeting criteria for treatment based on the lipid profile.

For many clinicians, it may seem surprising that markers of inflammation such as CRP have such potent predictive value. After all, as a classic acute-phase reactant, levels of CRP increase several hundredfold in response to injury or infection and increase with a variety of inflammatory stimuli.[343] However, as long as hs-CRP is not measured within 2 to 3 weeks of an acute inflammatory stimulus (e.g., intercurrent infection), levels in a given individual are quite stable over long periods.

TREATMENTS CAN MODIFY MARKERS OF INFLAMMATION.

Evidence also suggests that hs-CRP may represent a modifiable risk marker. In a randomized trial of low-dose aspirin, the relative efficacy of this agent in decreasing coronary risk was greatest among those with evidence of low-grade inflammation as determined by hs-CRP but was sequentially smaller as levels of hs-CRP declined, data that suggest potentially important antiinflammatory effects for aspirin.[334]

Similarly, in the Cholesterol and Recurrent Events (CARE) trial, the attributable risk reduction associated with pravastatin was greater among individuals with a persistent inflammatory response as determined by hs-CRP, such that statin therapy attenuated almost completely the elevated risk associated with inflammation.[341] Moreover, therapy with pravastatin in the CARE trial significantly reduced levels of hs-CRP over a 5-year period.[344] This finding corroborates in humans experimental studies that suggest that lipid lowering attenuates inflammation[345] [346] and that the use of statins reduces macrophage content and activity within atheromatous plaque.[347] [348] [349] Thus, lipid lowering by statins appears to mitigate the inflammatory processes that undermine plaque stability. Nonpharmacological methods to reduce hs-CRP include weight reduction and exercise.[350] [351] By contrast, cross-sectional[352] [353] and randomized data indicate that hormone replacement therapy may augment levels of hs-CRP.[354]

MECHANISMS OF INFLAMMATORY MARKER ELEVATIONS.

Although the mechanisms underlying CRP as a risk factor remain uncertain, the low-grade inflammation detected by hs-CRP probably serves as an indirect marker of an enhanced cytokine[355] response to a variety of inflammatory stimuli that ultimately proves critical both for plaque progression and plaque rupture (see Fig. 31-9. Plasma levels of the "messenger" cytokine IL-6 , the primary driver of hepatic CRP synthesis, also predict future myocardial infarction among currently healthy men[356] as well as total mortality in the elderly.[357] Furthermore, individuals with

Figure 31-12 The value of hs-CRP, serum amyloid A (SAA), soluble intercellular adhesion molecule (sICAM-1), and interleukin-6 as predictors of future vascular risk among women with high, medium, and low levels of total cholesterol. (From Ridker PM, Hennekens CH, Buring JE, et al: C-reactive protein and other markers of inflammation in the prediction of cardiovascular disease in women. N Engl J Med 342:836-843, 2000.)

acute coronary syndromes have elevated levels of IL-6, and this cytokine has both short- and long-term prognostic value among those with and without overt plaque rupture.[358] [359] Upstream effectors of IL-6 production also serve as markers of future vascular risk. Individuals with increased vascular risk also have elevated levels of tumor necrosis factor-alpha and IL-1 isoforms, which in turn may stimulate IL-6 expression.[359] [360] Cellular adhesion molecules responsible for recruitment of monocytes into the intima also appear to have a predictive role in vascular disease. In particular, those at risk for future coronary artery disease and stroke have elevated levels of soluble forms of ICAM-1 at baseline.[331] [361] [362] Soluble forms of other adhesion molecules that reflect endothelial activation or platelet adhesion may also indicate vascular disease progression.[129]

Sources of stimuli for the smoldering inflammatory response include not only the vessel wall itself but also extravascular sites. Extravascular foci of chronic infection might include the gingiva, the bronchi, the urinary tract (including the prostate), or diverticular disease. Chronic infection with agents such as *Chlamydia pneumoniae, Helicobacter pylori,* herpes simplex virus, or cytomegalovirus can lead to systemic inflammation. Such observations have heightened interest in the hypothesis that infection may contribute to coronary risk[363] [364] (see also Chap. 30) . Several cross-sectional and retrospective studies that suggest an increased prevalence of infection among individuals with known coronary disease support this hypothesis.[365] [366] [367] In addition, several studies have identified *Chlamydia* species[368] [369] as well as viral particles[367] [370] in atheromatous lesions. On the other hand, interpreting these data requires considerable caution. First, retrospective studies are prone to considerable confounding and the presence of infection may represent a result rather than a cause of atherosclerotic disease.[371] For example, several large-scale prospective studies have not found evidence that prior exposure to either *Chlamydia pneumoniae, Helicobacter pylori,* cytomegalovirus, or herpes viruses is associated with increased risk of future cardiovascular events.[372] [373] [374] [375] [376] Furthermore, recovery of infectious particles within atheromatous plaque does not prove causation but may simply represent an innocent commensal colonization.

It is thus uncertain whether infection plays an important etiological role in atherthrombosis. Available clinical trials of antibiotic therapy have been underpowered to demonstrate either a true benefit or a meaningful null result. It is important to recognize, however, several mechanisms by which infection might contribute to plaque instability. For example, *Chlamydia* species have been reported to induce macrophage foam cell formation and increase procoagulant activity.[377] [378] Human atheromas often contain chlamydial heat shock protein 60 (HSP-60), an effector of activation of macrophages, endothelium, and matrix metalloproteinase expression.[379] [380] [381] Ongoing large-scale clinical trials of antibiotic therapies in the setting of chronic and acute infarction will help resolve these controversies. Although the proximal stimuli remain unproven at this time, overwhelming evidence supports a major role for inflammation in atherosclerosis and establishes the clinical utility of measurement of the inflammatory response in identifying individuals at high risk for plaque rupture.

FUTURE DIRECTIONS IN CORONARY RISK ASSESSMENT

Although available data demonstrate the considerable potential of inflammatory markers such as hs-CRP to improve coronary risk prediction, determining the full utility of inflammatory markers as adjuncts to lipid screening in individual patients will require further clinical studies. The observation that elevated levels of CRP, IL-6, tumor necrosis factor, IL-1RA, and soluble ICAM-1 all associate with future vascular events provides a potent stimulus to consider targeted antiinflammatory therapies as a novel method to both treat and prevent vascular thrombosis.

Aside from inflammatory markers, future strategies to detect vascular risk will likely take several forms. Imaging techniques including carotid and intravascular ultrasonography, electron-beam computed tomography (CT), and magnetic resonance imaging all hold promise as methods to identify silent atheroma and perhaps vulnerable plaque.[330] Similarly, testing for endothelium-dependent vasodilation has proven highly effective in specialized research settings. However, each of these techniques requires carefully designed prospective evaluations to determine their clinical utility. Just as the extent of stenosis determined at coronary angiography does not necessarily predict plaque rupture, it is not at all certain that other imaging techniques will overcome this inherent limitation. For example, a recent study of coronary calcification as detected by electron-beam CT has found that this method does not predict accurately near-term vascular events, even in high-risk settings.[382] Furthermore, imaging studies and the consequences of false-positive testing can entrain considerable costs. Indeed, a recent American Heart Association position paper has advised against the use of electron-beam CT for coronary calcium scoring as a routine screening tool at present.

An alternative approach to improving risk prediction would be expansion of current lipid screening algorithms to include other vascular markers with a firm pathophysiological basis such as homocysteine, LDL particle size, Lp(a), or hs-CRP. Advantages of this approach include relatively low cost, a recognition that such variables could add to simple lipid screening in assessing the risk of thrombotic complications of atheroma, and their firm basis in pathophysiology. Moreover, in contrast to imaging techniques, abundant prospective data already exist for many of these markers that can guide clinicians in their use. This approach seems promising because inflammatory markers appear to add to the predictive value of lipid screening and provide a window onto clinically relevant plaque biology.

The "genomics revolution" mentioned earlier in relation to pharmacogenomics will also doubtless open new vistas of cardiovascular risk prediction. Over the next decade, considerable attention will focus on genetic detection of thrombotic risk. For venous thrombosis, genetic detection of factor V Leiden and of a common polymorphism in the promoter of the prothrombin gene have already entered clinical practice and have utility for targeting secondary prevention. In contrast, although family history contributes importantly to determining risk of myocardial infarction or stroke, studies of single gene polymorphisms and arterial thrombosis have proven disappointing, limiting enthusiasm for the use of genetic screening for abnormalities of hemostasis, thrombosis, and inflammation at present.[383] Nonetheless, screening of multiple loci and haplotyping hold the promise of better targeted pharmaceutical approaches based partly on genetic screening and will likely provide major avenues for coronary risk reduction in the future.

Chapter 32 - Primary and Secondary Prevention of Coronary Heart Disease

J. MICHAEL GAZIANO
JOANN E. MANSON
PAUL M RIDKER

The public health importance of both primary and secondary prevention of coronary heart disease (CHD) is indisputable. In view of the prevalence of CHD, preventing even a small proportion of cases would save thousands of lives, avoid inestimable suffering, and save billions of health care dollars. In addition, measures that prevent CHD may also mitigate other manifestations of atherosclerosis such as stroke and peripheral artery disease. Because cardiovascular diseases will become the number one killer worldwide early in the 21st century,[1] widespread deployment of affordable preventive strategies will be essential for both developed and developing countries.[2]

While researchers have made great strides in identifying a large number of life style, biochemical, and genetic factors potentially associated with CHD, the process of disease prevention must push beyond understanding disease mechanisms and identifying risk factors toward establishing intervention strategies that definitively reduce risk. Weighing the benefits of given interventions against their risks and costs has led to the establishment of guidelines for health providers and the general public. Implementing these guidelines, however, remains a difficult task.

DEVELOPMENT OF PREVENTIVE INTERVENTIONS

The multifactorial nature of atherogenesis makes the process of prevention complex. Potential risk factors for atherosclerotic disease include nonmodifiable factors such as age, sex, and race; behavioral characteristics such as smoking and physical activity; and biochemical variables such as the serum cholesterol level. Many factors are useful in assessing an individual's risk of development of a first or subsequent event. However, while predictive value is *necessary* to infer that modification of a risk factor will lead to reduced risk, it is not *sufficient*. Several additional steps are needed. First, the factor must be easy and inexpensive to measure--a major potential limitation for expensive techniques such as electron beam computed tomography. Second, the false-positive rate associated with screening must be low to avoid unnecessary and potentially hazardous consequences. Third, the benefit of intervention must clearly exceed any risks and be worth the cost. Finally, the intervention must be implemented in appropriate populations. Some factors, such as age, gender, and family history, are useful in assessing risk but are not modifiable. These factors will be considered only in the context of their ability to help us determine global risk.

Assessing Causality of a Given Factor

A crucial step in developing preventive strategies is the establishment of cause and effect. Consistent data from several types of research are needed to establish a causal relationship between exposure and disease (Table 32-1) . Basic research is providing insight into the mechanisms underlying atherogenesis and can help elucidate potential interventions to modify these effects. It is in the area of drug development that basic research has been particularly successful. The role of epidemiology in the development of preventive strategies involves a number of complementary methods, including descriptive studies (cross-sectional surveys and cross-cultural analyses), analytical studies (case-control and prospective cohort studies), and intervention studies (randomized trials).

DESCRIPTIVE STUDIES.

Descriptive studies include case reports, case series, cross-sectional surveys, cross-cultural

studies, and studies of population-based temporal trends. These studies are valuable primarily for their generation of hypotheses that can be tested in more analytical settings. The major contribution of descriptive studies, particularly cross-cultural studies and studies of temporal trends, has been the demonstration that environmental

factors play an important role in the development of atherosclerotic disease. The higher rates of heart disease in northern Europe than southern Europe,[3] the differences in cardiovascular disease rates among industrialized and less developed nations,[1] and changing rates of heart disease over the past three decades in the United States (Fig. 32-1) and other industrialized nations all support critical environmental components in the pathogenesis of atherosclerosis. Migration studies, such as the Ni-Hon-San Study, which showed increasing heart disease rates as Japanese men migrated from Japan to Honolulu and San Francisco, indicated that behavioral and environmental factors could explain a large portion of the cross-cultural differences in heart disease rates.[4] However, preventive strategies cannot be based solely on descriptive studies because their design prevents adequate control for potential factors that may confound apparent associations.

OBSERVATIONAL ANALYTICAL STUDIES.

In contrast to descriptive studies, observational analytical studies (case-control and prospective cohort studies) give researchers greater control over potential confounders. Observational studies suffer less from the biases of descriptive data since both outcome and exposure data are available for each individual in the study population, thus offering the possibility of better control for many potential confounders.

Case-Control Studies.

Case-control studies are designed to identify cases of a particular disease and appropriately matched controls and to compare the exposure status of potential risk factors typically ascertained at the time that disease status is established. Although case-control studies are more efficient and less costly than prospective cohort studies, recall bias may have an impact on risk estimates since exposure status is ascertained *after* the onset of disease. The selection process used to identify both cases and matched controls may also introduce bias since selected cases or controls may not adequately represent the intended source populations.

Prospective Cohort Studies.

In these studies, researchers ascertain exposure status at the beginning of the study and monitor individuals for the development of subsequent events. Prospective cohort studies are thus less subject to the biases of case-control studies because exposure data are collected *before* the development of disease. Furthermore, selection bias is less of an issue because subjects are not initially chosen on the basis of their disease status.

Case-control and prospective cohort studies are extremely useful in establishing risk attributable to a single factor, particularly when the effect of a given factor is large. Thus, as is the case for smoking and lung cancer, it is neither necessary nor ethical to conduct randomized trials to establish causality. On the other hand, when searching for small to moderate effects, the amount of uncontrolled confounding in observational studies may be as large as the probable risk reduction itself. In such cases, randomized trials are essential for confirming association. Even when causality is not in question, trials help quantify the magnitude of an intervention's effect. In addition, when the intervention is associated with competing risks and benefits, randomized trials are needed to determine the net clinical effect of the intervention. For example, observational studies indicate that estrogen replacement therapy may confer a protective effect in terms of coronary heart disease, but these benefits must be weighed against the potential increased risk of breast and uterine cancer.

Assessment of Benefits and Risks of Intervention

Once a factor has been established as causally related to disease, interventions to modify the factor must be developed and tested. This critical element in prevention is necessary because the magnitude of associated risk is not necessarily related to the magnitude of benefit derived from the intervention. Such lack of correlation may be due to the inability of the intervention to achieve the necessary change, or a change in the parameter may not result in the necessary change in risk in a proportional manner. An example is the difference between the observed risk associated with a 1-mm Hg rise in blood pressure and the lower than anticipated benefit on CHD derived from reducing blood pressure by this amount.[5] [6] Similarly, while elevated levels of homocysteine have been implicated as a risk factor for CHD and while folic acid reduces homocysteine levels, evidence from randomized trials indicating that reducing homocysteine levels with folic acid reduces vascular risk is not yet available.

In addition to providing information on the causal nature of an association, randomized trials generally provide the best data on the magnitude of benefit and risk from a given intervention. This information is essential for assessing cost efficacy and developing preventive strategies.

Figure 32-1 Change in age-adjusted mortality from coronary heart disease (CHD), stroke, and all causes in the United States, 1950 to 1996. CVD=cardiovascular disease. *(From 1998 Chartbook on Cardiovascular, Lung, and Blood Diseases. Bethesda, MD, National Institutes of Health, National Heart, Lung and Blood Institute, 1998, p 21.)*

Meta-Analysis

In some instances, data from individual randomized trials or observational studies fail to establish a clear risk or benefit, possibly because of small sample size. In these cases, it may be helpful to pool data from several studies in an overview, or meta-analysis. Pooling data is difficult if major differences exist in study design, interventional strategies, or definitions of exposure variables or outcome measures. Meta-analyses must be interpreted cautiously because the results may depend on the underlying assumptions dictating which studies were included or how data were summarized. Publication bias may also influence the results since it is often difficult to gain access to unpublished data for inclusion in the meta-analysis.

Cost Efficacy of Preventive Interventions (see also Chap. 2)

Once reasonable estimates of benefit and risk have been established for a given factor, cost-effectiveness analyses can be helpful in establishing guidelines for intervention. The common currency used to compare interventions is the quality-adjusted life-year (QALY) or disability-adjusted life-year (DALY). As with estimates derived from meta-analyses, those from cost- and risk-benefit analyses are dependent on the underlying assumptions made in a given analysis. In particular, because prevention measures have a long time horizon (decades or more), the consequences of initial assumptions can be much more significant than those of interventions with a short time horizon. Nonetheless,

Figure 32-2 Coronary heart disease (CHD) score sheets for calculating 10-year CHD risk according to age, total cholesterol (TC) (or low-density lipoprotein cholesterol [LDL-C]), high-density lipoprotein cholesterol (HDL-C), blood pressure, diabetes, and smoking. *A,* Score sheet for men based on the Framingham experience in men 30 to 74 years old at baseline. Average risk estimates are based on typical Framingham subjects, and estimates of idealized risk are based on optimal blood pressure, TC of 160 to 199 mg/dl (or LDL of 100 to 129 mg/dl), HDL-C of 45 mg/dl, no diabetes, and no smoking. *B,* Score sheet for women based on the Framingham experience in women 30 to 74 years old at baseline. Aerage risk estimates are based on typical Framingham subjects, and estimates of idealized risk are based on optimal blood pressure, TC of 160 to 199 mg/dl (or LDL of 100 to 129 mg/dl), HDL-C of 55 mg/dl, no diabetes, and no smoking. Use of the LDL-C categories is appropriate when fasting LDL-C measurements are available. Pts=points. *(From Wilson PW, D'Agostino RB, Levy D, et al: Prediction of coronary heart disease using risk factor categories. Circulation 97:1837-1847, 1998. By permission of the American Heart Association, Inc.)*

the cost-effectiveness of interventions to prevent heart disease is important because of both the prevalence of CHD and the high cost of treatment.

Cost-effectiveness estimates are calculated as the ratio of net cost to the gain in life expectancy. Interventions with an incremental cost-effectiveness ratio of less than $40,000 per QALY are comparable to other chronic interventions such as hypertension management and hemodialysis. Those with a cost-effectiveness ratio under $20,000 per QALY are very favorable, while those exceeding $40,000 per QALY tend to be higher than generally accepted by most insurers.

Assessing Absolute Risk

The cost efficacy of any intervention varies according to global risk in a given individual or population. Thus, a fundamental step in establishing a preventive strategy

involves assessing an individual's risk of development of clinically relevant outcomes. To illustrate this concept, assume that an intervention reduces mortality by 25 percent in both primary and secondary prevention. Furthermore, assume that a high-risk individual with CHD has a 20 percent chance of death from cardiovascular disease over the next 10 years while a low-risk individual has a 1 percent chance of death over the same period. To save a life among those at high risk, one would have to treat only 20 patients (4 of whom are destined to die) for 10 years so that a 25 percent relative risk reduction would result in 1 life saved (3 deaths instead of 4). On the other hand, one would have to treat 400 low-risk patients (4 of whom are also destined to die) so that the same 25 percent relative risk reduction would yield 3 deaths instead of 4. Thus, the total cost per

lives saved is considerably lower among individuals at higher absolute risk.

Investigators with the Framingham Heart Study have developed a useful tool to assess risk of a first cardiovascular event based on age, gender, total or low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, systolic and diastolic blood pressure, and history of diabetes and cigarette smoking[7] (Fig. 32-2) . Point-based weights are assigned to the presence and/or level of each risk factor. Once the points have been assigned and summed, the total score can be translated to an estimated absolute risk of a CHD event occurring within the next 10 years.

The European Society of Cardiology has also assembled

Figure 32-3 Risk assessment tool using cholesterol levels, blood pressure, and smoking status devised by a European task force on coronary prevention. *(From Wood D, De Backer G, Faergeman O, et al: Prevention of Coronary Heart Disease in Clinical Practice. Recommendations of the Second Joint Task Force of European and other Societies on Coronary Prevention. Eur Heart J 19:1434-1503, 1998.)*

recommendations for the prevention of heart disease that stratify preventive interventions according to whether a patient is at high, intermediate, or low risk.[8] Those with known CHD constitute the highest-risk category because most of these individuals have a greater than 20 percent chance of subsequent events over the next 10 years. Individuals without known CHD are assessed for risk with a modified Framingham assessment tool. This tool, presented in a series of easy-to-use charts, allows clinicians to assess risk over the next 10 years based on age, gender, smoking status, diabetes, level of cholesterol, and blood pressure (Fig. 32-3) . Those for whom the risk of a primary event exceeds 20 percent over the next 10 years are recommended for aggressive management. Those for whom risk is lower are prescribed a less intense and less costly approach. The major difference between the Framingham and the European Society of Cardiology scores is the absence of HDL cholesterol from the European formula, which was omitted because it is not routinely measured in general population screening in some countries.

Risk assessment scales are also available from the Framingham investigators for the secondary prevention of myocardial infarction and stroke. However, since all patients with prior evidence of cardiovascular disease are at high risk for recurrent events and require aggressive preventive efforts, the utility of these tools is unclear.

Primary Versus Secondary Prevention

A crude means of determining absolute risk is embedded in the concept of primary versus secondary prevention. While most factors that predict a first CHD event also predict subsequent events, the relative cost efficacy of an intervention for primary prevention versus secondary prevention varies. Preventive interventions tend to be more cost-effective in secondary prevention: Since absolute risk among those with known disease is higher, fewer higher-risk individuals require treatment to save one life in comparison to those at lower risk, even if relative risk reductions are identical in both groups.

Assessing an individual's absolute risk enables cost-effective targeting of interventions. Accordingly, the National Cholesterol Education Program (NCEP) and the Sixth Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI) use absolute risk to gauge the level of intensity of intervention. Guidelines from the NCEP Adult Treatment Panel II adjust treatment cut points and goals according to the level of underlying risk.[9] Individuals with clinical manifestations of CHD should receive the most aggressive lipid-lowering therapy (LDL goal of <100 mg/dl), while therapy can be less aggressive among those without overt CHD and two or more risk factors (LDL goal of <130 mg/dl) and least aggressive among those with no CHD and fewer than two risk factors (LDL goal of 160 mg/dl). Similarly, the JNC VI guidelines stratify interventions according to baseline risk[10] (see also Chap. 29) , while the American Diabetes Association recommends a tiered approach to management[11] (see Chap. 63) .

Incidence, Prevalence, and Population Attributable Risk

Sound public policy also requires evaluation of the impact of different factors on the *population*. Population risk depends not only on the strength of the factor-disease association and the benefit of intervention, but also on how common the factor is in the general population. These concepts are captured in incidence, prevalence, and population attributable risk. While incidence rates reflect the frequency of new cases of disease over a given period, prevalence reflects the proportion of individuals with a given condition or factor at a single point. Population attributable risk, or how much of the population's risk of disease is attributable to a given factor, is driven by the proportion of the public with a given risk factor and the magnitude of the associated risk.

Population attributable risk also reflects the shape of the relationship between the exposure and the disease. Many factors increase risk in a linear fashion, so population attributable risk can be computed against an ideal standard or a low-risk individual. For example, the relationship between hypertension and heart disease and stroke is linear. Thus, lowering blood pressure at any level in the pathological range reduces risk. In contrast, the shape of the risk curve for obesity appears nonlinear, with risk increasing logarithmically (Fig. 32-4) . Thus, each incremental pound gained is associated with much more risk in those who are already overweight. Population attributable risk is an important concept for determining resource allocation between various preventive interventions.

Implementation of Preventive Strategies

Three complementary approaches may be used to reduce the population burden of cardiovascular disease: (1) therapeutic interventions for secondary prevention in patients with known cardiovascular disease, (2) identification and targeting of high-risk individuals for primary prevention through mass screening or case finding, and (3) general recommendations disseminated throughout the population. Each of these approaches has merit in different situations. For example, targeted interventions such as specialized cardiac rehabilitation and life style programs show the greatest efficacy among motivated individuals who hope to avoid a recurrent myocardial infarction, whereas mass screening programs for high blood pressure and hyperlipidemia are cost-effective. Population-wide campaigns against cigarette smoking offer an example of an effective public health approach.

Figure 32-4 Association between body mass index and relative risk of nonfatal myocardial infarction and fatal coronary heart disease among women. Light bars show the relative risks adjusted for age, and dark bars show the relative risks adjusted for age and smoking. The vertical lines represent 95 percent confidence intervals. (Reprinted, by permission, from Manson JE, Colditz GA, Stampfer MJ, et al: A prospective study of obesity and risk of coronary heart disease in women. N Engl J Med 322:882-889, 1990.)

Classification of Interventions for Modifiable Risk Factors

Implementation of preventive strategies requires a practical, systematic approach to prioritizing interventions and allocating resources. The American College of Cardiology's Bethesda conferences placed risk factors into four categories according to the likelihood that modification of the factor will result in lower risk.[12] These categories include (1) factors for which interventions have been proved to reduce risk; (2) factors for which interventions are likely to lower the incidence of events; (3) factors clearly associated with CHD risk that, if modified, might lower the incidence of coronary events; and (4) factors associated with CHD risk that cannot be modified or, if modified, are not likely to decrease risk (Table 32-2) . Adapting this useful classification scheme to clinical practice requires consideration of cost efficacy. We present a modified classification scheme of interventions for major modifiable risk factors that is based not only on the strength of the association and evidence of

benefit of intervention but also on cost efficacy (Table 32-3) .

CLASS 1 INTERVENTIONS.

These interventions have a clear causal relationship with heart disease (Table 32-4) . Solid data, generally from randomized clinical trials, demonstrate the magnitude of the intervention's benefit, as well as its risks and cost. Cigarette smoking, hypercholesterolemia, and hypertension are causally related to CHD, and the corresponding interventions--smoking cessation, cholesterol reduction, and blood pressure management--are all cost-effective in both primary and secondary prevention. For management of hypertension and hyperlipidemia, extensive trial and cost efficacy data enable a tiered approach based on baseline absolute risk. Other pharmacological approaches proven to be beneficial and cost-effective include aspirin, beta blockers, and angiotensin-converting enzyme (ACE) inhibitors in secondary prevention and aspirin in some instances of primary prevention.

CLASS 2 INTERVENTIONS.

Class 2 includes interventions for which the available data (largely basic research and human observational studies) strongly indicate a causal relationship and suggest that intervention will probably reduce the incidence of events but for which data on the benefits, risks, and costs of intervention are limited. Class 2 factors that clearly increase the risk of CHD include diabetes, low HDL and high triglyceride levels, obesity, physical inactivity, and menopause. Light to moderate alcohol consumption appears to reduce the risk of CHD. Trial data on interventions are forthcoming for several of these factors,

TABLE 32-2 -- EVIDENCE SUPPORTING THE ASSOCIATION OF RISK FACTORS WITH CARDIOVASCULAR DISEASE, THE USEFULLNESS OF MEASURING THEM, AND THEIR RESPONSIVENESS TO INTERVENTION

RISK FACTOR	EVIDENCE FOR ASSOCIATION WITH CVD		CLINICAL MEASUREMENT: USEFUL?	RESPONSE TO	
	Epidemiological	Clinical Trials		Nonpharmacological Therapy	Pharmacological Therapy
Category I (Risk Factors for which Interventions Have Been Proved to Lower CVD Risk)					
Cigarette smoking	+++	++	+++	+++	++
LDL cholesterol	+++	+++	+++	+++	+++
High-fat/high-cholesterol diet	+++	++	++	++	--
Hypertension	+++	+++ (Stroke)	+++	+	+++
Left ventricular hypertrophy	+++	+	++	--	++
Category II (Risk Factors for which Interventions Are Likely to Lower CVD Risk)					
Diabetes mellitus	+++	+	+++	++	+++
Physical inactivity	+++	++	++	++	--
HDL cholesterol	+++	+	+++	++	+
Triglycerides; small, dense LDL	++	++	+++	++	+++
Obesity	+++	--	+++	++	+
Postmenopausal status (women)	+++	--	+++	--	+++
Category III (Factors Associated with Increased CVD Risk that if Modified, Might Lower Risk)					
Psychosocial factors	++	+	+++	+	--
Lipoprotein (a)	+	--	+	--	+
Homocysteine	++	--	+	++	++
Oxidative stress	+	--	--	+	++
No alcohol consumption	+++	--	++	++	--
Category IV (Factors Associated with Increased CVD Risk but Cannot be Modified)					
Age	+++	--	+++	--	--
Male gender	+++	--	+++	--	--
Low socioeconomic status	+++	--	++	--	--
Family history of earlyonset CVD	+++	--	+++	--	--

+=weak, somewhat consistent evidence; ++=moderately strong, rather consistent evidence; +++=very strong, consistent evidence; --=poor or nonexistent evidence. CVD=cardiovascular disease; HDL=high-density lipoprotein; LDL=low-density lipoprotein.

Modified from Pearson TA, McBride PE, Miller NH, Smith SC: 27th Bethesda Conference: Matching the intensity of risk factor management with the hazard for coronary disease events. Task Force 8. Organization of preventive cardiology service. J Am Coll Cardiol 27:1039-1047, 1996.

TABLE 32-3 -- CLASSIFICATION SCHEME FOR MODIFIABLE RISK FACTORS

Class 1	
	Basic research and human observational studies indicate a clear causal relationship
	Intervention data (typically from randomized trials) demonstrate the magnitude of the benefit and risk
	Interventions are cost-effective
Class 2	
	Basic research and human observational studies indicate a causal relationship
	Intervention data from large-scale trials are limited
	Lack of adequate intervention data precludes determination of cost-effectiveness
Class 3	
	Basic research and human observational studies demonstrate associations, but the independent nature of a causal relationship is not yet clear
	Interventions are not yet available or have not been adequately tested

such as hormone replacement therapy after menopause. For other factors, such as alcohol intake, there may never be data from large-scale randomized trials. Despite this limitation, class 2 interventions are useful in assessing global risk and have the potential to lower the risk of initial or recurrent CHD. While it makes sense to invest more resources to modify these factors in individuals at highest risk, guidelines for class 2 factors do not generally distinguish between high- and low-risk individuals.

CLASS 3 INTERVENTIONS.

These interventions are currently under active investigation. For many factors in this class, data are incomplete and an independent causal relationship with CHD cannot be inferred. For others, such as homocysteine and C-reactive protein, where data are promising, interventions are not yet available or widely tested even though causal relationships are apparent. Thus, while these factors may have utility for risk assessment, their role in preventing CHD is uncertain. For these reasons, dietary practices such as the consumption of nutritional supplements, psychological factors, and other novel biochemical and genetic markers are currently considered class 3 factors.

In several instances an intervention has proven efficacy in secondary prevention but data are not yet available to support that intervention in primary prevention. For this reason, a factor may be a class 1 intervention for secondary prevention but a class 2 intervention with respect to primary prevention.

CLASS 1 INTERVENTIONS

Cigarette Smoking (See Chap. 31)

PREVALENCE.

In the United States, per capita cigarette consumption rose dramatically in the first half of the 20th century. Over 65 percent of men born between 1911 and 1920 were smoking by 1945.[13] Annual per capita consumption of cigarettes hit an astonishing 4345 (more than 200 packs per year) in 1963.[14] The prevalence of smoking among adult men peaked at 55 percent in 1955 and, among women, 10 years later at 34 percent. [15] Since then, smoking rates have declined substantially, although the rate of decline differs by gender. Among men, smoking rates have declined by approximately half, while among women, rates have dropped by only one-third, primarily because of increasing smoking rates among women younger than 30 years. By 1997, approximately 27 percent of men aged 18 and older were current smokers, as compared with 22 percent of women.[16] Smoking rates tend to be higher among blacks, those with lower socioeconomic status, and those with a high school education or less.[16] Most alarming, smoking rates are increasing among children, with the prevalence of smoking among high school seniors rising from 30 percent in the mid-1980s to approximately 36.5 percent by 1997.[17]

ASSOCIATED RISK.

Smoking cigarettes increases the risk of CHD (see Chap. 31) . By the middle of the 20th century, seminal studies linking smoking and heart disease had been published by English and colleagues,[18] Doll and Hill,[19] and Hammond and Horn.[20] The Surgeon General's report in 1964 reaffirmed the epidemiological relationship between the two,[21] and by 1983 the Surgeon General firmly established cigarette smoking as the leading avoidable cause of cardiovascular disease.[22] The Surgeon General's 1989 report presented definitive data from observational case-control and cohort studies, largely among men, that demonstrated that smoking increases CHD mortality by 50 percent, that it doubles the incidence of CHD, and that the risk increases with age and with the number of cigarettes smoked.[14] Similar increases in the relative risk for CHD have been observed among women.[23] [24]

In the United States, cigarette smoking is the leading preventable cause of death and accounts for an estimated 430,000 deaths each year--more than 40 percent of which result from cardiovascular disease--and more than 7 million years of potential life lost.[25] Worldwide, smoking rates continue to rise, with the greatest increases in the developing world.[26] [27]

TABLE 32-4 -- CARDIOVASCULAR DISEASE RISK FACTORS AND INTERVENTIONS

RISK FACTOR	INTERVENTION	SECONDARY PREVENTION	PRIMARY PREVENTION
Cigarette smoking	Smoking cessation	Class 1	Class 1
High cholesterol	Cholesterol lowering	Class 1	Class 1
High blood pressure	Blood pressure management	Class 1	Class 1
	Aspirin therapy	Class 1	Class 2
	Beta blockers	Class 1	--
	ACE inhibitors	Class 1	--
	Oral anticoagulants	Class 1/2	--
Diabetes	Diabetes control	Class 2	Class 2
Low HDL	Increase HDL	Class 1/2	Class 2
High triglycerides	Triglyceride lowering	Class 2	Class 2
Physical inactivity	Increase activity	Class 2	Class 2
Obesity	Weight reduction	Class 2	Class 2
Menopause	Hormone replacement therapy	Class 2	Class 2
	Moderate alcohol consumption	Class 2/3	Class 2/3
Dietary factors	Improved diet	Class 3	Class 3

ACE=angiotensin-converting enzyme; HDL=high-density lipoprotein.

BENEFIT OF INTERVENTION.

While data from large-scale, randomized trials concerning the risk reduction associated with smoking cessation are limited, observational studies demonstrate clear benefits of smoking cessation. Smokers who quit reduce their excess risk of a coronary event by 50 percent in the first year or two after cessation, with much of this gain in the first few months. This period is followed by a more gradual decline, with the risk of former smokers approaching that of never smokers after 5 to 15 years.[28]

COST EFFICACY.

Smoking cessation is highly cost-effective. The intervention is usually short term and thus low cost. In fact, smoking cessation programs generally cost less than continued smoking. The gains in life expectancy are large, and the younger an individual stops smoking, the larger the potential gain--a 35-year-old male smoker may add 3 years to his life expectancy upon cessation. Costs vary, depending on the intensity of intervention and the use of pharmacological agents, with $1100 to $4500 (in 1995 dollars) spent for every QALY saved.[29]

GUIDELINES/RECOMMENDATIONS.

The U.S. Preventive Services Task Force recommends screening for smoking at every office visit.[30] Most people who give up smoking do not use an organized cessation program. Since the risks associated with smoking increase linearly with the number of cigarettes smoked, a modest reduction in smoking will probably reduce the risk. However, smoking reduction--as opposed to smoking cessation--is not an acceptable strategy, in view of the addictive nature of smoking and the tendency to increase smoking over time. The efficacy of smoking intervention programs ranges from a 6 percent 1-year success rate for physician counseling to 18 percent for self-help programs and 20 to 40 percent for pharmacological interventions with nicotine gum or patches. The use of antidepressant drugs also increases cessation rates.[31]

While it is important to counsel patients at all stages about the hazards of smoking and the benefits of quitting, the period soon after a cardiac event is an opportune time to encourage a patient to begin a smoking cessation effort.

FUTURE CHALLENGES.

In the United States, the prevalence of smoking is increasing among young women, particularly minority women. Worldwide, intense public health efforts are needed to reverse the alarming rise in smoking rates occurring in many developing countries.

Hypercholesterolemia (see also Chap. 31)

PREVALENCE.

Mean age-adjusted cholesterol levels have declined modestly in the United States since the early 1960s.[32] Even with this decline, the latest estimates suggest that half of all American adults have cholesterol levels greater than 200 mg/dl and that 20 percent of American adults have cholesterol levels of 240 mg or greater.[32] [33]

ASSOCIATED RISK.

Elevated serum cholesterol is causally associated with increased risk of CHD. Specifically, a 10 percent increase in serum cholesterol is associated with a 20 to 30 percent increase in risk for CHD, and elevations earlier in life may be associated with higher increases in risk.[34] [35] [36]

BENEFIT OF INTERVENTION (see Chap. 33) .

Clear benefits have been demonstrated for dietary and pharmacological treatments that lower serum cholesterol.[36A] Treatment aimed at lowering serum cholesterol by 10 percent reduces the risk of CHD death by 15 percent.[37] Treatment for more than 5 years yields a 25 percent reduction in CHD events.[36] Thus, long-term compliance is important for successful intervention.

Although early randomized trials generally showed a reduction in the risk of both fatal and nonfatal CHD in both primary and secondary prevention trials, some studies suggested that cholesterol lowering increased the risk of nonvascular mortality. Recently completed large-scale primary and secondary prevention trials using 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) confirm the reductions in fatal and nonfatal CHD and also provide reassuring data that cholesterol reduction does not increase the risk of nonvascular mortality.[38] [39] [40] [41] [42] A recent meta-analysis of these five primary and secondary trials (30,817 participants and more than 166,000 person-years of follow-up) demonstrated that statin therapy reduced the risk of major coronary events by 31 percent and all-cause mortality by 21 percent, with similar reductions in men and women, as well as in those younger and older than 65.[43] Cholesterol-lowering trials also demonstrate reductions in stroke.[44] [45]

COST EFFICACY (see Chap. 2) .

The cost efficacy of nonpharmacological interventions to lower LDL cholesterol is unclear. Pharmacological intervention, however, is clearly cost-effective under certain conditions, and available data permit tailoring recommendations to the level of baseline CHD risk. Early analyses of cholesterol reduction for secondary prevention (which used data from cholestyramine trials) resulted in very costly interventions, largely because the available drugs were relatively ineffective. In contrast, data for statin therapy is remarkably consistent.

For example, in the Scandinavian Simvastatin Survival Study, the direct cost per life-year saved was $5400 for men and $10,500 for women.[46] As expected, cost decreased as the baseline cholesterol level increased. For example, the direct cost per life saved was $11,400 for a man with a baseline total cholesterol of 213 mg/dl (5.5 mmol/liter) and $6700 for a man with a cholesterol level of 309 mg/dl (8.0 mmol/liter). Furthermore, the direct cost tended to be lower with increasing age, a finding in stark contrast to estimates based on the Coronary Heart Disease Policy Model.[47] [48] In further analyses of the Scandinavian Simvastatin Survival Study, the indirect cost per life-year saved was $1600 for men and $5100 for women.[46] Thus, the overall, incremental costs of treatment for secondary prevention were very attractive by most standards.

Cost-effectiveness data regarding statin therapy in primary prevention are limited. The Coronary Heart Disease Policy Model made estimates for lovastatin[47] and found that favorable cost per life-year was largely confined to middle-aged men with multiple coronary risk factors. However, if ongoing analyses based on the West of Scotland Coronary Prevention Study[39] and the Air Force/Texas Coronary Atherosclerosis Prevention Study[41] find that direct costs decrease with age for primary prevention, as they did for the Scandinavian Simvastatin Survival Study analysis of secondary prevention, cost-effectiveness estimates may prove more favorable for primary prevention in the elderly than the middle-aged.

GUIDELINES/RECOMMENDATIONS.

All patients with cardiovascular disease should be screened for serum cholesterol levels. In primary prevention, some controversy remains regarding screening, with the NCEP recommending screening of all adults older than 20 years[10] and the American College of Physicians (ACP) recommending screening only for men ages 35 to 65 and women ages 45 to 65. [49]

TREATMENT.

To reduce the prevalence of hyperlipidemia in the United States, the NCEP issued its first *Adult Treatment Panel* report in 1988[50] and a second report in 1993. [9] A third report is under way. The current guidelines recommend nonpharmacological interventions for approximately 30 percent of American adults and cholesterol-lowering drugs for about 7 percent. The goals of intervention are based on the level of CHD risk for an individual (Fig. 32-5) .

For primary prevention, the NCEP recommends as first-line strategy a step 1 diet to lower fat intake to 30 percent of total calories, with saturated fat accounting for less than 10 percent of fat intake and cholesterol intake limited to 300 mg/d per day. Carbohydrates should account for 55

Figure 32-5 Algorithm for lipid-lowering therapy based on findings from intervention trials. CHD=coronary heart disease; HDL-C=high-density lipoprotein cholesterol; LDL-C=low-density lipoprotein cholesterol; TG=triglycerides. *(From Ansell BJ, Watson KE, Fogelman AM: An evidence-based assessment of the NCEP Adult Treatment Guidelines Panel II guidelines. National Cholesterol Education Program. JAMA 282:2051-2057, 1999. Copyright 1999, American Medical Association.)*

percent of calories and protein for 15 percent. If after 3 months of dietary therapy the LDL goals are not met, the step 2 diet is recommended--less than 7 percent of calories from saturated fat and 10 percent from polyunsaturated fat with the remainder in monounsaturated fat (13 percent). Cholesterol intake is limited to 200 mg/d per day. Protein and carbohydrate intake is similar to step 1.

Since patients may find it difficult to understand percent calories, it can be helpful to translate these guidelines into grams of fat, protein, and other dietary constituents, the reporting of which is now mandated on labels of all food sold in the United States. Professional counseling with a dietitian may also be helpful. If dietary therapy does not achieve the target LDL level, drug therapy should be started (see Chap. 33) . In all cases, drug therapy should be an adjunct to dietary therapy and increased physical activity.

Guidelines from the European Society of Cardiology also have three tiers.[8] While the target is identical for all patients--total cholesterol of 190 mg/dl (5.0 mmol/liter) or less and LDL cholesterol of 115 mg/dl (3.0 mmol/liter) or less--the timing and intensity of drug therapy are different. For individuals with CHD, diet and drug therapy are initiated simultaneously. In primary prevention, if either the absolute 10-year risk of a CHD event or the projected risk at 60 years is greater than 20 percent, life style modifications are recommended and lipids are checked in 3 months (Fig. 32-6) . If at 3 months the total or LDL cholesterol level is above target, drug therapy may be instituted. For those with

a current or projected risk of less than 20 percent, life style advice but not drug therapy is recommended.

FUTURE CHALLENGES.

Additional randomized trial data will need to clarify the role of screening and treatment in older individuals and for stroke prevention. The Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) is currently testing whether reductions in plasma cholesterol levels with pravastatin will reduce the risk of major vascular events in approximately 5500 high-risk elderly subjects,[51] while the Risk Evaluation and Stroke Prevention in the Elderly--Cerivastatin Trial (RESPECT) is evaluating cerivastatin in the prevention of stroke. Although cholesterol levels are falling or stable in industrialized countries, they are rising in developing countries as "Western" diets are increasingly adopted.

Hypertension (see also Chaps. 28 , 29 , and 31)

PREVALENCE.

Approximately 30 percent of American adults are hypertensive, as defined by JNC VI.[32] [52] The prevalence of hypertension is greater among blacks than whites and among men than women; moreover, the prevalence of hypertension clearly increases with older age, from 9 percent of those aged 19 to 24 years to 75 percent of those older than 75 years.

ASSOCIATED RISK.

Elevated systolic or diastolic blood pressure is clearly associated with an increased risk of CHD (see Chaps. 28 , 29 , and 31) . The best estimates for the magnitude of associated risk derive from a meta-analysis of nine large prospective observational studies with 420,000 participants who accrued over 4850 CHD events during follow-up.[7] A 7-mm Hg increase in diastolic blood pressure over any baseline reading was associated with a 27 percent increase in CHD risk and a 42 percent increase in stroke risk. The shape of the risk curve is linear.

BENEFIT OF INTERVENTION.

For patients with malignant hypertension (defined as diastolic blood pressure greater than 115 mm Hg), the benefits of pharmacological intervention are clear and uncontroversial. Beginning in the late 1960s, a number of randomized trials confirmed the protective effect of treating mild to moderate hypertension, and these early trial data led to the establishment of treatment guidelines in the 1970s.[53] [54] The most precise estimates of risk reduction have come from meta-analyses reporting that lowering diastolic blood pressure by 5 to 6 mm Hg results in a 42 percent reduction in the risk of stroke and a 15 percent reduction in the risk of CHD events.[5] [55] A number of studies have demonstrated the utility of life style interventions, in particular, weight reduction and exercise, in reducing blood pressure. However, these trials have generally lacked the power to demonstrate a reduction in coronary events.

COST EFFICACY (see Chap. 2) .

Detection and management of hypertension are highly cost-effective. In general, for agents such as diuretics and beta blockers, the cost is

TABLE 32-5 -- CLASSIFICATION OF BLOOD PRESSURE FOR ADULTS AGED 18 AND OLDER,* WITH RECOMMENDATIONS FOR FOLLOW-UP

CATEGORY	SYSTOLIC BP (mm Hg)	DIASTOLIC BP (mm Hg)	FOLLOW-UP
Optimal	<120 and	<80	Recheck in 2 yr
Normal	<130 and	<85	Recheck in 2 yr
High-normal	130-139 or	85-89	Recheck in 1 yr
Hypertension§			
Stage 1	140-159 or	90-99	Confirm within 2 mo
Stage 2	160-179 or	100-109	Evaluate or refer to source of care within 1 mo

*Not taking antihypertensive drugs and not acutely ill.

Modify the scheduling of follow-up according to reliable information about past blood pressure measurements, other cardiovascular risk factors, or target organ disease.

Provide advice about life style modifications.
§Based on the average of two or more readings taken at each of two or more visits after an initial screening.

below $10,000 per QALY for patients with established CHD, even when blood pressure is only mildly elevated.[56] In primary prevention, cost ranges between $10,000 and $20,000 per QALY among individuals with moderate to severe elevations in blood pressure. However, the cost approaches an unacceptable range of $100,000 per QALY for higher-priced medications. In contrast to some estimates for lipid lowering, cost efficacy decreases with increasing age.

GUIDELINES/RECOMMENDATIONS.

The U.S. Preventive Services Task Force recommends routine blood pressure testing of all adults.[30] The JNC VI[10] defines six levels of blood pressure according to the risk imparted (Table 32-5) .

Recommendations for intervention from the JNC VI are based on the level of blood pressure and the level of absolute risk (Table 32-6) . Three strata of absolute risk are defined according to the presence or absence of target organ disease, clinical cardiovascular disease, diabetes, and cardiovascular risk factors such as smoking, hyperlipidemia, age older than 60 years, gender, and family history of early-onset cardiovascular disease. The JNC VI set a blood pressure goal of 140/90 for lower-risk patients and 130/85 for those with cardiovascular disease, diabetes, or proteinuria. Since the relationship of blood pressure to risk of cardiovascular disease is linear, a significant portion of the population's attributable risk occurs among those with blood pressure above the JNC VI optimal level of 120/80 and below the level of true hypertension. For all individuals with blood pressure of 130/85 or greater, JNC VI recommends life style modifications, including smoking cessation, weight reduction if needed, increased physical activity, limited alcohol intake, limited sodium intake, maintenance of adequate potassium and calcium intake, and adoption of a low-fat

diet.

Initiation of drug therapy should depend on blood pressure and the absolute level of risk. For example, among individuals with blood pressure as high as 140 to 159/85 to 99 but who show no evidence of end-organ damage, vascular disease, or diabetes and who have no cardiovascular disease risk factors, life style modification is recommended for up to 12 months. In contrast, individuals with blood pressure of 130/85 and end-organ damage, diabetes, or cardiovascular disease warrant early initiation of drug therapy. The specific therapeutic agents recommended by JNC VI are provided in Table 32-7 and discussed at length in Chapter 29 .

Guidelines from the European Society of Cardiology stratify initial therapy somewhat differently[8] (Fig. 32-7) . Drug therapy is recommended for individuals with less than 20 percent absolute risk and blood pressure in excess of 160/95 only after at least 6 months of life style modification; for individuals with greater than 20 percent absolute risk if their blood pressure exceeds 140/90 after 3 months of life style modification; and for individuals whose blood pressure exceeds 180/100, regardless of absolute risk. As with the JNC VI recommendations, life style modifications should always be used as an adjunct to drug therapy.

FUTURE CHALLENGES.

In the developed world, the prevalence of hypertension is increasing as these populations

age. In the United States, the proportion of hypertensives managed appropriately has recently decreased, thus reversing a two-decade trend.[10] In developing countries, hypertension rates are rising rapidly with urbanization and changes in life style habits. The attributable risk for hypertension tends to be greater in the developing world because the low rates of detection and treatment in such countries result in a proportionately higher rate of hypertensive heart disease and stroke.[57]

Cardiac Protection with Aspirin, Beta Blockers, ACE Inhibitors

Several pharmacological interventions have proved highly effective in the secondary prevention of cardiovascular disease. Pharmacological reduction of risk during or immediately after the development of CHD has been demonstrated for thrombolytic agents, aspirin, beta blockers, and ACE inhibitors.[58]

ASPIRIN IN SECONDARY PREVENTION (see also Chaps. 35 , 36 , and 62) .

Aspirin therapy in patients with existing cardiovascular disease reduces the risk of subsequent events by 25 percent.[59] Recent meta-analyses demonstrate clear reductions in mortality and nonfatal cardiovascular disease events among those with prior myocardial infarction,

Figure 32-7 Primary prevention guide to blood pressure management. BP=blood pressure; CHD=coronary heart disease; DBP=diastolic BP; SBP=systolic BP. *(From Wood D, De Backer G, Faergeman O, et al: Prevention of Coronary Heart Disease in Clinical Practice. Recommendations of the Second Joint Task Force of European and other Societies on Coronary Prevention. Eur Heart J 19:1434-1503, 1998.)*

stroke, bypass surgery, angioplasty, peripheral vascular surgery, or angina.[59] [60] Unless contraindicated, aspirin should be used by most patients with known cardiovascular disease. Other antiplatelet agents with demonstrated efficacy such as ticlopidine and clopidogrel should be considered for patients with aspirin allergy or intolerance. However, the cost efficacy of these agents remains to be determined and will clearly be less favorable than the cost efficacy of aspirin. In primary prevention, aspirin is a class 2 intervention (see below).

BETA BLOCKERS.

A number of trials have demonstrated the long-term efficacy of beta blockade after myocardial infarction in reducing mortality,[61] [62] and meta-analyses provide good estimates of the size of that benefit.[63] In longer-term secondary prevention, beta blockers lower the risk of a recurrent cardiovascular event by 18 percent.[64] Cross-trial comparisons suggest that the higher the level of beta blockade, as measured by heart rate reduction relative to the control group, the greater the benefit. Beta blockade after myocardial infarction is also extremely cost-effective.[65]

ACE INHIBITORS.

The benefit of ACE inhibitors among individuals at high risk for CHD events is substantial. Following myocardial infarction, the use of ACE inhibitors is associated with a 7 percent reduction in mortality at 30 days,[66] [67] [68] while among individuals with a low ejection fraction after myocardial infarction, total mortality is reduced by 26 percent[58] (see also Chap. 35) . Higher doses may afford greater protection.[69] Currently, an ACE inhibitor should be used in any patient with depressed systolic left ventricular function of less than 40 percent (see also Chap. 18) . Findings from the Heart Outcomes Prevention Evaluation (HOPE) Study suggest that the benefits of ACE inhibitors extend to those with clinical CHD (see Chap. 37) and diabetes, even in the absence of left ventricular dysfunction.[70]

RECOMMENDATIONS.

For secondary prevention, aspirin, beta blockers, and ACE inhibitors are cost-effective and should be considered standard therapy in appropriate patients--aspirin for any patient with cardiovascular disease, beta blockers after myocardial infarction, and ACE inhibitors in patients with a low ejection fraction, as well as in others with cardiovascular disease and diabetes. All three agents are recommended for secondary prevention by the American Heart Association, American College of Cardiology, and the European Society of Cardiology.

CLASS 2 INTERVENTIONS

Class 2 interventions relate to risk factors that appear to have strong causal associations with CHD risk and for which intervention has the potential to reduce risk but for which intervention data are limited (see Table 32-4) . Factors in this category include diabetes, HDL and triglycerides, obesity, physical inactivity, postmenopausal hormones, alcohol intake, and aspirin in primary prevention. In general, cost efficacy data are not available because of a lack of adequate intervention data.

Diabetes (see also Chap. 63)

PREVALENCE.

In the United States, nearly 16 million people have diabetes mellitus (DM); approximately 90 percent of cases are type II DM.[71] Fully one-third of people with diabetes are not aware they have this disease. The prevalence of DM will increase with the adoption of new recommendations revising the definition of diabetes to include those with a fasting plasma blood glucose level of 126 mg/dl or higher.[72] In addition, the prevalence of diabetes appears to have increased over the last decade, which may be a reflection of increasing body mass index (BMI).[71]

ASSOCIATED RISK.

Diabetes increases the risk of atherosclerotic disease, and CHD is a major complication of both type I and type II DM. By age 40, CHD is the leading cause of death in both diabetic males and females,[73] and a recent survey found that CHD was listed on 69 percent of death certificates in a representative national cohort of adults with diabetes.[74] Age-adjusted rates for CHD are two to three times higher among diabetic men and three to seven times higher among diabetic women than among their counterparts without diabetes.[75] The onset of clinically apparent CHD in those with type I DM occurs at an early age, with markedly increased risk by the third decade of life; risk is clearly related to the duration of disease.[76] [77] In the Danish Steno Hospital Study, mortality from myocardial infarction alone was 12.5 percent after 35 years of diabetes regardless of the age of onset.[78] Thus, individuals with diabetes must be considered at high risk for CHD, regardless of the presence or absence of other risk factors.

BENEFIT OF TREATMENT.

Maintaining normoglycemia may reduce the risk of microvascular (renal and eye) disease. However, data demonstrating reduced risk of CHD with tight glycemic control are scant. In the Diabetes Complications and Control Trial (DCCT), an apparent reduction in CHD events among patients with type I DM assigned to intensive therapy did not achieve statistical significance, possibly because of the small number of events in this relatively young cohort.[79] While oral hypoglycemic agents and insulin can improve glycemic control, their role in the reduction of risk from macrovascular complications of type II DM remains unclear.[80] [81] Interestingly, the recent HOPE trial showed that ACE inhibitor therapy could reduce onset of diabetes.[70] [81A]

GUIDELINES/RECOMMENDATIONS.

Diet and exercise are integral components of the treatment strategy for patients with diabetes. In many patients with type II DM, glycemic control can be achieved by modest weight loss through diet and exercise.[82] While tight control with insulin in type I DM is appropriate, its role in the prevention of CHD among those with type II DM remains unclear.

In contrast to patients with type I DM, those with type II DM are much more likely to have multiple coronary risk factors than is the case in the general population. Thus, aggressive modification of associated risk factors--including treatment of hypertension, aggressive reduction of serum cholesterol, reduction of weight, and increased physical activity--is of paramount importance in reducing the risk of CHD among people with diabetes. In addition, aspirin[83] and ACE inhibitors[70] have been demonstrated to have clear efficacy in reducing coronary events in this population.

HDL and Triglycerides (see also Chaps. 31 and 33)

PREVALENCE.

Low HDL and high triglyceride levels tend to coincide and often result from metabolic phenomena that are distinct from those leading to high levels of LDL cholesterol. Thus, low HDL and high triglyceride levels can occur alone or in combination with high LDL levels.

ASSOCIATED RISK.

HDL cholesterol has emerged as an important independent predictor of CHD--every 1 mg/dl decrease in HDL cholesterol causes a 3 to 4 percent increase in coronary artery disease.[84] [85] [86] Furthermore, an emerging body of evidence indicates that the ratio of total or LDL cholesterol to HDL cholesterol may be a better predictor of CHD risk than LDL alone. Data from the Physicians' Health Study, for example, suggest that a one-unit

decrease in this ratio (which is easily achievable with statin drugs) reduces the risk of myocardial infarction by 53 percent.[87]

Imprecision in triglyceride measurements, within-individual variability, and complex interactions between triglycerides and other lipid parameters may obscure the impact of triglycerides in the development of CHD. However, fasting triglyceride levels represent a useful marker of the risk for CHD, particularly when HDL levels are considered.[88] Trial data testing interventional strategies specifically targeted at individuals with low HDL or elevated triglycerides in the setting of normal LDL levels are limited.

BENEFIT OF INTERVENTION.

Data from the Helsinki Heart Study demonstrate that gemfibrozil, an agent that increases HDL and lowers triglyceride levels, reduces risk among those with high total and LDL cholesterol.[89] In the more recent Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT), a 22 percent reduction in cardiovascular events was observed with gemfibrozil treatment in a population with low HDL (<40 mg/dliter [1.0 mmol/liter]).[90] This risk reduction occurred in the absence of any substantial change in LDL cholesterol, data that support the potential for agents targeted at HDL and triglyceride levels.

RECOMMENDATIONS.

Screening of patients with cardiovascular disease should include a full lipid profile, including total cholesterol, HDL, and fasting triglycerides. For patients without cardiovascular disease, screening for HDL remains controversial, with the NCEP recommending screening and the ACP recommending against it. Because the ratio of total cholesterol to HDL cholesterol is a powerful predictor of risk and aids in the detection of individuals who have elevated LDL despite moderate levels of total cholesterol, it seems prudent to check HDL along with total cholesterol.

All patients with low HDL and/or high triglycerides should receive recommendations for life style modifications that include a diet low in saturated fat and increased physical activity. In secondary prevention, individuals with high LDL who also have low HDL or high triglycerides should be treated aggressively and consideration given to combination therapy (see Chaps. 31 and 33) . In primary prevention, nonpharmacological interventions are warranted for individuals who have a normal LDL level but a low HDL and/or high triglycerides because trial data regarding drug therapy in such cases are insufficient. Intervention data regarding patients with isolated elevated triglyceride levels are needed.

Physical Inactivity (see also Chap. 39)

PREVALENCE.

Physical activity is an exceptionally common modifiable risk factor for CHD. In a study of all CHD deaths occurring in the United States in 1986, more than 205,000 were attributable to physical inactivity, second only to the 253,000 attributable to hypercholesterolemia.[91] While the number of adults in the United States considered to be sedentary declined from over 40 percent in the early 1970s to approximately 27 percent by the early 1990s, more than three-quarters of adults do not exercise regularly or take part in leisure time physical activity.[92] Older individuals, who are most at risk for cardiovascular disease, are less likely to be physically active than younger individuals, and women tend to be less active than men.

ASSOCIATED RISK.

Morris and colleagues first reported in the mid-1950s that CHD rates were lower among bus conductors and mail carriers than sedentary bus drivers and postal supervisors.[93] By incorporating estimates of leisure time activity in their analyses, these investigators found that civil servants with sedentary jobs who engaged in vigorous sports were half as likely to suffer myocardial infarction than were those who did not engage in leisure time physical activity.[94] Since then, a number of observational studies have reported similar inverse associations between activity level from work or play and CHD. In a meta-analysis of 27 observational cohort studies, the risk of CHD in sedentary individuals was almost twice that of active individuals after controlling for other coronary risk factors.[95] Long-term prospective studies of men and women consistently demonstrate that regular physical activity protects against death from CHD.[96] [97] [98] These benefits apply to activities as simple as brisk walking, which has been shown to reduce the risk of CHD in women[99] and men,[100] as well as the risk of type II diabetes.[101] Shifting even late in life from a sedentary life style to a more active one confers a reduction in mortality from CHD.[102] Physical activity is also associated with a decreased risk of stroke in men,[103] [104] primarily because of its beneficial effects on body weight, blood pressure, serum cholesterol, and glucose tolerance.

While no large-scale, randomized trials of physical activity are available, numerous trials of moderate size and duration have been conducted among healthy individuals, those at high risk for cardiovascular disease, and those with existing cardiovascular disease. Despite differences in design, these trials generally demonstrate a benefit.[105] The ideal intensity, frequency, and duration of physical activity, however, have still not been determined.

BENEFIT OF INTERVENTION.

While cessation of activity appears to result in increased risk of CHD, the lack of large-scale, randomized, primary prevention trials on the benefits of physical activity makes it difficult to determine the precise benefit of exercise in terms of CHD reduction. Physical activity does, however, have clearly demonstrated benefits on cardiovascular risk factors. Exercise increases HDL, reduces LDL[106] and triglycerides, increases insulin sensitivity,[107] and reduces resting blood pressure. [108]

In secondary prevention, cardiac rehabilitation programs with an exercise component tend to report benefit in reducing subsequent events. Pooled data from many of these trials suggest reductions in total and cardiovascular mortality of about 25 percent.[109]

RECOMMENDATIONS.

The U.S. Preventive Services Task Force recommends a discussion of physical activity with all patients. All patients, including those with cardiovascular disease, should be strongly encouraged to engage in regular physical activity.[109A] Structured exercise programs may enhance long-term compliance. For primary prevention, the surgeon general's recommendation is an excellent starting point--every adult should accumulate 30 minutes of moderately intense physical activity on most, if not all days of the week.[92]

Obesity

PREVALENCE.

Since the late 1970s, the proportion of the U.S. population considered to be overweight (BMI
25.0) has risen dramatically from 43.3 percent in 1960 to 1962 to 54.9 percent in 1988 to 1994.[110] In the last decade of the 20th century, the proportion of people considered obese (BMI
30) increased from 12.0 percent in 1991 to 17.9 percent in 1998.[111] Obesity among children is also on the rise,[112] an alarming trend in view of the fact that early obesity is a strong predictor of later cardiovascular disease.[112A]

ASSOCIATED RISK.

Because of the use of various measures of obesity, reports on the magnitude of the association between obesity and CHD are conflicting. Considerable dispute on the independent status of obesity as a risk factor has also arisen because the impact of obesity on CHD risk

may be mediated, at least in part, by other coronary risk factors such as hypertension, dyslipidemia, glucose intolerance, and possibly hemostatic factors. In prospective studies in men, obesity appears to have an independent effect even after controlling for other risk factors.[113] Among women, greater than a threefold increased risk of fatal and nonfatal CHD is noted in those with the highest BMI (BMI
29), as well as an 80 percent increase in CHD in moderately overweight women (BMI of 25 to 29) when lipoprotein abnormalities, blood pressure, and diabetes are not included in multivariate models.[114] Whether any increased risk associated with obesity remains after controlling for these factors is uncertain. However, obesity is clearly associated with CHD and is an important and easily assessed marker of risk. The distribution of body fat may also play a role in the development of CHD, with abdominal adiposity posing a substantially greater risk in both women[115] and men.[116] A waist circumference of 35 inches in women and 40 inches in men is an easily measured marker of increased CHD risk.

BENEFIT OF INTERVENTION.

No large-scale trials of weight reduction as an isolated intervention are available on which to estimate the benefits of this intervention. However, in view of the clear improvements in glucose tolerance, blood pressure, and lipoprotein profile with weight loss, it is generally agreed that weight reduction has an important role in primary and secondary prevention programs.[105] [117] There is little consensus, however, on the ideal approach to weight reduction.[117A] Promoting life style changes to encourage weight reduction has been universally disappointing. While 25 percent of American men and 43 percent of American women may attempt to lose weight in any given year,[118] failure rates are exceedingly high. One reason may be that most individuals who are trying to lose weight are not following guidelines established by the National Heart, Lung, and Blood Institute[117] to reduce calorie intake and engage in at least 150 minutes of leisure time activity per week.[118] Effective treatment strategies generally involve a multifaceted approach, including dietary counseling, behavioral modification, increased physical activity, and psychosocial support.[119] [120] [121] Without precise estimates of the benefit and with substantial variability in the intervention strategy, it is currently impossible to estimate the cost/benefit ratio of this intervention.

RECOMMENDATIONS.

Weight reduction programs that include a structured exercise component should be considered in primary prevention for all obese (BMI >30) patients and in most overweight (BMI >25) patients with a history of CHD.

Postmenopausal Estrogen Therapy (see also Chap. 58)

RISK ASSOCIATED WITH MENOPAUSE.

In the United States, CHD is the number one cause of death in women by age 60.[122] While men exhibit a higher incidence of CHD at every age, as well as higher mortality rates from it, the gap narrows substantially after both natural menopause and bilateral oophorectomy.[123] Women seen with a first myocardial infarction tend to be older and have higher mortality than men with a first myocardial infarction. However, after adjustment for age and other indicators of severity and comorbidity, these differences are greatly attenuated.[124]

A wide range of factors may explain the increased risk of CHD after menopause, including adverse changes in lipid and glucose metabolism that result in an increase in LDL cholesterol and a decrease in HDL cholesterol, an increase in glucose intolerance, and changes in hemostatic factors and vascular function.[123] Endogenous estrogens appear to play a major role in reducing the risk of CHD in women. Substantial improvement in the lipoprotein profile, along with a reduction in LDL and an increase in HDL, is observed following the initiation of hormone replacement therapy.[125] [126] In addition, there appear to be protective effects on vascular function, as well as an apparent estrogen-related protection of LDL from oxidation.[127] Estrogens may also play one or more roles in maintaining normal hemostasis and improving glucose tolerance.

EFFECTS OF INTERVENTION.

The association between postmenopausal hormone therapy and CHD risk has been widely studied in case-control and prospective cohort studies. Overviews suggest that treatment with estrogen reduces the risk of CHD by 44 percent.[128] [129] In the Nurses' Health Study, the largest prospective cohort study to address this question, current users of estrogen had about half the risk of CHD (relative risk, 0.51; 95 percent confidence interval, 0.37 to 0.70) as nonusers did.[130] The association appears even stronger among women with known CHD.[131] However, these data are limited by their observational nature, and it is quite possible that women who self-select for estrogen therapy engage in other protective behavior that confounds this relationship.

Large-scale, randomized trial data in primary or secondary prevention are inadequate to fully assess the risks and benefits of postmenopausal hormone replacement. Recent data from the Heart and Estrogen/Progestin Replacement Study (HERS) suggested that among women with underlying CHD, combined estrogen and progesterone did *not* result in a reduction in cardiovascular events after 4 years of treatment.[126] In primary prevention, the ongoing Women's Health Initiative[132] will address the risks and benefits of treating postmenopausal women with estrogen alone, as well as the use of estrogen and progestin in combination, versus placebo. The use of selective estrogen receptor modulators and phytoestrogens in cardiovascular risk prevention remains unproven (see also Chap. 58) . [132A]

RECOMMENDATIONS.

Until more definitive data are available, decisions to begin hormone replacement therapy should be based on a woman's baseline risk for cardiovascular and other diseases, such as hyperlipidemia, as well as her personal preferences.[133] On the basis of current data, there is no mandate to either initiate or discontinue hormone replacement therapy in view of the complex balance of potential benefits and risks.

Moderate Alcohol Consumption

Alcohol consumption has complex effects on cardiovascular disease. Observational studies demonstrate that heavy alcohol intake increases total mortality[134] [135] and cardiovascular disease mortality,[136] [137] while moderate alcohol intake appears to exert a protective effect on CHD in comparison to no alcohol intake in both primary[138] [139] [140] [141] and secondary prevention.[142] Mechanisms underlying the effect of moderate alcohol consumption, defined as one to two drinks daily, include raising HDL levels,[143] [144] as well as improving fibrinolytic capacity[145] [146] and reducing platelet aggregation.[147]

RECOMMENDATIONS.

While the association of alcohol and CHD is likely to be causal, any individual or public health recommendation must consider the complexity of alcohol's metabolic, physiological, and psychological effects. With alcohol, the difference between daily intake of small to moderate quantities and large quantities may be the difference between preventing and causing disease. For appropriate patients, a discussion of alcohol intake can be a part of routine preventive counseling. In general, one or two drinks per day may be safe for men. For women, because

of their generally smaller BMIs and potential differences in liver metabolism, lower levels may be more prudent. However, counseling must be individualized--other medical problems, including other coronary risk factors (particularly hypertension and diabetes), liver disease, tendency toward excess use, family history of alcoholism, and possibly a family history of breast and colon cancer, should be taken into account when discussing alcohol consumption.

Aspirin in Primary Prevention (see also Chap. 62)

Four large-scale trials, performed primarily in men, have assessed the benefits of low-dose aspirin in the prevention of cardiovascular disease.[148] [149] [150] [151] Taken together, these studies suggest a benefit of prophylactic aspirin in primary prevention among men; however, concerns over increased risk of hemorrhagic stroke have not been fully assessed.[152] For women, the Women's Health Study, which is scheduled to end in 2001, is addressing the benefit-to-risk ratio of aspirin therapy for primary prevention of cardiovascular disease.

RECOMMENDATIONS.

While aspirin in doses between 81 and 365 mg daily is widely used, both the American Heart Association[153] and the U.S. Preventive Services Task Force[30] agree that the data are still insufficient to recommend this approach for the primary prevention of cardiovascular disease in healthy individuals. However, both these groups acknowledge that the benefits may outweigh the possible harm (particularly hemorrhagic stroke) in those with risk factors for cardiovascular disease. The European Society of Cardiology recommends low-dose aspirin (75 mg) in primary prevention only for men at particularly high risk of CHD.[8]

Oral Anticoagulants (see also Chap. 62)

Oral anticoagulants prevent embolic events in patients with prosthetic heart valves and atrial fibrillation. Less certain is their role, either alone or in combination with aspirin, in the secondary prevention of events in those with CHD. The results of randomized controlled trials are inconsistent, a troubling issue because oral anticoagulants have significant bleeding side effects.

A recent meta-analysis provided a comprehensive summary of existing data on high-, moderate-, and low-intensity oral anticoagulants alone or in combination with aspirin versus placebo or aspirin alone.[154] In this analysis, high- and moderate-intensity oral anticoagulation reduced myocardial infarction and stroke rates when compared with placebo but increased the risk of hemorrhage. The combination of low-intensity oral anticoagulation plus aspirin did not appear to confer any benefit over aspirin alone, while the combination of moderate- or high-intensity oral anticoagulation plus aspirin did appear to offer promising benefits. These findings require confirmation from ongoing clinical trials.

CLASS 3 INTERVENTIONS

Class 3 interventions relate to risk factors that are currently under investigation (see Table 32-4) . For some of them, a causal relationship with CHD cannot be

determined because of limited data. For others, where causal relationships are apparent, interventions are not yet available or tested.

Diet

Diet is an important component of any prevention program inasmuch as weight reduction can improve dyslipidemia, hypertension, and diabetes. One of the most consistent findings in dietary research is that individuals who consume higher amounts of fresh fruits and vegetables have lower rates of heart disease[155] and stroke.[156] The U.S. Department of Agriculture recommends two to four servings of fresh fruit and three to five servings of fresh vegetables per day.

Two randomized clinical trials of dietary interventions are worth noting. In the Dietary Approaches to Stop Hypertension (DASH) Trial, 459 adults with systolic blood pressure less than 160 mm Hg and diastolic pressure less than 80 to 95 mm Hg were randomized to (1) a control diet low in fruits, vegetables, and dairy products and with a fat content of 37 percent; (2) a diet rich in fruits and vegetables; or (3) a combination diet rich in fruits, vegetables, and dairy products. Both of the intervention diets substantially reduced systolic and diastolic blood pressure in individuals with and without hypertension.[157] The Lyon Diet Heart Study randomized 605 survivors of a first myocardial infarction to a Mediterranean-type diet or a "prudent Western-type diet." After a mean follow-up of 46 months, the risk of cardiac death or acute myocardial infarction was 65 percent lower for those consuming the Mediterranean diet.[158]

Low-fat diets have been shown to reduce the risk of myocardial infarction in healthy individuals and may even cause regression of coronary artery disease.[159] In the opposite direction, saturated and *trans*-fatty acids[160] appear to increase the risk of CHD. Not surprisingly, there is lively controversy over the health effects of the amount and type of fat and carbohydrates. While it is generally agreed that a reduction in saturated fat intake reduces the risk of CHD, it is unclear whether it is best to replace these fats with complex carbohydrates or monounsaturated or polyunsaturated fats.

Specific Nutrients

Specific foods and micronutrients under investigation as agents for reducing the risk of cardiovascular disease include whole grains, fiber, fish and fish oils, folate, vitamin B_6 , antioxidants such as vitamin E, and soy protein. Observational studies tend to report lower rates of CHD events among those who take antioxidant vitamins and perhaps folate supplements; however, studies are inconsistent and the effects are modest.

ANTIOXIDANT VITAMINS.

Basic research strongly suggests that oxidative stress plays an important role in the development of atherosclerotic disease and that vitamin E may delay or prevent various steps in atherosclerosis. Human observational data are compatible with the possibility that vitamin E intake from either foods or supplements may reduce the risk of cardiovascular disease. However, randomized trial data are not yet sufficient to fully assess the role of vitamin E, vitamin C, or other antioxidants in the primary or secondary prevention of atherosclerotic disease. Most trials to date have been relatively short, particularly with respect to primary prevention. In addition, studies vary greatly in the dose and form of antioxidant vitamins. Recently completed secondary prevention trials raise the possibility that some of the benefit from observational epidemiology may have been overestimated.[161] [162]

The evidence available does not establish that vitamin E reduces the risk of cardiovascular disease. Longer follow-up of the completed trials, as well as ongoing trials, will provide valuable information upon which rational clinical decision-making for individuals and policy for the health of the general public can be reliably based. Although it remains unclear whether antioxidant supplementation will reduce the risks of chronic disease, consumption of fruits and vegetables high in these micronutrients is an important part of a healthy diet.

Psychosocial Factors (see also Chaps. 31 and 70)

Psychosocial factors such as depression,[163] [164] absence of social support,[165] and anger appear to contribute to an elevated risk of CHD, although further data are needed to confirm these relationships and establish the efficacy of interventional strategies.

Studies of therapeutic interventions, while not blinded, suggest a role for improving psychosocial factors as part of prevention programs, particularly in secondary prevention. The strongest evidence comes from post-myocardial infarction patients.[166] While abundant data suggest that stress and depression are prevalent and predict events after myocardial infarction, data on interventions are limited. A recent meta-analysis of 37 small studies of health education and stress management programs for CHD patients suggested that such efforts might reduce cardiac mortality by 34 percent and recurrent myocardial infarction by 29 percent, quite possibly through favorable effects on blood pressure, cholesterol, body weight, smoking behavior, physical activity, and dietary habits.[166] Trials of antidepressants following myocardial infarction are under way.

Novel Biochemical and Genetic Markers

Hemostatic and inflammatory markers, novel lipid parameters, cellular adhesion molecules, indicators of prior infection, and markers of oxidative stress have all been linked to steps in atherogenesis, thrombosis, or cardiovascular disease events (see Chap. 30) . Several of these factors, such as C-reactive protein, fibrinogen, and extracellular adhesion molecules, are independent markers of coronary risk that add to the predictive value of cholesterol screening, whereas other factors such as homocysteine are easily treated with vitamin supplementation. The potential clinical utility of these markers[167] and current evidence regarding their modification are covered in Chapter 31 .

Thanks to recent advances, it is now possible to explore a number of gene polymorphisms that are associated with various coronary risk factors or directly with cardiovascular events. While genetic screening holds great promise for identifying individuals at risk for subsequent events, its role in primary or secondary prevention remains unclear. However, one can envision a time when genetic assays will play a role in identifying at-risk individuals and targeting therapies to reduce their risk of subsequent events.[168]

MULTIPLE-RISK FACTOR INTERVENTION PROGRAMS

While most prevention studies focus on changing a single factor, several have attempted to measure the impact of simultaneously changing multiple risk factors. In theory, the potential for synergistic effects between risk factors could lead to substantial reductions in risk that are multiplicative and offer the possibility of meaningful reductions in the risk of cardiovascular disease.[169]

Although these multiple-risk factor intervention trials (Table 32-8) have made major contributions to our understanding of cardiovascular risk, as well as our knowledge of what makes for effective--and ineffective--intervention strategies, their results have been mixed. It is clear that intervention on multiple levels can reduce risk factors and that this reduction can be sustained over time (Fig. 32-8) . In a Belgian study that was part of the World Health Organization (WHO) European Collaborative Trial in the Multifactorial Prevention of Coronary Heart Disease,[180] an intervention program composed of face-to-face counseling about eating habits, smoking, and physical activity substantially reduced predictors of coronary risk when compared with a control program that offered no such advice. The effect was sustained for 5 years.

A common result from multiple-risk factor intervention trials is a change in risk factor levels or composite scores among those receiving intervention. However, this change has not always translated into lower event rates. Explanations for this inconsistency include the possibility that the magnitude of intervention was too small or that control patients may also have improved their health habits over time. What is clear from these trials, however, is that multiple simultaneous interventions can reduce cardiovascular risk when the planned interventions are large enough and are adequately implemented.

In an analysis of seven multiple intervention trials, Kornitzer plotted change in the multiple logistic function of

Figure 32-8 In a multiple-risk factor intervention trial among workers in two Belgian factories, one receiving face-to-face advice on life style modification and the other receiving no such advice, a sustained and statistically significant reduction in the composite risk of coronary heart disease (CHD) was observed in the intervention group over the first 5 years of the 6-year study period. *(From Kornitzer M, De Backer G, Dramaix M, et al: Belgian heart disease prevention project: Incidence and mortality results. Lancet 1:1066-1070, 1983. © by The Lancet Ltd., 1983.)*

TABLE 32-8 -- MULTIPLE INTERVENTION TRIALS

TRIAL	POPULATION	INTERVENTION	CHANGE IN RISK FACTOR(S)	IMPACT ON ENDPOINT(S)
Multiple Risk Factor Intervention Trial[170]	12,866 men aged 35-57 at high risk for CHD; average 7-yr follow-up	Stepped care therapy for high BP, counseling for smoking cessation, and dietary advice for high cholesterol; *or* usual care	Coronary risk factors declined in both groups, though to a greater degree in intervention group	Nonsignificant change in CHD death: 17.9/1000 in intervention group, 19.3/1000 in usual care group
Oslo Trial[171]	1232 men aged 40-49 with coronary risk in upper quartile; 5-yr follow-up	Diet similar to AHA step 1, counseling to stop smoking; *or* usual care	LDL-C (13%), triglycerides (20%), tobacco consumption (45%), and weight were lower in intervention group than usual care group; in both groups, physical activity and BP unchanged vs. baseline	Significant reduction in fatal MI, nonfatal MI, sudden death, and cerebrovascular accidents in intervention vs. control; 55% decrease in CHD death and 32% decrease in total mortality
WHO Multifactorial Trial[172]	60,881 men aged 40-59 from 80 factories in Belgium, Italy, Poland, and United Kingdom; average 6 yr of intervention and follow-up	Educational materials or individual counseling regarding diet, smoking cessation, physical activity, and BP; drug therapy as needed for BP control; *or* no intervention	Coronary risk predictors were significantly lower in intervention group during first 5 yr of trial; by trial's end, differences were statistically significant only for high-risk subjects who received face-to-face counseling	Nonsignificant differences in all-cause mortality (-5.3%), total CHD (-10.2%; *p*=0.07), fatal CHD (6.9%), and nonfatal MI (-14.8%; *p*=0.06) for intervention group vs. nonintervention group
North Karelia Project[173]	11,992 men and women aged 25-59; 10-yr follow-up	Population-based prevention program with outreach for a smoking cessation, reducing BP and serum cholesterol and other CVD risk factors	In intervention group, 28% decrease in smoking, 3% decrease in serum cholesterol, and 3% decrease in BP vs. reference group	Age-adjusted CHD mortality decreased 22% in intervention group, 12% in reference group, and 11% in all of Finland (*p*0.05)
Goteborg Primary Prevention Trial[174]	Random sample of 20,000 men aged 47-55; average 10 yr of intervention and follow-up	Antihypertensive treatment in subjects with SBP >175 mm Hg or DBP >115 mm Hg, dietary advice for subjects with serum cholesterol levels >260 mg/dl, and smoking cessation advice; *or* usual care	BP, serum cholesterol, and smoking all decreased markedly in both intervention and control groups	No significant differences in total mortality, stroke, and CHD incidence
Minnesota Heart Health Program[175]	400,000 residents aged 30-74 of 6 (3 paired) Midwestern communities; 5- to 6-yr intervention program	Individual counseling and community outreach on decreasing BP and serum cholesterol, smoking cessation, and increasing physical activity; *or* no intervention	Generally favorable, though not statistically significant changes in intervention group vs. reference group	No significant difference in CAD death rate
Pawtucket Heart Health Program[176]	140,000 residents aged 18-64 of Pawtucket, RI, and a reference community; 7-yr intervention program	Community-wide educational programs designed to help individuals lower cholesterol and BP, stop smoking, maintain healthy weight, and increase physical activity	Small, not statistically significant decreases in serum cholesterol and BP in Pawtucket; slightly less smoking in the reference community	Projected CVD rates significantly (16%) less in Pawtucket during education program, but dropped to 8% after education program
Stanford Five-City Project[177]	320,300 residents of 5 California cities (2 intervention, 3 comparison); 5-yr intervention program	Individual counseling and community outreach regarding decreasing BP and serum cholesterol, smoking cessation, and increasing physical activity.	Statistically significant reductions in community averages of plasma cholesterol level (2%), BP (4%), resting pulse rate (3%), and smoking rate (13%) in intervention communities vs. reference communities	Decreased composite total mortality risk scores (15%) and CHD risk scores (16%) in intervention communities vs. reference communities
Lifestyle Heart Trial[169]	48 men and women aged 35-75 with ischemic heart disease; 4-yr intervention and follow-up	Low-fat vegetarian diet, moderate aerobic exercise, stress management training, smoking cessation, and group support; *or* usual care	After 4 yr, participants in intervention group were exercising more, practicing more stress management, and consuming less cholesterol and fewer fat calories than those in usual care group	In intervention group after 4 yr, significant reductions in frequency, duration, and severity of angina; fewer revascularizations (21% vs. 60%); and regression of atherosclerotic lesions (vs. continued worsening in usual care group)
Heidelberg Trial[178]	113 men and women recruited after coronary angiography for stable angina pectoris; 6-yr intervention and follow-up	Intervention group: AHA step 3 diet, 30 min of exercise daily, and two 60-min group counseling sessions per week; *or* advice about the AHA step 1 diet and encouragement of moderate aerobic exercise	Nonsignificant reductions in total cholesterol and triglycerides, maintenance of BMI, and significant increase in physical work capacity among those in intervention group	As assessed by coronary arteriography, significantly slower progression of coronary artery stenosis in intervention group, combined with significant improvements in myocardial perfusion
Stanford Coronary Risk Intervention Project[179]	300 men and women under age 75 without severe congestive heart failure, pulmonary disease, intermittent claudication, or noncardiac life-threatening illness	Low-fat diet (<20% of calories from fat and <75 mg of cholesterol/d), physical activity, and counseling for smoking cessation, with cholesterol-lowering medication as needed; *or* usual care with personal physician	Significant improvements in percent body fat, weight, BP, LDL-C, triglycerides, HDL-C, and exercise capacity in treatment group vs. controls	Although progression of coronary artery disease occurred in both groups, intervention group had a 47% lower rate of progression per individual and a 58% lower rate of progression in diseased vessel segments than reference group did

AHA=American Heart Association; BMI=body mass index; BP=blood pressure; CAD=coronary artery disease; CHD=coronary heart disease; CVD=cardiovascular disease; DBP=diastolic BP; HDL-C=high-density lipoprotein cholesterol; LDL-C=low-density lipoprotein cholesterol; MI=myocardial infarction; SBP=systolic BP; WHO=World Health Organization.

TABLE 32-9 -- MODIFIABLE RISK FACTORS FOR THE PREVENTION OF CARDIOVASCULAR DISEASE

Class 1 Risk Factors and Interventions in the Prevention of Cardiovascular Disease

FACTOR	EFFECT	INTERVENTION	COMMENT
Smoking	2- to 3-fold increased risk	Smoking cessation with behavior and pharmacological intervention	Smoking cessation results in a 60% reduction in CHD risk by 3 yr; about half of that benefit occurs in first 3-6 mo after quitting. Interventions are costeffective in both primary and secondary prevention
Hypercholesterolemia	10% increase in serum cholesterol increases risk of CVD by 20-30%	Dietary changes, lipid-lowering medications	Reduction in serum cholesterol by 10% reduces CVD death by 10% and CVD events by 18%. Treatment for >5 yr reduces CVD events by 25%. Extensive trial and cost efficacy data support a tiered approached based on underlying risk

Hypertension	7-mm Hg increase in BP over baseline increases risk of CVD by 27%	Life stye modifications, weight loss, limited alcohol intake, aerobic exercise, and medications	A 5- to 6-mm Hg reduction in BP results in 42% reduction in risk of stroke and 16% reduction in risk of CVD. Extensive trial and cost efficacy data support a tiered approached based on underlying risk.
Pharmacological Therapies			
Aspirin in secondary prevention	Reduces CVD events by 25%	Daily low-dose aspirin	Reduces risk among those with any form of CVD
Beta blockers following MI	Reduces CVD events by 18%	Daily beta blocker use	Trial data suggest that the benefit may increase with increasing dose.
ACE inhibitors for patients with low EF and following MI	Reduces CVD events by 22% in those with low EF and by 7% following MI	Daily ACE inhibitor use	Trial data suggest that the benefit may increase with increasing dose

Class 2 Risk Factors and Interventions in the Prevention of Cardiovascular Disease

FACTOR	EFFECT	INTERVENTION	COMMENT
Insulin-dependent diabetes	Increases risk 2- to 4-fold in men and 3- to 7-fold in women	Maintaining normoglycemia with diet, exercise, weight management, and insulin	Trial data strongly suggest that tight control with insulin reduces risk of microvascular disease and may reduce the risk of CVD events
Noninsulin-dependent diabetes	Increases risk 2- to 4-fold in men and 3- to 7-fold in women	Maintaining normoglycemia with diet, exercise, weight management, oral agents, and insulin as needed	Tight control appears to reduce microvascular disease, but data on the risk of CHD are not available. Those with NIDDM are likely to have multiple coronary risk factors that should be aggressively modified
Elevated fasting triglyceride levels and lower HDL levels	Increases risk	Diet, exercise, and lipid-lowering therapy	HDL and triglyceride measures are useful markers of CHD risk, and limited trial data suggest that intervention reduces risk
Obesity and physical inactivity	Increases risk	Diet, exercise, and weight management programs	In addition to improving other CVD risk factors, maintaining ideal body weight and a physically active life style may reduce risk of MI as much as 50%, but trial data are limited
Menopause	Increases risk	Hormone Replacement Therapy (HRT)	HRT in postmenopausal women may reduce risk of CVD by 40-50%; however, risk of endometrial or breast cancer may increase. Trial data are limited
Moderate alcohol intake (one drink per day)	Decreases risk of MI by 30-50%	Discussion of alcohol intake with all patients	Risk/benefit ratio for moderate alcohol consumption may vary widely by gender and is based on underlying risk of CHD. Recommendations must be made individually with careful regard for conditions such as hypertension, diabetes, liver disease, history of alcohol abuse, risk of breast cancer, etc.
Pharmacological Therapies			
Aspirin in primary prevention	Pooled trial data in men suggest a 33% reduction in risk of first MI	Daily or alternate-day low-dose aspirin	Prophylactic aspirin use in older men, particularly with risk factors, may reduce risk of MI. Data among women are limited but forthcoming

Class 3 Factors and Interventions in the Prevention of Cardiovascular Disease

CATEGORY	SPECIFIC FACTORS	COMMENT
Dietary factors	Fruit and vegetable intake, type and amount of fat, type and amount of carbohydrate, fiber, *trans*-fatty acids, dietary antioxidants, dietary bioflavonoids, dietary folate, fish and fish oils, garlic, etc.	USDA recommends 5 servings of fruit and vegetables per day. Reduction in saturated and *trans*-fatty acid intake appears to be warranted
Dietary supplements	Multivitamins, antioxidant supplements, folate, vitamins B_{12} , and B_6 , fish oils, etc.	Randomized trials of antioxidant supplements have been disappointing. Randomized trial data on antioxidants and folate are forthcoming
Psychological factors	Depression, lack of social support, stress, type A personality, etc.	Trials of antidepressants in secondary prevention are forthcoming
Novel biochemical markers	Fibrinogen, homocysteine, LP(a), t-PA, von Willebrand factor, factor VII, C-reactive protein, soluble adhesion molecules (sICAM, sVCAM), antibodies to various infectious agents, measures of oxidative stress, etc.	Additional observational data are needed to clarify the role of these factors in clinical practice
Genetic markers	LDL receptor, factor V Leiden, ACE, etc.	Potential genetic markers and therapies are emerging at a rapid rate

ACE=angiotensin-converting enzyme; BP=blood pressure; CHD=coronary heart disease; CVD=cardiovascular disease; EF=ejection fraction; HDL=high-density lipoprotein; HRT=hormone replacement therapy; LDL=low-density lipoprotein; Lp(a)=lipoprotein little A antigen; MI=myocardial infarction; NIDDM=non-insulin-dependent diabetes mellitus; sICAM=soluble intercellular adhesion molecule; sVCAM=soluble vascular cell adhesion molecule; t-PA=tissue-type plasminogen activator; USDA=U.S. Department of Agriculture.

risk against the reduction in risk of CHD.[181] The strong linear relationship (Fig. 32-9) suggests that as long as risk factors are truly modified, event rates will also be reduced.

Braunwald: Heart Disease: A Textbook of Cardiovascular Medicine, 6th ed., Copyright © 2001 W. B. Saunders Company

SUMMARY OF RECOMMENDATIONS

The appropriate strategy for any given patient begins with assessment of the overall risk of a first or subsequent cardiovascular event. Patients can be classified into two broad groups: those with overt cardiovascular disease, including previous myocardial infarction, stroke, peripheral vascular disease, angina, or prior vascular procedure, and those without overt cardiovascular disease. Those without cardiovascular disease can be further subdivided into three risk strata: diabetics, high-risk nondiabetics, and low-risk nondiabetics. Those with cardiovascular disease and diabetes are generally straightforward to identify. Stratifying the remaining group requires the use of an algorithm such as those developed by the Framingham Heart Study (see Fig. 32-2) or the European Society of Cardiology (see Fig. 32-3).

Table 32-9 summarizes the interventional approach for each of the class 1 and 2 factors. Many of these activities can be undertaken by allied health professionals in a prevention program. Case management models of prevention have been demonstrated as useful among higher-risk groups following myocardial infarction or bypass surgery.[182] [183]

CONCLUSIONS

Current data strongly support a role for risk factor modification in both primary and secondary prevention of CHD. For three risk factors--cigarette smoking, elevated serum cholesterol, and hypertension--the strength and consistency of association with atherosclerotic disease indicate a causal relationship, and the benefits of intervention are well documented

---

in both primary and secondary prevention. There is little doubt that diabetes, low levels of HDL cholesterol, elevated levels of triglycerides, physical inactivity, obesity, and menopause increase the risk of CHD and that light to moderate alcohol consumption reduces the risk, but the precise magnitude of the effect attributable to intervention for these factors has been difficult to document.

The trends of several modifiable risk factors are troubling. As the population ages, the number of individuals with factors that put them at risk for cardiovascular disease will increase even if age-adjusted risk factor rates decline. Similarly, the number of people living with cardiovascular disease will increase, thus necessitating greater secondary preventive efforts. Obesity and physical inactivity are epidemic among all sectors of the population, including children. These factors will tend to increase rates of diabetes and hypertension and slow the favorable trends in mean lipid levels.

Primary and secondary prevention has contributed substantially to the reduction in CHD mortality rates. Yet much remains to be done. In addition to developing a better understanding of the mechanistic and epidemiological determinants of atherosclerotic disease, we must pay more attention to finding effective strategies for prioritizing factors in prevention programs, implementing existing guidelines for risk factor modification, and developing low-cost interventions for factors for which guidelines are not yet available. Many life style changes are difficult to achieve and even harder to maintain over the long term. Such interventions need to involve not only the affected individuals but also families, workplaces, schools, and even whole communities.

For clinicians, identifying a successful strategy for each patient is of critical importance. Further research on cost- and risk-benefit ratios will enable better targeting of interventions for maximal individual and societal benefit. More widespread use of multifaceted self-help and health professional-directed prevention programs should help sustain the decline in cardiovascular disease mortality rates in the United States.

Figure 32-9 For seven trials, four of which made up the World Health Organization (WHO) European Collaborative Trial in the Multifactorial Prevention of Coronary Heart Disease, Kornitzer plotted the difference in a composite risk factor score between treated and untreated groups and showed a statistically significant correlation between the magnitude of risk factor improvement and coronary heart disease (CHD) mortality. *(From Kornitzer M: Changing individual behavior. In Marmot M, Elliott P [eds]: Coronary Heart Disease Epidemiology: From Aetiology to Public Health. Oxford, Oxford University Press, 1992, p 492.)*

Chapter 33 - Lipid-Lowering Trials

ANTONIO M. GOTTO JR.
JOHN A. FARMER

The decline in age-adjusted cardiovascular mortality during the past three decades in the United States has been dramatic. The mechanisms that underlie this encouraging decline in death rates represent a multifactorial interplay between enhanced diagnostic capabilities coupled with improved capacity to treat both preclinical and advanced atherosclerotic disease, thanks to refinements in medical therapy and revascularization techniques. The ability to identify persons at risk well before the onset of symptomatic vascular disease has likewise improved and may account for some of the observed epidemiological benefit. Medical treatment for coronary artery disease has evolved rapidly over the past 15 years with significant improvements in antithrombotic and antiplatelet therapy, hypertension control with safe and well-tolerated medications, and new agents to alter the lipid profile.

The central tenet of the "lipid hypothesis" of coronary disease etiology that dyslipidemia is central to the process of atherosclerosis has now been validated by numerous pathological, epidemiological, genetic, and interventional trials (see Chap. 31) . Great strides have been made in the past 5 years to enhance the clinician's ability to identify--and direct effective therapies against--the involved abnormal lipid fraction, which may include elevated total and low-density lipoprotein cholesterol (LDL-C), high triglycerides, low high-density lipoprotein cholesterol (HDL-C), and elevated lipoprotein (Lp)(a). In this chapter we discuss data from the more recent, representative epidemiological, angiographic and clinical lipid trials. Readers interested in the earlier classic trials (e.g., the Lipid Research Clinic Coronary Primary Prevention Trial, the Helsinki Heart Study) are referred to the fifth edition of *Heart Disease*.

EPIDEMIOLOGICAL STUDIES

A number of classic epidemiology studies (Seven Countries Study, Framingham Heart Study, Muenster, and others) have published recent updates, and new important information continues to be obtained from these trials.

Seven Countries Study

The Seven Countries Study measured total cholesterol levels at baseline in the years between 1958 and 1964 with subsequent 5-year and 10-year follow-up in the original cohort of 12,467 male subjects who were located at 16 centers in seven countries, including Europe, the United States, and Japan. The 25-year follow-up of the Seven Countries Study has been completed and the differences in cholesterol and cardiovascular mortality among the cohorts have been analyzed.[1] Considerable variability was observed in the mean cholesterol levels among nations, which ranged from 160 to 170 mg/dl in the Japanese cohort to 240 to 260 mg/dl in the United States and northern European population. The cholesterol levels correlated directly with the age-adjusted 25-year coronary heart disease (CHD) mortality rate, which was lowest in Japan (3.2 percent) and highest in northern Europe (20.3 percent) (Fig. 33-1). The low mortality in the Japanese cohort was present despite the relatively higher tobacco usage in this population compared with that in northern Europe (74.3 percent vs. 66.8 percent, respectively).

Although the absolute CHD mortality rates differed, the slopes of the event curves were comparable. The increase in risk associated with a 0.5-mg/dl increase in cholesterol was estimated. Only the relative risk in Japan did not differ from unity. In the other cohorts, the estimated increased relative risks ranged from 1.10 to 1.15. However, the power to detect a significant association in the Japanese cohort may be low because of the relatively few coronary patients and even fewer deaths due to CHD, possibly resulting from the low national cholesterol level in Japan. However, larger epidemiological studies performed with a similar trial design in China have demonstrated a positive linear relation between dyslipidemia and coronary mortality even at the extremely low cholesterol levels of the Chinese population. Cholesterol thus predicted the degree of CHD risk in different cultures, although the absolute level of significant clinical events associated with atherosclerosis was quite variable in the various countries analyzed in this trial. The changes in absolute CHD rates may be a function of dietary habits, favoring consumption of diets low in saturated fat and high in natural antioxidants that may have beneficial, anti-atherosclerotic effects.

Prospective Cardiovascular Muenster (PROCAM)

The PROCAM study reported that the epidemiological relation between dyslipidemia and coronary events could be correlated with an elevated total cholesterol to HDL-C ratio in combination with hypertriglyceridemia.[2] This observation corroborates a retrospective subset analysis in the Helsinki Heart Study, which demonstrated that 70 percent of the coronary events in this primary-prevention trial of gemfibrozil occurred in a similar subgroup of the total cohort that accounted for 10 percent of the randomized individuals.[3]

The PROCAM study has published 8-year follow-up data.[4] It analyzed a number of lipid parameters and clinical characteristics of 17,437 men (mean age 40.4 years) and 8,065 women (mean age 36 years). The PROCAM study implicated tobacco usage, diabetes mellitus, positive family history of myocardial infarction, and systolic blood pressure as independent predictors of risk for coronary disease in addition to the classic lipid parameters. The LDL-C:HDL-C ratio greater than 5, which had been used as a marker of increased risk in the earlier evaluations, was associated with a 19.2 percent probability of a patient developing a significant atherosclerotic event in the 8-year follow-up period. Additionally, in the subgroup of participants with the combination of hypertriglyceridemia with an adverse LDL-C:HDL-C ratio (> 5), the rate for developing a coronary event was approximately 26.9 percent. The risk for CHD

Figure 33-1 Seven Countries Study. Relationship between cholesterol and coronary heart disease (CHD) mortality rates. (From Verschuren WM, Jacobs DR, Bloemberg BP, et al: Serum total cholesterol and long-term coronary heart disease mortality in different cultures: Twenty-five-year follow-up of the seven countries study. JAMA 274:131-136, 1995. Copyright 1995, American Medical Association.)

was elevated approximately sixfold in this small subset of individuals (4.3 percent prevalence of this lipid constellation).

As have other epidemiological studies, the PROCAM study reported a J-shaped relation between cholesterol and mortality, with both low and high levels associated with increased deaths.[5] Previously, the validity and clinical implications of the J-shaped relation have been controversial and difficult to determine because of multiple confounding factors, such as poor health habits, alcoholism, malignancy, or cigarette smoking, that contribute potentially to a lower cholesterol and higher mortality. One interpretation of this relation has hypothesized that the increased mortality may be a deleterious consequence of low cholesterol levels and questioned the safety

of aggressive lipid modification.

The PROCAM investigators analyzed smoking habits and malignancies and determined that at high total cholesterol and LDL-C concentrations, the increased mortality was due to a higher death rate associated with coronary atherosclerosis. At the low levels, increased mortality was seen predominantly in smokers and could be related to an increase in smoking-related cancer deaths. Thus, in the PROCAM cohort, risks associated with smoking could explain the increased mortality at lower cholesterol levels.

The PROCAM study also extended the previously described data relating coronary mortality and hypertriglyceridemia as an independent risk factor for coronary events independent of HDL-C or LDL-C levels. Because of the inherent problems associated with epidemiological studies, the precise underlying mechanism or causality of the increased risk with this lipid pattern cannot be delineated. Possible mechanisms for this association include a link between hypertriglyceridemia and an increased incidence of atherosclerosis because of a propensity for hypercoagulability and persistence in the circulation of atherogenic subpopulations of triglyceride-rich particles.[6]

Framingham Heart Study

The Framingham Heart Study has provided a wealth of epidemiological information elucidating the relation between total cholesterol, LDL-C, HDL-C, and triglyceride levels and the risk for coronary atherosclerosis. Now extended to include the Offspring Study of the original cohort, the Framingham Heart Study has amplified the prior documentation of the increasing coronary risk associated with risk factor clustering.[7]

The Framingham investigators analyzed prospectively six metabolically linked risk factors, which include body mass index, systolic blood pressure, hypertriglyceridemia, glucose, cholesterol, and HDL-C levels. The Framingham Offspring Study examination from 1971 to 1974 analyzed measurements in 2406 men and 2569 women who ranged in age from 18 to 74 at the initial assessment. A risk factor sum that ranged from 0 to 6 was tabulated to determine the impact of risk factor clustering on the 16-year heart disease risk in these subjects. The Framingham Study previously reported the risk for developing coronary disease as a proportion of the associated risk factors. The prevalence of isolated risk factors occurred with a rate of approximately 30 percent, and clustering of three or more risk factors occurred in approximately 17 percent in both sexes, a finding compatible with a metabolic interrelation among the various elements of the risk factor profile. The risk factor sums of 0, 1, 2, and greater than 3 were associated with a 16-year relative risk for CHD of 1, 1.54, 2.02, and 2.39, respectively in male subjects, and 1, 1.21, 2.89, and 5.90, respectively in female subjects.

Obesity and weight gain were important determinants of risk factor clustering that raised the possibility that insulin resistance may be a predisposing cause, although insulin measurements were not available at the time of original evaluation. The Framingham Heart Study highlights the importance of risk factor clustering and places emphasis on the importance of weight control in middle-aged subjects to decrease the cardiac risk.

The Framingham investigators, using the concept of risk factor clustering, incorporated lipid and blood pressure categories from the National Cholesterol Education Program (NCEP) and Joint National Committee (JNC-V) recommendations for stratification and control to establish probabilities for development of ischemic heart disease in primary prevention.[8] The cohort consisted of 5345 men and women whose age ranged from 30 to 74 years at baseline examination and who had 12 years of follow-up.

Using the concept of risk factor clustering in severity stratification, the Framingham group has developed a simple coronary disease prediction algorithm that predicts 10-year CHD risk in subjects who have no clinical evidence of overt atherosclerosis (see Fig. 31-2). Hypertension was categorized according to recommendations made by the JNC-V committee: optimal (systolic <120 mm Hg, diastolic <80 mm Hg); normal blood pressure (systolic 120-129 mm Hg, diastolic 80-84 mm Hg); high normal blood pressure (systolic 130-139 mm Hg, diastolic 85-89 mm Hg); hypertension stage I (140-159 mm Hg, diastolic 90-99 mm Hg); hypertension stage II-stage IV (systolic 160 mm Hg, diastolic > 100 mm Hg). Diabetes was considered to be present if the subject was currently under treatment with either oral hypoglycemic agents or insulin therapy. Total cholesterol was subdivided into four categories (<200 mg/dl, 200-239 mg/dl, 240-279 mg/dl, 280 mg/dl). LDL-C categories were less than 130 mg/dl, 130 to 159 mg/dl, and

more than 160 mg/dl. HDL-C categories were less than 35 mg/dl, 35 to 59 mg/dl, and more than 60 mg/dl. The age of the subject and the use of tobacco products were also considered.

During the 12-year follow-up evaluation, a total of 383 men and 227 women developed symptomatic CHD that showed a positive significant statistical correlation with the categories of blood pressure, total cholesterol, LDL-C, and HDL-C. The categorical approach using the clustering of concomitant risk factors and their severity was comparable to CHD prediction when the continuous variables were analyzed after assigning a risk. Approximately 28 percent of the CHD events in men and 29 percent in women were attributable to hypertension that exceeded the high normal range. The corresponding multivariable-adjusted risk associated with a cholesterol value of 200 mg/dl or greater was 27 percent in men and 34 percent in women. Obesity, degree of physical activity, and family history for heart disease were not used in the algorithm because the contribution of these important risk factors is difficult to quantify.

The Framingham investigators have also evaluated the association between elevated plasma Lp(a) and CHD in a prospective manner.[9] The Framingham Offspring Study analyzed a total of 2191 men who were 20 to 54 years of age at the time of evaluation. The subjects had no history of known coronary artery disease and were followed for the subsequent development of symptomatic atherosclerosis as manifest by angina pectoris, myocardial infarction, coronary insufficiency, or sudden cardiac death. The cohort was followed for a median period of 15.4 years, during which time 129 cardiac events occurred. Lp(a) contributed a relative risk for the development of symptomatic vascular disease of 1.9 when analyzed in a proportional hazards model. Lp(a) was determined to be an independent risk factor in this cohort comparable to the attributable risk of a total serum cholesterol in excess of 240 mg/dl or an HDL-C level of less than 35 mg/dl. Assays of Lp(a) with standardized precision have been developed and are currently commercially available.

Copenhagen Male Study

The Copenhagen Male Study was initiated in 1970 as a prospective epidemiological trial that involved 6125 men who were eligible for the original study. In 1986, all survivors from the original trial were traced and invited to participate in a continuation of the trial. A total of 75 percent of the original cohort (3387 men with an average age of 63) agreed to participate in the follow-up. Subjects who had a history of acute myocardial infarction, stroke, or symptoms of coronary insufficiency were excluded, and 2906 men were eligible ultimately for this prospective study, which had an 8-year follow-up.[10]

The patients were categorized for both lipid and nonlipid risk factors for atherosclerosis according to tertiles of fasting triglyceride levels. Increasing triglyceride levels were associated with higher total and LDL cholesterol, higher systolic and diastolic blood pressure, higher body mass index, and a greater prevalence of hypertension and diabetes. Lower levels of HDL-C and physical activity were also associated with increasing triglyceride levels. Glucose levels were not measured, which prevented adjustment for the degree of glucose tolerance and glycemia. However, a relatively small number of patients in the Copenhagen Male Study carried the diagnosis of diabetes (1.1 percent, 1.5 percent, 3.0 percent in the increasing tertiles of triglyceride levels, respectively) and a smaller percent had glucosuria, which led the investigators to conclude that the majority of the patients did not have clinically significant diabetes.

During the follow-up period, a total of 229 subjects had an ischemic event, 66 of which were fatal. Total mortality was also documented, and a total of 426 men died during the trial. An association was found between triglyceride levels and the ischemic heart disease risk both overall and within each tertile of HDL-C, a relation that persisted with additional control for the potentially confounding effects of antihypertensive medications, sedentary life style, alcohol use, and socioeconomic class. Crude cumulative incidence rates of ischemic disease were 4.6 percent for the lowest tertile of triglyceride, 7.7 percent for the middle, and 11.5 percent for the highest third (p for trend <0.01). After controlling for other major risk factors, including HDL-C, the investigators found the relative risks for ischemic disease to be 1.5 (p=0.05) and 2.2 (p<0.001) for the middle and highest tertiles, respectively. Thus, the Copenhagen Male Study indicates that a gradient for risk for atherosclerosis can be demonstrated for increasing levels of triglycerides independent of other major risk factors. The Copenhagen Male Study further validates hypertriglyceridemia as an independent risk factor for coronary disease that may be considered in establishing a risk factor profile.

Johns Hopkins Precursor Study

The Johns Hopkins Precursor Study began in 1947 when an initial cohort of 1337 students who represented members of the graduating classes of 1948 to 1964 were enrolled. Beginning in 1949, serum cholesterol was measured in the nonfasting state in this cohort. A total of 1017 male students, whose average age at enrollment was 22 years, were followed for 27 to 42 years in an attempt to quantify the risk for cardiovascular disease and total mortality associated with serum cholesterol levels.[11] The subjects were evaluated after graduation using annual questionnaires, and between 87 and 94 percent of the population responded at least once over

any 5-year period. The vital status of more than 99 percent of the cohort had been established before evaluation of the data.

The subjects were analyzed for blood pressure and body mass index and a number of health habits. Of the men, 3.5 percent were hypertensive, defined as a systolic pressure in excess of 160 mm Hg and a diastolic pressure in excess of 95 mm Hg; 5 percent of the subjects were overweight, as defined by a body mass index greater than 27.8 kg/m^2 ; and, approximately 50 percent of the subjects smoked during medical school. Active physical training in the month before the initial examination was documented in 19 percent of the cohort. The average serum cholesterol at the beginning of the trial was 192 mg/dl. The cohort contributed a total of 27,871 person years of observation with a median follow-up of 30.5 years. A total of 125 cardiovascular disease events and 97 CHD events were reported during the follow-up period. A total of 95 participants died, and death was attributable to cardiovascular disease in 21 subjects, of which 18 had CHD. By 1985, only 10 subjects reported that they received hypolipidemic therapy and the mean cholesterol at the baseline examination of these subjects was 225 mg/dl. The prevalence of smoking decreased from 48 percent at baseline to 10.5 percent in 1986. The cumulative incidence of hypertension over the course of follow-up was 38.4 percent, and the cumulative incidence of diabetes was 6 percent.

Baseline serum cholesterol was strongly correlated with the subsequent incidence of CHD, which steadily increased for each quartile of serum cholesterol. In addition, there was a graded correlation between baseline serum cholesterol and subsequent fatal events. Multivariate analysis confirmed the relation for CHD and cholesterol. The Johns Hopkins Precursor Study clearly demonstrated a strong positive and progressive relation between dyslipidemia in early adult life and the subsequent incidence of CHD over approximately four decades of follow-up. Importantly, the risk

for cardiovascular disease was increased even among men whose serum cholesterol fell within the normal range.

Epidemiological studies are frequently confounded by socioeconomic considerations with an adverse health habit profile being more prevalent in patients with lower income levels, but the relatively homogeneous and high socioeconomic status in this cohort allows a reasonably unconfounded prospective assessment of the effect of cholesterol on mortality. The implication of the Johns Hopkins Precursor Study is that in generally healthy young males, the total serum cholesterol is a strong predictor of clinically evident cardiovascular disease occurring 25 years or more after the initial measurement.

DIET STUDIES

Lifestyle Heart Trial

The Lifestyle Heart Trial investigated the premise that comprehensive life style changes could alter the clinical and angiographic progression of coronary disease. The original trial analyzed both lipid and quantitative angiographic parameters after a 12-month intervention period that included intensive life style changes involving diet (strict vegetarian with 10 percent of calories obtained from fat), aerobic exercise, stress management, smoking cessation, and group psychosocial support. Comprehensive risk factor reduction resulted in a 37.2 percent reduction in LDL-C levels that was associated with a decrease of 91 percent in the frequency of anginal episodes. The Lifestyle Heart Trial also performed baseline and 12-month angiograms and demonstrated a striking improvement in the angiographic manifestations of CHD in the group randomized to intensive risk factor management. The intensive intervention group actually demonstrated angiographic regression to a 37.8 percent average percent diameter stenosis from a baseline of 40 percent stenosis. The usual care group demonstrated an increase in average percent diameter stenosis from 42.7 to 46.1 percent, suggesting progression.

The original Lifestyle Heart Trial was subsequently extended for a 5-year total trial duration and angiographic, clinical, and myocardial perfusion data were obtained.[12] A total of 48 subjects with moderate to severe CHD completed the 5-year follow-up. The experimental group decreased fat intake from approximately 30 percent of total calories to 8.5 percent. The average cholesterol intake had been 211 mg/d and was decreased to 18.6 mg/d. Patients in the experimental group lost 12.8 pounds after 5 years, compared with minimal changes in the control group. LDL-C, which had decreased by 40 percent at 12 months, remained 20 percent below baseline after 5 years of dietary and other hygienic interventions.

Striking angiographic changes were seen at the 5-year follow-up. In the intensive care group, the average baseline percent diameter stenosis was 41.3 percent; intensive therapy reduced this to 37.3 percent at 5 years. The control group, which demonstrated an average diameter stenosis of 40.7 percent at baseline, had increased to 51.9 percent stenosis at 5 years. This difference was highly statistically significant when analyzed with a between group two-tailed *t*-test (p=0.001).

Clinical events were tabulated, and the incidence of myocardial infarction, coronary angioplasty, coronary artery bypass surgical procedures, cardiac-related hospitalizations, and cardiac deaths were compared between the two groups. At 5 years, there were more total cardiac events in the control group compared with intensive therapy (45 events vs. 25 events, respectively). The Lifestyle Heart Trial emphasizes that comprehensive and rigorous modification of diet, smoking, exercise, and stress exposure in a highly motivated population may yield measurable benefits, using life style changes alone.

Lyon Diet Heart Study

The Lyon Diet Heart Study examined the effect of Mediterranean diet in a total of 605 subjects who had suffered an acute myocardial infarction. For a mean duration of 46 months per patient, the investigators compared the effect of a Mediterranean diet with that of a prudent Western-type diet on risk for recurrent coronary events.[13] The Mediterranean diet had fewer calories and a significantly lower content of both saturated fats and polyunsaturated fats relative to the Western diet. The composition of polyunsaturated fats in the Lyon Diet Heart Study consisted predominantly of oleic, linoleic, and linolenic, all of which were significantly increased when compared with the control diet.

A total of 275 cardiac events were documented during the 46-month follow-up period, and a significant reduction in recurrent event rates was achieved by the Mediterranean diet. At the 46-month follow-up period, the event rate for cardiac death and nonfatal myocardial infarction in the intervention group was 1.24 per 100 patients per year compared with 4.07 events per 100 patients per year in the control group (72 percent risk reduction, p=0.0001). All-cause mortality rate was also significantly reduced (56 percent risk reduction, p=0.03).

Multivariate analysis documented that the dietary pattern, cholesterol, hypertension, and leukocyte count were major independent and joint predictors of a nonfatal myocardial infarction or coronary death. Smoking was not independently related, but because the total prevalence of smokers in both groups was low (<20 percent) at the final visit, the impact of tobacco use was statistically inadequate for analysis. The protective effect of the Mediterranean diet in the Lyon Diet Heart Study was thus maintained up to a period of 4 years after an acute myocardial infarction. The composition of the Mediterranean diet appears to be cardioprotective and associated with improved outcomes in secondary prevention. This result emphasizes the importance of dietary therapy with optimal caloric and nutrient composition in patients with significant atherosclerosis.

Study on the Prevention of Coronary Atherosclerosis by Intervention with Marine Omega-3 Fatty Acids (SCIMO)

SCIMO was a randomized, double-blind study conducted at a single center and was designed to assess the effects of a fish oil concentrate on coronary angiographic parameters as a primary endpoint after 24 months of therapy.[14] The patients were initially stratified according to three criteria: (1) angioplasty in the 6 months before randomization; (2) current hypolipidemic therapy; and (3) risk factor stratification. A total of 223 subjects were randomly assigned to receive either a fish oil capsule containing omega-3 fatty acids or a matching placebo.

The angiograms were visually analyzed by three experts with the determination of a global score as the primary endpoint. The coronary segments in the fish oil group demonstrated less progression and more regression compared with subjects in the control group when analyzed on an "intent to treat" basis (p=0.041). The induced angiographic changes increased in significance when the extent of analysis was limited to more compliant patients. A total of eight predefined clinical endpoints were reported in the placebo group compared with four in the patients randomized to receive fish oil, a difference that did not reach statistical significance because of the small numbers.

Thus, treatment with omega-3 fatty acids resulted in less angiographic progression and more regression of coronary artery disease, overall, relative to placebo. This finding contrasts to those of previously described studies using marine fatty acids. Although SCIMO was not powered to evaluate clinical events, a beneficial trend was seen in the group randomized to receive omega-3 fatty acids. More data are needed on fish oil supplementation before definitive clinical recommendations can be made.

STATIN TRIALS

Angiographic

Statin Monotherapy

A number of angiographic trials using statin monotherapy have been performed that uniformly demonstrated benefit in altering the course of atherosclerosis (Table 33-1) .

Multicentre Anti-Atheroma Study

The Multicentre Anti-Atheroma Study (MAAS) was an angiographic trial that analyzed the effect of diet plus either 20 mg/d of simvastatin or placebo in a group of 381 subjects with documented coronary artery disease.[15] Quantitative angiographic analysis using the computer-assisted Cardiovascular Angiography Analysis System (CAAS) was performed to determine the mean lumen diameter for angiographically diseased segments, minimum lumen diameter, reference diameter, and percent diameter stenosis. Patients were included if they fell within the range of 30 to 67 years of age and had at least two coronary artery segments that were involved with atherosclerosis but not totally occluded. The patients were clinically stable in that angioplasty or bypass surgery was not considered to be absolutely necessary for control of symptoms or for management of a high-risk anatomic subgroup (severe triple-vessel or left main coronary artery disease). Exclusion criteria included prior coronary artery bypass surgery, recent myocardial infarction, unstable angina, significant hypertension, and congestive heart failure. The trial was conducted over a 48-month duration, at which time repeat angiography was performed.

Simvastatin plus diet therapy was successful in improving the lipid profile when compared with the changes induced by dietary intervention alone. A reduction in total cholesterol of 23 percent was achieved, which was accompanied by a 31 percent reduction in LDL-C. HDL-C levels were increased by 9 percent and triglyceride levels were reduced by 18 percent. The investigators analyzed a number of other lipid subfractions including apolipoprotein AI (APO AI), apolipoprotein B (APO B), and Lp(a). Lp(a) and APO AI were not significantly altered by simvastatin therapy, although a 28 percent reduction in levels of APO B was achieved.

Simvastatin therapy resulted in a beneficial alteration of the mean lumen diameter, minimum lumen diameter, and diameter stenoses when compared with diet alone. The patients were also classified as to their angiographic response to pharmacological or dietary interventions. Progression was the predominant angiographic picture in 54 patients randomized to placebo compared with 41 randomized to simvastatin. In the simvastatin group, 33 patients were classified as having undergone angiographic regression, compared with 20 in the placebo group. Thus, simvastatin therapy resulted in fewer patients experiencing angiographic progression and a higher proportion who demonstrated actual regression (p=0.02). Angiographic benefit was least evident in current smokers, who accounted for less than 25 percent of both treatment groups. Plaque stability was obtained in 94 patients randomized to simvastatin compared with 72 randomized to placebo. The MAAS trial was not powered for changes in mortality, but a total of 11 cardiac deaths occurred in the placebo group compared with 4 in the simvastatin group.

The MAAS trial was interpreted as demonstrating that improvement in both focal and diffuse coronary atherosclerosis could be induced by simvastatin. Fewer new lesions and complete occlusions were developed in the treatment group, and there were no significant differences in side effects or adverse reactions. Although the angiographic difference between treatment and control groups was small in absolute terms, the results of MAAS are consistent with other long-term angiographic trials.

Multicenter Coronary Intervention Study (CIS)

CIS was a 2.3-year, multicenter, randomized, double-blind, placebo-controlled trial that evaluated the effect of diet plus either simvastatin, 40 mg/d, or placebo in 254 male subjects with documented atherosclerosis and hypercholesterolemia.[16] Mean baseline cholesterol values for all patients were approximately total cholesterol, 240 mg/dl, and LDL-C, 165 mg/dl. The primary endpoints of the CIS were a comparison of the global change score of the treated and control groups as determined by visual evaluation and the per-patient mean change of minimum lumen diameter evaluated quantitatively by the CAAS system.

Simvastatin therapy resulted in a significant improvement in the lipid profile relative to diet. A 35 percent reduction in LDL-C was achieved by simvastatin when compared with placebo. Total cholesterol was decreased by 28.5 percent, and triglycerides were decreased by 28 percent, both of which were statistically significant differences. Simvastatin therapy increased HDL-C by 6.1 percent, which was not statistically different from changes induced by diet.

TABLE 33-1 -- ANGIOGRAPHIC STUDIES OF STATIN MONOTHERAPY: MODEST VASCULAR CHANGES ARE ASSOCIATED WITH DISPROPORTIONATE EVENT REDUCTIONS

TRIAL (INTERVENTION)	% LDL-C REDUCTION Rx-Pbo	deltaMLD Rx_{final} -$Rx_{baseline}$	CORONARY EVENT REDUCTION (pVALUE)
PLAC I[20] (pravastatin)	29	-0.03	60% (p=0.05)
CCAIT[17] (lovastatin)	27.4	-0.02	22% (NS)
MAAS[15] (simvastatin)	31.4	-0.02 (diffuse disease)	22% (NS)
LCAS[25] (fluvastatin)	26.5	-0.03	24% (NS)

Rx=Treatment; Pbo-placebo; PLAC I=Pravastatin Limitation of Atherosclerosis in the Coronary Arteries; CCAIT=Canadian Coronary Atherosclerosis Intervention Trial; MAAS=Multicentre Anti-Atheroma Study; LCAS=Lipoprotein and Coronary Atherosclerosis Study; NS=nonsignificant.

Follow-up angiography was obtained in 81 percent of the randomized patients. The mean global change score was +0.2 in the simvastatin group and +0.58 in the placebo group, representing a statistically significant decrease in the rate of progression in the group randomized to drug therapy (p=0.02). The mean quantitative change in minimum lumen diameter stenosis was -0.02 mm in the simvastatin group and -0.10 mm in the placebo group, again a statistically significant slowing of progression (p=0.002).

CANADIAN CORONARY ATHEROSCLEROSIS INTERVENTION TRIAL (CCAIT).

CCAIT was a double-blind, placebo-controlled, angiographic trial conducted over a 2-year period in 331 patients.[17] Angiograms were analyzed using the Cardiovascular Measurement System (CMS), which is a computer-based quantitative angiographic method for the determination of minimum lumen diameter. The CCAIT used relatively aggressive lipid-lowering therapy with lovastatin, which was begun at an initial dosage of 20 mg/d with the potential for titration up to 80 mg/d, which was intended to achieve an LDL-C level under 130 mg/dl. The CCAIT enrolled both men and women with a total cholesterol value between 220 and 300 mg/dl. Patients were excluded if triglyceride levels exceeded 500 mg/dl or if significant clinical instability was evident (ejection fraction <40 percent: left main coronary stenosis > 50 percent; recent myocardial infarction or unstable angina; or angioplasty within the 6 months before admission). The angiograms were analyzed in a quantitative manner and the investigators were blinded as to the treatment allocation or temporal sequence of the films. The primary endpoint was the coronary change score, which was defined as the per-patient mean of the minimum lumen diameter changes for all lesions that were greater than 25 percent obstructed on both angiograms. Secondary endpoints included the formation of new lesions, new total occlusions, presence of anatomic progression or regression, and the coronary score of all lesions that were at least 50 percent obstructed at baseline.

Lovastatin therapy significantly improved the lipid profile when compared with placebo patients. Total cholesterol was decreased by 21 percent, which was accompanied by a decrease in LDL-C of 29 percent. HDL-C was increased by 7.3 percent, and triglyceride levels were decreased by 8 percent. Accompanying the change in LDL-C, APO B levels were decreased by 21 percent. The placebo group demonstrated little or no alteration of circulating lipid values. The target LDL-C was achieved in 69 percent of patients randomized to lovastatin, and the mean dosage was 36 mg/d. Dietary therapy alone reduced LDL-C to less than 130 mg/dl in 10

percent of the placebo patients.

Progression of atherosclerosis was significantly reduced by lovastatin therapy when analyzed using the change in coronary score. Minimum lumen diameter decreased by 0.05 mm in patients randomized to receive lovastatin, compared with 0.09 mm in the placebo group, indicating a significant slowing of the atherosclerotic process. Percent diameter stenosis was also increased to a lesser degree with lovastatin (1.66 percent increase with lovastatin compared with 2.89 percent increase with placebo). The majority of lesions that underwent anatomic progression were considered to be minimally obstructed (<50 percent occlusion) on the baseline angiogram. In the lovastatin group, 6.8 percent of these lesions progressed compared with 11.2 percent in the placebo group. Lovastatin also significantly reduced the development of new lesions: 16 percent of lovastatin patients developed new lesions compared with 32 percent of placebo patients.

The results of CCAIT demonstrate that lovastatin was able to diminish the rate of angiographic progression and to retard the development of new atherosclerotic lesions when compared with a placebo group. However, subjects who demonstrated anatomic regression or recanalization of previously totally occluded vessels were uncommon. The absolute change in coronary score between the two randomized groups is of comparable magnitude with other angiographic trials. Lovastatin therapy appeared to be more beneficial in subjects whose baseline LDL-C was above the median level of 176 mg/dl, implying enhanced angiographic benefit in the treatment of more severely dyslipidemic patients. However, a threshold value below which no treatment benefit could be documented was not established and emphasizes the importance of lipid lowering irrespective of baseline LDL-C levels in patients with known coronary disease. Reduction of new lesions may also have additional clinical importance when patients are followed for a longer period of time than the relatively brief 24-month trial period used in CCAIT.

REGRESSION GROWTH EVALUATION STATIN STUDY (REGRESS).

The Regression Growth Evaluation Statin Study (REGRESS) evaluated a patient cohort with coronary atherosclerosis and lipid levels that approximated the distribution within the general population.[18] Earlier clinical trials focused on subjects who were markedly dyslipidemic and who were believed to be at the highest level of risk for both angiographic progression and clinical events. Whereas severely dyslipidemic patients constitute a high-risk subgroup, they are relatively uncommon and thus not representative of the general population, a fact that renders extrapolation of the early intervention trials to clinical practice problematic.

The REGRESS examined the role of pravastatin in a cohort that was representative of contemporary patient profiles. In addition to pharmacological and dietary interventions that alter the lipid profile, coronary interventions (coronary artery bypass grafting and percutaneous transluminal coronary angioplasty) were allowed. REGRESS was performed in a double-blind, placebo-controlled fashion over a 24-month trial duration. The patients were men with an average age of 56 years whose average cholesterol was 234 mg/dl (range 155-310 mg/dl). Patients were recruited from multiple centers on the basis of a qualifying angiogram that required the presence of at least one atherosclerotic lesion that was greater than or equal to a 50 percent obstruction. The primary endpoint of the trial was the alteration of the mean segment diameter and minimum lumen diameter when calculated on a per-patient basis. Pravastatin was used at a fixed dose of 40 mg/d, and a total of 885 subjects were randomized to receive either dietary therapy plus placebo or dietary therapy and pravastatin.

The administration of pravastatin resulted in a significant alteration of the lipid profile when compared with the group receiving dietary interventions alone. Total cholesterol was decreased by 20 percent, which was accompanied by a decrease in LDL-C of 29 percent. HDL-C was increased by 10 percent, and there was a 7 percent decrease in triglycerides. The changes in the lipid profile could be correlated with improvement in the angiographic parameters as defined by the primary endpoint of the trial. Mean segment diameter decreased by 0.06 mm in the pravastatin group compared with 0.10 mm in the placebo group. Pravastatin therapy thus demonstrated a reduction in the rate of the progression of atherosclerosis, as assessed by quantitative measurements of the mean segment diameter. Additionally, the minimum lumen diameter decreased by 0.03 mm in the group randomized to pravastatin and 0.09 mm in the placebo group. The benefit of pravastatin therapy was demonstrated across all baseline LDL-C quartiles, emphasizing the benefit of treating lipid disorders in patients with documented atherosclerosis irrespective of baseline lipid values. Pravastatin therapy reduced the risk for clinical events (89 percent of the pravastatin-treated patients were event free after 2 years vs. 81 percent of the placebo, p=0.002). It is interesting to note that the concomitant use of calcium

channel blockers in lipid-lowering therapy appears to have a synergistic effect in slowing the progression of coronary atherosclerosis in REGRESS, with fewer subjects who received combination therapy forming new lesions.[19]

PRAVASTATIN LIMITATION OF ATHEROSCLEROSIS IN THE CORONARY ARTERIES (PLAC-I).

PLAC-I was designed to examine the potential effects of pravastatin in patients with angiographically demonstrable CHD and mild to moderate hyperlipidemia.[20] The PLAC-I trial was conducted for a longer period of time (36 months) compared with other angiographic trials. Pravastatin was used at a fixed dose of 40 mg/d and was compared with dietary therapy as the control group. Subjects randomized in PLAC-I had a mean LDL-C level of 164 mg/dl (inclusion range, 130-190 mg/dl). Subjects were not randomized if triglyceride levels exceeded 350 mg/dl after dietary therapy. Angiograms were analyzed using quantitative coronary angiography. Qualifying angiograms were required to demonstrate at least one lesion, causing a greater than 50 percent stenosis before randomization. Pravastatin therapy resulted in a significant reduction in the lipid profile, with total cholesterol being decreased by 19 percent and LDL-C by 28 percent. HDL-C was increased by 7 percent, and triglycerides were decreased by 8 percent. The dietary therapy used in the control group did not result in significant lipid changes.

The alterations in the lipid profile induced by pravastatin therapy were associated with a reduction in angiographic progression. The primary endpoint was the absolute change in mean lumen diameter that was reduced by 0.02 mm/yr in pravastatin patients compared with 0.04 mm/yr in the dietary group. The beneficial trend in the alteration of mean lumen diameter did not achieve statistical significance (p=0.16). However, the change in minimum lumen diameter was significantly improved by pravastatin therapy and demonstrated a decrease of 0.03 mm/yr compared with 0.05 mm/yr in the dietary group (p=0.04). The effectiveness of pravastatin therapy appeared to be more significant in lesions of less hemodynamic significance at baseline (<50 percent obstruction). Additionally, the number of new lesions was reduced by more than 50 percent in the patients taking pravastatin. Clinical events were also monitored, and a 60 percent reduction in fatal and nonfatal myocardial infarctions (p=0.05) was achieved in the pravastatin arm of the trial.

PRAVASTATIN ATHEROSCLEROSIS INTERVENTION PROGRAM.

The Pravastatin Atherosclerosis Intervention Program compiled the clinical results from the four major regression trials using pravastatin (PLAC-I, PLAC-II, REGRESS, and KAPS).[21] The trials had similar designs in that they were placebo-controlled, double-blind, regression studies using pravastatin monotherapy for a period of 24 to 36 months and were analyzed by vascular imaging (angiography or B-mode ultrasound). A total of 1891 participants were enrolled in these trials and were characterized by atherosclerosis in the presence of mild-to-moderate dyslipidemia. Pravastatin therapy resulted in a uniform reduction in LDL-C (27-28 percent), which was correlated with the subsequent rate of cardiac events. Whereas the cumulative absolute number of events was small, nonfatal and fatal myocardial infarction was reduced by 62 percent (p=0.001). Additionally, all-cause mortality was also evaluated and, although not reaching statistical significance, a 46 percent relative risk reduction was achieved. Reduction in stroke approached statistical significance with a 62 percent relative risk reduction (p=0.054). Pravastatin therapy was able to reduce each clinical outcome measurement and emphasized the potential benefit of statin therapy in angiographically demonstrable atherosclerosis even in the presence of mild dyslipidemia.

MONITORED ATHEROSCLEROSIS REGRESSION STUDY (MARS).

The Monitored Atherosclerosis Regression Study (MARS) was an angiographic trial in 270 male and female patients that analyzed the effect of lovastatin, 80 mg/d, versus placebo on progression of atherosclerosis.[22] The total cholesterol values in the MARS trial ranged from 190 to 295 mg/dl, and angiographic requirements included at least two involved coronary segments with a minimum luminal narrowing in at least one vessel of 50 percent or greater (but not total occlusion). The MARS randomized both groups to receive dietary therapy, which consisted of 250 mg/d or less of cholesterol and 27 percent or less of the total calories obtained as fat. The primary endpoint was the per patient change in percent diameter stenosis using a blinded quantitative angiographic assessment. As a secondary endpoint, the global change score was determined, based on visual evaluation performed of expert angiographers who were blinded to treatment allocation and temporal sequence. Compared with baseline, lovastatin therapy lowered total cholesterol by 32 percent, which was accompanied by a decrease in LDL-C of 38 percent. APO B levels were decreased by 26 percent and HDL-C was increased by 8.5 percent. All of these were statistically significant changes.

The average percent diameter stenosis increased by 2.2 percent in patients who received dietary therapy alone and 1.6 percent in subjects randomized to lovastatin plus diet. The difference showed a favorable trend but was not statistically significant. However, when more angiographically significant lesions (> 50 percent luminal impingement at baseline) were analyzed, the average diameter stenosis was increased by 0.9 percent in placebo patients and decreased by 4.1 percent in lovastatin recipients, indicating highly statistically significant regression (p=0.005). Additionally, the visually analyzed mean global score was +0.9 and +0.4 in the diet and lovastatin group, respectively, indicating a slowing of progression (p=0.02). Twenty-eight lovastatin recipients had global change scores suggestive of regression, compared with only 13 patients randomized to dietary therapy alone (p=0.02).

The MARS also analyzed the role of triglyceride-rich lipoprotein particles in the progression of atherosclerotic lesions.[23] Although lovastatin significantly reduced the level of *cholesterol-rich* APO B-containing particles (designated as LpB), there was little effect on the more complex *triglyceride-rich* APO B-containing particles (designated as LpB_c). The latter set of lipoproteins were statistically higher in lovastatin-treated patients with progression in the study (p=0.02).

A possible explanation for this finding involves some discussion of triglyceride-rich lipoprotein metabolism. Apolipoprotein C-II (APO C-II) is the normally occurring activator of the endothelium-bound enzyme lipoprotein lipase, which is involved in the catabolism of triglyceride-rich VLDL and chylomicrons. Apolipoprotein C-III (APO C-III) appears to inhibit the activity of this enzyme. Thus, the relative concentrations of these apolipoproteins with opposing functions may play a role in the rate at which triglyceride-rich particles are catabolized. Increased amounts of APO C-III sequestered in HDL may be indicative of enhanced chylomicron and VLDL catabolism, thus decreasing the exposure of these potentially atherogenic particles to the vascular endothelium. This rationale seems to corroborate the findings in the placebo group, in which higher levels of triglyceride and APO C-III in very-low-density lipoprotein (VLDL)+LDL were associated with progression (p=0.05). In the combined groups, progressors had significantly higher on-trial triglycerides, VLDL-C, APO C-III in VLDL+LDL, APO C-III, APO B, and total cholesterol. Another important finding was that subjects who underwent angiographic progression had significantly lower levels of APO AI-containing particles (which include protective HDL) when compared with nonprogressors.

The potential role of triglyceride-rich lipoproteins was also analyzed in the MARS trial using carotid arterial wall intimal media thickness.[24] Analytical ultracentrifugation was used to determine the levels of lipoprotein subclasses, including triglyceride-rich intermediate-density lipoprotein (IDL). The rate of atherosclerotic progression of the distal common carotid artery was determined by measuring intimal media thickness by high-resolution B-mode ultrasound at 6-month intervals during the trial. The major APO B-containing lipoproteins were analyzed, and IDL levels had a strong positive correlation with the degree of progression of carotid artery intimal thickness (r=0.21, p<0.005). Carotid artery thickness has been used in other trials as a surrogate measure for the subsequent risk for developing stroke and CHD. Because the normally performed measurements of LDL also include measurement of IDL, the risk for atherosclerosis that is generally attributed to LDL may be at least in part a consequence of lipoproteins within the IDL subfraction.

LIPOPROTEIN AND CORONARY ATHEROSCLEROSIS STUDY (LCAS).

LCAS was an angiographic trial that analyzed the effect of fluvastatin on coronary atherosclerosis in 429 men and women (19 percent women), aged 35 to 75, with angiographic evidence of coronary disease but relatively normal LDL-C (mean LDL-C 146 mg/dl, inclusion range 115-190 mg/dl).[25] Patients qualified for randomization with an angiographically demonstrable stenosis of 35 to 75 percent using caliper measurements as a screening mechanism. Treatment was diet plus either placebo or fluvastatin, 20 mg twice a day. Because a number of angiographic and clinical trials had previously demonstrated angiographic and clinical benefits with lipid-lowering therapy, it was considered ethical to treat patients whose LDL-C levels remained above 160 mg/dl despite dietary intervention with adjunctive cholestyramine, up to 12 g/d. The cohort randomized to fluvastatin therapy demonstrated improvement in the lipid profile with an 18 percent reduction in total cholesterol and a 26.5 percent reduction in LDL-C. HDL-C levels were increased by 5.5 percent, and triglycerides were reduced by 10 percent. Dietary therapy as administered in the control patients had minimal impact on the lipid profile.

The primary angiographic endpoint was changed in the minimum lumen diameter, and fluvastatin therapy resulted in a 0.028-mm decrease in this endpoint compared with a 0.100-mm decrease in the placebo (p<0.01). The LCAS data were analyzed further based on subgroups of patients who received fluvastatin monotherapy and those who received adjunctive cholestyramine. Significant benefit was observed in monotherapy patients, with a decrease in minimum lumen diameter of 0.024 mm compared with 0.094 mm with placebo (p<0.02). A similar trend was also observed in the subgroup who received cholestyramine, although this result did not achieve statistical significance because of the small number of patients. The percent diameter stenosis increased by 0.6 percent in fluvastatin patients compared with a 2.8 percent increase in patients randomized to dietary therapy. Angiographic benefit was observed if the baseline LDL-C was either above 160 mg/dl or below 130 mg/dl, suggesting no threshold of angiographic benefit. The formation of new lesions also was decreased with fluvastatin therapy compared with placebo (p=0.03). Although LCAS was powered to assess angiographic changes, clinical events also were monitored for safety reasons. A trend in reduction in clinical event rates was seen using both fatal and nonfatal cardiac events. Myocardial revascularizations were reduced by 21 percent, and the rate for any cardiac morbid or any fatal event was reduced by 24 percent. Neither reduction was statistically significant.

In a post-hoc analysis, subgroup analysis of the LCAS patients stratified by baseline HDL-C levels was performed.[26] [26A] Patients with HDL-C levels less than 35 mg/dl had significantly more progression of angiographically determined atherosclerosis when analyzed by the decrease in minimum lumen diameter (Fig. 33-2) . However, fluvastatin therapy in this subgroup also resulted in the greatest angiographic benefit and improved event-free survival. This analysis of the LCAS data suggests that angiographic benefit may be obtained in patients with relatively normal LDL-C levels and reduced HDL-C levels with statin therapy and foreshadows the clinical findings of the larger AFCAPS/TexCAPS to be discussed later.

POST CORONARY ARTERY BYPASS GRAFT (POST-CABG) TRIAL.

The Post Coronary Artery Bypass Graft (Post-CABG) trial examined the role of aggressive versus moderate lipid lowering in the prevention of atherosclerotic progression in saphenous vein bypass grafts. In addition, the potential role of low-dose warfarin as an antithrombotic and potentially antiatherosclerotic agent was addressed by the study's 2×2 factorial manner (aggressive vs. moderate×warfarin vs. no warfarin).[27] The Post-CABG study evaluated angiographic

Figure 33-2 Lipoprotein and Coronary Atherosclerosis Study (LCAS). In LCAS, which enrolled coronary artery disease (CAD) patients with mildly to moderately elevated LDL-C, patients with low HDL-C randomized to placebo had the most CAD progression at 2.5-year follow-up angiography. The low HDL-C subgroup also had the greatest benefit with fluvastatin therapy, although the primary effect of fluvastatin, like the other statins, is to reduce LDL-C. MLD=minimum lumen diameter; HDL-C=high-density lipoprotein cholesterol. (From Ballantyne CM, Herd JA, Ferlic LL, et al: Influence of low HDL on progression of coronary artery disease and response to fluvastatin therapy. Circulation 99:736-743, 1999. Copyright 1999, American Heart Association.)

progression in both native and saphenous vein grafts. Atherosclerosis in saphenous vein bypass grafts is a complex process involving intimal fibrous hyperplasia (which is a universal finding after the use of saphenous vein grafts as conduits) and classical graft atherosclerosis. Dyslipidemia is a significant modifiable risk factor for graft atherosclerosis in subjects who have undergone a coronary bypass operation. The annual rate of occlusion in saphenous vein grafts is significant and results in both recurrence of symptoms and increased utilization of health care resources with rehospitalization, angioplasty, and repeat operations.

Thrombosis is thought to play a significant role in obstruction of vein grafts, an observation that provides the therapeutic rationale for the administration of warfarin in the Post-CABG trial. Warfarin had also been implicated as potentially playing a beneficial role in experimental atherosclerosis. The Post-CABG randomized 1351 men and women who had undergone bypass operations over a period of 1 to 11 years before the baseline angiogram. Qualifying lipids required the LDL-C level to fall between 130 and 175 mg/dl. At least one vein graft was required to be angiographically patent to qualify for randomization. The aggressive therapy group used an initial dosage of lovastatin of 40 mg/d, which could be uptitrated in an attempt to reduce LDL-C to less than 85 mg/dl. The moderate treatment group began lovastatin at 2.5 mg/d, and the dosage was doubled if necessary to achieve an LDL-C target level of less than 140 mg/dl. The Post-CABG trial was not a true statin monotherapy trial in that cholestyramine could be added if statin therapy did not achieve a level of at least 95 mg/dl in the aggressively treated group or 160 mg/dl in the moderate treatment group.

The Post-CABG trial used as its primary endpoint the mean per-patient percentage of initially patent grafts that had substantial progression of atherosclerosis (defined as a 0.6 mm or greater decrease in lumen diameter) using blinded computer-based quantitative angiography techniques. Aggressive therapy resulted in a significant reduction in LDL-C levels of approximately 40 percent from baseline, although the predefined goal of achieving LDL-C less than 85 mg/dl was not attained. The National Cholesterol Education Program guidelines for secondary prevention recommends an LDL-C level of less than 100 mg/dl, and lovastatin therapy was able to decrease LDL-C levels to a range between 93 and 97 mg/dl. In the moderate-treatment

group, an LDL-C reduction of approximately 15 percent achieved on-treatment LDL-C range between 132 and 136 mg/dl. Aggressive therapy did result in angiographic benefit, with 27 percent of the grafts in this group demonstrating progression compared with 39 percent of grafts for those who received moderate treatment (p<0.001). The addition of warfarin had no demonstrable benefit on the angiographic picture. The rate of revascularizations was 29 percent lower in the aggressive-treatment group than in the moderate-treatment group (p=0.03). The Post-CABG trial was the first trial to address the question of aggressive pharmacological lipid lowering versus a more moderate approach and the potential angiographic benefits of achieving LDL-C levels of less than 100 mg/dl as a predefined goal.

Combination Therapy

The two major combination therapy angiographic trials (Familial Atherosclerosis Treatment Study [FATS] and The Cholesterol Lowering Atherosclerosis Study [CLAS]) have been updated as to the mechanism of benefit of hypolipidemic therapy and the cumulative effects of long-term intensive treatment.

FAMILIAL ATHEROSCLEROSIS TREATMENT STUDY (FATS).

The FATS was originally performed as an angiographic trial that analyzed 146 men who were younger than 62 years of age at the time of randomization.[28] The entrance criteria were unique in that patients were selected on the basis of having an elevated level of APO B (
125 mg/dl), coronary atherosclerosis, and a family history of vascular disease. FATS was a 2 1/2 -year double-blind study that used both visual and quantitative analysis to assess the mean change in diameter stenosis and mean change in minimum luminal diameter in the 120 subjects who completed the study. Patients were randomized to one of three treatment groups: lovastatin, 20 mg twice a day, and colestipol, 10 g three times a day; nicotinic acid, 1 g four times a day, and colestipol, 10 g three times a day; or conventional therapy with diet, coupled with the potential to add colestipol if the LDL-C level remained elevated. The therapeutic interventions resulted in significant changes in LDL-C and HDL-C levels. The group randomized to receive lovastatin and colestipol lowered their LDL-C by 46 percent and raised their HDL-C by 15 percent. Nicotinic acid and colestipol therapy was associated with a reduction of 32 percent in LDL-C and an increase of 43 percent in HDL-C. Quantitative angiographic analysis revealed that 46 percent of the patients in the conventional therapy group demonstrated definite lesion progression in at least one of the nine proximal artery segments studied. Regression was the only change in 11 percent. By comparison, progression as the only change was less commonly documented among patients in the aggressive therapy group. Subjects who received lovastatin and colestipol had progression as the only change in 21 percent of the analyzed angiograms. Subjects who received niacin and colestipol had regression as the only change noted in 25 percent. Regression was documented more frequently in the lovastatin-colestipol and nicotinic acid-colestipol groups (32 percent and 39 percent, respectively, $p<0.005$). However, when the mean percentage change in stenosis was quantitatively determined, the absolute degree of change was relatively small. Colestipol-lovastatin resulted in a -0.7 percent change in stenosis, and colestipol-nicotinic acid resulted in a -0.9 percent change. The conventional therapy group demonstrated angiographic progression with an average of 2.1 percent increase in luminal stenosis.

Despite these relatively modest changes in angiographic appearance of the vessels, a significant impact on clinical cardiovascular events was demonstrated. The tabulation of clinical events included death, nonfatal myocardial infarction, or refractory ischemic symptoms that required revascularization. In the 52 patients originally assigned to conventional therapy, 11 events occurred compared with only 3 events in the 46 patients assigned to receive lovastatin-colestipol and 2 events in the 48 patients assigned to receive nicotinic acid-colestipol. Overall, intensive lipid therapy reduced the incidence of clinical events by 73 percent, which was statistically significant, with the majority of endpoints occurring in subjects with mild to moderate obstructions (<70 percent stenosis) at baseline.

The 10-year follow-up of the FATS trial has recently been presented. Subjects who completed the original 2.5-year angiographic study were offered the opportunity to continue indefinitely on triple therapy, which included nicotinic acid, 2.5 g/d, colestipol, 20 g/d, and lovastatin, 40 mg/d. A total of 75 patients agreed to continue in the trial and were followed for a period of 8 years. The remainder of the subjects were returned to their private physicians and received usual care (n=101). Triple therapy resulted in a dramatic alteration of the lipid profile in the 75 patients who continued in the trial. Baseline LDL-C was decreased from 202 to 106 mg/dl, which compared with a decrease from 188 to 166 mg/dl in the usual care group. HDL-C was increased by triple therapy from 43 to 53 mg/dl compared with an increase from 38 to 40 mg/dl change associated with usual care. Triglyceride levels were increased in the usual care group (208 to 220 mg/dl), and a significant decrease in triglycerides from 210 to 134 mg/dl was achieved by triple therapy. Morbidity and mortality data were obtained, and a 19.8 percent death rate was demonstrated in the usual care group compared with 1.3 percent death rate in triple therapy. Cardiovascular events, which included both cardiovascular deaths and nonfatal MI, were also significantly altered by triple therapy. A total of 5.3 percent of the triple therapy patients had a cardiovascular event compared with a 14.8 percent event rate in the usual care group. FATS demonstrates the benefits of long-term and aggressive therapy, and the event curves diverged steadily over the 10-year duration of the trial.

CHOLESTEROL LOWERING ATHEROSCLEROSIS STUDY (CLAS)

The original CLAS evaluated the combination of nicotinic acid and colestipol in subjects who had undergone coronary artery bypass. CLAS-I randomized 188 nonsmoking males, aged 40 to 50 years, whose cholesterol levels ranged from 185 to 350 mg/dl to receive nicotinic acid (3-12 g/d) and colestipol (30 g/d) versus dietary therapy over a 2-year period. Combination drug therapy reduced total cholesterol by 27 percent, which was associated with an LDL-C reduction of 43 percent. Triglyceride levels decreased 22 percent, and HDL-C levels increased 37 percent. All induced lipid changes in the dietary group were less than 5 percent when compared with baseline. Regression was demonstrated in 16 percent of the intervention group and 4 percent of the dietary group, a statistically significant improvement with combination therapy. At 2 years, the mean global score in the drug treatment group was 0.3, compared with 0.8 in the placebo group, indicating a reduction in the overall progression of coronary disease.

In CLAS-II, 103 men completed an additional 2 years of follow-up, during which they maintained the induced changes in the lipid profile.[29] Global coronary score indicated progression in 48 percent of the drug treated group compared with 85 percent of patients in the placebo group. Regression was observed in 18 percent in the drug-treated group and 6 percent in the placebo, a difference that attained statistical significance ($p=0.04$).

Annual follow-up for an average of 7 years has been carried out in the subjects who completed the 24-month angiographic study.[30] The cohort was evaluated for clinical coronary events, and a total of 55 of the 162 subjects had one or more documented coronary events (need for revascularization, nonfatal myocardial infarction, or coronary death). Combination drug therapy resulted in a reduction in cardiac events (22 vs. 33), and a statistically significant relative risk reduction of 40 percent for coronary events was attained and fatal and nonfatal myocardial infarctions were reduced by 60 percent. The risk for clinical coronary events was related to the degree of lesion progression in the native vessels or in bypass grafts. Additionally, reduction in minimum luminal diameter also contributed significantly to predict coronary events. The implication of the 7-year CLAS follow-up was that changes in sequential coronary angiographic lesions can be used as surrogate outcome measures for the risk for developing future clinical coronary events, thus providing justification for the utilization of shorter and less expensive trials of lipid and nonlipid therapies.

HARVARD ATHEROSCLEROSIS REVERSIBILITY PROJECT (HARP)

HARP was an angiographic trial of the effects of combination hypolipidemic treatment in a group of subjects with documented coronary artery disease whose cholesterol levels ranged between 182 and 250 mg/dl with a mean level of 213 mg/dl.[31] Eligible patients had a 30 percent or more narrowing of the luminal diameter of a major coronary artery as the qualifying lesion. Therapy targeted a total-cholesterol goal of less than 160 mg/dl, with an initial therapy of pravastatin,

40 mg/d. Nicotinic acid (1.5-3 g/d), cholestyramine (8-16 g/d), and gemfibrozil (600-1200 mg/d) were added sequentially, as needed, to achieve this goal. In addition to this target, treatment was intended to achieve a ratio of LDL-C to HDL-C of less than 2. The original cohort consisted of 91 predominantly male subjects with a mean age of 57 years, and 13 percent of the patients did not complete the trial. The final group consisted of 70 men and 9 women who underwent angiographic analysis. The baseline and follow-up angiograms were analyzed quantitatively by operators blinded to treatment status.

Compared with placebo, combination therapy resulted in significant alterations of the lipid profile. Total cholesterol was decreased by 28 percent, which was accompanied by a decrease in LDL-C and APO B levels of 41 percent and 31 percent, respectively. Triglycerides were decreased by 26 percent, and HDL-C rose 13 percent. Despite significant alterations of the lipid profile by pravastatin with the inclusion of nicotinic acid in 38 patients, cholestyramine in 24 patients, and gemfibrozil in 12 patients, no benefit was seen in coronary obstructions.

Combination therapy resulted in a decrease in minimum lumen diameter of 0.14 mm in the combination therapy group and 0.15 mm in the control group. Progression of stenosis occurred in 23 percent of lesions in the group receiving combination therapy and 28 percent in the control group. Definite regression occurred in 13 percent of both groups. Clinical events were also monitored, and no benefit to combination therapy was observed, although there was a nonsignificant beneficial trend in reduced incidence of cardiac events (10 patients with events in the control group and 6 in the combination-therapy group). Thus, HARP differs from other angiographic or clinical endpoint trials, which showed event benefit and slowing of the progression rate with lipid modification.

Although the trial did not report significant effects on progression, it was analyzed as to efficacy of stepped treatment in reaching NCEP lipid goals.[32] Approximately 70 percent of the treatment group in the HARP needed combination therapy to achieve the NCEP goal of less than 100 mg/dl for patients with evidence of coronary disease. In 18 of the 35 patients with baseline LDL-C greater than 130 mg/dl, pravastatin monotherapy at 40 mg/d decreased the mean LDL-C cholesterol level to 100 mg/dl after 6 weeks of therapy. The addition of nicotinic acid achieved this goal for an additional 15 subjects, so that a total of 33 of 35 patients in this group reached target. Based on these findings, the HARP investigators advocated pravastatin and nicotinic acid or pravastatin and gemfibrozil as reasonably well-tolerated

combination therapies that were most likely to achieve LDL-C target guidelines, reduce triglyceride, and increase HDL-C in this type of patient population.

HARP has also analyzed the influence of pretreatment LDL-C concentration on coronary disease.[33] As evidenced by the REGRESS and LCAS, the effect of treatment in "normocholesterolemic" patients would appear to be clinically relevant, because it addresses the epidemiological observation of relatively normal cholesterol values in patients who nevertheless develop evidence of atherosclerotic disease. As one explanation for the findings of this study, the HARP investigators hypothesized that alteration of LDL-C levels that fell in the normal range may demonstrate a differential impact on angiographically determined atherosclerosis when compared with the impact in patients with more significant dyslipidemia. A retrospective analysis of the HARP and other trials suggested that the improvement in coronary luminal measurements resulting from LDL-C modification may be most marked in those studies with initially more severe LDL-C elevations.

B-Mode Ultrasound Trials

ASYMPTOMATIC CAROTID ARTERY PROGRESSION STUDY (ACAPS)

The ACAPS was a randomized, double-blind, placebo-controlled clinical study in which lovastatin and warfarin were employed to analyze the progression of intimal medial thickness in the carotid arteries and the potential effect on cardiovascular events.[34] The patient cohort consisted of 919 asymptomatic men and women with an age range between 40 and 79 years with early carotid atherosclerosis defined by B-mode ultrasonography coupled with an LDL-C between the 60th and 90th percentiles. Low-dosage aspirin at 81 mg/d was recommended for all groups. Lovastatin was begun at an initial dosage of 20 mg/d and could be uptitrated to 40 mg/d. Warfarin was maintained at 1 mg/d. The goal of lipid therapy was to decrease LDL-C to a range of 90 to 110 mg/dl. The average daily dose of lovastatin in ACAPS was 26 mg/d and resulted in a 28 percent reduction in LDL-C. Minimal increases in HDL-C (ranging between 5 and 10 percent) were demonstrated.

Lovastatin therapy resulted in a significant benefit in the primary endpoint, which was the progression rate of the mean maximum intimal medial thickness. Based on ultrasound examination, an early increase in the progression rate in both the placebo and lovastatin groups over the initial 6- to 12-month period was followed by continued intimal thickening in the placebo group, as opposed to regression in the lovastatin group. Warfarin therapy did not result in significant alterations of the lipid profile or intimal thickness, although regular aspirin users demonstrated an increased benefit in LDL-C lowering with lovastatin administration. The changes in intimal medial thickness in the ACAPS trial were similar to changes in luminal diameter that had been reported in coronary angiographic trials using lipid lowering with statins. Cardiovascular events were substantially fewer in the active therapy group, with a total of 14 events in the placebo group compared with 5 events in the lovastatin group (p=0.04). Total mortality was also analyzed, and eight deaths occurred in the placebo group compared with 1 death in the lovastatin group, a statistically significant difference (p=0.02).

The role of estrogen replacement therapy was evaluated in a subset analysis of the 186 postmenopausal women enrolled in the ACAPS.[35] A total of 34 percent of the women in the ACAPS trial were on estrogen therapy and had a more favorable lipid profile, which was characterized by an improved LDL-C to HDL-C ratio. Body mass index, baseline blood pressure, and intimal medial thickness were not different between women who used estrogen and those who did not. However, intimal medial thickness tended to progress in women who were not utilizing estrogen replacement and tended to regress among estrogen users (p=0.05). The changes in intimal medial thickness appeared to be independent of changes in lipoprotein concentrations. Lovastatin was associated with a 25 percent reduction of LDL-C in both users and nonusers of estrogen and had a significant impact on progression in these women. Although estrogen did not appear to have an additive effect with lovastatin, estrogen therapy may have an effect on intimal medial thickness in women not receiving active statin therapy and may aid in the slowing of progression of early carotid atherosclerosis.

KUOPIO ATHEROSCLEROSIS PREVENTION STUDY (KAPS)

The KAPS was a population-based primary-prevention trial that analyzed the effect of pravastatin on LDL-C lowering and atherosclerotic progression in both carotid and femoral arteries.[36] The KAPS was designed with a 2 1/2 -month placebo and dietary lead-in period followed by a 36-month controlled treatment period. The femoral and carotid arteries were analyzed using high-resolution B-mode ultrasonography to analyze the extent of maximum carotid and femoral intimal thickness in four arterial segments. Pravastatin therapy resulted in significant improvement in the lipid profile with a 21 percent reduction in total cholesterol that was accompanied by a 27 percent reduction in LDL-C. HDL-C was decreased by 1.9 percent, and triglycerides were decreased by 7.6 percent. Minimal changes of the lipid profile were achieved in the placebo group.

Analysis of the ultrasonography data demonstrated that the annual rate of the progression in the placebo group was dependent on the degree of baseline intimal medial thickness. Subjects with a higher baseline degree of atherosclerotic involvement had a greater rate of progression over the duration of the trial. However, in the group randomized to pravastatin, there was no relation between the rate of progression and baseline intimal thickness. When analyzed for the determination of the rate of change quantified by millimeters per year, the pravastatin group demonstrated basically a continuous nonincreasing rate of progression regardless of smoking status or original intimal thickness. In contrast, the placebo group showed progressively increasing rates of intimal thickening that reached as high as 0.08 mm/yr in the smoking population of KAPS. Placebo nonsmokers experienced an increased progression rate for intimal thickness of 0.04 mm/yr, whereas pravastatin therapy yielded a progression rate of less than 0.02 mm/yr in both smokers and nonsmokers. The rate of progression in the pravastatin group was significantly slowed by approximately 45 percent relative to placebo. The beneficial effect of pravastatin was also enhanced in subjects with low levels of circulating alpha-tocopherol. Although the number of cardiovascular events in the pravastatin group was lower than in the placebo group, especially for myocardial infarctions, the difference was not statistically significant because of the relatively few events.

Clinical Trials: Primary Prevention

THE AIR FORCE/TEXAS CORONARY ATHEROSCLEROSIS PREVENTION STUDY (AFCAPS/TexCAPS).

The AFCAPS/TexCAPS examined the potential impact of statin monotherapy in a cohort of subjects that included both middle-aged men and women whose total cholesterol and LDL-C approximated the national average as determined by the National Health and Nutrition Examination Survey (NHANES) III.[37] The AFCAPS/TexCAPS patient population was also characterized by an HDL-C that was less than the national average. The AFCAPS/TexCAPS was designed in a prospective, randomized, double-blind, placebo-controlled fashion to test the hypothesis that primary prevention with a statin would reduce cardiac event rates in a relatively low-risk cohort of 6605 men and women with no clinical

evidence of atherosclerosis (Table 33-2) . The cohort ranged from 45 to 73 years of age for men and 55 to 73 years of age for women. Patients were excluded if there were historical evidence or symptoms of a definite prior myocardial infarction, anginal syndrome, claudication, or stroke. The entrance lipid criteria were cholesterol levels between 180 and 264 mg/dl, LDL-C of 130 to 190 mg/dl, and HDL-C of 45 mg/dl or lower in men or 47 mg/dl or lower in women. In addition to having no clinical evidence of CHD, only 12 percent of this cohort were active smokers, 22 percent were hypertensive, and 2 percent were categorized as diabetic. AFCAPS/TexCAPS is one of the first intervention trials to randomize a significant number of female subjects (n=997).

The primary endpoint was the effect of lipid lowering with lovastatin on the rate of first acute major coronary events, defined as a composite endpoint including fatal or nonfatal myocardial infarction, unstable angina, and sudden cardiac death. The study was designed with a 90 to 97 percent power to detect a 30 to 35 percent reduction in the number of participants with primary endpoint events. The inclusion of unstable angina as an endpoint was a unique feature of the trial and required the presence of new-onset exertional angina and/or accelerated or rest angina that was characterized by several objective clinical criteria. Unstable angina was prospectively defined, and the clinical criteria for the diagnosis were rigorously applied, including at least one of the following: electrocardiographic changes characterized by 1 mm ST segment depression in addition to a corresponding reversible defect on a stress perfusion study; angiographic findings of at least 90 percent epicardial stenosis, 50 percent left main coronary disease; or electrocardiographic stress testing that was associated with 1 mm ST segment depression with pain and stenosis of at least 50 percent in a major epicardial vessel.

A number of secondary endpoints were also included for analysis, including two components of the primary endpoint assessed individually. The secondary events were coronary revascularization procedures, unstable angina, fatal or nonfatal myocardial infarction, all fatal or nonfatal cardiovascular events, fatal or nonfatal coronary events, cardiovascular mortality, and CHD mortality. The trial was not powered for alteration of total mortality, but a tertiary objective was to investigate safety parameters including potential changes in both total mortality and noncardiac causes of death (e.g., violent death and malignancy).

A total of 3304 patients were randomized to receive lovastatin, which was administered over a 5-year trial period. Lovastatin was begun at 20 mg/d and could be titrated upward to 40 mg/d if the response was determined to be inadequate (LDL-C in excess of 110 mg/dl after 3 months of therapy). Lovastatin had a significant effect on lipid values, with a reduction of LDL-C of 25 percent compared with baseline. Total cholesterol was reduced by 18 percent, and triglycerides were reduced by 15 percent. HDL-C was increased by 6 percent, and the LDL-C:HDL-C ratio was decreased by 28 percent. The group randomized to diet and placebo had no significant changes in the lipid profile. Lovastatin therapy was equally effective in both men and women. Titration to a higher dose of lovastatin was required in 50 percent of the subjects in the AFCAPS/TexCAPS. Forty-two percent of the subjects randomized to lovastatin achieved the LDL-C goal of 110 mg/dl compared with 3 percent of the placebo group. Of the group randomized to lovastatin, treatment lowered LDL-C to more than 130 mg/dl for 81 percent compared with 12 percent of the placebo patients.

Lovastatin therapy resulted in a statistically significant 37 percent reduction in the incidence of a primary endpoint event ($p<0.001$). A total of 183 subjects in the placebo group had at least one primary endpoint compared with 116 subjects in the lovastatin group. Life-table plots suggest that a difference between treatment and placebo event curves began in the first year of therapy and continued to diverge throughout the remaining years of the trial. In absolute terms, 11 subjects per 1000 patient-years in the placebo group suffered an event compared with 7 subjects per 1000 patient-years in the lovastatin group. Lovastatin therapy resulted in consistent reductions in event rates in the secondary endpoints: a 33 percent risk reduction in revascularizations ($p=0.001$), a 32 percent risk reduction in unstable angina ($p=0.02$), 40 percent risk reduction in nonfatal or fatal myocardial infarctions ($p=0.002$), and 25 percent risk reductions in both coronary and cardiovascular endpoints ($p=0.006$ and 0.003, respectively). Among patient subgroups in the cohort (e.g., women, smokers, and hypertensives), the benefit of lovastatin treatment was comparable with the benefit in the overall cohort. The safety analysis demonstrated no increase in noncardiac mortality with lovastatin therapy, and the discontinuation rate was similar in the placebo and lovastatin-treated groups.

The AFCAPS/TexCAPS is the first major clinical trial of a statin to demonstrate reductions in first coronary events in a low-risk subgroup whose profile approximates the general U.S. population (Fig. 33-3). Additionally, a large proportion of the patient population was recruited from a wellness center, indicating a concern by the participants for a healthful life style. Primary-prevention trials in the past had focused on male subjects with severe dyslipidemia (e.g., Lipid Research Clinics Primary Prevention Trial) and excluded women. These results indicate that primary prevention is clinically feasible in a low-risk population, and benefit was consistent across the range of baseline LDL-C tertiles (Fig. 33-4). Of greater controversy is the issue of cost of primary prevention in this type of cohort.

Figure 33-3 The five large-scale trials of statin therapy have shown consistent relative risk reductions for nonfatal myocardial infarction (MI) or coronary heart disease (CHD) death, or comparable reported endpoint. In 4S, major coronary events included coronary death, nonfatal definite or probable MI, silent MI, or resuscitated cardiac arrest. LDL-C=low-density lipoprotein cholesterol; 4S=Scandinavian Simvastatin Survival Study; LIPID=Long-term Intervention with Pravastatin in Ischemic Disease; CARE=Cholesterol and Recurrent Events; WOSCOPS=West of Scotland Coronary Prevention Study; AFCAPS/TexCAPS=Air Force/Texas Coronary Atherosclerosis Prevention Study.

WEST OF SCOTLAND CORONARY PRIMARY PREVENTION STUDY (WOSCOPS).

WOSCOPS extended the role of statin therapy in primary prevention to a relatively high-risk cohort.[38] In a double-blind, placebo-controlled design, WOSCOPS evaluated the effects of either a fixed dose of pravastatin, 40 mg/d, or placebo over a 5-year period (see Table 33-2) . The primary endpoint of WOSCOPS was the combined incidence of nonfatal myocardial infarction or death from CHD. Additionally, WOSCOPS evaluated total mortality, death from cardiovascular cause, and the frequency of coronary revascularization procedures as secondary endpoints. The trial included patients with a history of documented myocardial infarction or a pathological Q wave and an entrance cholesterol level of at least 252 mg/dl. The WOSCOPS cohort had a number of characteristics that placed them in a relatively high-risk group despite the clinical absence of atherosclerosis as defined by a prior infarction. All subjects were men who averaged 55 years of age. The average cholesterol was 272 mg/dl, which was associated with an LDL-C of 192 mg/dl. Triglycerides averaged 164 mg/dl, and HDL-C was 44 mg/dl. Approximately 5 percent of the total cohort had a positive Rose Questionnaire for anginal symptoms, 3 percent reported intermittent claudication, and 78 percent of the patients were either current or ex-smokers.

WOSCOPS was analyzed on an "intent to treat" basis. Pravastatin therapy resulted in significant improvements in the lipid profile, even when analyzed with this conservative statistical protocol. Total cholesterol and LDL-C were decreased by 20 percent and 26 percent, respectively. Triglycerides were decreased by 12 percent, and HDL-C was increased by 5 percent. Diet plus placebo therapy resulted in no significant change in the lipid parameters from baseline. The benefits of pravastatin therapy in WOSCOPS may be underestimated because of the significant dropout rate, which was approximately 15 percent at 1 year, 19 percent at 2 years, 23 percent at 3 years, and 25 percent at 4 years. The placebo and pravastatin group had similar dropout rates at all periods during the trial. The use of an "intent to treat" analysis of the West of Scotland trial reduces the potential for introduction of bias but may also underestimate the beneficial impact of pravastatin therapy in this group.

A significant reduction of 31 percent was achieved in the primary endpoint. Total mortality was reduced by 22 percent, which closely approached statistical significance ($p=0.051$). No increase in noncardiovascular death rates could be demonstrated in the pravastatin group. When taking into account suspected coronary events, death from CHD was decreased by 33 percent ($p=0.042$). WOSCOPS also reported 31 and 37 percent reductions of coronary angiography and revascularization procedures, respectively ($p=0.007$ and 0.009, respectively). In the pravastatin group, 116 subjects had incident cancers compared with 106 in the placebo group; the difference was not significant. The number of patients in WOSCOPS reporting myalgia or elevated liver enzymes were also comparable between the two groups.

The West of Scotland trial established the benefit of statin therapy in a high-risk cohort who qualified for primary prevention by the absence of a known myocardial

infarction. Pravastatin therapy demonstrated a significant reduction in coronary death and nonfatal myocardial infarction, and the event curves began to diverge within the first 12 months of therapy.

Cost-Effectiveness (see also Chap. 2) .

Primary prevention has been criticized in even high-risk groups for economic considerations. However, WOSCOPS has been analyzed from the perspective of cost-effectiveness, using cost data derived from calculation of the number of subjects needed to be treated to prevent one event.[39] Pravastatin therapy in a cohort of male subjects with similar patient characteristics to the WOSCOPS trial would prevent one event in 31 subjects who began pravastatin therapy over a

Figure 33-4 Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS). Consistent benefit was observed across tertiles of LDL-C and HDL-C. Treatment appeared to "neutralize" risk associated with a low HDL-C or an elevated LDL-C. LDL-C, low-density lipoprotein cholesterol; HDL-C, high-density lipoprotein cholesterol. Endpoint rate is the rate of the first primary endpoint event per 1000 patient-years at risk. (Adapted from Downs JR, Clearfield M, Weis S, et al, for the AFCAPS/TexCAPS Research Group: Primary prevention of acute coronary events with lovastatin in men and women with average cholesterol levels: Results of AFCAPS/TexCAPS. JAMA 279:1615-1622, 1998. Copyright 1998, American Medical Association.)

5-year period. Restriction of therapy to the 40 percent of men at highest risk (20 percent event rate in 10 years, in accord with European guidelines) reduces the number needed to treat to 22.5. A conservative estimate of the feasibility of treating patients like those in WOSCOPS was determined to be well within the range of interventions that are considered to be cost effective (approximately £8200 [$13,000 US] per year of life saved).

Clinical Trials: Secondary Prevention

CHOLESTEROL AND RECURRENT EVENTS (CARE).

The CARE trial analyzed 4159 subjects (3583 men and 576 women) who had suffered an acute myocardial infarction between 3 and 20 months before randomization and whose total cholesterol levels at baseline were less than 240 mg/dl.[40] Additional lipid criteria required the LDL-C to be between 115 and 174 mg/dl and the fasting triglycerides to be less than 350 mg/dl. Women were excluded if they were premenopausal, and individuals with ejection fractions less than 25 percent were not allowed to be randomized. Pravastatin was administered at 40 mg/d in a fixed dose; cholestyramine, 8 to 16 g, could be added to the designated therapy if the LDL-C levels remained at 175 mg/dl or more after intensified dietary therapy in both groups. The primary endpoint analyzed in the CARE trial was nonfatal myocardial infarction and death from CHD, which included several fatal coronary events (sudden cardiac death, death during a coronary intervention, or mortality from other coronary causes). The CARE trial was designed with an 80 percent power to detect a 20 percent reduction in the number of recurrent primary-endpoint events with pravastatin and was conducted on an intent to treat analysis using two-sided *p* values (Table 33-3) .

Pravastatin therapy resulted in significant improvement in the lipid profile and was well tolerated (approximately 94 percent of the treatment group were still on the randomized medication during the final 12 months of the follow-up period). Additionally, 6 percent of the patients in either placebo or the pravastatin group required adjuvant cholestyramine therapy. LDL-C that averaged 139 mg/dl at the time of randomization was decreased by 32 percent to 98 mg/dl during the trial duration. The total cholesterol was approximately 20 percent lower when compared with the placebo group. The HDL-C level in the group randomized to pravastatin was 5 percent higher when compared with dietary therapy, and the triglyceride decrease was approximately 14 percent.

The improvements in the lipid profile relative to the dietary intervention resulted in a significant 24 percent reduction in the primary endpoint (p=0.003). In absolute terms, 13.2 percent of the dietary group had a qualifying recurrent event compared with 10.2 percent in the pravastatin group. In addition to the impact on the primary endpoint, the subjects randomized to pravastatin had a 26 percent reduction in the rate of coronary artery bypass procedures (p=0.005) and a 23 percent reduction in the rate of angioplasty (p<0.001).

The CARE trial was also analyzed for the effectiveness of pravastatin relative to the baseline lipids using a quartile analysis.[41] High levels of LDL-C were associated with a significantly elevated frequency of events. In the placebo group, the analysis demonstrated a 28 percent increase in risk for a primary-endpoint event for each 25 mg/dl increment in LDL-C. Additionally, an inverse relation between baseline HDL-C and cardiac events was demonstrated: 10 percent decrease in coronary risk for each 10 mg/dl increase in HDL-C levels. This analysis is compatible with the epidemiological curvilinear relation between cholesterol and coronary event rates.

Diabetes.

A number of subset analyses of the CARE trial have been performed, including evaluation of older subjects, diabetics, women, and persons with cerebrovascular disease. The CARE data base analyzed fasting blood sugar as part of the screening evaluation that allowed evaluation

TABLE 33-3 -- SECONDARY-PREVENTION TRIALS OF STATIN THERAPY

	SECONDARY PREVENTION		
	4S [48]	**CARE** [40]	**LIPID** [47]

HMG-CoA=3-hydroxy-3-methylglutaryl coenzyme A; 4S=Scandinavian Simvastatin Survival Study; CARE=Cholesterol and Recurrent Events; LIPID=Long-term Intervention with Pravastatin in Ischemic Disease; TC=total cholesterol; LDL-C=low-density lipoprotein cholesterol; HDL-C=high-density lipoprotein cholesterol; TG=triglyceride; MI=myocardial infarction; CHD=coronary heart disease; NS=nonsignificant; bold=study's primary endpoint; --=not reported.

of subjects with either frank diabetes or impaired glucose tolerance (110-125 mg/dl). A total of 586 patients in the CARE trial (14.1 percent of the total cohort) met the criteria for definite diabetes.[42] The nondiabetic population was subdivided into subjects with normal fasting glucose levels (<110 mg/dl) or impaired glucose tolerance (fasting blood sugar of 110-125 mg/dl). Diabetics experienced more recurrent coronary events (defined as coronary death, nonfatal myocardial infarction, or revascularization in this analysis) than nondiabetics (37 vs. 25 percent event rates, respectively). Pravastatin therapy resulted in a 25 percent reduction in the expanded endpoint in the diabetic patients. In 342 patients (8 percent of all subjects) who had impaired glucose tolerance, the rate of recurrent events was higher compared with those with normal glucose. Pravastatin was associated with a 50 percent lower recurrence rate (p=0.05 for nonfatal myocardial infarction).

The Elderly.

The CARE study examined the effects of pravastatin therapy in older subjects.[43] A total of 1283 patients whose age ranged between 65 and 75 years were enrolled in the CARE study and were included in a subgroup analysis. The older subjects had a higher frequency of hypertension and diabetes and, in addition, were more likely to be women. The older patients were less likely to be current or past smokers or to have a family history of CHD. Pravastatin therapy resulted in a qualitatively similar improvement in the lipid profile in the older population when compared with the younger group and there was no significant difference when patients were stratified to being older or younger than 65 years of age. In the older cohort, pravastatin therapy reduced the risk for a major coronary event by 32 percent, which was highly significant (p<0.001), and coronary death was decreased by 45 percent (p=0.004). Additionally, stroke rates were decreased by 40 percent (p=0.03). The CARE study is compatible with the premise that older patients should not be excluded from secondary intervention on the basis of chronological age alone, because the analysis revealed that for every 1000 patients, aged 65 years or older, who were treated for 5 years, 225 cardiovascular hospitalizations would be avoided compared with 121 cardiovascular hospitalizations in patients younger than 65 years of age.

Women.

The CARE study enrolled 576 postmenopausal women whose average age was 61 years, and these subjects were analyzed in a subgroup evaluation.[44] The baseline characteristics of the men and women in the CARE trial differed generally because the female subjects were older and had a higher prevalence of hypertension, diabetes, smoking, and a family history of coronary atherosclerosis. Women additionally had a higher mean total cholesterol and a higher HDL-C level when compared with men whereas the LDL and triglyceride levels were similar. Of the female patients in CARE, 10 percent were on estrogen replacement therapy and 3 percent were on progesterone. Risk reduction for combined coronary events was statistically significant for both women and men. The relative risk reduction for combined coronary events in women was 46 percent compared with 20 percent in men (p=0.001 for both, p=0.048 for the interaction), and the risk reduction occurred earlier with the pravastatin treatment group in women, separating at approximately 1 year. When the impact of therapy was analyzed in female subjects, approximately 228 cardiovascular events could be prevented by treating 1000 women, similar to the CARE population, with pravastatin for 5 years.

Stroke.

Another interesting finding from CARE was the reduction in risk for stroke, a prespecified endpoint in this trial. The CARE population was analyzed for the rates of both cerebrovascular accidents and transient ischemic attacks after myocardial infarction.[45] The risk factor profile in the patient groups was comparable, and no significant differences were observed. Additionally, equal proportions of both groups were using antiplatelet therapy during the trial (85 percent). The CARE cohort was documented with a total of 216 combined strokes or transient ischemic attacks (92 on pravastatin and 124 on placebo), which accounted for a 27 percent reduction in the combined rate of cerebrovascular events (p=0.02). A total of 128 completed strokes (52 on pravastatin vs. 76 in placebo) occurred. Pravastatin therapy resulted in a 32 percent reduction in the rate of acute strokes that was also statistically significant (p=0.03). The benefit of pravastatin therapy persisted in multivariate analysis when the data were adjusted for age, sex, hypertension, cigarette smoking, diabetes, left ventricular ejection fraction, and lipid levels. Epidemiological studies have long raised the question of whether lipid lowering would be associated with an increase in hemorrhagic strokes, possibly through the disruption of membrane integrity due to cholesterol lowering. The CARE study did not demonstrate a significant change in the incidence of hemorrhagic strokes (two with pravastatin vs. six with placebo). Pravastatin therapy thus significantly decreased the rate of both transient ischemic attacks and completed cerebrovascular accidents in a post-myocardial infarction cohort.

Inflammation (See also Chap. 31) .

The role of inflammation in the initiation and progression of atherosclerosis has been the focus of intense investigation, especially the predictiveness of C-reactive protein and serum amyloid A as markers of inflammation. The CARE trial was analyzed in a nested, case-controlled manner to investigate the correlation between risk and the levels of these markers, as determined from prerandomization blood samples from the 391 participants in the CARE trial who subsequently developed an acute myocardial infarction.[46] The patients who suffered an acute event were compared with age- and sex-matched controls. C-reactive protein and serum amyloid A were statistically increased in patients with events when compared with control patients. The population was divided into quintiles on the basis of C-reactive protein, and the highest quintile demonstrated a relative risk for a subsequent recurrent event to be 75 percent greater than that of subjects in the lowest quintile. The group with the greatest risk had elevated levels of both markers. The risk associated with elevated C-reactive protein and serum amyloid A appeared to be attenuated with pravastatin treatment. This subgroup analysis suggests a role for statin therapy above and beyond the traditional concept that attributes all of the benefits of such interventions solely to modification of LDL-C.

The CARE trial was a landmark study that demonstrated significant improvement in fatal and nonfatal myocardial infarction in secondary prevention despite normal baseline cholesterol levels. Subgroup analysis of the CARE trial demonstrated reductions in stroke and improvement in diabetics, elderly patients, and women. The CARE trial emphasizes the clinical utility of statin therapy in secondary prevention even with cholesterol levels that would be considered to be within the normal range.

THE LONG-TERM INTERVENTION WITH PRAVASTATIN IN ISCHAEMIC DISEASE (LIPID).

LIPID was an extremely large secondary-prevention trial that evaluated pravastatin in 9014 patients over a period of 6.1 years.[47] Patients enrolled in the LIPID trial had a broad range of cholesterol levels (155-271 mg/dl) and also included a large number of women (17 percent) (see Table 33-3) . Subjects randomized in the LIPID trial ranged from 31 to 75 years of age and were considered for inclusion if they had suffered an acute myocardial infarction or had a diagnosis of unstable angina that was established between 3 and 36 months before randomization. On the basis of post-myocardial infarction status, 64 percent of patients qualified for randomization whereas 36 percent were enrolled after a diagnosis of unstable angina. Patients were allocated to receive dietary advice and either 40 mg of pravastatin versus placebo. The

primary endpoint of the lipid trial was death from CHD. A number of secondary outcomes were also tabulated, including all-cause mortality, death from CHD, nonfatal myocardial infarction, stroke, revascularization procedures, hospital days, and death due to heart failure.

Pravastatin therapy effectively lowered lipid values, with the total cholesterol level falling 39 mg/dl from the original average value of 218 mg/dl. The pravastatin-induced reduction in total cholesterol was 18 percent greater than the effect of dietary therapy alone in the placebo group. The median LDL-C in the group randomized to pravastatin was initially 150 mg/dl and was reduced by 25 percent compared with placebo. Median triglyceride level was 142 mg/dl and was reduced by 11 percent. HDL-C was increased by 5 percent.

The primary outcome was significantly and favorably altered by pravastatin therapy. Overall mortality was 22 percent less in the group randomized to pravastatin, which was highly statistically significant (p<0.001). In absolute terms, 11 percent of subjects randomized to pravastatin suffered a fatal event, compared with 14.1 percent in the placebo group. The relative risk reduction by pravastatin in deaths from CHD was reduced by 24 percent compared with placebo (p<0.001). In absolute terms, death from CHD was 6.4 percent in subjects randomized to pravastatin compared with 8.3 percent in the placebo group. A number of secondary endpoints, including the incidence of myocardial infarction, revascularization procedures, hospitalization for unstable angina, stroke and hospital days, were also significantly reduced by pravastatin therapy. Pravastatin therapy did not result in an increase in noncardiac deaths, and there were actually fewer deaths from cancer, trauma, or suicide in the group randomized to drug therapy, although this did not achieve statistical significance.

The clinical qualifying event (myocardial infarction or unstable angina) did not alter clinical benefit from pravastatin. The subgroup who entered the LIPID trial on the basis of a previous myocardial infarction demonstrated a reduction in mortality from CHD of 23 percent (p=0.004), and overall mortality was 21 percent lower when these events were compared with the placebo group (p=0.002). The cohort of patients who qualified for LIPID by unstable angina criteria reduced both coronary and overall mortality by 26 percent (p=0.036 and 0.004, respectively). The LIPID investigators prespecified a number of subgroups for detailed analysis, including older,

hypertensive, and diabetic patients and patients who were smokers. The analysis demonstrated no evidence of significant heterogeneity of the treatment effect in any of these subgroups, suggesting consistency with the overall 24 percent risk reduction for the entire LIPID cohort. The LIPID trial evaluated a number of safety parameters, including malignancy. A total of 403 primary cancers occurred in patients randomized to receive pravastatin compared with 417 cancers in the control group, indicating no increase in malignancy from statin therapy. Deaths from violent behavior, suicide, or accidents were also not increased in the treatment group. Laboratory variables, including liver function tests and creatine kinase levels associated with myopathy, were evaluated and were essentially similar in the two groups.

Because of its large and diverse population, the LIPID trial provides extremely strong evidence that pravastatin therapy in secondary prevention is of clinical benefit across a broad range of baseline cholesterol values and is associated with a reduction in total and cardiac mortality without an increase in noncardiac deaths. The LIPID investigators estimated that for every 1000 patients assigned to treatment with pravastatin over a period of 6 years, a total of 30 deaths, 28 nonfatal myocardial infarctions, and nine nonfatal strokes could be avoided with effective lipid-lowering therapy.

SCANDINAVIAN SIMVASTATIN SURVIVAL STUDY (4S).

The Scandinavian Simvastatin Survival Study (4S) was a large-scale, double-blind, placebo-controlled trial that evaluated the effect of simvastatin therapy in dyslipidemic patients who were either myocardial infarction survivors (63 percent), patients with the anginal syndrome (21 percent), or both (16 percent) in a 5.4-year trial.[48] The age inclusion criteria ranged from 35 to 70 years. Selected exclusion criteria included documentation of a recent myocardial infarction (<6 months); congestive heart failure requiring digitalis, diuretics, or vasodilators; cardiomegaly; atrial fibrillation; significant valvular heart disease; completed stroke; concomitant serious illness; premenopausal status with childbearing potential; or statin hypersensitivity. Screening cholesterol values were required to exceed 213 mg/dl before randomization, and the range of cholesterol values after a 2-week placebo and diet phase had to range between 213 and 310 mg/dl. Patients were randomly assigned to receive either placebo or 20 mg of simvastatin per day with the allowance of dosage titration in an attempt to reduce the serum cholesterol to 116 to 200 mg/dl.

The primary endpoint of the 4S trial was the impact of simvastatin on total mortality. A number of secondary endpoints were also determined and included major coronary events (coronary deaths, acute myocardial infarction, resuscitated cardiac arrest, and definite silent myocardial infarction). Tertiary endpoints were also evaluated by the 4S investigators, which included any coronary or atherosclerotic event, death, myocardial revascularization, hospital admission for acute coronary events, and health care costs. A total of 4444 subjects fulfilled the entry criteria, with the major reasons for exclusion being hypertriglyceridemia, unwillingness to participate in a clinical trial, and cholesterol levels outside the prescribed range.

Simvastatin therapy resulted in a significant beneficial alteration of the lipid profile. A total of 37 percent of the patients randomized to simvastatin were uptitrated to 40 mg in the first 6 months of the trial because of failure to achieve the predefined lipid goal. Placebo and diet therapy resulted in essentially minimal changes in the lipid group except for the induction of mild hypertriglyceridemia. In the simvastatin group, total cholesterol was reduced by 28 percent, which was accompanied by a reduction in LDL-C levels of 38 percent (see Table 33-3) . The patients with significant hypertriglyceridemia before randomization had been excluded, and simvastatin therapy resulted in a 15 percent decrease in the patients who had initial triglyceride levels within the prescribed range of the trial. HDL-C was increased by 8 percent. Approximately 72 percent of the simvastatin therapy cohort achieved the total cholesterol goal.

The primary endpoint was achieved by simvastatin therapy, with a highly statistically significant relative risk reduction of 30 percent (p=0.0003) (Fig. 33-5). The absolute number of deaths totaled 438, with 256 subjects dying in the placebo group compared with 182 patients in the simvastatin group. The absolute risk reduction was 4 percent. Adjustment for baseline covariates resulted in no difference in total mortality or other endpoints. Safety analysis revealed no statistically significant alteration in the number of deaths from noncardiovascular causes when the simvastatin and placebo groups were compared. Specifically, there was no increase in the incidence of malignancies or violent deaths associated with hypolipidemic therapy that had been implicated in other epidemiological and intervention trials. The total frequency of adverse experience was similar within the treated and placebo group. A total of 6 percent of the patients (who were equally distributed in both active therapy and placebo) discontinued the study medication secondary to adverse events. One case of clinically significant rhabdomyolysis was documented in the simvastatin group.

Figure 33-5 Scandinavian Simvastatin Survival Study (4S). Kaplan Meier curves for all-cause mortality. Number of patients at risk at the beginning of each year is shown below the horizontal axis. (From Scandinavian Simvastatin Survival Study Group: Randomised trial of cholesterol lowering in 4444 patients with coronary heart disease: The Scandinavian Simvastatin Survival Study [4S]. Lancet 344:1383-1389, 1994.)

The 4S study was a landmark trial and demonstrated clearly that statin therapy could reduce total mortality in a secondary prevention trial. The most significant impact on mortality was due to the reductions in cardiovascular events. A number of substudies were also performed and demonstrated that simvastatin therapy was effective in women and older patients (age > 60 years).[49] Cerebrovascular events and new carotid bruits were also significantly reduced by simvastatin therapy.[50] Lp(a) was also measured in the 4S study and was a major predictor of morbidity in major coronary events.[51] The impact on clinical events is compatible with the angiographic studies (e.g., MAAS, CIS), which demonstrated that simvastatin therapy was able to alter beneficially the progression of angiographically demonstrable coronary artery disease.

Comparison Trials

ATORVASTATIN VERSUS REVASCULARIZATION TREATMENT (AVERT).

The AVERT trial was designed to evaluate the potential benefits of aggressive lipid lowering with atorvastatin, 80 mg/d, on ischemic events in a cohort of patients with stable atherosclerosis who were scheduled to undergo a percutaneous revascularization procedure.[52] The AVERT trial was an 18-month, open-label, randomized, multicenter study that evaluated 341 patients who were scheduled for elective angioplasty. Qualification requirements included at least one native coronary vessel with 50 percent or greater stenosis and an LDL-C in excess of 115 mg/dl. Subjects were excluded if the triglyceride levels were in excess of 500 mg/dl, ejection fraction was less than 40 percent, or the patients could not complete 4 minutes of exercise on a Bruce treadmill. Additionally, patients were excluded if angiography revealed left main or triple-vessel coronary atherosclerosis. Recent unstable angina and myocardial infarction (<14 days) also were major exclusion criteria.

The primary endpoint in the AVERT trial was the composite incidence of ischemic events, defined as cardiac death, resuscitation after cardiac arrest, nonfatal myocardial infarction, stroke, worsening angina, or revascularization (coronary artery bypass graft or repeat angioplasty). The patients randomized to usual care received traditional balloon angioplasty, and approximately one third of the treated lesions underwent placement of an intravascular coronary stent. The patients treated with angioplasty were allowed to receive hypolipidemic therapy as part of usual care. Lipid-lowering drugs were administered in 73 percent of patients in this group at some time during the follow-up (71 percent of the total group received statins). The subjects randomized to receive atorvastatin had a significant reduction in lipid levels with an LDL-C decrease from mean baseline value 145 to 77 mg/dl (46 percent reduction). Total cholesterol was decreased from 223 to 151 mg/dl (31 percent reduction). Triglycerides were also decreased from 168 to 139 mg/dl (11 percent reduction), and HDL-C increased from 45 to 47 mg/dl. The usual care group experienced a decrease in LDL-C from 147 to 119 mg/dl (18 percent reduction). Total cholesterol decreased from 222 to 197 mg/dl (10 percent decrease). Triglycerides increased from 161 to 165 mg/dl, and HDL-C increased from 43 to 46 mg/dl. Total cholesterol, LDL-C, and triglycerides were significantly improved by atorvastatin relative to usual care.

The composite endpoint of ischemic events was reduced by atorvastatin therapy. A total of 22 ischemic events occurred in the group randomized to receive aggressive lipid-lowering therapy compared with a total of 37 events in the usual care group (36 percent reduction, p=0.048). The difference in the treatment arms trended toward adjusted statistical significance because the significance level was reduced to 0.045 because of the performance of two interim analyses. An increase in ischemic events, especially as related to the potential for enhanced rate of repeat percutaneous revascularization, may be expected in the early period after angioplasty.

An early increase in events in the intervention group was seen in the Randomised Intervention Treatment of Angina (RITA-2) trial, which compared angioplasty with medical therapy, although the event rate in angioplasty and medical care groups converged at the completion of the trial.[53] However, in the AVERT study, the difference between usual care and aggressive medical therapy continued to remain separate during the trial period. The AVERT study was evaluated for safety, and there was no clinically significant differences in other adverse events. A total of 2.4 percent of patients in the atorvastatin group had persistently elevated levels of aspartate aminotransferase and alanine aminotransferase compared with no patients in the angioplasty and usual care group. Rhabdomyolysis was not seen in either group. Seventeen serious adverse events were reported in the atorvastatin group, although none was attributed to atorvastatin. Twenty-eight of the patients in the angioplasty group had serious adverse events; six of these patients had events attributable to the angioplasty.

FIBRATE TRIALS

Angiographic

BEZAFIBRATE CORONARY ATHEROSCLEROSIS INTERVENTION TRIAL (BECAIT)

BECAIT was a double-blind, placebo-controlled, randomized trial using bezafibrate in young (<45 years of age) male survivors of a first myocardial infarction.[54] The patients were treated for 3 months with a dietary intervention before randomization. The young, post-myocardial infarction patients were chosen due to the fact that the investigators had previously identified a number of hemostatic and metabolic disturbances, including elevated fibrinogen, insulin resistance, and a lipid triad (high triglycerides, low HDL-C, and small dense LDL) in these and similar subjects. The study was designed to examine the

feasibility of altering the angiographic progress of atherosclerosis with diet and bezafibrate. The mean minimum lumen diameter was used as an index of focal atherosclerosis at the site of most severe atherosclerotic narrowing in the analyzed segment. Mean segment diameter was calculated in all coronary segments irrespective of the presence of visually detectable atherosclerosis as a means to establish an index of diffuse disease.

BECAIT was conducted for a 5-year period and randomized 92 patients (of whom a total of 42 patients randomized to bezafibrate and 39 patients randomized to placebo completed the trial). Angiographic analysis demonstrated that the median change in minimum lumen diameter was, on average, 0.13 mm less in the bezafibrate group when compared with placebo (p=0.049). The difference in mean change in segment diameter was not significant, although a trend was demonstrated that was compatible with slowing progression of atherosclerosis.

A number of lipid and hemostatic parameters were measured. Fibrinogen concentrations fell significantly in the bezafibrate group when compared with dietary therapy. Additionally, the increase in APO AI was three times greater in patients treated with bezafibrate compared with placebo. Serum concentrations of APO B were also decreased significantly in patients treated with bezafibrate. In the placebo group, 11 of the 45 patients had a coronary event (three reinfarctions, one reinfarction plus coronary artery bypass, three percutaneous transluminal coronary angioplasties, four coronary artery bypass surgeries), compared with three cardiac events in the bezafibrate group (one sudden cardiac death, one reinfarction plus CABG, one reinfarction and coronary death) (p=0.02). The cumulative event rates began to diverge after 2 years of follow-up.

Subsequently, the investigators evaluated the relative effects of apolipoproteins, LDL particle size, and other lipoprotein variables on angiographic progression.[55] Analysis revealed that the on-trial HDL_3 cholesterol and APO B concentrations were independent predictors of alteration of mean luminal diameter (r=-0.23, p<0.05) and percent stenosis (r=0.30, p<0.01), respectively. Alteration in the level of small, dense LDL was not related to progression of coronary disease nor were VLDL lipid concentration levels. The major effect of bezafibrate was a decrease in the rate of progression of coronary occlusions that were associated with a less than 50 percent stenosis at baseline.[56]

BECAIT was a small trial but is important in that it emphasizes the effect of patient selection relative to drug therapy. Whereas the phenotypic pattern of alterations of the lipid parameters in BECAIT appears different relative to the induced changes in the statin angiographic trials, bezafibrate retarded the progression of atherosclerosis to a similar degree. Although the precise mechanism of the benefit of bezafibrate cannot be deduced from the BECAIT, the results may be caused by a combination of triglyceride lowering, fibrinogen lowering, or other mechanisms involved in lipoprotein composition or apolipoprotein levels, in addition to classic alteration of lipid parameters.

LOPID CORONARY ANGIOGRAPHY TRIAL (LOCAT)

The LOCAT study group analyzed the effect of gemfibrozil in a cohort of male coronary artery bypass patients.[57] Patients were excluded if the HDL-C exceeded 42.5 mg/dl, the LDL-C exceeded 174 mg/dl, or triglycerides were in excess of 354 mg/dl. Additionally, patients who consumed more than 20 cigarettes per week or who had left ventricular ejection fraction less than 35 percent were also excluded. All patients were begun on a diet that contained approximately 30 percent of the caloric intake from fat. Patients underwent angiography, which was analyzed in a blinded fashion by a single investigator using quantitative computer-assisted analysis (Cardiovascular Measurement System).

A total of 395 subjects were randomized to receive sustained-release gemfibrozil, 1200 mg/d, or to continue on dietary therapy. The follow-up in LOCAT was excellent, with 94 percent of originally randomized patients receiving a follow-up angiogram that was performed at 32 months after allocation to treatment or placebo groups. Gemfibrozil reduced triglycerides by 36 percent, which was associated with an increase in HDL-C of 21 percent from baseline. Minimal changes in total cholesterol and LDL-C were obtained, and reductions of 5.5 percent and 4.5 percent, respectively, were achieved by gemfibrozil therapy.

The primary angiographic endpoint was the determination of changes in the average diameter of segments and minimum luminal diameter. The change in per-patient mean of average diameter in the native coronary segment was -0.04 mm in the placebo group and -0.01 mm in the group randomized to gemfibrozil (p=0.009). The changes in minimum luminal diameter of vessels involved by stenotic lesions were -0.09 mm in the placebo group and -0.04 mm in the gemfibrozil group (p=0.002). New lesions were also analyzed, and a total of 14 percent of the patient population who were assigned to dietary therapy developed new lesions compared with 2 percent in the group assigned to gemfibrozil (p<0.001). A trend toward treatment benefit was also demonstrated both in the segments that were not grafted and the coronary vessels distal to graft insertions, although neither reached statistical significance.

The LOCAT trial emphasizes the clinical importance of determination of the lipid phenotype as a guide to pharmacological decisions. Although all hypolipidemic agents exert some effect on total cholesterol, LDL-C, HDL-C, and VLDL-C levels, fibric acid derivatives may play an important role in patients with isolated low HDL-C or mild to moderate hypertriglyceridemia. The angiographic outcome in the LOCAT trial, which was designed for the evaluation of the impact of therapy on low HDL-C, was qualitatively similar to that of other angiographic trials that used statin therapy in patients with atherosclerosis and dyslipidemia characterized predominantly by elevated total cholesterol or LDL-C.

B-Mode Ultrasound

THE ST. MARY'S, EALING, NORTHWICK PARK DIABETES CARDIOVASCULAR DISEASE PREVENTION (SENDCAP)

The SENDCAP study analyzed cardiac outcomes in subjects with type II diabetes in a double-blind, randomized, placebo-controlled trial using bezafibrate.[58] Men and women with type II diabetes with an age range of 25 to 35 years and no history of clinical cardiovascular disease were considered for randomization. Entry requirements included a serum cholesterol value greater than 200 mg/dl, HDL-C less than 43 mg/dl, and triglyceride levels above 160 mg/dl. Additionally, the total cholesterol to HDL-C ratio had to be in excess of 4.7. Patients were analyzed for clinical evidence of acute myocardial infarction using hospital records, serial electrocardiograms (evaluated by the Minnesota code), and enzyme changes. The primary endpoint of the SENDCAP trial was the change in carotid intima media thickness analyzed by B-mode ultrasound over a 3-year trial period.

A total of 164 subjects were initially randomized, and 128 remained in the study for 3 years with no significant differences in the dropout rates between patients randomized to diet plus placebo or bezafibrate. Bezafibrate therapy resulted in significant alterations of the lipid profile relative to the dietary group. Total cholesterol was decreased by 7 percent, which was accompanied by a reduction in serum triglycerides of 32 percent (both of which were statistically significant). HDL-C was increased by 6 percent, and the total cholesterol to HDL-C ratio was decreased by 12 percent, which also reached statistical significance. A trend toward reduction of fibrinogen was noted (-18 percent with bezafibrate vs. -6 percent with placebo) that did not reach statistical significance (p=0.08). The primary endpoint of the SENDCAP trial was not achieved, and alteration of the intimal medial thickness was minimal, resulting in an inability to differentiate the bezafibrate and placebo groups. However, despite the lack of change in carotid ultrasound parameters, a statistically significant reduction in ischemic changes on the electrocardiogram combined with documented heart attack was observed. A total of 7 percent of the bezafibrate group had a definite coronary event compared with 23 percent of the control population (p=0.01).

The lack of correlation between carotid measurements and cardiac events could not be definitely explained by the data, although the relatively short follow-up period may have played a role in the failure to achieve a statistically significant correlation. Additionally, diabetics may have vascular changes that were present early in the course of disease that may not be identifiable by changes in intimal medial thickness and, additionally, may not be amenable to alteration of the lipid profile. However, the SENDCAP study did emphasize the impact of diabetes on coronary risk and demonstrated that alteration of HDL-C and triglyceride levels in a diabetic population may play a role in the reduction of coronary events using fibric acid therapy. This finding is compatible with retrospective subset analysis of the Helsinki Heart Study and also the analyses of the diabetic subgroups in major statin prevention trials such as the CARE[42] and 4S.[59]

Clinical Fibrate Trials

VETERANS AFFAIRS COOPERATIVE STUDIES PROGRAM HIGH DENSITY LIPOPROTEIN CHOLESTEROL INTERVENTION TRIAL (VA-HIT).

VA-HIT was a multicenter, randomized study that assessed the potential effects of gemfibrozil at a dose of 1200 mg/d versus dietary therapy on the incidence of cardiovascular events in 2531 men with known coronary artery disease associated with low HDL-C levels.[60] Enrollment criteria for HIT required the HDL-C to be 40 mg/dl or less or the LDL-C to be less than 140 mg/dl and triglycerides to be 300 mg/dl or less.

The mean age in the VA-HIT trial was 64 years with more than 75 percent of the patients older than 60 years of age. A total of 90 percent of patients enrolled in HIT were white. The participants in the HIT trial were characterized by body mass index of 29 kg/m[2] and a waist-hip ratio of 0.96, with a 25 percent prevalence of diabetes mellitus. Approximately 57 percent of the population were hypertensive

Figure 33-6 Veteran's Affairs HDL Intervention Trial (VA-HIT): summary of major results. MI=myocardial infarction; CHD=coronary heart disease. (From Rubins HB, Robins SJ, Collins D, et al, for the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial Study Group. Gemfibrozil for the secondary prevention of coronary heart disease in men with low levels of high-density lipoprotein cholesterol. N Engl J Med 341:410-418, 1999.)

and 20 percent were smokers. Baseline lipids in the HIT trial revealed a total cholesterol of 175 mg/dl, HDL-C of 32 mg/dl, LDL-C of 111 mg/dl, and triglycerides of 161 mg/dl. Gemfibrozil therapy resulted in essentially minimal alterations in total cholesterol and LDL levels. Total cholesterol was decreased by 4 percent compared with placebo, and no significant change was demonstrable with LDL-C concentrations. Triglycerides, on the other hand, were decreased by 31 percent and HDL-C increased by 6 percent. The primary endpoint of the HIT trial was the combination of coronary death and nonfatal myocardial infarction. Patients randomized to receive placebo accounted for 275 events compared with 219 events in the gemfibrozil group. The decline in coronary events represented a 22 percent risk reduction that was statistically significant (p=0.006) (Fig. 33-6). The event curves began to diverge at approximately 2 years after the beginning of the trial.

A number of safety analyses were performed, and there was no difference in death from malignancies or violent deaths, as had been inferred from prior studies; and the only adverse event observed more frequently in the gemfibrozil group was dyspepsia (40 percent in gemfibrozil group and 34 percent in placebo group). The VA-HIT is an important study that reinforces the importance of targeting low HDL-C as a major coronary risk factor.

OVERVIEW

A recent meta-analysis has assessed the efficacy of a variety of pharmacological lipid-modifying interventions on the major mortality outcomes.[61] The MEDLINE database from 1966 to 1996 was searched for placebo-controlled trials of cholesterol-lowering intervention that reported mortality data. A total of 59 trials had been reported at the time of the analysis, involving 85,431 subjects randomized to lipid lowering and 87,729 control patients, although the large AFCAPS/TexCAPS and LIPID trials were not included. A number of pharmacological interventions were used, including statins (13 trials), fibrates (12 trials), bile acid sequestrants (8 trials), hormones (8 trials), nicotinic acid (2 trials), n-3 fatty acids (3 trials), and diet (16 trials). The mortality data were analyzed using a 95 percent confidence interval for each mode of cholesterol lowering and two-sided p values.

The trials that used statin therapy achieved the highest degree of cholesterol lowering, with an average cholesterol reduction of 22.9 percent. The statin trials were the only agents to demonstrate a statistically significant reduction of mortality due to CHD, with a 31 percent reduction in death rates (0.69 risk ratio with a 95 percent confidence interval: 0.59 to 0.80). The trials using resins demonstrated a risk ratio of borderline significance (0.71 risk ratio with a 95 percent confidence interval of 0.51 to 0.99). The summary estimates for coronary mortality did not reach statistical significance for the other interventions.

Earlier meta-analyses had raised the possibilities that cholesterol lowering was associated with increased noncardiac mortality. In this review, the statins and n-3 fatty acids demonstrated a significant reduction in total mortality. The decrease in all-cause mortality risk was 21 percent in the statin trials and 32 percent in trials of the n-3 fatty acids (although the n-3 fatty acid trials evaluated relatively fewer subjects); noncoronary mortality was not increased with either drug class. Of the trials summarized, only those of hormone therapy suggested a potentially deleterious effect, with an increased risk for mortality from noncoronary and all causes. These findings provide evidence that lipid-lowering therapy with the statin class is effective and safe. Multivariate meta-regression analysis suggested that the degree of cholesterol lowering was the most powerful factor in determining the difference in mortality reduction across these trials.

Concepts and Controversies in Lipid Management

The current body of clinical trial evidence demonstrates persuasively the potential benefits of lipid modification, especially in the judicious application of pharmacological interventions. The clinical trials have sparked vigorous discussion over a number of important clinical questions: What is the best course of treatment and who should receive it? Which lipids and other risk factors should be targeted for intervention or risk stratification? What should be the goal of lipid-modifying therapy?

What Is the Best Course of Treatment and Who Should Receive It?

Although specific treatment recommendations are outside the purview of this chapter, life style modification remains the first line of treatment for most patients. Because of the clear benefits reported in clinical trials, drug treatment merits additional consideration when appropriate. Early trials of resins or nicotinic acid have shown beneficial effects on coronary events and angiographic progression. In comparison with statins, resins and nicotinic acid are generally not as well tolerated and there is less evidence concerning event reductions (e.g., total mortality). Of the fibrates, data with gemfibrozil have been the most conclusive, although newer trials of fibrate agents may add to the therapeutic implications of this group.

Available data support the use of simvastatin, pravastatin, and lovastatin to prevent clinical cardiovascular events and angiographic progression and of fluvastatin to prevent angiographic progression. Trials are ongoing or in development to assess the clinical efficacy of atorvastatin, cerivastatin, and fluvastatin. The five landmark, large-scale trials of the HMG-CoA reductase inhibitors (see Fig. 33-3) have shown consistent, statistically significant reductions in relative coronary risk on the order of 20 to 40 percent, although the individual populations studied varied by composition, geographical location, and absolute risk for such events.

Subgroup analyses of the studies' cohorts suggest statin therapy was generally beneficial in women, hypertensives, older patients, and diabetics. In AFCAPS/TexCAPS, lovastatin

treatment appeared to neutralize the excess absolute risk associated with a risk factor, such as low HDL-C (see Fig. 33-4) or cigarette smoking. Pending the results of trials designed specifically to assess treatment effects in special populations such as the elderly, the overall benefit observed in these trials may be extended to the following groups: the majority (if not all) patients with established coronary disease (4S, CARE, LIPID), high-risk primary prevention (WOSCOPS), and low-to-moderate risk primary prevention (AFCAPS/TexCAPS) (Fig. 33-7).

In secondary prevention, LIPID and 4S reported significant reductions in all-cause mortality, proving not only safety but also improved survival. WOSCOPS, LIPID, and CARE employed a fixed dosage of pravastatin (40 mg/day), whereas drug titration was used in 4S (20 to 40 mg of simvastatin) and AFCAPS/TexCAPS (20 to 40 mg of lovastatin) to achieve a cholesterol target. In practice, the decision to use a fixed-dosage or a titration strategy to treat dyslipidemia should be at the discretion of the physician's judgment, although both approaches yielded clinical benefit in trials.

Given the clear benefit and safety of statin treatment across the continuum of baseline risk for coronary disease, the question becomes then, who should receive treatment? The answer is controversial. In primary prevention, some investigators have argued that the relatively modest absolute risk reductions achieved in some lower risk cohorts, such as that of AFCAPS/TexCAPS, are disproportionate to the potentially prohibitive costs of providing such treatment to the general population.[62] [62A] [62B] Joint European guidelines have recommended that global risk assessment guide the decision to intervene, with drug treatment reserved only for patients who have an estimated absolute CHD risk of at least 2 percent a year.[63] Although issues of cost-effectiveness are important in the modern medical office, patients should

not be excluded from at least the consideration of effective intervention on the basis of economics alone. It is likely that this issue will be revisited in the next iteration of U.S. guidelines of the NCEP.

Which Lipids and Other Risk Factors Should Be Targeted for Intervention or Risk Stratification?

The increasing emphasis on global risk assessment represents a promising avenue in refining the identification of patients at risk for CHD. Policymakers will need to reconcile such assessment with the current U.S. practice of using a target LDL-C goal, as well as incorporate triglyceride and HDL-C into a treatment algorithm that favors LDL-C. Clearly, the results of the VA-HIT support the need for this latter refinement because benefit accrued from treatment in the face of an unchanged level of LDL-C.[61] In AFCAPS/TexCAPS, patients with below-average HDL-C benefited from a statin, despite the fact that the major effect of treatment was in reducing LDL-C.[38] With the results of both VA-HIT and AFCAPS/TexCAPS to consider, an open question remains of whether statin or fibrate therapy would be the ideal therapy for a population with isolated low HDL-C. Also, it remains to be answered whether the current NCEP definition of low HDL-C (<35 mg/dL) is the appropriate one for defining the risk factor or whether a new definition or possibly a target goal of treatment for HDL-C will need to be developed.

Another important area of inquiry will be to dissect out the relative contributions of lipid modification versus nonlipid effects of statins (e.g., improving endothelial function, reducing inflammatory activity) to the observed risk reductions. In WOSCOPS, the investigators hypothesized that a greater than predicted decrease in events in the treatment group may be due to such effects related to pravastatin.[64]

Finally, the incorporation of other risk factors such as insulin resistance,[65] endothelial function,[65A] genetic markers, [66] and inflammatory markers,[67] like C-reactive protein,[68] may help to define more precisely the individuals who would benefit the most from statin therapy, at what level of dyslipidemia, and at what age intervention should begin.

What Should Be the Goal of Lipid-Modifying Therapy?

Benefit was seen across the spectrum of clinical events associated with atherosclerotic cardiovascular disease, including fatal and nonfatal MI, unstable angina, coronary mortality (in secondary prevention), and the number of coronary artery bypass grafts and angioplasty procedures. One of the unexpected findings was the significant reduction in stroke or cerebrovascular events (stroke+transient ischemic attacks) observed in the secondary-prevention trials.[69]

Based on 4S and AFCAPS/TexCAPS data, no threshold value of cholesterol could be identified below which clinical benefit was not achieved, although the benefit of treatment may become attenuated as the cholesterol value declines.[70] In contrast, CARE investigators have reported that CHD patients with a baseline LDL-C of less than 125 mg/dl did not benefit from treatment in this study.[71] Furthermore, in WOSCOPS, the investigators concluded that an approximately 24 percent reduction of LDL-C was all that was needed to achieve maximum clinical benefit and that further reductions were without additional advantage.[64] These post-hoc analyses have fueled the discussion of whether the relation between risk reduction and LDL-C change is linear (i.e., a straight-line function) or curvilinear or whether a threshold exists below which no further benefit can be obtained.[72] [72A] Of the reported trials, only the Post-CABG study has compared prospectively the efficacy of an aggressive versus moderate lipid-lowering strategy in patients with CHD.[27] However, larger clinical-event studies such as the Treating to New Targets (TNT) of atorvastatin and the Study of the Effectiveness of Additional Reductions of Cholesterol and Homocysteine (SEARCH) of simvastatin and folic acid are currently under way and have the potential to resolve this controversy.

Figure 33-7 Large-scale clinical trials have supported the lipid hypothesis. The pyramid reflects relative applicability to the overall population, with the greater number of individuals at the base and the fewest represented at the apex. 4S=Scandinavian Simvastatin Survival Study; LIPID=Long-term Intervention with Pravastatin in Ischemic Disease; CARE=Cholesterol and Recurrent Events; VA-HIT=Veteran's Affairs HDL Intervention Trial; WOSCOPS=West of Scotland Coronary Prevention Study; LRC-CPPT=Lipid Research Clinics Coronary Primary Prevention Trial; Helsinki=Helsinki Heart Study; AFCAPS/TexCAPS=Air Force/Texas Coronary Atherosclerosis Prevention Study.

CONCLUSIONS

The earlier clinical primary-prevention trials (Lipid Research Clinic Coronary Primary Prevention Trial and Helsinki Heart Study) demonstrated that cholesterol lowering with bile acid sequestrants or fibric acid derivatives could decrease coronary morbidity and mortality. The advent of the statins has revolutionized the ability to manage dyslipidemia using agents that are highly efficacious with a favorable risk-to-benefit ratio. The lipid hypothesis has been validated by the large-scale trials that demonstrate clinical benefit across the spectrum of risk factor profiles (Fig. 33-7) . Meta-analysis of the majority of available lipid-lowering trials demonstrates clear clinical benefits of such intervention. The case for secondary prevention with lipid modification is compelling. Current and renewed efforts should be directed at determining long-term safety effects with pharmacological intervention and at implementing effective risk factor reduction in primary-prevention patients at increased risk for clinical coronary events.

Chapter 34 - Coronary Blood Flow and Myocardial Ischemia

PETER GANZ
WILLIAM GANZ

HYPOXIA AND ISCHEMIA

Ischemia is characterized by an imbalance between myocardial oxygen supply and demand (Fig. 34-1) (Figure Not Available) . In some situations this imbalance is caused by a reduction of blood flow and oxygen supply secondary to increased coronary vascular tone, intracoronary platelet aggregation, or thrombus formation (see Fig. 36-1) ; This condition, termed *supply ischemia* or *low-flow ischemia,* is responsible for myocardial infarction and most episodes of unstable angina. In other instances, usually in the presence of chronic coronary obstruction, exercise, tachycardia, or emotion leads to an increase in coronary blood flow that is insufficient to meet the rise in myocardial oxygen demand. This condition is termed *demand ischemia* or *high-flow ischemia*. It is responsible for many episodes of chronic stable angina. Typically, myocardial ischemia results from both an increase in oxygen demand and a reduction in myocardial oxygen supply. For example, although exercise leads to an overall increase in coronary blood flow, most of the additional flow is distributed toward the subepicardium, whereas subendocardial blood flow may even drop below its resting level. The ischemia of the subendocardium is then caused by both an increase in myocardial oxygen demand and a reduction in regional blood flow. *Hypoxia* is the condition in which oxygen supply is reduced despite adequate perfusion. It may be present in asphyxiation, carbon monoxide poisoning, cyanotic congenital heart disease, and cor pulmonale.

Low-flow ischemia, in contrast to *high-flow ischemia or hypoxia*, is characterized not only by oxygen deprivation but also by inadequate removal of metabolites consequent to reduced perfusion and by loss of vascular turgor.[1] Coronary flow and coronary perfusion pressure augment left ventricular systolic performance (Gregg effect) and reduce left ventricular diastolic distensibility (Salisbury effect). Buildup of tissue metabolites, especially inorganic phosphate, reduces calcium sensitivity of myofilaments, thereby diminishing contractility. Accordingly, in patients with low-flow ischemia, left ventricular systolic performance is lower and left ventricular diastolic distensibility greater than when the same patients were exposed to high-flow ischemia or hypoxia[1] (Fig. 34-2) . Myocardial ischemia may be manifest as anginal discomfort, breathlessness, deviation of the ST segment on the electrocardiogram, reduced uptake of a tracer substance in myocardial perfusion images, or regional or global impairment of ventricular function.

In this chapter, we consider first the determinants of myocardial oxygen consumption, then the control of coronary blood flow, and, finally, the hemodynamic consequences of ischemia.

Figure 34-1 (Figure Not Available) Factors influencing myocardial oxygen supply and demand.*(From Ardehali A, Ports TA: Myocardial oxygen supply and demand. Chest 98:699, 1990.)*

Figure 34-2 Differences among the left ventricular hemodynamic responses during low-flow versus high-flow ischemia. Tracings from a patient undergoing cardiac catheterization and balloon coronary angioplasty of two surface leads (I and II) and one precordial lead (V_5) of the electrocardiogram; the left ventricular dP/dt signal; and the left ventricular pressure recording at rest, at cessation of pacing during pacing-induced angina, at the end of a regular angioplasty balloon coronary occlusion, and at the end of an equally long angioplasty balloon coronary occlusion with distal hypoxic perfusion. Left ventricular diastolic pressure was higher (and left ventricular compliance lower) during pacing angina and at the end of balloon coronary occlusion with distal perfusion of hypoxic fluid (examples of high-flow ischemia) than at the end of the regular balloon coronary occlusion (example of low-flow ischemia).*(From De Bruyne B, Bronzwaer JG, Heyndrickx GR, Paulus WJ: Comparative effects of ischemia and hypoxemia on left ventricular systolic and diastolic function in humans. Circulation 88:461, 1993. Copyright 1993, American Heart Association.)*

DETERMINANTS OF MYOCARDIAL OXYGEN CONSUMPTION

The heart is an aerobic organ; it relies almost exclusively on the oxidation of substrates for the generation of energy, and it can develop only a small oxygen debt. Therefore, in a steady state, myocardial oxygen consumption (MV_{O_2}) provides an accurate measure of its total metabolism.[2] The total metabolism of the arrested, quiescent heart is only a small fraction of that of the working organ. The MV_{O_2} of the beating canine heart ranges from 8 to 15 ml/min/100 gm, whereas the MV_{O_2} of the noncontracting heart is approximately 1.5 ml/min/100 gm. The latter is required for those physiological processes not directly associated with contraction. Increases in the frequency of depolarization of the noncontracting heart are accompanied by only small increases of MV_{O_2} [2] [3] [4] (Tables 34-1 and 34-2) .

MYOCARDIAL TENSION.

As early as 1916 Evans and Matsuoka concluded from studies of the Starling heart-lung preparation that "there is a relation between the tension set up on contraction and the metabolism of the contractile tissue."[5] In a systematic investigation of the relative effects of ventricular pressure, stroke volume, and heart rate on MV_{O_2} , it was found that ventricular pressure development is a key determinant of MV_{O_2} . These investigations suggested that MV_{O_2} per beat correlates well with the area

TABLE 34-1 -- MYOCARDIAL O_2 CONSUMPTION COMPONENTS

	TOTAL: 6-8 ml/min/100 gm		
Distribution			
Basal	20%	Volume work	15%
Electrical	1%	Pressure work	64%
Effects on MV_{O_2} of 50% Increases In			
Wall stress	25%	Heart rate	50%
Contractility	45%	Volume work	4%
Pressure work	50%		

The table demonstrates the dominant contribution to myocardial O_2 consumption (MVO_2) made by pressure work and prominent effects of increasing pressure work and heart rate on MVO_2

From Gould KL: Coronary Artery Stenosis, New York, Elsevier, 1991, p 8.

under the left ventricular pressure curve, termed the *tension-time index.*[5A] Subsequently, it was emphasized that the myocardial wall tension time integral is a more accurate determinant of MVO_2 than is the developed pressure.[6] [7] Later studies demonstrated that frequency of contraction is an important determinant as well. An augmentation of heart rate elevates MVO_2 by increasing the frequency of tension development per unit of time, as well as by increasing contractility.[6] [8]

Rooke and Feigl have provided evidence that MVO_2 is influenced by the degree of myocardial shortening during ejection of stroke volume, although less so than by tension development.[9] They also provided an experimental basis for the use of the systolic pressure-rate product as an estimate of MVO_2 in the clinical setting. This index, frequently referred to as "double product," is used widely to estimate changes in MVO_2 during stimuli such as exercise or pacing tachycardia, although with only limited accuracy.[10] Reexamination of the determinants of MVO_2 has emphasized that they correlate closely with the left ventricular systolic pressure volume area,[11] [12] which consists of the sum of the area within the systolic pressure-volume loop, that is, the external mechanical work and the end-systolic elastic potential energy in the ventricular wall, the area enclosed by the systolic pressure-volume trajectory, and the E_{max} line[12] [13] (Fig. 34-3) .

MYOCARDIAL CONTRACTILITY.

In addition to the systolic pressure-volume area and heart rate, myocardial contractility is the third major determinant of MVO_2 [13A] The net effect of positive inotropic stimuli (e.g., Ca^{2+} and catecholamines) on MVO_2 is the end result of their influence on two

Figure 34-3 Myocardial oxygen consumption correlates with the left ventricular pressure-volume area (PVA). PVA is the area in the P-V diagram that is circumscribed by the end-systolic P-V line (E-C), the end-diastolic P-V relation curve (D-A), and the systolic segment of P-V trajectory (E-A-B-C-E). PVA consists of the external work (EW) performed during systole and the end-systolic elastic potential energy (PE) stored in the ventricular wall at end systole. EW is the area within the P-V loop trajectory (A-B-C-D-A), and PE is the area between end-systolic P-V line and end-diastolic P-V relation curve to the left of EW (E-C-D-E).*(From Kameyama T, et al: Energy conversion efficiency in human left ventricle. Circulation 85:988, 1992. Copyright 1992, American Heart Association.)*

major determinants that change in opposite direction in the intact heart.[2] These are wall tension, which declines as a consequence of reduction in heart size, and myocardial contractility, which, by definition, is augmented by inotropic stimuli. In the failing, dilated ventricle, the increased contractility reduces the left ventricular pressure and volume. On the basis of the Laplace relation, the reduction in ventricular volume leads to a reduction in myocardial tension, which reduces MVO_2 . However, the decrease in MVO_2 that might be expected to result from falling ventricular wall tension is opposed by the increase in contractility, which tends to augment MVO_2 . Thus, the change in MVO_2 consequent to an inotropic stimulus depends on the extent to which intramyocardial tension is reduced in relation to the extent to which contractility is augmented. In the absence of heart failure, drugs that stimulate myocardial contractility elevate MVO_2 because heart size and therefore wall tension are not reduced substantially and do not off-set the effect on metabolism of the stimulation of contractility.

It has been suggested by Suga that almost the entire increase in MVO_2 produced by the administration of positive inotropic agents such as Ca^{2+} and epinephrine results from the energy costs of enhanced excitation-contraction coupling.[11] Specifically, the increased energy costs result from the greater and more rapid Ca^{2+} uptake by the sarcoplasmic reticulum (see Chap. 14) as well as from the increased contractile activity, rather than from a direct stimulating effect of positive inotropic agents on basal myocardial metabolism. In experiments in which the relative effects of changes in tension development and in myocardial contractility on MVO_2 were assessed in the same heart, the quantitative effects of changes of MVO_2 in contractility and tension development were found to be both substantial and of the same order of magnitude.[14]

MVO_2 is also influenced by the substrate used. Specifically, it correlates directly with the fraction of energy derived from the metabolism of fatty acids, which varies directly with the arterial concentration of fatty acids and inversely with that of glucose and insulin.[15]

REGULATION OF CORONARY BLOOD FLOW

During diastole, when the aortic valve is closed, aortic diastolic pressure is transmitted without impediment through the dilated sinuses of Valsalva to the coronary ostia. The aortic arch and sinuses then act as a miniature reservoir, facilitating maintenance of relatively uniform coronary inflow through diastole. The major coronary arteries and their principal branches that course across the epicardial surface of the heart serve as conductance (or conduit) vessels. Normal epicardial coronary arteries in humans are typically 0.3 to 5 mm in caliber and do not offer appreciable resistance to blood flow. Even at the highest level of blood flow, there is no detectable pressure drop along the length of human epicardial arteries.[16] Conductance arteries give rise to arterioles, which are resistance vessels 10 to 200 mum in diameter across which a larger pressure drop occurs. The dense network of about 4000 capillaries per square millimeter ensures that each myocyte is adjacent to a capillary. Capillaries are not uniformly patent because precapillary sphincters appear to serve a regulatory function in accordance with the flow needs of the myocardium. This capillary density is reduced in the presence of ventricular hypertrophy.

As in any vascular bed, blood flow in the coronary bed depends on the driving pressure and the resistance offered by this bed. Coronary vascular resistance, in turn, is regulated by several control mechanisms that will be reviewed: myocardial metabolism (metabolic control), endothelial (and other humoral) control, autoregulation, myogenic control, extravascular compressive forces, and neural control. These control mechanisms may be impaired in diseases and thereby contribute to the development of myocardial ischemia.

HETEROGENEITY IN THE CORONARY RESISTANCE VESSELS.

Experimental methods to visualize coronary resistance vessels in the beating hearts of animals have become available,[17] and it has been learned that arterioles are specialized according to their size. For example, metabolic vasodilation occurs predominantly in the smallest arterioles less than 30 mum; intermediate arterioles 30 to 60 mum are the principal site of myogenic regulation, whereas the large arterioles 100 to 150 mum appear to be the sites of flow-mediated dilation.[17] [18] The system of multiple valves permits fine control of the coronary circulation. For example, according to a scheme proposed by Chilian,[17] the smallest arterioles dilate during metabolic stress, resulting in reduced microvascular resistance and increased myocardial perfusion. As the upstream arteriolar pressure decreases owing to a fall in distending pressure, myogenic dilation of slightly larger arterioles upstream occurs and causes an additional decrease in resistance. Increased flow in the largest arterioles augments shear stress and triggers flow-mediated dilation, further reducing the resistance of this network. Thus, coronary arterioles appear to have specialized regulatory elements along their length that operate "in series" in an integrated manner.

Metabolic Regulation

RELATIONSHIP BETWEEN CORONARY BLOOD FLOW AND MYOCARDIAL OXYGEN CONSUMPTION.

Coronary blood flow is closely coupled to MV_{O_2} in normal hearts. [7] This linkage is necessary because (1) the myocardium depends almost entirely on aerobic metabolism; (2) the oxygen saturation of coronary venous blood is low (25 to 30 percent at rest), permitting little additional oxygen extraction; and (3) oxygen stores in the heart are meager.

Changes in myocardial oxygen requirement lead to alterations in coronary vascular resistance with great rapidity,

generally in less than 1 second. For example, occlusion of a coronary artery for less than 1 second produces an increase in coronary blood flow above baseline after release of the occlusion.[19] This response is called *reactive hyperemia*. The mechanisms that link increases in metabolic activity to reductions in coronary vascular resistance have been investigated extensively, but uncertainty still remains regarding the role of various mediators released from the myocytes and the endothelium.

ADENOSINE.

Adenosine has been investigated most extensively.[20] Adenosine is formed by degradation of adenine nucleotides under conditions in which ATP utilization exceeds the capacity of myocardial cells to resynthesize high-energy phosphate compounds (a process dependent on oxidative phosphorylation in mitochondria). This results in the production of adenosine monophosphate (AMP), and the enzyme 5
-nucleotidase is responsible for the formation of adenosine from AMP[21] (Fig. 34-4) . Accordingly, adenosine diffuses from myocytes into the interstitial fluid and the coronary venous effluent.[22] [23] Adenosine is a powerful coronary dilator and is considered to be an important, perhaps the critical, mediator of local metabolic regulation.[22] [23] Its production increases at times of an imbalance in the supply-to-demand ratio for oxygen,[20] and the rise in the interstitial concentration of adenosine parallels the increase in coronary blood flow.[24]

Many investigators believe that adenosine fulfills most of the criteria of a metabolic regulator of blood flow.[20] However, inhibition of adenosine, either by its destruction by adenosine deaminase or by administration of adenosine receptor antagonists, does not always reduce the magnitude of the hyperemia in response to metabolic stimuli in animals[25] or humans.[24] Thus, despite its acknowledged importance, adenosine is almost certainly not the *only* vasoactive factor involved in the metabolic regulation of coronary blood flow. Others may include nitric oxide (NO), vasodilator prostaglandins, adenosine triphosphate (ATP)-sensitive K^+ channels (K^+_{ATP} channels; see later), as well as myocardial oxygen and carbon dioxide tensions.[26]

NITRIC OXIDE (NO).

This substance increases blood flow during metabolic stimuli. Inhibition of NO reduces the magnitude of metabolic dilation in animals[22] [23] [27] and in the peripheral[28] and coronary circulation in humans.[29] NO production is augmented in response to metabolic stimuli by at least two mechanisms. Hypoxia is a stimulus to release of NO from the endothelium.[30] Furthermore, NO is a principal mediator of flow-mediated dilation. Although hypoxia may initiate hyperemia, flow-mediated dilation sustains

Figure 34-4 Schematic depiction of a myocardial interstitial space, an arteriole, and a capillary with the localization of enzymes involved in the formation and fate of adenosine. Adenosine formed by 5
-nucleotidase from adenosine monophosphate (AMP) (which in turn arises from adenosine triphosphate) can enter the interstitial space. There it can induce arteriolar dilation and reenter the myocardial cell, where it is either phosphorylated to AMP by adenosine kinase or deaminated to inosine monophosphate (IMP) by adenosine deaminase, or it can enter the capillaries and leave the tissue. A large fraction of adenosine that crosses the capillary wall is deaminated to inosine, which in turn is split to hypoxanthine and ribose-1-PO_4 by nucleoside phosphorylase located in the endothelial cells, pericytes, and erythrocytes. Most of the adenosine is taken up by the myocardial cells, and that escaping into the circulation is largely in the form of inosine and hypoxanthine. Because adenylic acid deaminase (which deaminates AMP to IMP) is in low concentration in heart muscle, the major degradative pathway from AMP is by means of dephosphorylation to adenosine. Open circles=adenosine deaminase; closed circles=adenylic acid deaminase; triangles=nucleoside phosphorylase; dashed lines=5
-nucleotidase; dotted lines=adenosine kinase.*(From Berne RM, Rubio R: Coronary circulation. In Berne RM, Sperelakis N, Geiger SR [eds]: Handbook of Physiology, Section 2. The Cardiovascular System. Bethesda, MD, American Physiological Society, 1979, p 924.)*

and amplifies it. In support of this, inhibition of nitric oxide attenuates the late phase of reactive hyperemia, when flow-mediated dilation would be expected to occur.[28]

OTHER METABOLIC MEDIATORS.

Inhibition of the synthesis of vasodilator prostaglandins[29] and inhibition of K^+_{ATP} channels[31] also reduces metabolic vasodilation. It is likely that vasoactive factors act in concert to regulate coronary flow in response to metabolic needs. A loss or inhibition of one mediator is compensated for by upregulation of others. Although the inhibition of K^+_{ATP} channels, adenosine, and NO individually has at most a modest effect on the increase in coronary blood flow during exercise in dogs, inhibition of all three simultaneously nearly abolishes the flow increase.[32]

Endothelial Control of Coronary Vascular Tone

Vasoactive agents that influence the tone of large and small coronary vessels can be carried in the blood plasma (e.g., epinephrine, vasopressin) or released from circulating blood elements such as platelets (e.g., serotonin, adenosine diphosphate) or from nerve endings in the vascular adventitia (e.g., norepinephrine, vasoactive intestinal peptide). Furthermore, vasoactive factors can be formed locally by the vascular endothelium.

The vascular endothelium performs a wide array of homeostatic functions within normal blood vessels. Located between the vascular lumen and the smooth muscle cells of the vessel wall, the monolayer of endothelial cells is able to transduce blood-borne signals, sense mechanical forces within the lumen, and regulate vascular tone through the production of a variety of factors.[33] [34] Endothelium produces both potent vasodilators, such as endothelium-derived relaxing factor (EDRF, NO), prostacyclin, and endothelium-derived hyperpolarizing factor (EDHF), and vasoconstrictors, such as endothelin-1. Endothelium-derived vasoactive factors are of great interest because endothelium can be damaged by atherosclerosis and by cardiovascular risk factors. Endothelial dysfunction may then lead to disturbances in coronary blood flow, can contribute to the pathogenesis of myocardial ischemia, and is a central feature in the evolution of atherosclerosis and thrombosis[35] (Fig. 34-5) (see also Chap. 30) .

ENDOTHELIUM-DERIVED RELAXING FACTOR.

Perhaps the most important vasodilator substance produced by endothelial cells is endothelium-derived relaxing factor (EDRF).[36] The discovery of EDRF in 1980 by Furchgott resulted from the observation that intact endothelium is required for acetylcholine-induced vasodilation.[37] In the presence of endothelium, acetylcholine produces dose-dependent vasodilation. When the endothelium is removed, only constriction is induced by acetylcholine. It became apparent that acetylcholine has two distinct and opposite actions on blood vessels: an endothelium-mediated dilation and a smooth muscle-mediated constriction (Fig. 34-6) . In any blood vessel, the net response is related to the sum of these two actions. In most healthy arteries, endothelium-dependent vasodilation predominates over direct vasoconstriction.[33]

EDRF has been identified as the nitric oxide (NO) radical.[38] [39] NO is formed in endothelial cells from the substrate L-arginine by the action of NO synthase (Fig. 34-7) . In this reaction, the terminal nitrogen from the guanadino group of L-arginine gives rise to NO. This reaction requires molecular oxygen, tetrahydrobiopterin (THB_4), NADPH, flavin adenine dinucleotide, and flavin mononucleotide as cofactors and produces L-citrulline as a byproduct that can be recycled to L-arginine. The activity of the enzyme is controlled by calcium and calmodulin.[38] [39] The relaxing effect of NO is mediated by its diffusion to smooth muscle cells,

Figure 34-5 Normal and dysfunctional endothelial cells, with some of the functions adversely influenced by hypercholesterolemia and atherosclerosis, which may contribute to acute coronary syndromes. t-PA:PAI-1=the ratio of tissue plasminogen activator to plasminogen-activator inhibitor type 1. EDRF=endothelial derived relaxing factor.*(From Levine GN, Keaney JF, Vita JA: Cholesterol reduction in cardiovascular disease. N Engl J Med 332:312, 1995. Copyright 1995, Massachusetts Medical Society.)*

where it causes an activation of intracellular guanylate cyclase, a rise in cyclic guanosine monophosphate (GMP), and a consequent fall in intracellular calcium.[40] Once released from endothelial cells NO has a very short half-life, limited by interaction with other free radicals in tissues, principally superoxide, and by entering red blood cells to react with oxyhemoglobin.[41]

In many vascular beds, NO is released continuously, contributing to the maintenance of a vasodilator state. Aside from acetylcholine, the release of NO above this basal level is stimulated by products of thrombosis (thrombin), aggregating platelets (serotonin, ADP), other chemical stimuli (histamine, bradykinin), and increased shear stress resulting from an increase in blood flow; the latter is responsible for so-called flow-mediated vasodilation[33] (Fig. 34-8) .

Figure 34-6 Relaxation by acetylcholine (ACh) of rings of rabbit thoracic aorta precontracted by norepinephrine (NE). Aortic rings were exposed to increasing concentrations of ACh with endothelium either intact or removed by rubbing with a wooden applicator stick. This representative tracing shows loss of relaxation in response to ACh with removal of endothelium and appearance of mild constriction.*(From Furchgott RF: Role of endothelium in responses of vascular smooth muscle. Circ Res 53:557, 1983. Copyright 1983, American Heart Association.)*

Vasoconstrictors, such as alpha-adrenergic agonists, may also stimulate the release of NO. Although their net effect on the blood vessel may be vasoconstriction, the presence of an endothelium-dependent vasodilating influence attenuates this constriction. Only a few vasodilators can act independently of the endothelium and directly on vascular smooth muscle. These include the nitrovasodilators (e.g., nitroglycerin, nitroprusside) and prostacyclin.[33] Adenosine elicits both endothelium-independent and endothelium-dependent dilation; at high concentration of adenosine, endothelium-independent dilation dominates while NO contributes to the dilator effects of adenosine at lower adenosine concentration.[42]

ENDOTHELIUM-DEPENDENT VASODILATION IN HEALTHY HUMAN EPICARDIAL ARTERIES.

Endothelium-dependent vasodilation as an important mechanism has been documented in many vascular beds throughout animal kingdom, including mammals, birds, and reptiles. The importance of

Figure 34-7 Endothelial cell production of nitric oxide (NO) by the action of nitric oxide synthase (eNOS) on L-arginine. This reaction requires a number of cofactors such as tetrahydrobiopterin (BH_4), calmodulin, and NADPH. eNOS stimulation by vasodilator agonists or shear stress is mediated by rise in intracellular calcium (Ca^{2+}). NO may be broken down by free radicals (O_2^-), producing peroxinitrite ($OONO^-$), which is vasoinactive. NO acts on vascular smooth muscle cells to cause relaxation by activating guanylate cyclase (GC), thereby increasing intracellular cyclic guanosine monophosphate (cGMP).

NO secretion in vasodilation of healthy human epicardial arteries was first demonstrated by intracoronary infusion of acetylcholine at the time of cardiac catheterization.[33] This vasodilation can be inhibited by specifically blocking NO synthesis with N^G -monomethyl-L-arginine (L-NMMA). Likewise, L-NMMA inhibits flow-mediated dilation of human epicardial arteries.[29] Other endothelium-dependent substances that have been shown to dilate healthy human coronary arteries include serotonin, histamine, bradykinin, and substance P.[33]

IMPAIRMENT OF ENDOTHELIUM-DEPENDENT VASODILATION IN HUMAN EPICARDIAL ARTERIES.

Evidence has accumulated that the tendency to inappropriate vasoconstriction that characterizes atherosclerosis is related to vasodilator dysfunction of the endothelium, permitting unopposed constriction of vascular smooth muscle. Responses to endothelium-dependent stimuli that dilate healthy human coronary arteries have been found to be markedly impaired in patients with both early and advanced atherosclerosis. Acetylcholine constricts atherosclerotic coronary arteries, reflecting the loss of NO and acetylcholine's unopposed

Figure 34-8 High-resolution ultrasound images of the human brachial artery at baseline; dilation during reactive hyperemia following the release of a 5-minute occlusion (i.e., flow-mediated dilation); and dilation after the administration of sublingual nitroglycerin (endothelium-independent dilation). This flow-mediated dilation is mediated principally by nitric oxide.

Figure 34-9 Mechanisms of endothelial dysfunction with cardiovascular risk factors. Cardiovascular risk factors, including cholesterol, reduce the bioavailability of nitric oxide by reducing the transcription (1) or stability (2) of messenger RNA encoding for nitric oxide synthase; (3) interfering with coupling of endothelial receptors to associated pertussis-sensitive G-proteins; (4 and 5) causing accumulation of asymmetric dimethyl arginine (ADM-arginine), a competitive antagonist to L-arginine, the substrate for nitric oxide synthesis; (6) reducing the availability of tetrahydrobiopterin (TBH_4), a cofactor for nitric oxide synthase; and (7) increasing the generation of superoxide (O_2^-), which combines with nitric oxide to generate a vasoinactive product $ONOO^-$

constrictor effects on vascular smooth muscle.[33] [43] Although abnormal vasomotor responses to acetylcholine have served as a convenient marker of endothelial dysfunction, the role of acetylcholine in the physiological regulation of vascular tone has not been established. The finding of endothelial vasodilator dysfunction in human coronary atherosclerosis has been confirmed for other more physiological stimuli that release NO, including serotonin, ADP, and increased coronary blood flow (flow-mediated dilation). For example, whereas serotonin, a product released from aggregating platelets, dilates normal human coronary arteries it constricts atherosclerotic arteries.[33] [44] [45]

The loss of endothelium-dependent dilation occurs early in atherosclerosis, even prior to its detection by angiography.[46] [47] This loss of NO bioavailability is related to risk factors for atherosclerosis[48] and is caused by reduced synthesis as well as accelerated breakdown of NO (Fig. 34-9) .

TABLE 34-3 -- RISK FACTORS ASSOCIATED WITH IMPAIRED ENDOTHELIUM-DEPENDENT VASODILATION

Dyslipidemia
Hypertension
Diabetes mellitus
Cigarette smoking
Menopause
Hyperhomocysteinemia
Aging
Family history of coronary artery disease
Mutations in eNOS

All of the traditional risk factors and several newly described risk factors have been shown to be associated with a loss of endothelium-dependent dilation in human arteries (Table 34-3) . One of the first risk factors found to be associated with loss of endothelium-dependent dilation was dyslipidemia.[33] Although native LDL may be involved in this process, there is much evidence that damaging effects on endothelial NO bioavailability are mediated by its most atherogenic forms, including oxidized LDL[49] [50] [51] and small, dense LDL particles.[33] Lipoprotein lipases act on triglyceride-rich particles, such as chylomicrons and very low-density lipoprotein, to produce

remnant particles. Remnant particles are also highly atherogenic and associated with endothelial dysfunction and reduced NO.[52] Subjects with lipoprotein lipase deficiency, less able to generate remnant particles, have preserved endothelial function despite having a marked elevation in triglycerides.[53] Lipoprotein (a) also leads to a reduction in NO, especially when levels of LDL cholesterol are concomitantly elevated,[54] whereas HDL appears to be protective. [55]

Cause and effect between risk factors and loss of endothelial function was established when risk factors were introduced experimentally (and temporarily) into healthy volunteers. Infusion of high concentration of glucose (to mimic an aspect of diabetes mellitus),[56] methionine loading (to raise homocysteine concentration),[57] or ingestion of fatty meal (to raise the concentration of lipoprotein remnant particles)[58] promptly reduced the availability of NO. Surgical ovariectomy in women free of cardiovascular disease (which produces premature menopause) is also followed by a rapid loss of NO, which can be reversed with estrogen replacement therapy.[59] Mutations in the enzyme NO synthase can be associated with impaired production of NO and are clinically manifested by propensity to coronary vasospasm, hypertension, and myocardial infarction.[60] [61] [62] This genetic aberration provides further proof of the importance of the NO system in the clinical setting.

ENDOTHELIUM-DEPENDENT VASODILATION IN HUMAN CORONARY RESISTANCE VESSELS.

Endothelium-dependent vasodilation operates not only in large (conductance) arteries, but it is also an important mechanism that controls dilation in small (resistance) vessels (Fig. 34-10) . Studies in the human forearm have suggested that *continuous* basal release of NO is an important determinant of resting vascular resistance and blood flow. When a specific inhibitor of NO synthesis, L-NMMA, was infused into the forearm of healthy subjects, resting blood flow was cut in half.[63] Systemic administration of L-NMMA induces hypertension in normal volunteers, suggesting that NO acts to lower systemic vascular resistance.[64] NO release also reduces basal coronary vascular resistance and contributes to dilation in response

Figure 34-10 Increase in coronary blood flow velocity in response to acetylcholine, an endothelium-dependent agonist, in a patient free of coronary atherosclerosis. Coronary blood flow velocity was measured with a Doppler flow wire and increased 2.4-fold during acetylcholine administration; this increase in flow velocity (and blood flow) is indicative of normal endothelial function of resistance arterioles.

to a variety of endothelium-dependent agonists.[43] However, L-NMMA typically inhibits less than half of the vasodilation *stimulated* by various agonists in coronary and most other resistance vessels, suggesting that factors other than NO may play a role in the dilation of arterioles.[43] [65] [66]

Although atherosclerosis does not directly involve resistance vessels, coronary risk factors markedly impair the responses of resistance vessels to endothelium-dependent vasodilator stimuli.[33] [67] [68] This may not be altogether surprising, because risk factors are "systemic" in nature, potentially affecting the endothelial lining of all blood vessels.[69] The close correlation between the extent of NO deficiency in coronary resistance vessels and the failure of coronary blood flow to respond appropriately to metabolic stimuli suggests that endothelial dysfunction in resistance vessels may be an important factor in preventing coronary blood flow from rising during times of increased metabolic stress.[70] An inadequate augmentation of coronary blood flow in the presence of an increased metabolic demand may represent one of the mechanisms by which disturbances in endothelial function can lead to the development of myocardial ischemia in the setting of risk factors and atherosclerosis.

ENDOTHELIAL DYSFUNCTION AS A CAUSE OF MYOCARDIAL ISCHEMIA.

Impairment of endothelial function that occurs in atherosclerosis and in the presence of risk factors for atherosclerosis plays an important role in the subsequent development of coronary syndromes. When superimposed on coronary artery stenoses, loss of endothelium-dependent dilation and resultant unopposed coronary constriction predisposes to myocardial ischemia.[71] Several studies have documented the physiological importance of this mechanism in patients with stable angina. With exercise, performed at the time of coronary angiography, epicardial arteries of healthy subjects were noted to dilate. In patients with stable angina, however, paradoxical vasoconstriction typically occurred at the site of coronary stenoses or even mildly irregular arterial segments.[72] Changes during exercise parallel the responses observed in response to the endothelium-dependent agent acetylcholine. Exercise causes dilation of the arteries with normal endothelium (evidenced by a normal response to acetylcholine) but constriction of vessels with evidence of endothelial dysfunction.

A similar pattern of dilation of normal coronary arteries and paradoxical constriction of atherosclerotic coronary arteries with dysfunctional endothelium has been observed with mental stress, the cold pressor test, and increase in heart rate.[68] [71] [73] These stimuli are normally accompanied by activation of the sympathetic nervous system, by an increase in circulating catecholamines, and by increases in coronary blood flow secondary to a rise in myocardial oxygen demand. In patients with dysfunctional endothelium,

Figure 34-11 Nitric oxide, a multipotent molecule, inhibits recruitment of inflammatory cells, including monocytes, into the subendothelial space and their differentiation into macrophages. Specifically, nitric oxide inhibits the production of proinflammatory cytokines and chemokines (e.g., monocyte chemotactic protein-1 [MCP-1], interleukin-6 [IL-6], and interleukin-8 [IL-8]), reduces the expression of leukocyte adhesion molecules (LAMs), and inhibits factors that facilitate differentiation of monocytes into macrophages (e.g., macrophage colony stimulating factor [M-CSF]).

Figure 34-12 Increase in coronary blood flow evoked by graded doses of acetylcholine in control subjects and patients with microvascular angina. The dose-dependent increases in coronary blood flow produced by acetylcholine were significantly smaller in patients with microvascular angina than in control subjects ($p<0.001$ by two-way analysis of variance). Bars indicate the standard deviation.*(From Egashira K, et al: Evidence of impaired endothelium-dependent coronary vasodilatation in patients with angina pectoris and normal coronary angiograms. N Engl J Med 328:1659, 1993. Copyright 1993, Massachusetts Medical Society.)*

the loss of flow-mediated and catecholamine-stimulated NO release permits unopposed constriction by catecholamines. Thus, the loss of NO may contribute to impaired dilation or exaggerated constriction of epicardial and resistance vessels and thereby to myocardial ischemia. Conversely, improvement in endothelial vasodilator function, achieved by cholesterol lowering therapy, is paralleled by a reduction in myocardial ischemia.[74]

Plaque fissuring or rupture with superimposed platelet aggregation and thrombus is a hallmark of unstable angina and myocardial infarction, but coronary constriction also plays an important role in these conditions.[75] The products of platelet aggregation and thrombosis, although dilating normal arteries, can severely constrict the atherosclerotic arteries of patients with coronary disease. As already noted, intracoronary administration of serotonin, a product released by aggregating platelets, constricts atherosclerotic coronary arteries.[76] The clinical significance of these findings is supported by the observations that patients with unstable coronary syndromes and complex plaques demonstrate augmented release of serotonin into the coronary circulation.[76] Patients with a recent history of myocardial infarction or unstable angina show evidence of endothelial vasodilator dysfunction in the infarct-related artery when tested with acetylcholine that is more pronounced than in arteries with stable stenoses of similar severity.[77]

Reductions in NO are associated not only with enhanced vasoconstriction at sites of disrupted atherosclerotic plaques but also with a predilection toward the destabilization of plaques. Such plaque destabilization is characterized by an infiltration of inflammatory cells, release of enzymes that degrade extracellular matrix, and thinning of the overlying fibrous cap with propensity to rupture.[68] [78] Enhanced production of highly thrombogenic tissue factor by inflammatory cells also plays a central role in this syndromes.[79] NO is a multipotent molecule (see Fig. 34-5) that inhibits the recruitment and differentiation of inflammatory cells by inhibiting the production of chemoattractant cytokines, leukocyte adhesion molecules, and factors that encourage the differentiation of monocytes into macrophages[75] (Fig. 34-11) . NO also reduces the production of tissue factor. For these reasons, nitric oxide has become viewed as an important antiatherogenic[80] and plaque stabilizing[68] molecule.

The coronary resistance vessels may be affected by endothelial dysfunction in the *absence* of obstructive epicardial artery disease. Impaired endothelium-dependent dilation of coronary resistance vessels accounts for some of the cases of syndrome X, that is, anginal discomfort, evidence of myocardial ischemia on stress testing, and angiographically normal coronary arteries[81] [82] (Fig. 34-12) (see also Chap. 37) .

MANAGEMENT OF ENDOTHELIAL DYSFUNCTION.

The use of cholesterol-lowering agents (statins or cholestyramine) in patients with hypercholesterolemia has led to a rapid and significant improvement in

endothelium-dependent dilation of coronary and peripheral arteries in patients with hypercholesterolemia[33] [68] [83] [84] (Figs. 34-13 and 34-14) . Interestingly, such rapid improvement in endothelial function could not be demonstrated in patients with relatively low serum concentrations of cholesterol, a finding that has a clinical counterpart in the results of several recent clinical event trials.

Aggressive reduction in cholesterol is associated with improved myocardial perfusion on positron-emission tomography[85] and a reduction in myocardial ischemia.[74] [86] Cholesterol-lowering markedly reduced evidence of myocardial ischemia on ambulatory electrocardiographic monitoring in patients with stable coronary disease and hypercholesterolemia over a period of 4 to 6 months, a time period that parallels the observed improvement in endothelium-dependent dilation observed in similar patients and duration of treatment[74] [86] (Fig. 34-15) .

Other strategies are effective at restoring endothelium-dependent dilation, augmenting myocardial perfusion, and reducing the severity of myocardial ischemia or symptoms of angina. These include the use of angiotensin-converting enzyme inhibitors,[87] antioxidants[88] [89] and the oral administration of L-arginine.[89]

ENDOTHELIUM-DERIVED HYPERPOLARIZING FACTOR.

Convincing evidence has accumulated that factors other than NO and prostacyclin (see later) can mediate endothelium-dependent vasodilation by hyperpolarizing the underlying smooth muscle. This hyperpolarization occurs through activation of Ca^{2+} -activated K^{+} channels in vascular smooth muscle cells and has been attributed to a diffusible factor termed *endothelium-derived hyperpolarizing factor (EDHF).*[90] EDHF appears to be far more important in small arterioles than in larger conduit arteries.[91] [92] It is released by many of the same stimuli that stimulate NO, including acetylcholine, bradykinin, substance P, and shear stress.[90] [93] [94] [95] Although there may be more than one EDHF molecule, cytochrome P450 (CYP)-dependent metabolites of arachidonic acid (AA), especially the epoxide 11,12-epoxyeicosatrienoic acid, fulfill the essential criteria as mediators of endothelium-dependent hyperpolarization.[96]

EDHF has been demonstrated in human coronary[91] and peripheral arterioles in vitro. NO inhibits the production of EDHF.[97] It has been therefore suggested that when diseases reduce NO bioavailability, release of this intrinsic inhibition may maintain endothelial vasodilator function by upregulation of EDHF.[90] [97] Nevertheless, aging and long-standing hypercholesterolemia appear to reduce EDHF as well as NO in human peripheral arterioles. Just as NO, EDHF (11,12-epoxyeicosatrienoic acid) is a multipotent molecule with antiinflammatory properties.[96] The full significance of EDHF in normal human coronary physiology and abnormal pathophysiology remains to be established and awaits the availability of specific inhibitors of this pathway.

PROSTACYCLIN.

This is a potent vasodilator derived from the endothelium through the actions of cyclooxygenase. The role of prostacyclin in the control of vascular tone in humans has been controversial, at least until recently.[29] Administration of aspirin has little effect on arterial blood pressure in humans, suggesting that inhibition of cyclooxygenase does not cause generalized systemic vasoconstriction. Administration of indomethacin does reduce resting coronary blood flow in humans.[98] It has been suggested, however, that these coronary constrictor effects of indomethacin are not due to inhibition of prostacyclin synthesis.[98]

Although vascular prostacyclin production under physiological conditions appears to be low, patients with atherosclerosis have increased prostacyclin production.[99] In patients with coronary atherosclerosis or risk factors, administration of aspirin to inhibit cyclooxygenase has revealed that prostacyclin contributes importantly to resting vasodilator tone in epicardial arteries and resistance arterioles

Figure 34-13 Mean (+SE) change in coronary artery diameter in response to serial infusions of acetylcholine at baseline and after 1 year of therapy in the three study groups. The improvement in the response from baseline to follow-up in the LDL-lowering-antioxidant group was significantly greater than that in the diet group ($p>0.05$). Negative numbers indicate vasoconstriction.*(From Anderson TJ, Meredith IT, Yeung AC, et al: The effect of cholesterol-lowering and antioxidant therapy on endothelium-dependent coronary vasomotion. N Engl J Med 332:488, 1995. Copyright 1995, Massachusetts Medical Society.)*

Figure 34-14 Segment of the circumflex coronary artery at initial and follow-up (5.5 months) studies in a patient with coronary atherosclerosis assigned to lovastatin. Both left panels demonstrate baseline (control) arteriograms; both right panels demonstrate postacetylcholine arteriograms. Substantial vasoconstriction occurs in response to the peak infusion of acetylcholine in the initial study, with marked improvement (a mild vasodilator response) in the follow-up study.*(From Treasure CB, et al: Beneficial effects of cholesterol-lowering therapy on the coronary endothelium in patients with coronary artery disease. N Engl J Med 332:481, 1995. Copyright Massachusetts Medical Society.)*

and plays a role in flow-mediated coronary dilation and metabolic vasodilation.[29] Thus, the prostacyclin-mediated coronary vasodilation appears to be most important in a setting characterized by a deficiency of nitric oxide and may provide a useful compensatory mechanism.

ENDOTHELIUM-DERIVED CONSTRICTING FACTORS.

The endothelium not only mediates vasodilation but it is a source of vasoconstrictor factors as well (Fig. 34-16) . The best characterized of these are the endothelins.[100] [101] Endothelin-1 (ET-1) is a 21-amino-acid peptide that has a potent vasoconstrictor activity. Two other isoforms of endothelin have been discovered (ET-2 and ET-3), but endothelium produces only ET-1. Synthesis of ET-1 is complex, starting with a large precursor molecule, preproendothelin, which is processed to "big endothelin" and finally converted by the action of endothelin-converting enzyme to the fully active ET-1.[100]

Unlike NO, which can be released rapidly in response to vasodilator stimuli and then inactivated within seconds, ET-1-mediated constriction is slow in onset and lasts over minutes to hours.[100] [101] Agents that stimulate ET-1, such as thrombin, angiotensin II, epinephrine, or vasopressin, do so by de novo transcription of messenger RNA. On the basis of these considerations, it is likely that ET-1 contributes to the regulation of vascular tone primarily by exerting a tonic vasoconstrictor influence. In addition to its vasoactive properties, ET-1 also stimulates smooth muscle proliferation,[102] vascular remodeling,[103] and leukocyte adhesion and recruitment[104] ; it may thereby play a role in inflammation and in atherogenesis.

Plasma concentrations of ET-1 are elevated in a number of cardiovascular disorders,[101] [105] including hypercholesterolemia, hypertension, atherosclerosis, acute myocardial infarction, and congestive heart failure (see also Chap. 16) . Aside from the endothelium, macrophages and activated smooth muscle cells are a rich source of ET-1 in the vessel wall. These cells are numerous in vulnerable or ruptured plaques. Consistent with this finding the culprit plaques of patients with acute coronary syndromes express significantly greater ET-1 immunoreactivity than plaques of patients with stable angina.[106] These plaques are also rich in lipid, and oxidized LDL is a potent stimulus to ET-1 synthesis.[107] [108]

ENDOTHELIN RECEPTORS.

ET-1 exerts its vascular effects by binding to two specific receptors named ET_A and ET_B . ET_A receptors are present on vascular smooth muscle cells and promote vasoconstriction[109] and smooth muscle proliferation. [102] ET_B receptors are located on endothelial cells where they mediate endothelium-dependent dilation

Figure 34-15 Effect of cholesterol lowering or placebo over 6 months on the number of episodes of ischemic ST-segment depression in patients with coronary disease. Two of 20 in the placebo group vs. 13 of 20 in the treatment group show resolution of ischemia.*(From Andrews TC, Raby K, Barry J, et al: The effect of LDL cholesterol reduction on myocardial ischemia in patients with coronary disease. Circulation 95:324-328, 1997.)*

by releasing NO and are also located on smooth muscle cells where they mediate constriction.[110] Antagonists of the ET receptors and inhibitors of the endothelin-converting enzyme have become available and are helpful in assessing the role of ET-1 in cardiovascular diseases. Bosentan, a mixed ET_A /ET_B receptor antagonist, was found to lower blood pressure in patients with essential hypertension,[111] which suggests a role for ET-1 in the pathogenesis of hypertension.[112] Inhibition of ET_A receptor by intracoronary infusion of a specific antagonist BQ-123 results in significant dilation of normal human epicardial arteries. This finding suggests that ET-1, through the ET_A receptor, is important to the maintenance of tonic coronary tone in humans. The use of ET inhibitors will be helpful in assessing the role that ET-1 plays in exaggerated constriction in patients with atherosclerotic coronary arteries.

Autoregulation of Coronary Blood Flow

When sudden alterations in perfusion pressure are imposed in many arterial beds (including the coronary), the resulting abrupt changes in blood flow are only transitory, with flow returning promptly to the previous steady-state level[113] (Fig. 34-17) . This ability to maintain myocardial perfusion at constant levels in the face of changing driving pressure is termed *autoregulation*. Demonstration of autoregulation in the coronary bed is difficult in intact animals because aortic pressure is not only the perfusion pressure for the coronary circulation, but it is also the afterload for the left ventricle, a major determinant of MV_{O_2} . Coronary autoregulation has therefore been studied under experimental conditions where the coronary circulation is cannulated and perfused separately. [114] Under such controlled conditions perfusion pressure is altered, but ventricular pressure, cardiac contractility and heart rate--the principal determinants of MV_{O_2} (see p. 1088)--are maintained constant and autoregulation is clearly evident. In dogs the upper limit of autoregulation is 130 mm Hg, whereas the lower limit of autoregulation is 40 mm Hg.[115] That is to say, when mean aortic pressure is within this range, coronary perfusion is relatively constant. When aortic pressure falls below 40 mm Hg, coronary blood flow precipitously declines. When aortic pressure exceeds 130 mm Hg, coronary flow rises sharply.

Although autoregulation cannot be studied in detail in humans, it is perhaps the principal reason why patients with coronary artery disease and epicardial stenoses do not have evidence of resting perfusion deficits or myocardial ischemia at all times! Reductions in perfusion pressure distal

Figure 34-17 Autoregulation of coronary blood flow in the beating dog heart. The point where the curves cross represents the control steady-state pressure and flow. A sudden, sustained charge in perfusion pressure caused an abrupt change in flow represented by the filled symbols and black line (transient flow). The open symbols and red line represent the steady-state flows obtained at each perfusion pressure. The points represented by triangles were obtained after blockade of cardiac prostaglandin synthesis with indomethacin. *(From Rubio K, Berne KM: Regulation of coronary blood flow. Prog Cardiovasc Dis 18:105, 1975.)*

to stenoses are compensated for by autoregulatory dilation of the resistance vessels. Recently, perfusion pressure distal to coronary stenoses was measured in patients with a pressure wire and myocardial perfusion in the same territory was assessed by positron emission tomography. Myocardial perfusion remained relatively constant over a pressure range of 45 to 125 mm Hg.[116] These data suggest that the autoregulatory range may be as large in humans as it is in conscious dogs.[115]

The ability of autoregulation to compensate for the effect of a proximal epicardial obstruction may be compromised in several clinical situations. A fall in aortic pressure can lower perfusion pressure distal to a stenosis below the critical levels at which autoregulation is effective, thereby compromising myocardial perfusion, intensifying myocardial ischemia, and increasing left ventricular filling pressure, which reduces the perfusion gradient further. These events may cause a vicious cycle, especially in patients with left main or three-vessel coronary disease. Insertion of an intraaortic balloon pump in this setting raises diastolic perfusion pressure and restores coronary pressure so that autoregulation is reestablished and myocardial ischemia is lessened.

Chronic hypertension and left ventricular hypertrophy narrow the range of autoregulation, especially in the subendocardium, in which autoregulation is ordinarily more limited than in the subepicardium.[117] This amplifies the detrimental effects of coronary stenoses on myocardial perfusion and in patients with severe hypertrophy may lead to subendocardial ischemia even in the absence of coronary stenosis.

Conditions that alter the function of vascular smooth muscle in coronary arterioles attenuate autoregulation. For example, adenosine and dipyridamole abolish autoregulation. In the setting of stenoses, this may cause myocardial ischemia, especially in the subendocardium.[118] In endotoxemic shock, the myocardium produces massive amounts of nitric oxide, a potent vasodilator, which causes autoregulatory dysfunction and potentially predisposes to myocardial ischemia.[119]

MECHANISMS OF AUTOREGULATION

NITRIC OXIDE.

Evidence suggests a role for NO in coronary autoregulation. Inhibition of NO raises the lower autoregulatory threshold by about 15 mm Hg.[120] The involvement of NO may be related to the ability of the endothelium to sense changes in perfusion pressure through pressure-sensitive ion channels.[121] Currently, there is little evidence to support the role of adenosine or K^+_{ATP} in coronary autoregulation.[122]

MYOGENIC CONTROL.

Arteriolar smooth muscle reacts to increased intraluminal pressure by contracting. The consequent augmentation of resistance tends to return blood flow toward normal despite the higher perfusion pressure. This regulatory mechanism, referred to as *myogenic control*, is an important mechanism in some vascular beds. Although data demonstrate that myogenic responses are present in coronary resistance arteries,[123] their contribution to autoregulation is relatively small.[124]

Extravascular Compressive Forces

SYSTOLIC COMPRESSIVE FORCES.

Because systolic ventricular wall compresses intramyocardial vessels, most of the coronary blood flow to the left ventricle occurs during diastole. Thus, the contracting heart obstructs its own blood supply. At peak systole, there is even backflow in the coronary arteries, particularly in the intramural and small epicardial arteries.[125]

The extravascular systolic compressive force has two components. The first is left ventricular systolic intracavitary pressure, which is transmitted fully to the subendocardium but falls off to almost zero at the epicardial surface. The second, and perhaps even more important, is the vascular narrowing caused by compression and bending of vascular arterioles coursing through the ventricular wall as the heart contracts.[126]

The important resistance to coronary blood flow caused by left ventricular systolic compression can be demonstrated experimentally in a beating heart perfused at constant pressure in which transient asystole is induced by vagal stimulation. At that point, coronary blood flow suddenly increases by approximately 50 percent because of the relief of the compressive effect.[127]

The "throttling" effect of systole on myocardial perfusion is particularly important when systolic intraventricular pressure is elevated to levels exceeding coronary perfusion, as occurs with obstruction to left ventricular outflow by valvular or subvalvular aortic stenosis,[128] or with severe aortic regurgitation.[129] Because an increase in heart rate augments the total duration of systolic time per minute during which coronary vascular compression occurs, while augmenting myocardial oxygen demand, tachycardia may cause myocardial ischemia. The importance of extravascular compressive forces is greatly magnified when coronary vascular tone is diminished[130] as may occur during administration of arteriolar vasodilators or during metabolic vasodilation associated with physical activity.

Because compressive forces exerted by the right ventricle are ordinarily far smaller than those of the left ventricle, ventricular perfusion is reduced but not interrupted during systole. When the right ventricular systolic pressure is elevated by disease (e.g., pulmonic stenosis), the phasic blood flow pattern of the arteries perfusing the right ventricle resembles that of the left ventricle.

DIASTOLIC COMPRESSIVE FORCES.

The coronary perfusion or effective driving pressure has been assumed to be the pressure gradient between the coronary arteries and the pressure in either the right atrium or the left ventricle in diastole, because coronary flow drains primarily into these two chambers during this phase of the cardiac cycle. When coronary perfusion pressure is lowered, diastolic blood flow ceases when coronary driving pressure reaches 40 to 50 mm Hg, the so-called pressure at zero flow (P_{zf}).[131] This pressure is determined largely by diastolic compressive forces.

Transmural Distribution of Myocardial Blood Flow

Extravascular compressive forces are greater in the subendocardium than in the subepicardial layer (Fig. 34-18) (Figure Not Available) . Subendocardial arterioles are particularly susceptible to compression as they arborize from long, transmural vessels.[132] Therefore, *systolic* flow is more reduced in the subendocardium than the subepicardium. Nevertheless, in conscious dogs under resting physiological conditions, the ratio of endocardial to epicardial flow averaged throughout the cardiac cycle is approximately 1.25:1 due to preferential dilatation of the subendocardial arterioles, causing a large increase in diastolic flow in the subendocardium.[133] [134] The greater subendocardial blood flow appears to be secondary to the wall stress (and therefore oxygen consumption per unit weight), which is normally about 20 percent greater than that of subepicardial muscle.[135]

SUBENDOCARDIAL ISCHEMIA.

The subendocardium is more vulnerable to ischemic damage than the midmyocardium or subepicardium.[136] Epicardial coronary stenoses are associated with reductions in the subendocardial to subepicardial flow ratio.[134] When coronary arteries were constricted sufficiently to reduce total coronary flow to approximately 40 percent of control, endocardial to epicardial flow ratio fell from 1.16 at baseline to 0.37. This pattern of redistribution of flow away from the endocardium is further exaggerated during exercise, mental stress, and pacing-induced tachycardia.[137] Potent arteriolar vasodilators, such as dipyridamole or adenosine, also cause redistribution of blood flow from the endocardium to the epicardium.

Figure 34-18 (Figure Not Available) Cross-section of the left ventricular wall in diastole and systole. Factors involved in the susceptibility of the subendocardium to the development of ischemia include the greater dependence of this region on diastolic perfusion and the greater degree of shortening, and therefore of energy expenditure, of this region during systole.*(From Bell JR, Fox AC: Pathogenesis of subendocardial ischemia. Am J Med Sci 268:2, 1974.)*

When the absolute amount of blood flow is restricted, as in the presence of epicardial stenoses, this transmural redistribution leads to a "coronary steal," with the subendocardial flow even falling below resting values. Severe pressure-induced left ventricular hypertrophy,[133] as well as heart failure with elevated left ventricular end-diastolic pressure,[138] may also reduce the endocardial-to-epicardial flow ratio. When the markedly elevated left ventricular end-diastolic pressure in heart failure is corrected, subendocardial coronary flow reserve is restored and the endocardial-to-epicardial flow ratio is normalized.[138] Thus, impairment of endocardial perfusion in heart failure may be a direct consequence of the elevated left ventricular diastolic pressure and the *diastolic* compressive forces exerted on subendocardial perfusion.

A low subendocardial-to-subepicardial flow ratio can be increased by elevation of aortic pressure, which preferentially increases perfusion of the subendocardial region whose arterioles are maximally dilated and in which flow is pressure dependent. Overperfusion of the epicardial region is prevented by autoregulatory arteriolar constriction. Potent vasoconstrictors such as endothelin-1 and alphaadrenergic agonists[139] or inhibitors of adenosine-induced arteriolar dilation such as theophylline[140] cause arteriolar constriction and redistribution of blood flow to the endocardium. As long as the absolute blood flow is not reduced appreciably, this may result in lessening of myocardial ischemia. Reduction of myocardial oxygen demand, for example by beta blockers, also decreases epicardial blood flow and increases perfusion pressure and thereby flow to the ischemic subendocardial region.[141]

Neural and Neurotransmitter Control

Coronary blood flow is controlled predominantly by local metabolic, autoregulatory and endothelial factors that match coronary blood flow to myocardial oxygen demand and to the driving perfusion pressure. Neural control of the coronary circulation complements these local effects.[142] Epicardial arteries and coronary arterioles are extensively innervated by sympathetic and parasympathetic fibers,[142] and adrenergic and muscarinic receptors are expressed in these locations.[143] [144] [145] Investigations of the control of coronary circulation by the autonomic nervous system have been challenging because autonomic activation almost invariably leads to changes in myocardial oxygen demand and, therefore myocardial blood flow, through alterations in heart rate, blood pressure, and contractility. Experiments have been designed to separate the direct from the indirect (metabolic) actions of the sympathetic and the parasympathetic nervous systems. The problems of investigating the sympathetic system are compounded by the opposing actions of vasoconstrictor alpha-adrenergic receptors and vasodilator beta-adrenergic receptors.

Sympathetic Control

ALPHA-ADRENERGIC VASOCONSTRICTION.

When its cardiac inotropic and chronotropic actions are blocked by beta-adrenoreceptor antagonists, electrical activation of sympathetic fibers results in coronary vasoconstriction. This constriction is mediated by means of alpha receptors (it is attenuated by alpha-adrenergic antagonists) and competes with metabolic regulation.[142] [142A]

Reflex Alpha-adrenergic Vasoconstriction.

The carotid baroreceptor reflex responds to changes in blood pressure. Hypotension leads to activation of sympathetic fibers and inhibition of vagal discharge. The resultant increase in myocardial oxygen demand and blood flow is countered by alpha-adrenergic mediated vasoconstriction.[142] [143] This restraint imposed by the alpha-adrenergic system results in increased myocardial oxygen extraction.[142] In humans, alpha-adrenergic coronary constriction can be demonstrated by activation of another reflex sympathetic pathway by the cold pressor test (immersion of a hand into ice-cold water). In some patients, the cold pressor stimulation results in coronary vasoconstriction that can be blocked by a selective $alpha_1$ -adrenergic antagonist.[146]

Alpha-adrenergic coronary vasoconstriction has also been observed during exercise in conscious dogs. During near-maximal exercise in dogs, myocardial oxygen delivery increased markedly but not maximally, because the increase in blood flow was blunted by alpha-adrenergic activation[147] (Fig. 34-19) . Feigl has proposed an explanation for the apparent paradox of sympathetic coronary constriction during exercise by its potentially beneficial effects on the transmural distribution of blood in the left ventricular wall.[148] Alpha-adrenergic blockade during exercise results in adverse transmural flow redistribution away from the endocardium.[149] This effect of the alpha-adrenergic activation is not simply due to a reversal of intramural steal but is associated with a reduction in vascular compliance and backward arterial systolic blood flow with each systole.[142]

BETA-ADRENERGIC VASODILATION.

Under experimental conditions during which adrenergic activation does not alter myocardial oxygen demand, beta-receptor activation leads to coronary vasodilation. This is mediated predominantly by a $beta_1$ receptor in conduit arteries and by $beta_2$ receptors in resistance arterioles.[142]

PARASYMPATHETIC CONTROL

When myocardial oxygen demand is held constant, stimulation of the parasympathetic nervous system leads to dilation of epicardial arteries and coronary arterioles in dogs[143] and baboons,[150] whereas it leads to constriction in pigs.[151] This species variability can be accounted for by the dual actions of the neurotransmitter acetylcholine, which causes smooth muscle constriction and endothelium-dependent dilation by release of NO and other factors. Although release of acetylcholine from nerve terminals occurs at the medial-adventitial junction, sufficient amount diffuses to stimulate the endothelium. However, in pigs, muscarinic receptors are absent on the endothelium and only smooth muscle constriction is observed. In humans, the coronary response to acetylcholine is vasodilation in healthy subjects. However, vasoconstriction predominates in patients with atherosclerosis or its risk factors.[48]

Reflex parasympathetic control has been studied extensively in the canine circulation. Presumably, similar regulation applies to healthy humans with normal

Figure 34-19 Comparison of the effects of exercise on changes in mean left circumflex coronary blood flow (CBF, top panel) and late diastolic coronary resistance (LDCR, bottom panel) in the same dogs studied in the presence of beta-adrenergic receptor blockade with propranolol (solid lines) and combined beta- and alpha-adrenergic receptor blockades (broken lines). Increases in coronary blood flow and reductions in coronary resistance were greater after alpha blockade, indicating that sympathetic stimulation increases coronary vascular resistance during exercise by alpha-receptor stimulation.*(From Murray PA, Vatner SF: Alpha-adrenoceptor attenuation of the coronary vascular response to severe exercise in conscious dogs. Circ Res 45:654, 1979.)*

endothelial function but reflex parasympathetic control has not been characterized in patients with atherosclerosis or its risk factors. In dogs, parasympathetic reflex stimulation leads to coronary vasodilation through several pathways, including (1) carotid baroreceptors that respond to changing blood pressure, (2) carotid bodies that are activated by hypoxia and hypercarbia, and (3) cardiac mechanoreceptors that are stimulated by reduced cardiac filling or small end-systolic volume.[142]

Much remains to be learned about the neural control of the coronary circulation. As was noted previously, coronary arterioles have specialized functions according to their size, a feature that may facilitate finer control of blood flow. It is, therefore, of interest that sympathetic stimulation leads to dilation of the larger arterioles (through the beta-adrenergic system) and constriction of the smaller arterioles.[152] The physiological advantage of this specialized regulation will require further study.

Effects of Coronary Stenoses

Limitation of coronary blood flow imposed by atherosclerosis is related principally to the geometric features of stenoses, including their severity and length, their stiffness or partial distensibility permitting active or passive vasomotion, and the presence of superimposed platelet aggregation and thrombosis.

As blood traverses a stenosis, pressure (energy) is lost. Principles of fluid dynamics have been applied to estimate this pressure loss and validated in animals models as well as in patients. Although the formulas are complex, they can been simplified as follows:

where DeltaP is the pressure drop across a stenosis in millimeters of mercury (mm Hg), Q is the flow across the stenosis in milliliters per second, and d_{sten} is the minimal diameter of the stenosis lumen in millimeters. The first term accounts for viscous friction between layers of fluid in the stenotic segment leading to frictional energy losses. The second term reflects energy losses when the "pressure energy" of normal arterial flow is transferred first to the kinetic energy of high-velocity flow and then, at the exit from the stenosis, to the turbulent energy of distal flow eddies (separation losses due to disturbed laminar flow) (Fig. 34-20) .

RELATIONS BETWEEN CORONARY FLOW AND RESISTANCE.

At normal levels of coronary arterial flow, both frictional and separation losses contribute to the stenosis resistance and to the presence of a pressure gradient. As flow increases, separation losses, which increase with the square of the flow, become increasingly prominent and viscous losses become negligible. Thus, increases in blood flow and pressure drops across the stenosis are related in an exponential manner (Fig. 34-21) . Augmentation of coronary blood flow is associated with elevations in pressure gradient across the stenotic orifice and reductions in poststenotic perfusion pressure (driving pressure for myocardial perfusion).

Brown and colleagues[153] have called attention to several common clinical situations in which reduction in poststenotic pressure contributes to the pathogenesis of myocardial ischemia. First, pharmacological dilators of coronary resistance arterioles, such as adenosine or dipyramidole, increase transstenotic blood flow and reduce poststenotic pressure. When subendocardial resistance vessels become near fully dilated their perfusion becomes pressure dependent (autoregulation fails). Redistribution of flow away from the subendocardium to the subepicardium develops. This is one mechanism of "coronary steal." Second, during physical activity, coronary blood flow rises to meet the increase in myocardial oxygen demand, leading to an increase in transstenotic pressure gradient and a fall in the distal perfusion pressure. This results in a reduction of blood flow from to the subendocardium while the flow to the subepicardium continues to increase, an effect similar to that observed with the administration of pharmacological vasodilators. Furthermore, the fall in intraluminal distending pressure may lead to a passive collapse of the artery at the site of the obstruction, exaggerating the degree of stenosis. Third, the reduced oxygen-carrying capacity of anemia is

Figure 34-20 Energy losses across a stenosis. The pressure gradient due to friction losses within the stenosis (DeltaP) is directly proportional to blood flow (Q), whereas separation losses at the exit to the stenosis due to formation of eddies increase with blood flow squared (Q^2). Separation losses predominate at high blood flows.

Figure 34-21 Relation between pressure reduction across a stenosis (DeltaP) and flow through the stenosis (Q). Relations are shown for concentric stenoses of 30, 50, 70, 80, and 90 percent internal diameter. The numbers in parentheses below each percent diameter stenosis represent residual luminal cross-sectional area, calculated on the basis of a normal internal diameter of 3 mm and cross-sectional area of 7.1 mm^2 . The level of flow corresponding to basal metabolic needs is represented by the vertical dotted line; stenosis resistances for this level of flow are shown as the dashed tangent lines to the individual pressure-flow relations. In the inset at right, stenosis resistance (R) is plotted as a function of degree of stenosis.*(From Klocke FJ: Measurements of coronary blood flow and degree of stenosis: Current clinical implications and continuing uncertainties. Newsletter of the Council on Clinical Cardiology of the American Heart Association. Vol 7, No. 3, July 1982.)*

compensated for by increase in coronary blood flow because the myocardium cannot increase its oxygen extraction significantly. This decreases poststenotic pressure and compromises subendocardial perfusion. Not surprisingly, therefore, anemia is poorly tolerated in patients with coronary artery disease.

SEVERITY OF STENOSIS.

At any level of blood flow, the single most important determinant of stenosis resistance is the minimum diameter of the stenosis. The transstenotic pressure drop is inversely proportional to the *fourth* power of the minimum luminal diameter. As a consequence, a relatively small change in luminal diameter (such as caused by active or passive vasomotion) is amplified to produce marked hemodynamic effects in the presence of severe stenoses (see Fig. 34-21) . For example, when the diameter stenosis is increased from 80 to 90 percent, the resistance of a stenosis rises nearly threefold.

ENTRANCE AND EXIT EFFECTS.

Blood flow velocity (kinetic energy) increases and pressure (static energy) decreases in a narrowed arterial segment. The conversion of static to kinetic energy would occur with little loss of energy if the flow remained laminar, according to the Bernoulli principle. Laminar flow can be preserved if the entrance and the exit of the stenotic segment taper gradually. However, most stenoses have abrupt transitions where energy losses associated with separation of laminar flow into eddy currents (vortices) occurs. The separation energy losses are particularly pronounced at the exits of stenoses.

LENGTH OF STENOSES.

For most stenoses, the length of the narrowing has only a modest effect on its physiological significance. However, in very long narrowed segments, significant turbulence occurs along the wall of the stenotic segment and energy is dissipated as heat when eddies impact on the wall; stenosis may become important under these

conditions.

DYNAMIC CHANGES IN STENOSIS SEVERITY.

Examination of the morphology of pressure-fixed human coronary arteries has revealed eccentricity of atherosclerotic plaques. In many cases, plaques involve only a portion of the arterial wall whereas the remaining arc of the wall is relatively normal and often compliant. This provides a mechanism by which changes in vascular tone may alter luminal caliber and stenosis resistance. For example, most atherosclerotic stenoses in patients can dilate actively in response to nitroglycerin or constrict in response to acetylcholine, ergonovine, or alpha-adrenergic stimuli.

Dynamic changes in stenosis severity and resistance can also occur passively due to alterations in intraluminal distending pressure. Such changes can be demonstrated both in experimental models and in patients with coronary artery disease. As blood flow velocity rises in the stenotic segments, distending pressure falls, leading to passive collapse of a pliable segment. Passive collapse of a stenosis associated with the use of vasodilators occurs with agents that selectively dilate distal resistance vessels. The administration of dipyridamole to patients with coronary artery disease can cause narrowing of severely stenotic pliable segments as well as of the normal arterial segments distal to the stenoses. Passive collapse of pliable stenoses may also occur when central aortic pressure is lowered.

EFFECTS OF CORONARY STENOSIS IN THE INTACT CORONARY BED.

The physiological effect of a coronary stenosis depends on the degree to which the resistance to flow caused by the stenosis can be compensated for by dilation of arterioles distal to the stenosis. Gould and Lipsomb concluded that in normal dogs, resting coronary flow is not altered until the constriction reaches at least 85 percent of the diameter. Therefore, resting coronary flow is not impeded by mild or moderate stenoses and is an insensitive measure for evaluation of coronary artery disease. *Maximal* coronary blood flow, however, begins to decline when diameter stenosis exceeds 30 to 45 percent (Fig. 34-22) . The capacity to increase coronary blood flow in response to

Figure 34-22 Relationship between resting (dashed line) and maximal coronary blood flow (solid line) and percentage of diameter stenosis in a dog. Progressive coronary stenosis was achieved by progressively narrowing a short segment of a proximal coronary artery. Resting coronary blood flow did not change until coronary diameter stenosis exceeded 80 percent. *(From Marcus ML: The Coronary Circulation in Health and Disease. New York, McGraw-Hill, 1983, and modified from Gould KL, Lipscomb L: Effects of coronary stenoses on coronary flow reserve and resistance. Am J Cardiol 34:50, 1974.)*

increased oxygen demand is abolished when diameter stenosis exceeds 90 percent.

Insights derived from such animal studies must be applied cautiously in clinical practice. The simple use of relative percent diameter stenosis determined by coronary arteriography has important limitations, because it does not account for other geometric characteristics of the stenosis such as its absolute diameter, length, entrance and exit angles, or eccentricity. The determination of relative percent diameter narrowing may be misleading in the setting of diffuse disease where segments adjacent to the stenosis are also reduced in caliber. The hemodynamic effects of serial stenoses are also difficult to assess from arteriograms. It is not surprising, then, that the correlation between percent diameter stenosis and the physiological significance of a given obstruction in patients is poor, especially for lesions of moderate severity.[154] [155] [156] [157] [158]

Coronary Flow Reserve and Reactive Hyperemia

Severe myocardial ischemia produces maximal coronary dilation.[159] Therefore, when a coronary artery is occluded, release of the occlusion is followed by a marked increase in coronary flow. This response is termed *reactive hyperemia* (Fig. 34-23) . Reactive hyperemia follows an occlusion as short at 200 milliseconds. *Maximal reactive hyperemia* follows coronary occlusion of 20 seconds. Longer occlusion increases the duration but not the amplitude of the hyperemic response.

Reactive hyperemia is partly a response driven by a requirement to repay oxygen debt. However, the hyperemic response is less pronounced when coronary arteries are perfused with deoxygenated blood for the same duration.[160] This suggests that factors other than the mere lack of oxygen stimulate the hyperemic response, including the local accumulation of adenosine (see p. 1090), prostacyclin (see p. 1095) and NO (see pp. 1090 , 1091 , 1092 , 1093 , and 1094).[28]

After the release of coronary occlusion, the coronary resistance vessels are maximally dilated. Under this condition, autoregulation is abolished and coronary blood flow is directly related to the driving pressure. Therefore, maximal hyperemic coronary blood flow is closely dependent on the coronary arterial (or central aortic) pressure at the time of the measurement.[161]

Assessment of the Physiological Significance of Coronary Stenoses

Because of the limitations inherent in coronary angiography, attention has been directed to using physiological approaches for determining the severity of coronary stenoses.

Figure 34-23 Mean coronary flow before, during, and after coronary occlusion. Arrow indicates the release of occlusion. Area A represents the flow debt, and area B its repayment. *(From Gould KL: Coronary Artery Stenosis. New York, Elsevier, 1991, p 13.)*

As noted earlier, maximal blood flow is a more sensitive stimulus for assessing the hemodynamic severity of stenoses than the resting blood flow. Three types of stimuli have been used to elicit maximal coronary blood flow in humans: transient coronary occlusion, pharmacological vasodilators, and metabolic stresses. In humans, coronary blood flow responses can be evaluated after a brief coronary occlusion with balloon angioplasty.[162] A potent stimulus causing a threefold or greater increase in blood flow coronary occlusion cannot be used for diagnostic purposes outside the angioplasty setting. Adenosine and papaverine are the principal pharmacological vasodilators used to elicit hyperemia. Adenosine can be administered by the intravenous or intracoronary route. It has a rapid onset and a brief duration of action and is generally safe. Papaverine is administered by the intracoronary route. It has a slower onset and a longer duration of action. Although it has been considered to be the gold standard for maximally stimulating blood flow, it tends to have more side effects. In appropriate concentrations, papaverine causes a maximal increase in coronary blood flow similar to that obtained with reactive hyperemia after balloon angioplasty.[162] Intense treadmill or bicycle exercise, a potent metabolic stimulus, also yield near maximal flow increases. Exercise is the most physiological stress particularly suited for the noninvasive laboratory, but it is difficult to apply at the time of catheterization. Rapid atrial pacing produces only modest, submaximal increases in coronary blood flow.[163]

INVASIVE MEASUREMENT OF FLOW RESERVE.

Several techniques for determining coronary flow reserve have been developed for use during cardiac catheterization. Doppler wires have a miniaturized Doppler crystal placed at the tip of an angioplasty guidewire, permitting measurement of phasic and mean coronary blood flow velocities.[155] [164] Because this technique does not measure absolute coronary blood flow, several indices of flow *velocity* have been used for assessing the physiological significance of coronary stenoses. Coronary flow velocity reserve is the ratio of maximum to baseline flow velocity. Patients with a coronary flow velocity ratio less than 2 typically have other, corroborating evidence of myocardial ischemia[165] and improve symptomatically with revascularization. Conversely, patients with a ratio greater than 2 usually lack other objective evidence of myocardial ischemia and have a favorable outcome with conservative management (Fig. 34-24) . Hence, flow velocity measurements can be helpful in the management of patients with coronary lesions of intermediate severity. Diastolic to systolic velocity ratio has also been used to evaluate stenosis severity. While in normal arteries, diastolic flow velocity far exceeds systolic velocity, the two are more equal distal to significant stenoses. A ratio less than 1.7 has been used to define significant coronary lesions.[166]

During coronary interventions, the Doppler guidewire can be used to judge the adequacy with which stenosis severity has been reduced. Patients with higher coronary flow reserve at completion of the procedure have a lower incidence of abrupt reocclusion and restenosis.[167]

Myocardial fractional flow reserve (FFR) is a recently developed index of the functional severity of coronary stenoses that is calculated only from simultaneous pressure measurements proximal and distal to a stenosis obtained with a pressure monitoring guidewire.[168] FFR represents the fraction of the normal maximal coronary flow that can be achieved in an artery in which flow is restricted by a coronary stenosis. The concept of FFR is founded in the observation noted previously, that during

maximal hyperemia, myocardial perfusion is entirely pressure dependent. Therefore, maximal blood flow in the presence of a stenosis is determined by the driving pressure distal to the stenosis (Pd) while the theoretical normal maximal blood flow is determined by the pressure proximal to the stenosis (Pp).

Figure 34-24 Recording of blood flow velocity using a Doppler wire (schematic illustration in top panel) in the left anterior descending artery of a patient with an "intermediate" stenosis by angiography and exercise testing negative for ischemia. Blood flow velocity increased 3.5-fold after intracoronary (I.C.) adenosine (right lower panel) compared with baseline (left lower panel). Coronary flow velocity ratio (CFVR)=3.5 indicates that the "intermediate" stenosis is not hemodynamically significant.

FFR is calculated during maximal hyperemia, obtained with adenosine or papaverine as
FFR = Pd/Pp.
FFR less than 0.75 is typically associated with other objective evidence of myocardial ischemia (Fig. 34-25) . Measurement of FFR in patients with coronary stenoses of moderate severity has been shown to be a useful index of the functional severity of the stenoses and the need for coronary revascularization.[158] [169] [170] Measurement of FFR can also guide the adequacy of reducing coronary stenosis severity with balloon angioplasty[171] or stenting. [172]

NONINVASIVE MEASUREMENT OF FLOW RESERVE.

Radionuclide stress myocardial perfusion imaging (thallium-201, sestamibi) is used widely to quantify coronary flow reserve (see Chap. 9) . Some laboratories are using positron-emission tomography and nuclear magnetic resonance imaging for the same purpose.[173] [174] Flow reserve is typically assessed by these techniques during exercise or with pharmacological coronary vasodilators. In contrast to invasive techniques that measure an index of *absolute* flow reserve (an index related to the quotient of maximal and basal flow), cardiac imaging techniques assess *relative* coronary flow reserve by comparing the perfusion of ischemic regions of the left ventricle with presumably normally perfused reference regions.

Imaging techniques yield a less quantitative index of flow reserve than do catheter-based techniques. In addition, results can be misleading in the setting of diffuse coronary disease when a normal reference region is not available. However, unlike most measures of absolute flow reserve, relative flow reserve is independent of the loading conditions, because these affect all regions of the left ventricle equally. Taken together, absolute and relative coronary flow reserve provide a more complete description of physiological stenosis severity than does either alone.[175]

STENOSIS SEVERITY AND CLINICAL EVENTS.

There is a poor correlation between the severity of stenoses and their propensity to cause myocardial infarction, unstable angina, or sudden coronary death. Pathological studies have revealed that myocardial infarctions and unstable angina are most often caused by rupture of atherosclerotic plaques with formation of a superimposed occlusive thrombus (see Chap. 35) . The majority of atherosclerotic lesions responsible for these serious events are mild stenoses of inconsequential hemodynamic significance and are characterized by abundance of lipid, numerous inflammatory cells, and a thin, fragile fibrous cap.[75] [78] [176] These observations suggest that although measurements of coronary flow reserve may be useful in the assessment of the severity of stenoses and in the identification of lesions responsible for effort angina, they are *not* likely to identify the more dangerous plaques responsible for unstable angina, acute myocardial infarction, and ischemic sudden death.

Figure 34-25 Recording of arterial pressure (P) proximal to (by means of coronary catheter) and distal to (by means of a pressure wire) an "intermediate" stenosis in the left anterior descending coronary artery of a patient with exercise test positive for ischemia. Fractional flow reserve (FFR, a ratio of distal-to-proximal pressure after adenosine)=0.56 indicates that the "intermediate" stenosis is hemodynamically significant.

CORONARY COLLATERAL CIRCULATION AND ANGIOGENESIS

Coronary Collateral Vessels

After total or near-total occlusion or a coronary artery, perfusion of ischemic myocardium occurs by way of collaterals--vascular channels that interconnect epicardial arteries.[177] Preexisting collaterals are thin-walled structures ranging in diameter from 20 to 200 mum.[178] The density of preexisting collaterals varies greatly among different species.[179] Acute coronary occlusion produces no infarction at all in guinea pigs because of an exceptionally well developed network of preexisting collaterals. The dog has an intermediate density of preexisting collaterals that can deliver, on average, 5 to 10 percent of preocclusional, basal flow. Pigs, rats, and rabbits have virtually no preexisting collaterals, and infarcts develop rapidly and completely with acute coronary occlusion.[179] The density of preexisting collateral channels in humans appears to be somewhat more modest than in dogs.

COLLATERAL FORMATION (ARTERIOGENESIS)

Preexisting collaterals are normally closed and nonfunctional, because no pressure gradient exists between the arteries they connect. After coronary occlusion, the distal pressure drops precipitously and preexisting collaterals open virtually instantly. The transformation of preexisting collaterals into mature collaterals is called *arteriogenesis* and occurs in three stages. The initial stage (first 24 hours) involves *passive widening* of the preexisting channels facilitating increased flow. Endothelial cells become *activated* by increased blood flow velocity and shear stress and secrete proteolytic enzymes that fragment the basement membrane and dissolve extracellular matrix, an essential process in the upcoming migration of endothelial cells.[180] The second stage (1 day to 3 weeks) is characterized by *inflammation and cellular proliferation*. [177] [178] [181] [182] [183]

Monocytes migrate into the vascular wall and secrete cytokines and growth factors. This phase of vascular enlargement is marked by cellular proliferation involving the endothelium, smooth muscle cells, and fibroblasts.[177] [184] Endothelial cells and inflammatory cells also secrete matrix degrading enzymes, which create spaces necessary to accommodate the expanded collateral vessels as well as facilitate cell migration. These enzymes belong to the plasminogen activator/plasmin and matrix metalloproteinase families.[185] [186] Additional space for the larger vessels is created by the process of apoptosis.[177] [187] Over several weeks, endothelial and smooth muscle cells arrange themselves into circular and longitudinal layers. During these first two phases, the luminal diameter of collateral channels increases nearly 10-fold. The third stage of collateral maturation (3 weeks to 6 months) involves thickening of the vessel wall due to *deposition of extracellular matrix* and further cellular proliferation.[177] In its final stage, the mature collateral vessel may reach 1 mm in luminal diameter. Its three-layer structure is nearly indistinguishable from a normal coronary artery of the same size.[177] [178]

MECHANISMS PROMOTING COLLATERAL GROWTH

SHEAR STRESS.

Mechanical forces determine the size of collateral channels in the early minutes and hours after coronary occlusion. Pressure gradients across preexisting rudimentary collaterals augment blood flow velocity and shear stress. Shear stress induces widespread functional changes in the endothelium, many of which reflect new gene expression. These include upregulation in leukocyte adhesion molecules[188] and increased production of proinflammatory cytokines (monocyte chemoattractant protein-1, tumor necrosis factor-alpha, granulocyte-macrophage colony-stimulating factor).[184] The end result of this process is an inflammatory environment.

INFLAMMATION.

Inflammatory cells are a rich source of matrix degrading enzymes (see earlier) and growth factors.[189] The invasion of inflammatory cells is rapidly followed by mitosis of endothelial and smooth muscle cells.[181]

GROWTH FACTORS.

More than 15 growth factors that can stimulate collateral growth (arteriogenesis) or angiogenesis have been identified.[180] [190] Among these, vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF) are believed to play the most important roles in vivo. Angiogenesis in response to VEGF is mediated by NO, and deficiency of NO (e.g., in the presence of coronary risk factors; see later) may account for impaired collateral formation in that setting.[191]

INHIBITORY FACTORS.

Growth factors can be detected in adult tissues in which endothelial cells are quiescent. Absence of angiogenesis in the presence of growth-promoting factors can be partly attributed to the presence of endogenous inhibitors of this process.[180] Potent angiogenesis inhibitors include angiostatin (a fragment of plasminogen),[192] endostatin (a proteolytic fragment of collagen XVIII),[193] and thrombospondin-1.[194] It is believed that the rate of angiogenesis is determined by a balance between stimulators and inhibitors.[194A]

HYPOXIA.

Tissue hypoxia is associated with rapid upregulation of VEGF. This increase in VEGF occurs by augmented mRNA synthesis and enhancement of its stability.[184] [195] [196] A hypoxia-sensitive element has been identified in the promoter region of VEGF gene.[197] Furthermore, hypoxia upregulates the number of VEGF receptors.[198] This latter observation may provide an explanation by which intravenous administration of growth factors could induce angiogenesis preferentially and selectively in ischemic tissues.

Nevertheless, hypoxia is not likely an essential requirement for the formation of collaterals. In many cases, the collateral artery originates from a vessel far removed from the site of ischemia.[184]

SEVERITY OF OBSTRUCTION.

The severity of coronary obstruction is a critical determinant of the development of coronary collateral channels. In dogs, the growth of collaterals is not stimulated until a coronary stenosis reduces the luminal cross-sectional area by at least 80 percent. In patients, coronary collaterals do not develop until a coronary stenosis of at least 70 percent diameter narrowing is present. Beyond this threshold value, the growth of collateral channels is directly related to the severity of stenosis.[199]

CORONARY RISK FACTORS.

Patients with diabetes mellitus have an impaired ability to develop collateral blood vessels in the setting of obstructive coronary artery disease.[200] Similarly, rabbits with experimental hyperlipidemia have a limited collateral growth in response to arterial restriction.[201] Thus, the same risk factors that predispose to atherosclerosis may limit a major compensatory mechanism--formation of collateral pathways.

EXERCISE.

This has no effect on the preexisting (rudimentary) collaterals in the absence of coronary occlusions or stenoses. Even in the presence of severe coronary stenoses, the effects of exercise training have been inconsistent and overall neutral in animals.[179] In the clinical studies that used serial angiographic follow-up, increase in collaterals occurred with progression in the severity of coronary artery stenoses, rather than with long-term exercise programs.[202] The reduction of myocardial ischemia associated with exercise is likely the result of improved conditioning.

REGULATION OF COLLATERAL TONE.

The mature coronary collaterals can appreciably dilate or constrict in respond to vasoactive stimuli. The release of endogenous vasodilators NO[203] and prostacyclin maintains collaterals in a dilated state. Conditions that reduce endothelium-derived NO, including coronary risk factors, may reduce the dilator reserve of coronary collaterals, a condition correctable by the administration of exogenous nitrates.[203]

Conversely, serotonin[204] and vasopressin[205] constrict collaterals. Serotonin is released into the circulation during episodes of ischemia triggered by platelet aggregation or thrombosis and may exacerbate myocardial ischemia by reducing collateral blood flow.

CORONARY COLLATERALS IN PATIENTS WITH CORONARY ARTERY DISEASE.

Because coronary collaterals develop in patients whose symptoms of angina pectoris tend to be severe,[199] controversy arose in the past about their clinical utility.[179] However, it is now clear that coronary collaterals can mitigate the severity of myocardial ischemia[206] and, in acute myocardial infarction, collateral circulation can contribute significant amount of blood flow, decrease infarct size, improve left ventricular function, reduce the likelihood of left ventricular aneurysm formation, and improve survival.[207] [208]

Recently, it has become possible to quantify collateral blood flow in conscious humans undergoing coronary angioplasty. Coronary pressure distal to the site of angioplasty balloon occlusion (coronary wedge pressure) can be measured and reflects recruitable collateral perfusion.[209] Patients in whom recruitable collateral blood flow exceeded 28 percent of normal maximal myocardial blood flow were free of ischemia at the time of coronary occlusion induced by balloon angioplasty. Conversely, ischemia was frequently present at the time of coronary occlusion when recruitable collateral blood flow was less than 28 percent of normal maximal myocardial blood flow.[209] This approach has also shown that collateral circulation rarely provides blood flow increases adequate to meet the myocardial oxygen demand of maximal physical exercise; it is typically limited to less than 50 percent of maximal coronary flow reserve.[209]

Angiogenesis

Arteriogenesis (discussed earlier) refers to formation of mature collaterals by enlargement of *preexisting rudimentary collaterals*. Typically, epicardial collaterals fall into this category. *Angiogenesis* refers to *sprouting of new vessels* from preexisting blood vessels and usually results in formation of smaller, capillary-like structures. Subendocardial collaterals may be formed in this manner. In *therapeutic angiogenesis*, exogenous angiogenic growth factors (or genes encoding these growth factors) are administered to stimulate neovascularization of ischemic issues.[177] [190] [210] [210A]

MECHANISMS OF ANGIOGENESIS.

Angiogenic stimuli initiate activation of endothelial cells of capillaries or postcapillary venules. This results in local vasodilation, increased vascular permeability, and degradation of the basement membrane. Migration and proliferation of endothelial cells occurs with formation of capillary sprouts. Furthermore, endothelial proliferation elongates the sprouts and adjacent sprouts connect to form capillary loops that can carry blood flow. Maturation of the sprouts is associated with deposition of basement membrane.[180]

THERAPEUTIC ANGIOGENESIS: PRECLINICAL STUDIES.

Preclinical studies in several animal species have established that angiogenic growth factors can promote formation of new collateral channels in models of peripheral and myocardial ischemia.[190] [210] The angiogenic growth factors used in these studies were administered as recombinant protein or by gene transfer and included vascular endothelial growth factor (VEGF), fibroblast growth factor-1 (FGF-1) and FGF-2, hepatocyte growth factor (HGF), and hypoxia inducible factor-1 (HIF-1). Each of these growth factors can stimulate the critical steps in angiogenesis, including endothelial activation and mitogenesis and upregulation of matrix proteins and matrix proteinases.[210]

Much interest has focused on the role of VEGF because it is a potent angiogenic factor and because the receptors for VEGF are relatively specific for endothelial

cells.[211] This specificity favors a targeted therapeutic response and limits the potential for pathological angiogenesis.[190] Four forms of VEGF are formed by alternative splicing of the messenger RNA from a single gene. These forms encode for protein molecules of 121, 165, 189, and 206 amino acids that vary in heparin-binding properties and therefore the avidity with which they bind to cell membranes and extracellular matrix. All forms of VEGF are mitogenic for endothelial cells.

FGF comprises a family of growth factors that are potent stimulants of angiogenesis. Unlike VEGF, FGF also stimulates the proliferation of smooth muscle cells and fibroblasts.

Although potentially associated with adverse effects, stimulation of smooth muscle cell growth and its incorporation into the vascular wall might permit formation of a muscular conduits resembling true collaterals rather than capillaries.

The initial demonstration by Isner and colleagues that intraarterial injection of VEGF augmented collateral formation in the ischemic rabbit hind limb has generated great interest in therapeutic angiogenesis[212] (Fig. 34-26) . Therapeutic angiogenesis has since been carried out successfully in several animal species for the treatment of peripheral ischemia using intraarterial and intramuscular routes of injection and for the treatment of myocardial ischemia using intracoronary, intravenous, intrapericardial, and intramyocardial routes of administration. In the rabbit hind limb model, morphometric analysis has revealed a significant increase in capillary density, accompanied by an increase in vascular conductance (a reduction in resistance).[181] Premortem angiography has also demonstrated growth of larger collaterals.[210] Whether these formed from preexisting rudimentary collaterals by arteriogenesis or whether they are

Figure 34-26 Selective internal iliac angiography of control rabbit performed at day 40 (control, untreated, top) and of vascular endothelial growth factor (VEGF)-treated rabbit at day 40 (bottom). VEGF was administered as a single intraarterial bolus into the internal iliac artery of rabbits with severe ipsilateral ischemia. The angiogram shown here has yielded angiographic scores of 0.17 and 0.41. Distal reconstitution, barely apparent in the control group (arrows), was evident in the VEGF-treated group (arrows). Direct and linear extension of internal iliac artery to popliteal and/or saphenous arteries was also more evident in the VEGF-treated group (open arrows).*(From Takeshita S, et al: Therapeutic angiogenesis. J Clin Invest 93:662, 1994. Copyright, 1994 American Society of Clinical Investigation.)*

newly vessels formed by angiogenesis remains to be determined.

THERAPEUTIC ANGIOGENESIS: CLINICAL STUDIES.

Demonstration of successful angiogenesis in preclinical studies has led to its application in a number of small-scale trials. In patients with critical limb ischemia, the administration of VEGF by intramuscular injection of plasmid DNA resulted in improved angiographic evidence of collateral blood flow, healing of ulcers, and resolution of rest pain.[213] In another study, administration of FGF improved blood flow to the calf and reduced the symptoms of intermittent

claudication. [190] In patients with ischemic heart disease, administration of intramyocardial or intracoronary growth factors (VEGF or FGF) led to an improvement in myocardial perfusion and apparent reduction in symptoms.[214] [215] These early uncontrolled results, while exciting, need to be validated by controlled, randomized trials.

A number of issues will have to be addressed systematically to optimize therapeutic angiogenesis. These involve methodology (e.g., optimal angiogenic factor(s) and synergistic combinations; methods of delivery and dosing schedule) and potential for pathological angiogenesis at undesired sites (e.g., growth of tumors, proliferative retinopathy, progression of atherosclerosis). Furthermore, further advances in the understanding of the biology of angiogenesis are needed to create muscular collaterals with large perfusion capacity rather than a blush of capillaries.

THERAPEUTIC VASCULOGENESIS.

Vasculogenesis is the formation of new blood vessels that typically occurs during early embryonic development. Endothelial stem cells and circulating endothelial precursors, angioblasts, may persist into adult life.[216] The concept that circulating angioblasts could be harvested and used to create new blood vessels in adults is under investigation.[210]

CONSEQUENCES OF MYOCARDIAL ISCHEMIA

Myocardial Stunning (See also Chap. 14)

For four decades after Tennant and Wiggers's classic observation on the effects of coronary occlusion on myocardial contraction,[217] it was believed that transient severe ischemia caused either irreversible cardiac injury, that is, infarction, or prompt recovery. However, in the 1970s Heyndrickx and colleagues reported that regional contraction remained depressed for more that 3 hours after a 5-minute coronary occlusion and for more than 6 hours after a 15-minute occlusion in conscious dogs.[218] It became clear that after a brief episode of severe ischemia, prolonged myocardial dysfunction with gradual return of contractile activity occurs, a condition termed *myocardial stunning* (Fig. 34-27) . Subsequently, myocardial stunning was observed by other investigators under a variety of additional experimental conditions, including multiple, brief episodes of ischemia; prolonged ischemia resulting in an admixture of myocardial necrosis and stunning of adjacent, viable myocardium; global myocardial ischemia (e.g., cardioplegia arrest); and stunning after exercise-induced ischemia.[219] [220] [221]

Myocardial stunning has been observed in patients with coronary artery disease in a variety of clinical conditions. It also has been observed after exercise-induced ischemia.

Persistent wall motion abnormalities can be observed by echocardiography at a time when chest pain, ST segment deviation, and regional perfusion had recovered.[219] [222] It affects both systolic and diastolic function.[223]

Clinically, global myocardial stunning occurs most frequently in patients who have undergone ischemic cardiac arrest during cardiopulmonary bypass, despite modern cardioplegia techniques.[224] Such hearts may not recover for days, and many patients require inotropic support. In patients with a myocardial infarction (both with and without the administration of thrombolytic therapy), stunned myocardium lies adjacent to infarcted myocardium. Improvement in ventricular function occurs gradually over the course of days to weeks.[219] [221] Myocardial stunning is also an important feature of unstable angina.[225]

Coronary angioplasty in patients parallels the observations in animal studies of brief coronary occlusion and reperfusion and provides a useful clinical model of stunning. Occlusions of 1 minute or less induce diastolic dysfunction,

Figure 34-27 Schematic diagram of stunned myocardium. During coronary occlusion, a wall motion abnormality of the left ventricle is present in the region supplied by the occluded artery. With relief of ischemia and reestablishment of coronary blood flow, there is a persistent wall motion abnormality despite reperfusion and viable myocytes. There is then gradual improvement in function that requires hours to days for recovery.*(From Kloner RA, Przyklenk K, Patel B: Altered myocardial states: The stunned and hibernating myocardium. Am J Med 86[Suppl 1A]:14, 1986.)*

whereas longer occlusions (over 5 minutes) induce systolic dysfunction that persists 24 to 36 hours.[219]

CELLULAR AND MOLECULAR MECHANISMS OF STUNNING.

A number of factors converge in the pathogenesis of myocardial stunning (see Fig. 14-35) . Probably, the three most important are (1) generation of oxygen derived free radials, (2) calcium overload, and (3) reduced sensitivity of myofilaments to calcium and loss of myofilaments.[219] [220] These mechanisms interact synergistically in the pathophysiological process of stunning.

Transient myocardial ischemia followed by reperfusion results in increased production of superoxide radicals and hydroxyl radicals. Free radicals inactivate enzymes and cause lipid peroxidation. The generation of free radicals in the ischemia-reperfusion setting has been documented by a direct measurement (spin-trapping and aromatic hydroxylation techniques) and by reduction of stunning with administration of antioxidants. The damaging free radicals are generated in the first minute after reperfusion as antioxidant therapy can reduce stunning if administered at the time of reperfusion but not if it is begun 1 minute later. The presumed targets of oxygen derived free radicals include sarcolemmal Na^+ ,K^+ -ATPase and calcium-stimulated ATPase and, in the sarcoplasmic reticulum, calcium-stimulated ATPase. The result

is increased influx of calcium through the sarcolemma, diminished calcium reuptake by the sarcoplasmic reticulum resulting in cellular calcium overload, and, ultimately, in impaired excitation-contraction coupling.[219] [220] Calcium overload can also activate enzymes that further damage the sarcolemma and sarcoplasmic reticulum. Ischemia followed by reperfusion also results in decreased calcium sensitivity of myofilaments, at least in part due to oxidation of critical thiol groups and in part due to partial proteolysis of troponin.[219] [220] [226] Recent evidence suggests that calcium overload may activate calpains, resulting in selective proteolysis of myofibrils.[220]

Although antioxidants are effective, they do not prevent stunning completely. It has been postulated that stunning involves two components, one related to ischemia (not responsive to antioxidants) and a larger component related to reperfusion.[219]

TREATMENT OF MYOCARDIAL STUNNING.

Myocardial stunning is an important clinical problem because it contributes to heart failure. Various therapies have been effective

in *preventing* stunning in the experimental setting, including antioxidants, angiotensin-converting enzyme inhibitors, calcium channel antagonists, and nitrates.[227] [228] Their effectiveness in the clinical setting remains to be established. Once stunning develops, it can be *reversed* with inotropic agents.

Hibernation (See also Chap. 14 and Chap. 37)

The term *hibernating myocardium* refers to the presence of impaired resting left ventricular function, owing to reduced coronary blood flow that can be restored toward normal by revascularization.[229] Hibernation was first noted in patients with coronary artery disease who had no evidence of ongoing ischemia yet whose left ventricular function improved after coronary artery bypass grafting. Even akinetic segments can occasionally regain systolic contraction after revascularization. These observations led to the concept that myocardium can reduce its contractility (and myocardial oxygen demand) to match reduced perfusion, preserving its viability.[219] [230] [231]

Hibernating myocardium is present in approximately one third of patients with coronary artery disease and impaired left ventricular function.[232] [233] The time course of recovery of hibernating myocardium after revascularization is quite variable, ranging from days to months.[219] Slower recovery is typically associated with longer duration of hibernation. Revascularization can be effective whether achieved by coronary bypass grafting as described originally or by coronary angioplasty.[234]

Detection of hibernation (Fig. 37-18) is of great practical significance because it can alleviate symptoms of heart failure and, in the long term, can forestall myocardial necrosis (see later). Detection of hibernating myocardium consists of finding that akinetic or hypokinetic segments of the left ventricular segment are still viable (see Chaps. 9 and 13) . This viability can be detected either by the persistence of metabolic activity within the regions of dysfunctional myocardium or by demonstrating improvement in the contraction of the hibernating myocardial segment with appropriate stimulation, such as inotropic stimulation. The improvement in function would not have occurred if the dysfunction had been due to myocardial infarction and scarring.[231] None of the available methods for the detection of myocardial viability is clearly superior to others. Such methods include dobutamine stress echocardiography, thallium-201 redistribution study, imaging with technetium-99m sestamibi, and positron-emission tomography with agents that detect residual metabolic activity such as ^{18} F-fluorodeoxyglucose or ^{11} C-acetate.[219] [231]

Histopathological studies of hibernating myocardium have revealed changes consistent with myocyte dedifferentiation. It has been assumed that these findings are reversible after revascularization. However, areas of hibernating myocardium also show evidence of apoptosis,[194A] [235] necrosis, and fibrosis.[229] [236] Finding of these irreversible changes suggests that revascularization of hibernating myocardium should be performed on an urgent basis.

Unlike stunning, which was described first in the experimental laboratory, hibernation was described initially in the clinical setting, and suitable animal models have been lacking.

Therefore, the cellular and molecular basis of hibernation has not been as extensively investigated. A recent study suggested that in hibernation it is the mitochondria that sense hypoxia. Partial inhibition of cytochrome oxidase during hypoxia allows mitochondria to function as the oxygen sensors, limiting ATP utilization and oxygen consumption.[237]

HIBERNATION VERSUS REPETITIVE STUNNING (see Table 14-6) .

There is a debate as to whether hibernation is always caused by a chronic reduction in resting myocardial blood flow or whether, at least in some cases, the same syndrome might be caused by repeat episodes of myocardial stunning. Animal models of short-term hibernation have clearly revealed that reductions in blood flow achieved by placement of stenoses are directly correlated with a decrease in contractile function.[238] [239] However, clinical studies have suggested that some patients with coronary artery disease who appear to have hibernating myocardium (poorly contracting but viable myocardium) have normal resting myocardial blood flow but diminished coronary flow reserve. It is likely that these patients suffer episodes of ischemia each time oxygen demand is increased. The final effect of multiple episodes of ischemia is cumulative stunning, mimicking hibernation.[238] [239]

Ultimately, with either scenario, revascularization therapy should improve left ventricular function.

Hemodynamic Consequences of Ischemia

Because the heart has virtually no stores of oxygen and relies almost entirely on aerobic metabolism, within seconds of coronary occlusion its relatively high rate of energy expenditure results in a sudden, striking decline of myocardial oxygen tension and impairment in left ventricular function. For example, sudden coronary occlusion in conscious dogs that produces regional myocardial ischemia is associated with evidence of systolic dysfunction within four beats of occlusion and diastolic dysfunction within nine beats.[240] Impairment of systolic and diastolic function are likely related to alterations in intracellular calcium handling, because calcium is ultimately responsible for regulating both systolic and diastolic function.[241] [242] Because left ventricular dysfunction is so readily induced by ischemia, its detection by echocardiography (see Chap. 7) or radionuclide imaging (see Chap. 9) has become a valuable diagnostic tool in the clinical diagnosis of coronary artery disease.[240]

Clinical evidence of heart failure occurs when regional asynergy is so severe and extensive that the uninvolved myocardium cannot sustain the normal hemodynamic burden (systolic failure). Symptoms of left ventricular failure usually develops when contraction ceases in 20 to 25 percent of the left ventricle. With loss of 40 percent or more of

Figure 34-28 Progression of cell death versus time after circumflex coronary occlusion in dogs. Necrosis occurs first in the subendocardial myocardium. With longer occlusions, a wavefront of cell death moves from the subendocardial zone across the wall to involve progressively more of the transmural thickness of the ischemic zone. In contrast, the lateral margins in the subendocardial region of the infarct are established as early as 40 minutes after occlusion and are sharply defined by the anatomic boundaries of the ischemic bed. AP=anterior papillary muscle; PP=posterior papillary muscle.*(From Reimer KA, Hill ML, Jennings RB: Prolonged depletion of ATP and of the adenine nucleotide pool due to delayed resynthesis of adenine nucleotides following reversible myocardial ischemic injury in dogs. J Mol Cell Cardiol 13:229, 1981.)*

Figure 34-29 *A,* Schematic diagram showing a transverse section through a canine left ventricle subjected to a permanent coronary occlusion without reperfusion. The white area represents nonischemic myocardium supplied by the nonoccluded vessel. The infarct (hatched area) is transmural or near-transmural. There are scattered zones of hemorrhage (solid black). A small layer of viable subendocardium is present that derives its oxygen directly from the ventricular cavity. Where collateral flow is high, there may be a small rim of surviving subepicardium (shaded areas). *B,* Schematic diagram showing a transverse section through a canine left ventricle subjected to coronary occlusion followed within 1 or 2 hours by coronary reperfusion. The hatched and solid black areas represent the infarct that is confined to the inner half of the myocardium. The solid black areas represent the zone of gross microvascular damage, including zones of no-reflow and hemorrhage. It is smaller than and contained within the total infarct. The remainder of the infarct without severe microvascular damage is represented by the hatched area and is located in the mid myocardium. The epicardial portion of the ischemic zone (stippled area) has been salvaged by coronary reperfusion. It is nonnecrotic but stunned (postischemic ventricular dysfunction) for hours to days after coronary reperfusion.*(From Braunwald E, Kloner RA: Myocardial reperfusion: A double-edged sword? J Clin Invest 76:1715, 1985. Copyright 1985, American Society for Clinical Investigation.)*

the left ventricular myocardium, severe pump failure ensues, and, if this loss is acute, cardiogenic shock may develop. A shift in the diastolic pressure-volume

relationship (diastolic failure) increases the resistance to ventricular filling and leads to elevated ventricular filling pressures, causing symptoms of pulmonary congestion.[243]

The "Wavefront" of Necrosis

As already noted (see p. 1104), within seconds of a coronary occlusion, blood begins to flow through preexisting collateral channels to the occluded segment of the artery. Collateral flow is lowest and myocardial oxygen consumption highest in the subendocardium, and therefore ischemia is most severe in this region. In the normal myocardium, thickening and shortening are greater in the subendocardium, as is wall stress, accounting for the higher subendocardial energy requirements.[244] [245] Consistent with these findings, higher rates of metabolic activity, lower tissue oxygen tension,[246] and greater oxygen extraction have been found in this region.[247] As a consequence, ischemia becomes most severe and myocardial cells undergo necrosis first in the subendocardium, beginning as early as 15 to 20 minutes after coronary artery occlusion. Necrosis progresses toward the epicardium, gradually involving the less severely ischemic outer layers (Figs. 34-28 and 34-29) . The progression of the wavefront of necrosis[248] is slowed by the presence of residual blood flow when the coronary occlusion is incomplete or when mature collaterals are present at the time of occlusion.[248] The progression of the wavefront of necrosis is accelerated when myocardial ischemia is unusually severe, when collateral blood flow is low, in the presence of marked arterial hypotension (e.g., in patients in cardiogenic shock), and in the presence of elevated myocardial oxygen demand, as may be caused by inotropic stimulation, tachycardia, or fever.

In dogs with acute coronary occlusion, the subendocardial lateral boundaries of myocardial infarcts are established early in the first hour, whereas the myocardial infarct enlarges in the transmural direction over 4 to 6 hours.[248] Transmural progression of myocardial infarction has also been observed in humans.[249] The recognition of the time-dependent progression of necrosis is the basis of interventions designed to arrest the progression of necrosis as rapidly as possible by reperfusion of occluded coronary arteries, using thrombolytic therapy or angioplasty (see Chap. 35) . Functional recovery that occurs in the subepicardial regions after reperfusion therapy is a mechanism for improvement in regional and global ejection fraction.[249]

Chapter 35 - Acute Myocardial Infarction

ELLIOTT M. ANTMAN
EUGENE BRAUNWALD

CHANGING PATTERNS IN CLINICAL CARE OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

Despite impressive strides in diagnosis and management over the past three decades, acute myocardial infarction (AMI) continues to be a major public health problem in the industrialized world and is becoming an increasingly important problem in developing countries.[1] In the United States, nearly 1.0 million patients annually suffer from AMI.[2] More than 1 million patients with suggested AMI are admitted yearly to coronary care units (CCUs) in the United States.[2] Although the death rate from AMI has declined by about 30 percent over the past decade, its development is still a fatal event in approximately one third of patients. About 50 percent of the deaths associated with AMI occur within 1 hour of the event and are attributable to arrhythmias, most often ventricular fibrillation. Because AMI may strike an individual during the most productive years, it can have profoundly deleterious psychosocial and economic ramifications.

Of particular concern from a global perspective are projections from the World Heart Federation that the burden of disease in developing countries will become more closely aligned with that now afflicting developed countries[2] [3] (see Chap. 1) . With a decline in infectious disease-related deaths accompanied by accelerated economic development and life style change promoting atherosclerosis, developing countries especially in Eastern Europe, Asia, and parts of Latin America are expected to experience a sharp increase in ischemic heart disease and AMI.[3] Given the wide disparity of available resources to treat AMI in developing countries, major efforts are needed on an international level to strengthen primary prevention programs at the community level.[1]

IMPROVEMENTS IN OUTCOME.

A steady decline in the mortality rate from AMI has been observed across several population groups since 1960.[1] [4] This appears to be caused by a fall in the incidence of AMI (replaced in part by an increase in the rate of unstable angina[5]) and a fall in the case-fatality rate once an MI has occurred[6] [7] (Fig. 35-1) .

Several phases in the management of patients have contributed to the decline in mortality from AMI.[8] [9] The "clinical observation phase" of coronary care consumed the first half of the 20th century and focused on a detailed recording of physical and laboratory findings; treatment consisted of strict bed rest and sedation. Subsequently, the "coronary care unit phase" beginning in the mid-1960s occurred and was notable for detailed analysis and vigorous management of cardiac arrhythmias. The "high-technology phase" was ushered in by the introduction of the pulmonary artery balloon flotation catheter, setting the stage for bedside hemodynamic monitoring and more precise management of heart failure and cardiogenic shock associated with AMI. The modern "reperfusion era" of coronary care was introduced by intracoronary and then intravenous thrombolysis, increased use of aspirin, and development of primary percutaneous transluminal coronary angioplasty (PTCA) and implantation of coronary stents for AMI. A battery of tests sometimes providing overlapping information was typically ordered during the high-technology phase.

Driven in large part by the need for cost-saving measures, contemporary care of patients with AMI has entered the "evidence-based coronary care phase" and is becoming increasingly influenced by managed care systems and guidelines for clinical practice[10] [11] Although increased responsibility has been placed in the hands of primary care physicians, they have begun to express concern about the potential adverse impact of an excessive increase in the scope of care they are being asked to provide.[12] Coronary care practice is better equipped than other areas of cardiology to face this transition from pathophysiologically based decision-making to evidence-based decision-making, given the rich data base of patients with suspected AMI studied in clinical trials and registries and efforts at summarizing a vast amount of data using metaanalysis.[13] [14] [15] [16] New therapies for AMI are being evaluated not only for evidence of safety and efficacy but also for their cost-effectiveness in caring for patients and their impact on quality of life. However, despite an abundance of cost-effectiveness information analyzed from a societal perspective with data from clinical trials, clinicians weighing the risk-benefit ratio at the bedside of an individual patient with AMI may have difficulty applying the findings for several reasons: uncertainty whether the benefits observed in a strictly defined trial population are applicable to a wider selection of patients,[17] limited data on specific subgroups, variations

Figure 35-1 *A,* The impact of medical therapy for AMI on short-term mortality. In the pre-CCU era AMI short-term mortality (30-day) was estimated to be 30 percent. Implementation of the CCU concept with defibrillation, sophisticated hemodynamic monitoring, and beta blockade reduced this to 15 percent. A further mortality reduction was ushered in by the reperfusion era; combinations of thrombolysis, primary percutaneous transluminal coronary angioplasty, and aspirin are now employed. *(Modified from Antman EM: General hospital management. In Julian D, Braunwald E (eds): Management of Acute Myocardial Infarction. London, WB Saunders, 1994, p 31.) B,* Cumulative incidence of CHD death as function of time period of initial Q-wave MI. *(Modified from Guidry UC, et al: Temporal trends in event rates after Q-wave myocardial infarction: The Framingham Heart Study. in the absolute level of baseline risk,[18] and variations in patient preferences. The information in this chapter on various treatment strategies should therefore be used as a guide and not a substitute for carefully reasoned clinical decision-making on a case-by-case basis.

LIMITATIONS OF CURRENT THERAPY AND VARIATIONS IN CLINICAL RESPONSE IN KEY SUBGROUPS.

Despite the gratifying success of medical therapy for AMI, several observations indicate that considerable room for improvement exists. The short-term mortality of patients with AMI who receive aggressive pharmacological reperfusion therapy as part of a randomized trial is in the range of 6.5 to 7.0 percent,[19] [20] [21] [22] whereas observational data bases such as The National Registry of Myocardial Infarction and Cooperative Cardiovascular Project suggest that the mortality rate in AMI patients is about 20 percent.[16] In addition, the mortality rate from AMI in patients enrolled in randomized trials is considerably lower than that observed among patients who are excluded from such trials.

Although the survival of elderly patients (> age 65) after AMI has improved significantly, advanced age consistently emerges as one of the principal determinants of mortality in AMI.[23] Despite reluctance to use potentially life-saving drug therapies in the elderly,[23A] [23B] cardiac catheterization and other invasive procedures are being performed more commonly at some point during hospitalization in elderly AMI patients. Nevertheless, evidence suggests that the greatest reductions in mortality for elderly patients are derived from those strategies employed during the first 24 hours, the time frame in which prompt and appropriate use of life-saving

pharmacotherapy is of paramount importance, emphasizing the need to extend advances in drug therapy for AMI to the elderly.[24]

Despite trends toward greater use of mortality-reducing therapies such as thrombolytics, aspirin, and beta-adrenoceptor blockers in patients with AMI, these drugs still appear to be underused.[25] [26] [27] [28] [29] [29A] Considerable variation exists in practice patterns for management of patients with AMI. This variation is seen not only on an international level but also regionally within countries[26] [30] and across medical specialties[26] [31] [32] ; such variations in practice are correlated with differences in outcome after AMI.[33] Intriguing data have indicated that mortality rates for AMI are lower in hospitals with a high clinical volume, a high rate of invasive procedures, and a top ranking in quality reports.[33] [34] [35] [35A]

Variation has also been observed in the treatment patterns of certain population subgroups with AMI, notably women and blacks.[29A] [36] Although the unadjusted rates of thrombolytic use and referral for cardiac catheterization and angioplasty are lower and unadjusted mortality rates are higher in women with AMI, gender differences are less apparent (but may not disappear entirely) once adjustment is made for baseline variables such as comorbidities and age[29A] [37] (see Chap. 58) . Of interest, after AMI, younger women but not older women have higher rates of in-hospital mortality than do men of the same age.[38]

Pathology

Almost all MIs result from coronary atherosclerosis, generally with superimposed coronary thrombosis. Nonatherogenic forms of coronary artery disease are discussed on pages 1123 and 1336, and causes of AMI without coronary atherosclerosis are shown in Table 35-1 .

Before the thrombolytic era, clinicians typically divided AMI patients into those suffering a Q-wave or non-Q-wave infarct, based on the evolution of the pattern on the electrocardiogram (ECG) over several days after AMI. The term "Q-wave infarction" was frequently considered to be virtually

Figure 35-2 Nomenclature of acute coronary syndromes. Patients with ischemic discomfort may present with or without ST segment elevation on the ECG. The majority of patients with ST segment elevation (large arrows) ultimately develop a Q-wave acute myocardial infarction (QwMI), whereas a minority (small arrow) develop a non-Q-wave AMI (NQMI). Patients who present without ST segment elevation are either experiencing unstable angina or a non-ST segment elevation MI (NSTEMI). The distinction between these two diagnoses is ultimately made based on the presence or absence of a cardiac marker detected in the blood. Most patients with NSTEMI do not evolve a Q wave on the 12-lead ECG and are subsequently referred to as having sustained a non-Q-wave MI (NQMI); only a minority of NSTEMI patients develop a Q-wave AMI and are later diagnosed as having a Q-wave MI. The spectrum of clinical conditions ranging from unstable angina to non-Q-wave AMI comprise the acute coronary syndromes (ACS). *(From Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA guidelines for the management of patients with unstable angina: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients With Unstable Angina). J Am Coll Cardiol 36:970-1062, 2000.)*

synonymous with "transmural infarction," whereas "non-Q-wave infarction" was often referred to as a "subendocardial infarction." Phibbs and colleagues have summarized the arguments that previous distinctions between Q-wave infarction and non-Q-wave infarction were based on erroneous interpretation of pathological data and should not serve as the basis for designing therapy.[39] A more suitable framework is based on the pathophysiology of AMI, leading to a reorganization of clinical presentations into what is now referred to as the *acute coronary syndromes* (Fig. 35-2) (see p. 1118).

ROLE OF ACUTE PLAQUE CHANGE

Slowly accruing high-grade stenoses of epicardial coronary arteries may progress to complete occlusion but do not usually precipitate AMI, probably because of the development of a rich collateral network (see p. 1123) over time. However, during the natural evolution of atherosclerotic plaques, especially those that are lipid laden, an abrupt and catastrophic transition may occur, characterized by plaque rupture. Evidence exists that some patients have a systemic predisposition to plaque rupture that is independent of traditional risk factors.[40] [40A] After plaque rupture there is exposure of substances that promote platelet activation and aggregation, thrombin generation, and, ultimately, thrombus formation[41] [42] [42A] [42B] (Figs. 35-3 and 35-4) . The resultant thrombus that is formed interrupts blood flow and leads to an imbalance between oxygen supply and demand and, if this imbalance is severe and persistent, to myocardial necrosis (Fig. 35-5) .

Figure 35-3 Schematic diagram suggesting probable mechanisms responsible for the conversion from chronic coronary heart disease to acute coronary artery disease syndromes. In this scheme, endothelial injury, usually at sites of atherosclerotic plaques and usually plaque ulceration or fissuring, is associated with platelet adhesion and aggregation and the release or activation of selected mediators, including thromboxane A_2 , serotonin (5HT), adenosine diphosphate (ADP), platelet-activating factor (PAF), thrombin, tissue factor, and oxygen-derived free radicals. The accumulation of these mediators promotes platelet aggregation and mechanical obstruction of the narrowed artery. Thromboxane A_2 , 5HT, thrombin, and PAF are vasoconstrictors at sites of endothelial injury. ADP, 5HT, and tissue factor have mitogenic influences and promote the development of neointimal proliferation. Therefore, the conversion from chronic stable to acute unstable coronary heart disease syndromes is most likely associated with endothelial injury, platelet aggregation, accumulation of platelet and other cell-derived mediators, further platelet aggregation, and vasoconstriction, with consequent dynamic narrowing of the coronary artery lumen. The relative absence of prostacyclin (PGI_2), tissue plasminogen activator (t-PA), and endothelium-derived relaxing factor (EDRF; nitrous oxide) at sites of endothelial injury contributes to the development of thrombosis, vasoconstriction, and neointimal proliferation. There are many different reasons for endothelial injury in addition to atherosclerotic plaque fissuring or ulceration, including flow shear stress, hypertension, immune complex deposition with complement activation, and mechanical injury to the endothelium as it occurs with coronary artery angioplasty, atherectomy, and stent placement and after heart transplantation. *(From Willerson JT, Cohen LS, Maseri A: Pathophysiology and clinical recognition. In Willerson JT, Cohen JN [eds]: Cardiovascular Medicine. New York, Churchill Livingstone, 1995, p 335.)*

COMPOSITION OF PLAQUES.

At autopsy, the atherosclerotic plaque of patients who died of MI is composed primarily of fibrous tissue of varying density and cellularity with superimposed thrombus. Calcium, lipid-laden foam cells, and extracellular lipid each constitute 5 to 10 percent of the remaining area. The atherosclerotic plaques that are associated with thrombosis and a total occlusion, located in infarct-related vessels, are generally more complex and irregular than those in vessels not associated with MI.[43] Histological studies of these lesions often reveal plaque rupture or erosion.[43] Angiographic morphology suggestive of plaque rupture has been identified in the majority of stenoses associated with AMI or abrupt onset of unstable angina.[44] This finding is rare in the non-infarct-related vessels of AMI patients and in the vessels of patients with chronic, stable angina.

Platelet-rich thrombi are often associated with the surface of the most advanced atherosclerotic lesions, called complicated plaques, which are characterized by fibrocalcific degeneration, deposition of lipid, calcium, fibrous tissue, necrotic debris, extravasated blood, and a fibrous cap (see Fig. 35-3) . Impaired endothelial cell function may contribute to atherogenesis through release of growth factors. Luminal narrowing may potentiate platelet activation through augmentation of shear forces.

In patients with MI, coronary thrombi are usually superimposed on or adjacent to atherosclerotic plaques (see Figs. 35-3 and 35-4) .[45] These coronary arterial thrombi, which are approximately 1 cm in length in most cases, adhere to the luminal surface of an artery and are composed of platelets, fibrin, erythrocytes, and leukocytes. The composition of the thrombus may vary at different levels: a white thrombus is composed of platelets, fibrin, or both; and a red thrombus is composed of erythrocytes, fibrin, platelets, and leukocytes.[46] Early thrombi are usually small and nonocclusive and are composed predominantly of platelets.[40A] [47]

PLAQUE FISSURING AND RUPTURE.

The process of plaque fissuring is an area of intense investigation and is likely to be multifactorial in nature (see Fig. 35-3) . In atherosclerotic plaques prone to rupture there is an increased rate of formation of metalloproteinase enzymes such as collagenase, gelatinase, and stromelysin that degrades components of the protective interstitial matrix.[48] These proteinases may be elaborated by activated macrophages and mast cells that have been shown to accumulate in high concentration at the site of atheromatous erosions and plaque rupture in patients who died of AMI.[45] Examination of specimens from atherectomy reveals a much higher content of macrophages and tissue factor in patients with unstable angina or AMI compared with patients with chronic stable angina.[49] In addition to these structural aspects

Figure 35-4 Thrombus propagation. *A,* Left anterior descending coronary artery cut open longitudinally, showing a dark (red) stagnation thrombosis propagating upstream from the initiating rupture/platelet-rich thrombus at the arrow. In this case, the thrombus has propagated proximally up to the nearest major side branch (the first diagonal branch). *B,* The right coronary artery cut open longitudinally, showing a huge stagnation thrombosis propagating downstream from the initiating rupture/platelet-rich thrombus at the arrow. Unlike upstream thrombus propagation, downstream propagation may, as in this case, occlude major side branches. O = coronary ostium; c = contrast medium injected postmortem. *(From Falk E: Coronary thrombosis: Pathogenesis and clinical manifestations. Am J Cardiol 68:28B, 1991.)*

Figure 35-5 Schematic representation of the progression of myocardial necrosis after coronary artery occlusion. Necrosis begins in a small zone of the myocardium beneath the endocardial surface in the center of the ischemic zone. This entire region of myocardium (dashed outline) depends on the occluded vessel for perfusion and is the area at risk. Note that a very narrow zone of myocardium immediately beneath the endocardium is spared from necrosis because it can be oxygenated by diffusion from the ventricle. *(Redrawn with permission from Schoen FJ: The heart. In Cotran RS, Kumar V, Collins T (eds): Pathologic Basis of Disease. 6th ed. Philadelphia, WB Saunders, 1999, p 557.)*

of vulnerable plaques, stresses induced by intraluminal pressure, coronary vasomotor tone, tachycardia (cyclic stretching and compression), and disruption of nutrient vessels combine to produce plaque rupture at the margin of the fibrous cap near an adjacent plaque-free segment of the coronary artery wall (shoulder region of plaque).[41] [43] A number of key physiological variables such as systolic blood pressure, heart rate, blood viscosity, endogenous tissue plasminogen activator (t-PA) activity, plasminogen activator inhibitor-1 (PAI-1) levels, plasma cortisol levels, and plasma epinephrine levels that exhibit circadian and seasonal variations and are increased at times of stress act in concert to produce a heightened propensity for plaque rupture and coronary thrombosis, yielding the clustering of AMI in the early morning hours and especially in the winter and after natural disasters.[50] [51]

Acute Coronary Syndromes

If a sufficient quantity of thrombogenic substances is exposed when plaque rupture occurs, the coronary artery lumen may become obstructed by a combination of fibrin, platelet aggregates, and red blood cells (see Figs. 35-3 and 35-4) .[51A] An adequate collateral network that prevents necrosis from occurring can result in clinically silent episodes of coronary occlusion. The rupture of plaques is now considered to be the common pathophysiological substrate of the *acute coronary syndromes* (see Fig. 35-2) .[5] [42A] [52] [52A] The dynamic process of plaque rupture may evolve to a completely occlusive thrombus, typically producing ST segment elevation on the ECG. Typically, such completely occlusive thrombi lead to a large zone of necrosis involving the full or nearly full thickness of the ventricular wall in the myocardial bed subtended by the affected coronary artery (see Fig. 35-5) . The infarction process alters the sequence of depolarization ultimately reflected as changes in the surface of the QRS complex.[39] The most characteristic change in the QRS complex that develops in about 75 percent of patients initially presenting with ST segment elevation is the evolution of Q waves in the leads overlying the infarct zone, leading to the term "Q-wave infarction" (see Fig. 35-2) . In about 25 percent of patients presenting with ST segment elevation, no Q waves develop[53] but other abnormalities of the QRS are seen, such as diminution in R wave height and notching or splintering of the QRS complex.

Less obstructive thrombi and/or those that are constituted by less robust fibrin formation and a greater proportion

---

of platelet aggregates typically produce ST segment depression and/or T wave inversion on the ECG (see Fig. 35-2) . Relief of transient vasospasm (induced by thromboxane A_2 and serotonin released from activated platelets) (see Fig. 35-3) or spontaneous lysis and restoration of antegrade flow in the culprit coronary vessel in less than 20 minutes usually does not result in histological evidence of necrosis, the release of biochemical markers of necrosis, or persistent changes on the ECG. Episodes of plaque rupture more prolonged and more severe typically result in release of biochemical markers of necrosis but a less extensive pattern of necrosis than found in patients with ST segment elevation MI (STEMI). Patients presenting without ST segment elevation are initially diagnosed as suffering either from a non-ST segment elevation MI (NSTEMI) or unstable angina (see Fig. 35-2) . The distinction between NSTEMI and unstable angina is based on whether a cardiac marker indicative of necrosis is detected in the blood, a finding that is now possible in a greater number of patients using sensitive markers such as cardiac-specific troponin T or I (see p. 1133). The majority of patients presenting with NSTEMI do not develop Q waves on the ECG and are ultimately diagnosed as having had a non-Q-wave MI. However, a minority of patients with NSTEMI develop Q waves and are ultimately diagnosed as having had a Q-wave MI (see Fig. 35-2) .

The acute coronary syndrome spectrum concept, organized around a common pathophysiological substrate, is a useful framework for developing therapeutic strategies.[52A] [54] Patients presenting with persistent ST segment elevation are candidates for reperfusion therapy (either pharmacological or catheter-based) to restore flow in the occluded epicardial infarct-related artery. Patients presenting without ST segment elevation are not candidates for pharmacological reperfusion but should receive vigorous antiischemic therapy (see Chap. 36) . Antithrombin therapy and antiplatelet therapy should be administered to all patients with an acute coronary syndrome regardless of the presence or absence of ST segment elevation. Thus, the 12-lead ECG remains at the center of the decision pathway for management of patients with an acute coronary syndrome to distinguish between presentations with ST segment elevation and those without ST elevation (see Fig. 35-2) .[55] [56] The ECG lacks sufficient sensitivity and specificity to permit reliable distinction of transmural from subendocardial infarcts. Categorization of patients into those with Q-wave and non-Q-wave infarction patterns is best conceived of as only a crude guide to the extent of ventricular damage. Prognostic considerations must take into account other important factors, such as whether the ECG abnormality is due to a first infarct versus subsequent infarct, the location of infarction (anterior vs. inferior), infarct size, and demographic factors such as patient age.[39]

Some patients with stenotic atherosclerotic lesions experience AMI without evidence of plaque rupture or superimposed thrombosis. AMI occurs in clinical circumstances that produce a marked reduction in myocardial oxygen supply (e.g., prolonged severe vasospasm, as in Prinzmetal's variant angina [see Chap. 37], or associated with a marked increase in myocardial oxygen demand [see later]). These infarcts are located along the least well-perfused inner one third to one half of the ventricular wall and often extend beyond the target territory perfused by a single coronary vessel.[57] The ECG in such patients may show deep T wave inversions or diffuse ST segment depression.

GROSS PATHOLOGICAL CHANGES

The location and extent of AMI can be assessed on pathological examination (Fig. 35-6). On gross inspection, AMI may be divided into two major types: (1) transmural infarcts,

Figure 35-6 Acute myocardial infarct, predominantly of the posterolateral left ventricle, demonstrated histochemically by a lack of staining by the triphenyltetrazolium chloride (TTC) stain in areas of necrosis. The staining defect is due to the enzyme leakage that follows cell death. Note the myocardial hemorrhage at one edge of the infarct that was associated with cardiac rupture (at the 3 o'clock position) and the anterior scar (at the 7 o'clock position), indicative of old infarct. (Specimen oriented with posterior wall at top.) (From Schoen FJ: The heart. *In* Cotran RS, Kumar V, Collins T [eds]: Pathologic Basis of Disease. 6th ed. Philadelphia, WB Saunders, 1999, p 559.)

in which myocardial necrosis involves the full thickness (or nearly full thickness) of the ventricular wall, and (2) subendocardial (nontransmural) infarcts, in which the necrosis involves the subendocardium, the intramural myocardium, or both without extending all the way through the ventricular wall to the epicardium.[57]

An occlusive coronary thrombus appears to be far more common when the infarction is transmural and localized to the distribution of a single coronary artery (see Fig. 35-4) . Nontransmural infarctions, however, frequently occur in the presence of severely narrowed but still patent coronary arteries. Patchy nontransmural infarction may arise from thrombolysis or PTCA of an originally occlusive thrombus with restoration of blood flow *before* the wave front of necrosis has extended from the subendocardium across the full thickness of the ventricular wall (see Fig. 35-5) . The histological pattern of necrosis may differ, with contraction band injury (see later) occurring almost twice as often in nontransmural as in transmural infarction. Paradoxically, before their infarction, patients with nontransmural infarcts have, on average, a more severe stenosis in the infarct-related coronary artery than do patients suffering from transmural infarcts. This finding suggests that a more severe obstruction occurring before infarction protects against the development of transmural infarction, perhaps by fostering the development of collateral circulation. It also accords with the concept that less severely stenotic but lipid-laden plaques with a fragile cap are responsible for the abrupt presentation of ST segment elevation that may evolve into transmural infarctions.

THE FIRST HOURS.

Gross alterations of the myocardium are difficult to identify until at least 6 to 12 hours have elapsed after the onset of necrosis (Fig. 35-7) (Figure Not Available) . However, a variety of histochemical stains can be used to identify zones of necrosis that can be discerned after only 2 to 3 hours. Tissue slices of suspected infarct sites are immersed in a solution of triphenyltetrazolium chloride (TTC), which stains viable myocardium brick red (because of preserved dehydrogenase enzymes that form a red formazan precipitate) and leaves the infarcted region pale as a result of failure of uptake of the vital dye (see Fig. 35-6). The nitroblue tetrazolium (NBT) staining technique can similarly distinguish viable zones of myocardium, which stain dark blue, from necrotic areas of myocardium that therefore remain uncolored and identifiable. Other approaches include autofluorescence staining, immunohistochemical analysis, and, more recently, special DNA staining techniques to identify

apoptotic bodies in myocardial sections.[58]

Initially, the myocardium in the affected region may appear pale and slightly swollen. Eighteen to 36 hours after the onset of the infarct, the myocardium is tan or reddish purple (due to trapped erythrocytes), with a serofibrinous exudate evident on the epicardium in transmural infarcts. These changes persist for approximately 48 hours; the infarct then turns gray, and fine yellow lines, secondary to neutrophilic infiltration, appear at its periphery. This zone gradually widens and during the next few days extends throughout the infarct.

THE FIRST DAYS.

Eight to 10 days after infarction the thickness of the cardiac wall in the area of the infarct is reduced as necrotic muscle is removed by mononuclear cells. The cut surface of an infarct of this age is yellow, surrounded by a reddish purple band of granulation tissue that extends through the necrotic tissue by 3 to 4 weeks. Commencing at this time and extending over the next 2 to 3 months, the infarcted area gradually acquires a gelatinous, ground-glass, gray appearance, eventually converting into a shrunken, thin, firm scar that whitens and firms

Figure 35-7 (Figure Not Available) Temporal sequence of early biochemical, ultrastructural, histochemical, and histological findings after onset of MI. At the top of the figure are schematically shown the time frames for early and late reperfusion of the myocardium supplied by an occluded coronary artery. For approximately one-half hour after the onset of even the most severe ischemia, myocardial injury is potentially reversible; after that there is progressive loss of viability that is complete by 6 to 12 hours. The benefits of reperfusion (both early and late) are greatest when it is achieved early, with progressively smaller benefits occurring as reperfusion is delayed. *(From Schoen FJ: Pathologic considerations of the surgery of adult heart disease. In Edmunds LH [ed]: Cardiac Surgery in the Adult. New York, McGraw-Hill, 1997, p 85.)*

progressively with time[57] (see Fig. 35-6). This process begins at the periphery of the infarct and gradually moves centrally. The endocardium below the infarct increases in thickness and becomes gray and opaque.

Histological and Ultrastructural Changes

ELECTRON MICROSCOPY.

In experimental infarction, the earliest ultrastructural changes in cardiac muscle after ligation of a coronary artery, noted within 20 minutes, consist of reduction in the size and number of glycogen granules, intracellular edema, and swelling and distortion of the transverse tubular system, the sarcoplasmic reticulum, and the mitochondria[58] (see Fig. 35-7) (Figure Not Available) . These early changes are reversible. Changes after 60 minutes of occlusion include myocardial cell swelling, mitochondrial abnormalities such as swelling and internal disruption, development of amorphous, flocculent aggregation and margination of nuclear chromatin, and relaxation of myofibrils. After 20 minutes to 2 hours of ischemia, changes in some cells become irreversible, and there is progression of these alterations; additional changes include indistinct, tight junctions at the intercalated discs, swollen sacs of the sarcoplasmic reticulum at the level of the A band, greatly enlarged mitochondria with few cristae, thinning and fractionation of myofilaments, disappearance of the heterochromatin, rarefaction of the euchromatin and peripheral aggregation of chromatin in the nucleus, disorientation of myofibrils, and clumping of mitochondria. Cells irreversibly damaged by ischemia are usually swollen, with an enlarged sarcoplasmic space; the sarcolemma may peel off the cells, defects in the plasma membrane may appear, and the mitochondria are fragmented. The swollen mitochondria obtained from ischemic myocardium contain deposits of calcium phosphate and amorphous matrix densities. Many of these changes become more intense when blood flow is restored.[57]

LIGHT MICROSCOPY.

It was previously believed that no light microscopic changes could be seen in infarcted myocardium until 8 hours after interruption of blood flow. However, in some infarcts a pattern of wavy myocardial fibers may be seen 1 to 3 hours after onset, especially at the periphery of the infarct (see Figs. 35-7 (Figure Not Available) and 35-8). It is hypothesized that wavy fibers result from the stretching and buckling of noncontractile fibers as forces are transmitted to them from adjacent viable contractile fibers.[57] After 8 hours, edema of the interstitium becomes evident, as do increased fatty deposits in the muscle fibers, along with infiltration of neutrophilic polymorphonuclear leukocytes and red blood cells. Muscle cell nuclei become pyknotic and then undergo karyolysis, and small blood vessels undergo necrosis.

By 24 hours there is clumping of the cytoplasm and loss of cross striations, with appearance of focal hyalinization and irregular cross bands in the involved myocardial fibers. The nuclei become pyknotic and sometimes even disappear. The myocardial capillaries in the involved region dilate, and polymorphonuclear leukocytes accumulate, first at the periphery and then in the center of the infarct. During the first 3 days, the interstitial tissue becomes edematous and red blood cells may extravasate (see Fig. 35-7) (Figure Not Available) . Generally, on about the fourth day after infarction, removal of necrotic fibers by macrophages begins, again commencing at the periphery (see Figs. 35-7 (Figure Not Available) and 35-8). Later, lymphocytes, macrophages, and fibroblasts infiltrate between myocytes, which become fragmented. At 8 days, the necrotic muscle fibers have become dissolved; by about 10 days, the number of poly-morphonuclear

Figure 35-8 Microscopic features of myocardial infraction. *A,* One-day-old infarct showing coagulative necrosis, wavy fibers with elongation, and narrowing, compared with adjacent normal fibers (lower right). Widened spaces between the dead fibers contain edema fluid and scattered neutrophils. *B,* Dense polymorphonuclear leukocytic infiltrate in an area of acute myocardial infarction of 3 to 4 days' duration. *C,* Nearly complete removal of necrotic myocytes by phagocytosis (7 to 10 days). *D,* Granulation tissue with a rich vascular network and early collagen deposition, approximately 3 weeks after infarction. *E,* Well-healed myocardial infarct with replacement of the necrotic fibers by dense collagenous scar. A few residual cardiac muscle cells are present. (In *D* and *E,* collagen is highlighted as blue in this Masson trichrome stain). *F,* Myocardial necrosis with hemorrhage and contraction bands, visible as dark bands spanning some myofibers (arrows). This is the characteristic appearance of markedly ischemic myocardium that has been reper[chfused. (From Schoen FJ: The heart. *In* Cotran RS, Kumar V, Collins T [eds]: Pathologic Basis of Disease. 6th ed. Philadelphia, WB Saunders, 1999, pp 560-561.)

leukocytes is reduced and granulation tissue first appears at the periphery (see Figs. 35-7 (Figure Not Available) and 35-8). Ingrowth of blood vessels and fibroblasts continues, along with removal of necrotic muscle cells, until the fourth to sixth week after infarction, by which time much of the necrotic myocardium has been removed. This process continues along with increasing collagenization of the infarcted area. By the sixth week, the infarcted area has usually been converted into a firm connective tissue scar with interspersed, intact muscle fibers (see Figs. 35-7 (Figure Not Available) and 35-8).

PATTERNS OF MYOCARDIAL NECROSIS

COAGULATION NECROSIS.

This results from severe, persistent ischemia and is usually present in the central region of infarcts, which results in the arrest of muscle cells[59] in the relaxed state and the passive stretching of ischemic muscle cells. On light microscopy the myofibrils are stretched, many with nuclear pyknosis, vascular congestion, and healign by phagocytosis of necrotic muscle cells (see Fig. 35-7) (Figure Not Available) . There is evidence of mitochondrial damage with prominent amorphous (flocculent) densities but no calcification.

NECROSIS WITH CONTRACTION BANDS.

This form of myocardial necrosis, also termed "contraction band necrosis" or "coagulative myocytolysis," results primarily from severe ischemia followed by reflow.[57] It is caused by increased calcium ion (Ca^{2+}) influx into dying cells, resulting in the arrest of cells in the contracted state. It is seen in the periphery of large infarcts and is present to a greater extent in nontransmural than in transmural infarcts. The entire infarct may show this form of necrosis when reperfusion occurs experimentally or by surgery[59] (see Figs. 35-8 and 35-9) . Although patches of contraction band necrosis are found after successful reperfusion by thrombolytic therapy, their presence in a large segment of the infarcts of patients who did not receive such therapy suggests that reperfusion through spontaneous thrombolysis or the release of spasm or both have occurred. It is characterized by hypercontracted myofibrils with contraction bands and mitochondrial damage, frequently with calcification, marked vascular congestion, and healign by lysis of muscle cells.

MYOCYTOLYSIS.

Ischemia without necrosis generally causes no acute changes that are visible by light microscopy. However, severe prolonged ischemia can cause myocyte vacuolization, often termed "myocytolysis." Prolonged severe ischemia, which is potentially reversible, causes cloudy swelling, as well as hydropic, vascular, and fatty degeneration. Frequently seen at the borders of an infarct as well as in patchy areas of infarction in patients with chronic ischemic heart disease, myocytolysis is characterized by edema and cell swelling, lysis of myofibrils and nuclei, no neutrophilic response, and healign

Figure 35-9 Several potential outcomes of reversible and irreversible ischemic injury to the myocardium. *(From Schoen FJ: The heart. In Cotran RS, Kumar V, Robbins SL (eds): Pathologic Basis of Disease. 5th ed. Philadelphia, WB Saunders, 1994, p 538.)*

by lysis and phagocytosis of necrotic myocytes and ultimately scar formation.

MODIFICATION OF PATHOLOGICAL CHANGES BY REPERFUSION

Early after the onset of ischemia, contractile dysfunction is observed that is believed to be due in part to shortening of the action potential duration, reduced cytosolic free calcium levels, and intracellular acidosis. When reperfusion of myocardium undergoing the evolutionary changes from ischemia to infarction occurs sufficiently early (i.e., within 15 to 20 minutes), it may successfully prevent necrosis from developing. Beyond such a very early stage, the number of salvaged myocytes and therefore the amount of salvaged myocardial tissue (area of necrosis/area at risk) is directly related to the length of time the coronary artery has been totally occluded, the level of myocardial oxygen consumption, and the collateral blood flow (see Fig. 35-9) . Typical pathological findings of reperfused infarcts include a histological mixture of necrosis, hemorrhage within zones of irreversibly injured myocytes, coagulative myocytolysis with contraction bands, and distorted architecture of the cells in the reperfused zone[58] (see Fig. 35-9) . After reperfusion, mitochondria in nonviable myocytes develop deposits of calcium phosphate and ultimately a large fraction of the cells may calcify. Reperfusion of infarcted myocardium also accelerates the washout of intracellular proteins ("serum cardiac markers"), producing an exaggerated and early peak value of substances such as the MB isoenzyme of creatine kinase (CK-MB) and cardiac-specific troponin T and I[60] (see p. 1134).

CORONARY ANATOMY AND LOCATION OF INFARCTION

In over 75 percent of patients with MI who come to autopsy, more than one coronary artery is severely narrowed. One third to two thirds of patients with AMI have critical obstruction (to less than 25 percent of luminal area) of all three coronary arteries, whereas the remainder are equally divided between those having one-vessel disease and those having two-vessel disease. Coronary arteriographic studies in surviving patients show that a higher percentage have one-vessel disease. Angiographic studies performed in the earliest hours of AMI in patients presenting with ST segment elevation have revealed approximately a 90 percent incidence of total occlusion of the infarct-related vessel.[61] Recanalization from spontaneous thrombolysis[62] as well as attrition due to some mortality among those patients with total occlusion results in a diminishing incidence of angiographically totally occluded vessels in the period after MI (Fig. 35-10) (Figure Not Available) . Pharmacological thrombolysis markedly increases the proportion of patients with a patent infarct-related artery early after AMI (see Fig. 35-10) (Figure Not Available) . In contrast to patients presenting with ST segment elevation, those patients who present without ST segment elevation have a much lower incidence of complete occlusion of the infarct-related coronary artery.

Thus, transmural infarcts occur distal to an acutely totally occluded coronary artery with thrombus superimposed on a ruptured plaque. However, the converse is not the case, in that chronic total occlusion of a coronary artery is not always associated with myocardial infarction. Collateral blood flow and other factors--such as the level of myocardial metabolism, the presence and location of stenoses

Figure 35-10 (Figure Not Available) Comparison of angiographically documented infarct-related coronary artery patency rates in 10 separate clinical studies and time from MI as modulated by early administration of a thrombolytic agent versus nonthrombolytic (conventional) therapy. The *x* axis is a semilogarithmic scale of time in days from myocardial infarction. Note that the difference in patency rates becomes diminishingly small within the first 2 to 3 weeks after infarction. *(From Rumberg JA, Gersh BJ: Coronary artery patency and left ventricular remodeling after myocardial infarction: mechanisms and mechanics. In Califf RM, Mark DB, Wagner GS [eds]: Acute Coronary Care. St. Louis, Mosby-Year Book, 1995, p 122.)*

in other coronary arteries, the rate of development of the obstruction, and the quantity of myocardium supplied by the obstructed vessel--all influence the viability of myocardial cells distal to the occlusion. In many series of patients studied at necropsy or by coronary arteriography, a small number (5 percent) of patients with AMI are found to have normal coronary vessels. In these patients, an embolus that has lysed, a transiently occlusive platelet aggregate, or a prolonged episode of severe coronary spasm may have been responsible for the reduction in coronary flow.

Studies of patients who ultimately develop AMI after having undergone coronary angiography at some time before its occurrence have been helpful in clarifying coronary anatomy before infarction. Although high-grade stenoses, when present, more frequently lead to AMI than do less severe lesions, the majority of occlusions actually occur in vessels with a previously identified stenosis of less than 50 percent on angiograms performed months to years earlier. This finding supports the concept that AMI occurs as a result of sudden thrombotic occlusion at the site of rupture of previously nonobstructive but lipid-rich plaques.

Rather frequently, when an area of the ventricle is perfused by collateral vessels, an infarct occurs at a distance from a coronary occlusion. For example, after the gradual obliteration of the lumen of the right coronary artery, the inferior wall of the left ventricle may be maintained viable by collateral vessels arising from the left anterior descending coronary artery. In this circumstance, an occlusion of the left anterior descending artery may cause an infarct of the diaphragmatic wall.

RIGHT VENTRICULAR INFARCTION.

Depending on the criteria used, approximately 50 percent of patients with inferior infarction have some involvement of the right ventricle.[63] [63A] Among these patients, right ventricular infarction occurs exclusively in those with transmural infarction of the inferoposterior wall and the posterior portion of the septum. Right ventricular infarction almost invariably develops in association with infarction of the adjacent septum and left ventricular myocardium, but isolated infarction of the right ventricle is seen in 3 to 5 percent of autopsy-proven cases of MI.

Regardless of whether it is combined with involvement of the left ventricle, right ventricular infarction is generally associated with obstructive lesions of the right coronary artery. However, right ventricular infarction occurs less commonly than would be anticipated from the frequency of atherosclerotic lesions involving the right coronary artery. This discrepancy probably can be explained by the lower oxygen demands of the right ventricle, because right ventricular infarcts occur more commonly in conditions associated with increased right ventricular oxygen needs, such as pulmonary hypertension and right ventricular hypertrophy.[63] Moreover, the intercoronary collateral system of the right ventricle is richer than that of the left, and the thinness of the right ventricular wall allows the chamber to derive some nutrition from the blood within the right ventricular cavity. For the reasons just noted, the right ventricle can sustain long periods of ischemia but still demonstrate excellent recovery of contractile function after reperfusion.[64]

ATRIAL INFARCTION.

This may be seen in up to 10 percent of patients with AMI if PR segment displacement is used as the criterion for atrial infarction. Although isolated atrial infarction may be observed in 3.5 percent of autopsies of patients with AMI, it often occurs in conjunction with ventricular infarction and can cause rupture of the atrial wall. This type of infarct is more common on the right than the left side, occurs more frequently in the atrial appendages than in the lateral or posterior walls of the atrium, and can result in thrombus formation. The difference in incidence between right and left atrial infarction might be explained by the considerably higher oxygen content of left atrial blood. Atrial infarction is frequently accompanied by atrial arrhythmias.[65] [66] It has also been reported to be associated with reduced secretion of atrial natriuretic peptide and a low cardiac output syndrome when right ventricular infarction coexists.

CORONARY ARTERY SPASM.

In addition to causing AMI in patients with Prinzmetal angina (see p. 1324), coronary artery spasm may also

cause intimal damage that can initiate formation of an atherosclerotic plaque. Epicardial coronary artery spasm has been identified in patients with fixed atherosclerotic coronary artery stenosis before, during, and after AMI. An association between coronary artery spasm and coronary artery thrombosis has also been documented clinically.

COLLATERAL CIRCULATION IN ACUTE MYOCARDIAL INFARCTION

The coronary collateral circulation is particularly well developed in patients with (1) coronary occlusive disease, especially when it is severe, with the reduction of the luminal cross-sectional area by more than 75 percent in one or more major vessels; (2) chronic hypoxia, as occurs in severe anemia, chronic obstructive pulmonary disease, and cyanotic congenital heart disease; and (3) left ventricular hypertrophy, which intensifies coronary collateral vessels.

The magnitude of coronary collateral flow is one of the principal determinants of infarct size. Indeed, it is rather common for patients with abundant collateral vessels to have totally occluded coronary arteries without evidence of infarction in the distribution of that artery; thus, the survival of the myocardium distal to such occlusions must depend on collateral blood flow. Even if collateral perfusion existing at the time of coronary occlusion is not successful in improving contractile function, it may still exert a beneficial effect by preventing the formation of a left ventricular aneurysm. Some collaterals are seen in nearly 40 percent of patients with an acute total occlusion, and more begin to appear soon after the total occlusion occurs.[61] It is likely that the presence of a high-grade stenosis (90 percent), possibly with periods of intermittent total occlusion, permits the development of collateral vessels that remain only as potential conduits until a total occlusion occurs or recurs. The latter event then brings these channels into full operation.[67]

The incidence of collateral vessels 1 to 2 weeks after AMI varies considerably and may be as high as 75 to 100 percent in patients with persistent occlusion of the infarct vessel or as low as 17 to 42 percent in patients with subtotal occlusion.

NONATHEROSCLEROTIC CAUSES OF ACUTE MYOCARDIAL INFARCTION

Numerous pathological processes other than atherosclerosis can involve the coronary arteries (see p. 1336) and result in MI (see Table 35-1) . For example, coronary arterial occlusions can be the result of embolization of a coronary artery. Emboli most frequently lodge in the distribution of the left anterior descending coronary artery, commonly in the distal epicardial and intramural branches. The causes of coronary embolism are numerous: infective endocarditis and nonbacterial thrombotic endocarditis (see Chap. 47) , mural thrombi, prosthetic valves, neoplasms, air that is introduced at the time of cardiac surgery, and calcium deposits from manipulation of calcified valves at operation. In situ thrombosis of coronary arteries can occur secondary to chest wall trauma (see Chap. 51) .

VASCULAR INFLAMMATION.

A variety of inflammatory processes can be responsible for coronary artery abnormalities, some of which mimic atherosclerotic disease and may predispose to true atherosclerosis. Epidemiological evidence suggests that viral infections, particularly with Coxsackievirus B, may be an uncommon cause of AMI. Viral illnesses precede AMI occasionally in young persons who are later shown to have normal coronary arteries.

Syphilitic aortitis may produce marked narrowing or occlusion of one or both coronary ostia, whereas Takayasu arteritis may result in obstruction of the coronary arteries (see Chap. 40) . Necrotizing arteritis, polyarteritis nodosa, mucocutaneous lymph node syndrome (Kawasaki disease) (see Chap. 45) , systemic lupus erythematosus (see Chap. 67) , and giant cell arteritis (see Chap. 67) can cause coronary occlusion. Therapeutic levels of mediastinal radiation can cause thickening and hyalinization of the walls of coronary arteries, with subsequent infarction. AMI may also be the result of coronary arterial involvement in amyloidosis (see Chap. 48) , Hurler syndrome, pseudoxanthoma elasticum, and homocystinuria.

COCAINE.

As cocaine abuse has become more common, reports of AMI after the use of cocaine have appeared with increasing frequency. Cocaine may cause AMI in patients with normal coronary arteries, preexisting MI, documented coronary artery disease, or coronary artery spasm.[52] AMI associated with cocaine has also been reported after its topical use in nasal septoplasty and in neonates whose mothers used the drug. Recurrent MI after further cocaine abuse has been reported as well.

Cocaine may cause AMI by at least three mechanisms: (1) increasing myocardial oxygen demand through increases in heart rate and blood pressure, (2) diminishing coronary artery flow resulting from either coronary vasospasm or thrombosis, and (3) active myocarditis (either hypersensitivity or toxicity). In very high doses, cocaine appears to have a direct toxic effect on heart muscle that may produce cardiac failure and sudden death with extensive myocyte necrosis.

MYOCARDIAL INFARCTION WITH ANGIOGRAPHICALLY NORMAL CORONARY VESSELS

Approximately 6 percent of all patients with AMI and perhaps four times that percentage of patients with this diagnosis younger than the age of 35 years do not have coronary atherosclerosis demonstrated by coronary arteriography or at autopsy.[61] Perhaps half the patients of this group, in turn, have a variety of other lesions involving the coronary vessels or myocardium (see Table 35-1) , whereas the others have no detectable coronary obstructive lesions. Patients with AMI and normal coronary arteries tend to be young and to have relatively few coronary risk factors, except that they often have a history of cigarette smoking. Usually, they have no history of angina pectoris before the infarction. The infarction in these patients is usually not preceded by any prodrome, but the clinical, laboratory, and ECG features of AMI are otherwise indistinguishable from those present in the overwhelming majority of patients with AMI who have classic obstructive atherosclerotic coronary artery disease. In patients who recover, areas of localized dyskinesis and hypokinesis can often be demonstrated by left ventricular angiography. Many of these cases are caused by coronary artery spasm and/or thrombosis, perhaps with underlying endothelial dysfunction or small plaques that are not apparent on coronary angiography. Additional suggested causes include (1) coronary emboli (perhaps from a small mural thrombus, a prolapsed mitral valve, or a myxoma); (2) coronary artery disease in vessels too small to be visualized by coronary arteriography or coronary arterial thrombosis with subsequent recanalization (see Table 35-1) ; (3) a variety of hematological disorders causing in situ thrombosis in the presence of normal coronary arteries (polycythemia vera, cyanotic heart disease with polycythemia, sickle cell anemia, disseminated intravascular coagulation, thrombocytosis, and thrombotic thrombocytopenic purpura); augmented oxygen demand (thyrotoxicosis, amphetamine use); (5) hypotension secondary to sepsis, blood loss, or pharmacological agents; and (6) anatomical variations such as anomalous origin of a coronary artery (see Chap. 44) , coronary arteriovenous fistula (see Chap. 44) , or a myocardial bridge (see Chap. 12) .

PROGNOSIS.

The long-term outlook for patients who have survived an AMI with angiographically normal coronary vessels on arteriography appears to be substantially better than that for patients with MI and obstructive coronary artery disease. After recovery from the initial infarct, recurrent infarction, heart failure, and death are unusual in patients with normal coronary arteries. Indeed, most of these patients have normal exercise ECGs and only a minority develop angina pectoris.

Pathophysiology

LEFT VENTRICULAR FUNCTION

Systolic Function

On interruption of antegrade flow in an epicardial coronary artery, the zone of myocardium supplied by that vessel immediately loses its ability to shorten and perform contractile work. Four abnormal contraction patterns develop in sequence: (1) dyssynchrony (i.e., dissociation in the time course of contraction of adjacent segments), (2) hypokinesis (reduction in the extent of shortening), (3) akinesis (cessation of shortening), and (4) dyskinesis (paradoxical expansion, systolic bulging).[68] [69] Accompanying dysfunction of the infarcting segment initially is hyperkinesis of the remaining normal myocardium. The early hyperkinesis of the noninfarcted zones is believed to be the result of acute compensatory mechanisms, including increased activity of the sympathetic nervous system and the Frank-Starling mechanism. A portion of this compensatory hyperkinesis is ineffective work because contraction of the noninfarcted segments of myocardium causes dyskinesis of the infarct zone. Increased motion of the noninfarcted region subsides within 2 weeks of infarction, during which time some degree of recovery can be seen in the infarct region as well, particularly if reperfusion of the infarcted area occurs and myocardial stunning diminishes.

Patients with AMI often also show reduced myocardial contractile function in noninfarcted zones. This may result from previous obstruction of the coronary artery supplying the noninfarcted region of the ventricle and loss of collaterals from the freshly occluded infarct-related vessel, a condition that has been termed "ischemia at a distance."[70] Conversely, the presence of collaterals developing before MI may allow for greater preservation of regional systolic function in an area of distribution of the occluded artery and improvement in left ventricular ejection fraction early after infarction.

If a sufficient quantity of myocardium undergoes ischemic injury, LV pump function becomes depressed; cardiac output, stroke volume, blood pressure, and peak dP/dt are reduced[69] ; and end-systolic volume is increased. The degree to which end-systolic volume increases is perhaps the most powerful predictor of mortality after AMI.[71] Paradoxical systolic expansion of an area of ventricular myocardium further decreases LV stroke volume. As necrotic myocytes slip past each other, the infarct zone thins and elongates, especially in patients with large anterior infarcts, leading to infarct expansion. As the ventricle dilates during the first few hours to days after infarction, regional and global wall stress increases according to Laplace's law. In some patients a vicious cycle of dilatation begetting further dilatation is initiated.[72] [73] The degree of ventricular dilatation, which depends closely on infarct size, patency of the infarct-related artery,[74] and activation of the local renin-angiotensin system in the noninfarcted portion of the ventricle, can be favorably modified by angiotensin-converting enzyme (ACE) inhibition therapy even in the absence of symptomatic LV dysfunction.[75]

With the passage of time, edema, cellular infiltration, and ultimately fibrosis, increase the stiffness of the infarcted myocardium back to and beyond control values. Increasing stiffness in the infarcted zone of myocardium improves LV function because it prevents paradoxical systolic wall motion.

A linear relationship exists between specific parameters of LV function and the likelihood of developing clinical symptoms such as dyspnea and ultimately a shocklike state. The earliest abnormality is a reduction in diastolic compliance (see later), which can be observed with infarcts that involve only 8 percent of the total left ventricle on angiographic examination. When the abnormally contracting segment exceeds 15 percent, the ejection fraction may be reduced and elevations of LV end-diastolic pressure and volume occur. The risk of developing physical signs and symptoms of LV failure also increases proportionally to increasing areas of abnormal left ventricular wall motion.[69] Clinical heart failure accompanies areas of abnormal contraction exceeding 25 percent, and cardiogenic shock, often fatal, accompanies loss of more than 40 percent of the left ventricular myocardium.

Unless infarct extension occurs, some improvement in wall motion takes place during the healign phase, as recovery of function occurs in initially reversibly injured (stunned) myocardium (see Fig. 35-9) . Regardless of the age of the infarct, patients who continue to demonstrate abnormal wall motion of 20 to 25 percent of the left ventricle are likely to manifest hemodynamic signs of LV failure.

Diastolic Function (See Chap. 15)

Left ventricular diastolic properties are altered in infarcted and ischemic myocardium, leading initially to an increase but later to a reduction in LV compliance. These changes are associated with a decrease in the peak rate of decline in left ventricular pressure (peak [-] dP/dt), an increase in the time constant of the fall in left ventricular pressure, and an initial rise in LV end-diastolic pressure. Over a period of several weeks, end-diastolic volume increases and diastolic pressure begins to fall toward normal. As with impairment of systolic function, the magnitude of the diastolic abnormality appears to be related to the size of the infarct.

CIRCULATORY REGULATION

The abnormality in circulatory regulation that is present in AMI is diagrammed in Figure 35-11 . The process begins with an anatomical or functional obstruction in the coronary vascular bed, which results in regional myocardial ischemia and, if the ischemia persists, in infarction. If the infarct is of sufficient size, it depresses overall left ventricular function so that LV stroke volume falls and filling pressures rise. A marked depression of LV stroke volume ultimately lowers aortic pressure and reduces coronary perfusion pressure; this condition may intensify myocardial ischemia and thereby initiate a vicious cycle (see Fig. 35-11) . The inability of the left ventricle to empty also leads to an increased preload, that is, it dilates the well-perfused, normally functioning portion of the left ventricle. This compensatory mechanism tends to restore stroke volume to normal levels but at the expense of a reduced ejection fraction. However, the dilatation of the left ventricle also elevates ventricular afterload, because Laplace's law dictates that at any given arterial pressure the dilated ventricle must develop a higher wall tension. This increased afterload not only depresses left ventricular stroke volume but also elevates myocardial oxygen consumption, which in turn intensifies myocardial ischemia. When regional myocardial dysfunction is limited and the function of the remainder of the left ventricle is normal, compensatory mechanisms sustain overall LV function. If a large portion of the left ventricle becomes necrotic, pump failure occurs; that is, overall left ventricular function becomes so depressed that the circulation cannot be sustained despite the dilatation of the remaining viable portion of the ventricle.

Figure 35-11 The vicious circle in cardiogenic shock. LVEDP = left ventricular end-diastolic pressure. *(From Hollenberg SM, Kavinsky CJ, Parrillo JE: Cardiogenic shock. Ann Intern Med 131:47-59, 1999.)*

VENTRICULAR REMODELING

As a consequence of MI, the changes in left ventricular size, shape, and thickness involving both the infarcted and the noninfarcted segments of the ventricle just described occur and are collectively referred to as *ventricular remodeling.* This process, in turn, can influence ventricular function and prognosis.[72] A combination of changes in left ventricular dilation and hypertrophy of residual noninfarcted myocardium is responsible for remodeling.[72A] After the size of infarction, the two most important factors driving the process of left ventricular dilatation are ventricular loading conditions and infarct artery patency[72] [74] [76] (Fig. 35-12) . Elevated ventricular pressure contributes to increased wall stress and the risk of infarct expansion, and a patent infarct artery accelerates myocardial scar formation and increases tissue turgor in the infarct zone, reducing the risk of infarct expansion and ventricular dilatation.

INFARCT EXPANSION.

An increase in the size of the infarcted segment, known as infarct expansion, is defined as "acute dilatation and thinning of the area of infarction not explained by additional myocardial necrosis."[77] Infarct expansion appears to be caused by (1) a combination of slippage between muscle bundles, reducing the number of myocytes across the infarct wall; (2) disruption of the normal myocardial cells; and (3) tissue loss within the necrotic zone.[77] It is characterized by disproportionate thinning and dilation of the infarct zone before formation of a firm, fibrotic scar.[72A] The degree of infarct expansion appears to be related to the preinfarction wall thickness, with existing hypertrophy possibly protecting against infarct thinning. The apex is the thinnest region of the ventricle and an area of the heart that is particularly vulnerable to infarct expansion.[78] Infarction of the apex secondary to occlusion of the left anterior descending coronary artery causes the radius of curvature at the apex to increase, exposing this normally thin region to a marked elevation in wall stress.

When it is present, infarct expansion is associated with both a higher mortality and a higher incidence of nonfatal complications, such as heart failure and ventricular aneurysm.[79] Infarct expansion has been noted in more than three fourths of the hearts of patients succumbing to AMI and in one third to one half of all patients with anterior Q-wave infarctions.[79] Infarct expansion is best recognized echocardiographically as elongation of the noncontractile region of the ventricle. When expansion is severe enough to cause symptoms, the most characteristic clinical finding is deterioration of systolic function associated with new or louder gallop sounds and new or worsening pulmonary congestion. Rupture of the ventricle may be considered to be a consequence of extreme infarct expansion.

VENTRICULAR DILATATION.

Although infarct expansion plays an important role in the ventricular remodeling that occurs early after MI, remodeling is also caused by dilatation of the viable portion of the ventricle, commencing immediately after AMI and progressing for months or years thereafter (Fig. 35-12) .[72A] As opposed to distention, dilatation may be accompanied by a shift of the pressure-volume curve of the left ventricle to the right, resulting in a larger left ventricular volume at any given diastolic pressure. This global dilatation of the noninfarct zone may be viewed as a compensatory mechanism that maintains stroke volume in the face of a large infarction. However, ventricular dilatation is also associated with nonuniform repolarization of the myocardium that predisposes the patient to life-threatening ventricular arrhythmias.

After AMI, an extra load is placed on the residual functioning myocardium, a load that presumably is responsible for the compensatory hypertrophy of the uninfarcted myocardium. This hypertrophy could help to compensate for

Figure 35-12 Therapeutic maneuvers in various stages of ischemia and infarction. Severely ischemic tissue (2) may be reperfused, thereby averting MI (*A*). Infarcting tissue (3) may be reperfused, leading to sparing of myocardial tissue (*B*). If blood flow is restored only in part (*B*), the myocardium may remain noncontractile although viable (i.e., hibernating). After completion of the infarct (4), late reperfusion (*C*) may still be useful. Mechanical reperfusion of moderately ischemic myocardium (*C*) may restore contractility of hibernating myocardium to normal. Ventricular unloading may be useful throughout the preinfarct and postinfarct periods. Unloading may reduce ischemia (D_2), infarct size (D_3), infarct expansion (D_4), and ventricular dilation ($D_{5,6}$). *(From Braunwald E, Pfeffer MA: Ventricular enlargement and remodeling following acute myocardial infarction: Mechanisms and management. Am J Cardiol 68:4D, 1991.)*

Figure 35-13 Flow chart showing postulated sequence of events from an unstable atherosclerotic plaque to death. The original paradigm emphasizing early reperfusion is shown at the left; the expanded paradigm illustrating the benefits of late reperfusion is shown at the right. *(From Kim CB, Braunwald E: Potential benefits of late reperfusion of infarcted myocardium: The open artery hypothesis. Circulation 88:2426, 1993. Copyright 1993, American Heart Association.)*

the functional impairment caused by the infarct and may be responsible for some of the hemodynamic improvement seen in the months after infarction in some patients.[72A]

EFFECTS OF TREATMENT.

Ventricular remodeling after AMI can be affected by several factors, the first of which is infarct size (see Fig. 35-12) . Acute reperfusion and other measures to restrict the extent of myocardial necrosis limit the increase in ventricular volume after AMI, and evidence suggests that an open infarct artery per se achieved even late after coronary occlusion also attenuates ventricular enlargement[72A] [74] (Fig. 35-13) . The second factor is scar formation in the infarct. Glucocorticosteroids and nonsteroidal anti-inflammatory agents given early after MI can cause scar thinning and greater infarct expansion, whereas ACE inhibitors[72] attenuate ventricular enlargement (see p. 1169 and Figs. 35-12 and 35-13) . Additional beneficial consequences of inhibition of angiotensin II that may contribute to myocardial protection include attenuation of endothelial dysfunction and direct antiatherogenic effects.[72A] [80]

PATHOPHYSIOLOGY OF OTHER ORGAN SYSTEMS

PULMONARY FUNCTION

Changes in pulmonary gas exchange, ventilation, and distribution of perfusion all occur with AMI. Hypoxemia is a frequent consequence, with a severity, in general, proportional to that of left ventricular failure. There is an inverse relation between pulmonary artery diastolic pressure and arterial oxygen tension in patients with AMI. This suggests that increased pulmonary capillary hydrostatic pressure leads to interstitial edema, which results in arteriolar and bronchiolar compression that ultimately causes perfusion of poorly ventilated alveoli with resultant hypoxemia. In addition to hypoxemia, there is a fall in diffusing capacity. Hyperventilation often occurs in patients with AMI and may cause hypocapnia and respiratory alkalosis, particularly in restless, anxious patients with pain. With reversal of heart failure, hypoxemia and intrapulmonary shunting diminish.

INCREASE IN INTERSTITIAL WATER.

A positive correlation has been demonstrated between pulmonary extravascular (interstitial) water content, left ventricular filling pressure, and the clinical signs and symptoms of left ventricular failure. The increase in pulmonary extravascular water may be responsible for the alterations in pulmonary mechanics observed in patients with AMI (i.e., reduction of airway conductance, pulmonary compliance, forced expiratory volume, and midexpiratory flow rate and an increase in closing volume--the last presumably related to the widespread closure of small, dependent airways during the first 3 days after AMI). Ultimately, severe increases in extravascular water may lead to pulmonary edema. Recovery of LV function or diuresis reduces abnormally elevated values for closing volumes (i.e., the lung volume at which airway closure commences) to normal.

The "closing volume" can encroach on and sometimes exceed functional residual volume. This can lead to arterial hypoxemia by the shunting of blood through alveoli that are not well ventilated.

REDUCTION OF VITAL CAPACITY.

Virtually all lung volume indices--total lung capacity, functional residual capacity, and residual volume, as well as vital capacity--fall in the presence of AMI.[81] These reductions correlate with the elevations of left-sided filling pressures and are most probably due to increases in pulmonary extravascular water. Lung volumes, oxygenation, and airway resistance all return toward normal by the time of hospital discharge for most patients.[81] Increased pulmonary venous pressure also results in redistribution of pulmonary blood flow from the bases to the apices of the lung in patients with AMI, altering the relationship between ventilation and perfusion. However, at follow-up examination 3 to 25 weeks after MI, the ventilation-perfusion relationship has usually returned to normal or almost so.

REDUCTION OF AFFINITY OF HEMOGLOBIN FOR OXYGEN.

In patients with MI, particularly when complicated by LV failure or cardiogenic shock, the affinity of hemoglobin for oxygen is reduced (i.e., the P_{50} is increased). The increase in P_{50} results from increased levels of erythrocyte 2,3-diphosphoglycerate (2,3-DPG), which constitutes an important compensatory mechanism, responsible for an estimated 18 percent increase in oxygen release from oxyhemoglobin in patients with cardiogenic shock.

ENDOCRINE FUNCTION

PANCREAS.

Hyperglycemia and impaired glucose tolerance are common in patients with AMI. Although the absolute levels of blood insulin are often in the normal range, they are usually inappropriately low for the level of blood sugar, and there may be relative insulin resistance as well. Stress-induced hyperglycemia in the setting of AMI is associated with an increased risk of mortality even in patients without diabetes mellitus.[81A] Patients with cardiogenic shock often demonstrate marked hyperglycemia and depressed levels of circulating insulin, often with complete suppression of insulin secretion in response to tolbutamide.[82] These abnormalities in insulin secretion and the resultant impaired glucose tolerance appear to be secondary to a reduction in pancreatic blood flow as a consequence of splanchnic vasoconstriction accompanying severe LV failure. In addition, increased activity of the sympathetic nervous system with augmented circulating catecholamines inhibits insulin secretion and augments glycogenolysis, also contributing to the elevation of blood sugar.[83]

Glucose appears to be a more favorable energy source than free fatty acids for the ischemic myocardium by more efficiently replenishing the Krebs cycle and stimulating contractile performance.[84] Because hypoxic heart muscle derives a considerable portion of its energy from the metabolism of glucose (see Chap. 63) and because insulin is essential for the uptake of glucose by the myocardium as well as for myocardial protein synthesis and inhibition of lysosomal activity, the deleterious effects of insulin deficiency are clear. These metabolic considerations, combined with epidemiological observations that diabetic patients have a markedly worse prognosis, have served as the foundation for efforts to more aggressively administer insulin-glucose infusions to diabetics with AMI (see p. 1172).

ADRENAL MEDULLA.

Excessive secretion of catecholamines produces many of the characteristic signs and symptoms of AMI. The plasma and urinary catecholamine levels are highest during the first 24 hours after the onset of chest pain,[83] with the greatest rise in plasma catecholamine secretion occurring during the first hour after the onset of MI. These high levels of circulating catecholamines in patients with AMI correlate with the occurrence of serious arrhythmias and result in an increase in myocardial oxygen consumption, both directly and indirectly, as a consequence of catecholamineinduced elevation of circulating free fatty acids. As might be anticipated, the concentration of circulating catecholamines correlates with the extent of myocardial damage and incidence of cardiogenic shock, as well as both early and late mortality rates.

Circulating catecholamines enhance platelet aggregation; when this occurs in the coronary microcirculation, the release of the potent

vasoconstrictor thromboxane A_2 may further impair cardiac perfusion. The marked increase in sympathetic activity associated with AMI serves as the foundation for beta-adrenoceptor blocker regimens in the acute phase (see p. 1168).

LOCAL MYOCARDIAL AND SYSTEMIC RENIN-ANGIOTENSIN SYSTEM.

Noninfarcted regions of the myocardium appear to exhibit activation of the tissue renin-angiotensin system with increased angiotensin II production. Both locally and systemically generated angiotensin II may stimulate the production of various growth factors, such as platelet-derived growth factor and transforming growth factor, that promote compensatory hypertrophy in the noninfarcted myocardium as well as control the structure and tone of the infarct-related coronary and other myocardial vessels.[72A] Additional potential actions of angiotensin II that have a more negative impact on the infarction process include release of endothelin, PAI-1, and aldosterone, which may cause vasoconstriction, impaired fibrinolysis, and increased sodium retention, respectively. Inhibition of generation of circulating and tissue angiotensin II is one of the proposed mechanisms of benefit from ACE inhibitors in AMI.

NATRIURETIC PEPTIDES.

The peptides atrial natriuretic factor (ANF) and N-terminal pro-ANF are released from cardiac atria in response to elevation of atrial pressure. In a case-control study from the Thrombolysis in Myocardial Infarction (TIMI) II trial, Hall and colleagues have shown that elevated N-terminal pro-ANF levels within the first 12 hours of AMI are highly predictive of an increased mortality risk in the year after infarction. A novel protein, brain natriuretic peptide (BNP), originally isolated from porcine brain, has been shown to be secreted by human ventricular myocardium. It appears to be released early after AMI, peaking at about 16 hours. Patients with anterior infarction, lower cardiac index, and more significant congestive heart failure after AMI have higher levels of BNP and also show a second peak of BNP release about 5 days after infarction. These intriguing observations suggest that BNP levels may be a marker of the degree of left ventricular dysfunction in AMI and that markedly elevated levels of BNP correlate with a worse prognosis.

ADRENAL CORTEX.

Plasma and urinary 17-hydroxycorticosteroids and ketosteroids, as well as aldosterone, are also markedly elevated in patients with AMI.[83] Their concentrations correlate directly with the peak level of serum creatine kinase, implying that the stress imposed by larger infarcts is associated with greater secretion of adrenal steroids. The magnitude of the elevation of cortisol correlates with infarct size and mortality. Glucocorticosteroids also contribute to the impairment of glucose tolerance.

THYROID GLAND.

Although patients with AMI are generally euthyroid, evidence indicates a significant transient decrease in serum triiodothyronine (T_3) levels, a fall that is most marked on about the third day after the infarct. This fall in T_3 is usually accompanied by a rise in reverse T_3 , with variable changes or no change in thyroxine (T_4) and thyroid-stimulating hormone (TSH) levels. The alteration in peripheral T_4 metabolism appears to correlate with infarct size and may be mediated by the rise in endogenous levels of cortisol that accompanies AMI.

RENAL FUNCTION

Both prerenal azotemia and acute renal failure can complicate the marked reduction of cardiac output that occurs in cardiogenic shock. On the other hand, an increase in circulating atrial natriuretic peptide occurs after AMI, an increase that is correlated with the severity of left ventricular failure. An increase in atrial natriuretic peptide is also found when right ventricular infarction accompanies inferior wall infarction, suggesting that this hormone may play a role in the hemodynamic disturbances that accompany right ventricular infarction.

HEMATOLOGICAL FUNCTION

PLATELETS.

AMI generally occurs in the presence of extensive coronary and systemic atherosclerotic plaques, which may serve as the site for the formation of platelet aggregates, a sequence that has been suggested as the initial step in the process of coronary thrombosis, coronary occlusion, and subsequent MI. Circulating platelets are hyperaggregable in patients with AMI. The role of platelets in AMI is discussed in Chapter 62 . Platelets from AMI patients have an increased propensity for aggregation locally in the area of a disrupted plaque and also release vasoactive substances such as thromboxane A_2 (see Fig. 35-3) .

HEMOSTATIC MARKERS.

Elevated levels of serum fibrinogen degradation products, an end product of thrombosis--as well as release of distinctive proteins when platelets are activated (i.e., platelet factor 4 and beta-thromboglobulin)--have been reported in some patients with AMI. Fibrinopeptide A, a protein released from fibrin by thrombin, is a marker of ongoing thrombosis and is increased during the early hours of AMI. Marked elevation of hemostatic markers such as FPA, TAT, and F1&2 is associated with an increased risk of mortality in AMI patients[85] (see Chap. 62 and Fig. 35-7) (Figure Not Available) . The interpretation of the coagulation tests in patients with AMI may be complicated by elevated blood levels of catecholamines, concomitant shock, and/or pulmonary embolism, conditions that are all capable of altering various tests of platelet and coagulation function. Thus, it is not yet clear whether the aforementioned changes are the causes or consequences of AMI.

LEUKOCYTES.

An elevated leukocyte count is an epidemiologic marker for coronary heart disease.[86] AMI is usually accompanied by leukocytosis, which is related to the magnitude of the necrotic process, elevated glucocorticoid levels, and possibly inflammation in the coronary arteries. The magnitude of elevation of the leukocyte count is associated with in-hospital mortality after AMI.[87] [87A] Activation of neutrophils may produce important intermedaries, such as leukotriene B_4 and oxygen free radicals, that have important microcirculatory effects.

BLOOD VISCOSITY.

Clinical and epidemiological studies suggest that several hemostatic and hemorheological factors (e.g., fibrinogen, factor VII, plasma viscosity, hematocrit, red blood cell aggregation, total white blood cell count) are involved in the pathophysiology of atherosclerosis and also play an integral role in acute thrombotic events. An increase in blood viscosity also occurs in patients with AMI. During the first few days after infarction, this is mainly attributable to hemoconcentration, but later the increases in plasma viscosity and red cell aggregation correlate with elevated serum concentrations of $alpha_2$ -globulin and fibrinogen, which are nonspecific reactions to tissue necrosis and are also responsible for the elevated sedimentation rate characteristic of AMI. The high values of blood viscosity indices are observed most frequently in patients with complications such as left ventricular failure, cardiogenic shock, and thromboembolism.

Clinical Features

PREDISPOSING FACTORS

The risk factors for atherosclerosis and coronary artery disease are discussed in Chapter 31 .

In as many as one half of patients with AMI, a precipitating factor or prodromal symptoms can be identified.[88] Evidence suggests that unusually heavy exercise (particularly in fatigued or emotionally stressed, habitually inactive patients) may play a role in precipitating AMI.[89] [90] Such infarctions could be the result of marked increases in myocardial oxygen consumption in the presence of severe coronary arterial narrowing. It has been suggested that unusually heavy exertion or mental stress such as that caused by anger[91] may trigger plaque disruption, leading to AMI. Patients with known coronary artery disease who have been hospitalized for treatment of an acute coronary syndrome-related event and who subsequently report a high level of stress in their life have an increased risk of rehospitalization for cardiovascular reasons and also for "hard" events such as death and MI. Of interest, however, one study has provided evidence that, in a multivariate analysis adjusting for other cardiac risk factors, job strain did not affect the outcome (including nonfatal AMI) in patients with angiographically proven coronary artery disease.[92]

Accelerating angina and rest angina, two patterns of unstable angina (see Chap. 36) , may culminate as AMI (see Fig. 35-2) .[40A] Noncardiac surgical procedures have also been noted as precursors of AMI (see Chap. 61) . Perioperative risk stratification and the use of beta blockers may reduce the likelihood of AMI and cardiac-related mortality.[93] [94] Reduced myocardial perfusion secondary to hypotension (e.g., hemorrhagic or septic shock) and increased myocardial oxygen demands secondary to aortic stenosis, fever, tachycardia, and agitation can also be responsible for myocardial necrosis. Other factors reported as predisposing to AMI include respiratory infections, hypoxemia of any cause, pulmonary embolism, hypoglycemia, administration of ergot preparations, use of cocaine, sympathomimetics, serum sickness, allergy, and on rare occasion wasp stings. In patients with Prinzmetal's angina (see Chap. 37) , AMI

may develop in the territory of the coronary artery that repeatedly undergoes spasm.[95] Rarely, munitions workers exposed to high concentrations of nitroglycerin may develop MI when they are withdrawn from this exposure, suggesting that it is caused by vasospasm.[96]

Trauma may precipitate an AMI in one of two ways. Myocardial contusion and hemorrhage into the myocardium may actually cause cell necrosis, or the injury may involve a coronary artery, causing occlusion of that vessel with resultant AMI (see Chap. 51) . Neurological disturbances (transient ischemic attacks or strokes) may also precipitate AMI. Concern has been raised on the basis of a case-control study that patients with hypertension who are receiving short-acting calcium antagonists, particularly in high doses, are at increased risk of developing AMI. Because of possible selection bias in the patients who received calcium antagonists, these results must be viewed cautiously and clinicians should await the results of ongoing multicenter trials (e.g., ALLHAT) before withdrawing calcium antagonists from patients who might be benefiting from their antihypertensive effect (reduction of stroke).

CIRCADIAN PERIODICITY.

An analysis of a large number of patients hospitalized with MI, studied as a part of the Multicenter Investigation of Limitation of Infarct Size (MILIS), revealed a pronounced circadian periodicity for the time of onset of AMI, with peak incidence of events between 6 a.m. and 12 p.m. Circadian rhythms affect many physiological and biochemical parameters; the early morning hours are associated with rises in plasma catecholamines and cortisol and increases in platelet aggregability.[97] Interestingly, the characteristic circadian peak was *absent* in patients receiving beta blocker or aspirin therapy before their presentation with AMI. The concept of "triggering" an AMI is a complex one and likely involves the superimposition of multiple factors such as time of day, season, and the stress of natural disasters.[50] [98]

HISTORY

PRODROMAL SYMPTOMS.

Despite recent advances in the laboratory detection of AMI, the history remains of substantial value in establishing a diagnosis. The prodrome is usually characterized by chest discomfort, resembling classic angina pectoris (see Chap. 37) , but it occurs at rest or with less activity than usual and can therefore be classified as unstable angina. However, the latter is often not disturbing enough to induce patients to seek medical attention; if they do, they may not be hospitalized. Of the patients with AMI presenting with prodromal symptoms of unstable angina, approximately one third have had symptoms from 1 to 4 weeks before hospitalization; in the remaining two thirds, symptoms predated admission by 1 week or less, with one third of these patients (20 percent of all with prodromes) having had symptoms for 24 hours or less. A feeling of general malaise or frank exhaustion often accompanies other symptoms preceding AMI.

NATURE OF THE PAIN.

The pain of AMI is variable in intensity; in most patients it is severe and in some instances intolerable. The pain is prolonged, usually lasting for more than 30 minutes and frequently for a number of hours. The discomfort is described as constricting, crushing, oppressing, or compressing; often the patient complains of a sensation of a heavy weight or a squeezing in the chest. Although the discomfort is typically described as a choking, viselike, or heavy pain, it may also be characterized as a stabbing, knifelike, boring, or burning discomfort. The pain is usually retrosternal in location, spreading frequently to both sides of the anterior chest, with predilection for the left side. Often the pain radiates down the ulnar aspect of the left arm, producing a tingling sensation in the left wrist, hand, and fingers. Some patients note only a dull ache or numbness of the wrists in association with severe substernal or precordial discomfort. In some instances, the pain of AMI may begin in the epigastrium and simulate a variety of abdominal disorders, a fact that often causes MI to be misdiagnosed as "indigestion." In other patients the discomfort of AMI radiates to the shoulders, upper extremities, neck, jaw, and interscapular region, again usually favoring the left side. In patients with preexisting angina pectoris, the pain of infarction usually resembles that of angina with respect to location. However, it is generally much more severe, lasts longer, and is not relieved by rest and nitroglycerin.

In some patients, particularly the elderly, AMI is manifested clinically not by chest pain but rather by symptoms of acute left ventricular failure and chest tightness or by marked weakness or frank syncope.[98A] [98B] These symptoms may be accompanied by diaphoresis, nausea, and vomiting. The pain of AMI may have disappeared by the time the physician first encounters the patient (or the patient reaches the hospital), or it may persist for many hours. Opiates--in particular morphine--usually relieve the pain. Both angina pectoris and the pain of AMI are thought to arise from nerve endings in ischemic or injured, but not necrotic, myocardium. Thus, in MI, stimulation of nerve fibers in an ischemic zone of myocardium surrounding the necrotic central area of infarction probably gives rise to the pain.

Pain often disappears suddenly and completely when blood flow to the infarct territory is restored. In patients in whom reocclusion occurs after thrombolysis, pain recurs if the initial reperfusion has left viable myocardium. Thus, what has previously been thought of as the "pain of infarction," sometimes lasting for many hours, probably represents pain caused by ongoing ischemia. The recognition that pain implies ischemia and not infarction heightens the importance of seeking ways to relieve the ischemia, for which the pain is a marker. This finding suggests that the clinician should not be complacent about ongoing cardiac pain under any circumstances.

OTHER SYMPTOMS.

Nausea and vomiting occur in more than 50 percent of patients with transmural MI and severe chest pain, presumably owing to activation of the vagal reflex or to stimulation of left ventricular receptors as part of the Bezold-Jarisch reflex. These symptoms occur more commonly in patients with inferior MI than in those with anterior MI. Moreover, nausea and vomiting are common side effects of opiates. When the pain of AMI is epigastric in location and is associated with nausea and vomiting, the clinical picture may easily be confused with that of acute cholecystitis, gastritis, or peptic ulcer. Occasionally, a patient complains of diarrhea or a violent urge to evacuate the bowels during the acute phase of MI. Other symptoms include feelings of profound weakness, dizziness, palpitations, cold perspiration, and a sense of impending doom. On occasion, symptoms arising from an episode of cerebral embolism or other systemic arterial embolism are the first signs of AMI. The aforementioned symptoms may or may not be accompanied by chest pain.

Differential Diagnosis

The pain of AMI may stimulate the pain of acute pericarditis (see Chaps. 3 and 50) , which is usually associated with some pleuritic features; that is, it is aggravated by respiratory movements and coughing and often involves the shoulder, ridge of the trapezius, and neck. An important feature that distinguishes pericardial pain from ischemic discomfort is that ischemic discomfort never radiates to the trapezius ridge, a characteristic site of radiation of pericardial pain.[99] Pleural pain is usually sharp, knifelike, and aggravated in a cyclical fashion by each breath, which distinguishes it from the deep, dull, steady pain of AMI. Pulmonary

embolism (see Chap. 52) generally produces pain laterally in the chest, is often pleuritic, and may be associated with hemoptysis. The pain due to acute dissection of the aorta (see Chap. 40) is usually localized in the center of the chest, is extremely severe and described by the patient as a "ripping" or "tearing" sensation, is at its maximal intensity shortly after onset, persists for many hours, and often radiates to the back or the lower extremities. Often one or more major arterial pulses are absent. Pain arising from the costochondral and chondrosternal articulations may be associated with localized swelling and redness; it is usually sharp and "darting" and is characterized by marked localized tenderness. Episodes of retrosternal discomfort induced by peristalsis in patients with increased esophageal stiffness and also episodes of sustained esophageal contraction can mimic the pain of AMI.[100] [101]

SILENT MI AND ATYPICAL PRESENTATION.

Population studies suggest that between 20 and 60 percent of nonfatal MIs are unrecognized by the patient and are discovered only on subsequent routine ECG or postmortem examinations. Of these unrecognized infarctions, approximately half are truly silent, with the patients unable to recall any symptoms whatsoever. The other half of patients with so-called silent infarction can recall an event characterized by symptoms compatible with acute infarction when leading questions are posed after the ECG abnormalities are discovered. Unrecognized or silent infarction occurs more commonly in patients without antecedent angina pectoris and in patients with diabetes[98A] and hypertension.[102] Silent MI is often followed by silent ischemia (see p. 1330). The prognoses of patients with silent and symptomatic presentations of AMI appear similar.

Atypical presentations of AMI include the following: (1) congestive heart failure--beginning de novo or worsening of established failure; (2) classic angina pectoris without a particularly severe or prolonged attack; (3) atypical location of the pain; (4) central nervous system manifestations, resembling those of stroke, secondary to a sharp reduction in cardiac output in a patient with cerebral arteriosclerosis; (5) apprehension and nervousness; (6) sudden mania or psychosis; (7) syncope; (8) overwhelming weakness; (9) acute indigestion; and (10) peripheral embolization.

PHYSICAL EXAMINATION

GENERAL APPEARANCE.

Patients suffering an AMI often appear anxious and in considerable distress. An anguished facial expression is common, and--in contrast to patients with severe angina pectoris, who often lie, sit, or stand still, recognizing that all forms of activity increase the discomfort--some patients suffering an AMI may be restless and move about in an effort to find a comfortable position. They often massage or clutch their chests and frequently describe their pain with a clenched fist held against the sternum (the "Levine" sign, named after Dr. Samuel A. Levine). In patients with left ventricular failure and sympathetic stimulation, cold perspiration and skin pallor may be evident; they typically sit or are propped up in bed, gasping for breath. Between breaths, they may complain of chest discomfort or a feeling of suffocation. Cough productive of frothy, pink, or blood-streaked sputum is common.

Patients in cardiogenic shock often lie listlessly, making few if any spontaneous movements. The skin is cool and clammy, with a bluish or mottled color over the extremities, and there is marked facial pallor with severe cyanosis of the lips and nailbeds. Depending on the degree of cerebral perfusion, the patient in shock may converse normally or may evidence confusion and disorientation.

HEART RATE.

The heart rate may vary from a marked bradycardia to a rapid regular or irregular tachycardia, depending on the underlying rhythm and the degree of left ventricular failure. Most commonly, the pulse is rapid and regular initially (sinus tachycardia at 100 to 110 beats/min), slowing as the patient's pain and anxiety are relieved; ventricular premature beats (VPBs) are common, occurring in more than 95 percent of patients evaluated within the first 4 hours after the onset of symptoms.

BLOOD PRESSURE.

The majority of patients with uncomplicated AMI are normotensive, although the reduced stroke volume accompanying the tachycardia may cause declines in systolic and pulse pressures and elevation of diastolic pressure. Among previously normotensive patients, a hypertensive response occasionally is seen during the first few hours, with the arterial pressure exceeding 160/90 mm Hg, presumably as a consequence of adrenergic discharge secondary to pain and agitation. It is common for previously hypertensive patients to become normotensive without treatment after AMI, although many of these previously hypertensive patients eventually regain their elevated levels of blood pressure, generally 3 to 6 months after infarction. In patients with massive infarction, arterial pressure falls acutely, owing to left ventricular dysfunction and venous pooling secondary to administration of morphine or nitrates or both; as recovery occurs, the arterial pressure tends to return to preinfarction levels.

Patients in cardiogenic shock (see p. 1178), by definition, have systolic pressures below 90 mm Hg and evidence of end-organ hypoperfusion. However, hypotension alone does not necessarily signify cardiogenic shock because some patients with inferior infarction in whom the Bezold-Jarisch reflex is activated may also transiently have systolic blood pressure below 90 mm Hg. Their hypotension eventually resolves spontaneously, although the process can be accelerated by intravenous atropine (0.5 to 1.0 mg) and assumption of the Trendelenburg position. Other patients who are initially only slightly hypotensive may demonstrate gradually falling blood pressures with progressive reduction in cardiac output over several hours or days as they develop cardiogenic shock as a consequence of increasing ischemia and extension of infarction (see Fig. 35-11) . Evidence of autonomic hyperactivity is common, varying in type with the location of the infarction. At some time in their initial presentation, more than half of patients with inferior MI have evidence of excess parasympathetic stimulation, with hypotension, bradycardia, or both, whereas about half of patients with anterior MI show signs of sympathetic excess, having hypertension, tachycardia, or both.[103]

TEMPERATURE AND RESPIRATION.

Most patients with extensive AMI develop fever, a nonspecific response to tissue necrosis, within 24 to 48 hours of the onset of infarction. Body temperature often begins to rise within 4 to 8 hours after the onset of infarction, and rectal temperature may reach 101° to 102°F. Fever usually resolves by the fourth or fifth day after infarction.

The respiratory rate may be slightly elevated soon after the development of an AMI; in patients without heart failure, it results from anxiety and pain because it returns to normal with treatment of physical and psychological discomfort. In patients with left ventricular failure, the respiratory rate correlates with the severity of failure; patients with pulmonary edema may have respiratory rates exceeding 40 breaths/min. However, the respiratory rate is not necessarily elevated in patients with cardiogenic shock. Cheyne-Stokes (periodic) respiration (see Chap. 17) may occur in elderly individuals with cardiogenic shock and heart failure, particularly after opiate therapy and in the presence of cerebrovascular disease.

JUGULAR VENOUS PULSE.

The height and contour of the jugular venous pulse reflect right atrial and right ventricular diastolic pressures (see Chap. 4) . Because these pressures are usually normal or only slightly elevated in patients with AMI (even in the presence of mild to moderate LV failure), it is not surprising that usually the jugular

venous pulse fails to show any abnormalities. The a wave may be prominent in patients with pulmonary hypertension secondary to LV failure or reduced compliance. In contrast, right ventricular infarction (whether or not it accompanies left ventricular infarction) often results in marked jugular venous distention and, when it is complicated by necrosis or ischemia of right ventricular papillary muscles, tall c-v waves of tricuspid regurgitation are evident. In patients with AMI and cardiogenic shock, the jugular venous pressure is usually elevated. In patients with AMI, hypotension, and hypoperfusion (findings that may resemble those of patients with cardiogenic shock) but who have flat neck veins, it is likely that the depression of left ventricular performance may be related, at least in part, to hypovolemia. The differentiation can be made only by assessing left ventricular performance using echocardiography or by measuring left ventricular filling pressure with a pulmonary artery flotation catheter.

CAROTID PULSE.

Palpation of the carotid arterial pulse provides a clue to the left ventricular stroke volume; a small pulse suggests a reduced stroke volume, whereas a sharp, brief upstroke is often observed in patients with mitral regurgitation or ruptured ventricular septum with a left-to-right shunt. Pulsus alternans reflects severe left ventricular dysfunction.

THE CHEST.

Moist rales are audible in patients who develop left ventricular failure and/or a reduction of left ventricular compliance with AMI. Diffuse wheezing may be present in patients with severe left ventricular failure. Cough with hemoptysis, suggesting pulmonary embolism with infarction, may also occur. In 1967 Killip and Kimball proposed a prognostic classification scheme based on the presence and severity of rales detected in patients presenting with AMI.[104] Class I patients are free of rales and a third heart sound (S_3). Class II patients have rales but to only a mild-moderate degree (<50 percent of lung fields) and may or may not have an S_3 . Patients in Class III have rales in more than half of each lung field and frequently have pulmonary edema. Finally, Class IV patients are in cardiogenic shock. Despite overall improvement in mortality in each class, compared with data observed during the original development of the classification scheme, the latter remains useful today, as evidenced by data from more recently conducted large MI trials.[15] [22]

Cardiac Examination

PALPATION.

Despite severe symptoms and extensive myocardial damage, the findings on examination of the heart may be quite unremarkable in patients with AMI. Palpation of the precordium may yield normal findings, but in patients with transmural AMI it more commonly reveals a presystolic pulsation, synchronous with an audible fourth heart sound (S_4), reflecting a vigorous left atrial contraction filling a ventricle with reduced compliance. In the presence of left ventricular systolic dysfunction, an outward movement of the left ventricle may be palpated in early diastole, coincident with an S_3 . When the anterior or lateral portion of the ventricle is dyskinetic, an abnormal systolic pulsation is present in the third, fourth, or fifth intercostal space to the left of the sternum. In some patients, this paradoxical precordial impulse is clearly separable from the point of maximal impulse, which is more lateral and to the left. In other patients, the abnormal impulse is a diffuse, rippling, precordial movement, approximately 5 to 10 cm in diameter, not clearly separable from the point of maximal impulse and can be appreciated near the left anterior axillary line. Patients with long-standing hypertension or previous infarction with left ventricular hypertrophy often demonstrate a laterally displaced, sustained apical impulse.

AUSCULTATION.

The heart sounds, particularly the first sound (S_1), are frequently muffled and occasionally inaudible immediately after the infarct, and their intensity increases during convalescence. A soft S_1 may also reflect prolongation of the PR interval. Patients with marked ventricular dysfunction and/or left bundle branch block may have paradoxical splitting of the second heart sound (S_2) (see Chap. 4) . Patients with postinfarction angina may also develop a transient, paradoxically split S_2 during anginal episodes.

Third and Fourth Heart Sounds.

An S_3 in AMI usually reflects severe left ventricular dysfunction with elevated ventricular filling pressure. It is caused by rapid deceleration of transmitral blood flow during protodiastolic filling of the left ventricle with resultant oscillations of the cardiohemic system (i.e., myocardium and stream of blood flowing from left atrium to left ventricle) and is usually heard in patients with large infarctions. This sound is detected best at the apex, with the patient in the left lateral recumbent position, and is more common in patients with transmural anterior infarctions than in those with inferior or nontransmural infarctions. The mortality of patients who manifest an S_3 during the acute phase of MI is higher than that of patients without such a sound. An S_3 may be caused not only by left ventricular failure but also by increased inflow into the left ventricle, as occurs when mitral regurgitation or ventricular septal defect complicates AMI. The S_3 and S_4 emanating from the left ventricle are heard best at the apex; in patients with right ventricular infarcts, these sounds may be heard along the left sternal border and are intensified by inspiration.

An S_4 is almost universally present in patients with AMI in sinus rhythm and is usually best heard between the left sternal border and the apex. This sound reflects the atrial contribution to ventricular filling and is particularly prominent in AMI patients due to a reduction in LV compliance and elevation of LV end-diastolic pressure (LV-EDP), even in the absence of left ventricular systolic dysfunction. This finding is of limited diagnostic value because it is commonly audible in most patients with chronic ischemic heart disease and is recordable, although not often audible, in many normal subjects older than 45 years.

Murmurs.

Systolic murmurs, transient or persistent, are commonly audible in patients with AMI and generally result from mitral regurgitation secondary to dysfunction of the mitral valve apparatus (papillary muscle dysfunction, left ventricular dilatation). A new, prominent apical holosystolic murmur, accompanied by a thrill, may represent rupture of a head of a papillary muscle (see p. 1184). The findings in rupture of the interventricular septum are similar, although the murmur and thrill are usually most prominent along the left sternal border and may be audible at the right sternal border as well. The systolic murmur of tricuspid regurgitation (caused by right ventricular failure due to pulmonary hypertension and/or right ventricular infarction or by infarction of a right ventricular papillary muscle) is also heard along the left sternal border. It is characteristically intensified by inspiration and is accompanied by a prominent c-v wave in the jugular venous pulse and a right ventricular S_4 .

Pericardial Friction Rubs.

These may be heard in patients with AMI, especially those sustaining large transmural infarctions.[99] Rubs are notorious for their evanescence and, hence, are probably even more common than reported; frequent auscultation in patients with transmural infarction often results in the discovery of a rub that might otherwise have gone unnoticed. Although friction rubs may be heard within 24 hours or as late as 2 weeks after the onset of infarction, most commonly they are noted on the second or third day.[99] Occasionally, in patients with extensive infarction, a loud rub may be heard for many days. Patients with AMI and a pericardial friction rub may have a pericardial effusion on echocardiographic study, but only rarely are the classic ECG changes of pericarditis (see Chap. 5) seen.[99] Delayed onset of the rub and the associated

discomfort of pericarditis (as late as 3 months' postinfarction) are characteristic of the now rare post-MI (Dressler) syndrome (see p. 1196).

Pericardial rubs are most readily audible along the left sternal border or just inside the point of maximal impulse. Loud rubs may be audible over the entire precordium and even over the back. Occasionally, only the systolic portion of a rub is heard; it may be confused with a systolic murmur, and the diagnosis of rupture of the ventricular septum or mitral regurgitation may be incorrectly considered.

OTHER FINDINGS

FUNDI.

Hypertension, diabetes, and generalized atherosclerosis commonly accompany AMI, and because these conditions may produce characteristic changes in the fundus, a careful funduscopic examination may provide information concerning the underlying vascular status; this is particularly useful in patients unable to provide a detailed history.

ABDOMEN.

As already noted, in patients with AMI, particularly in an inferior location with diaphragmatic irritation, the pain may be localized to the epigastrium or the right upper quadrant. Pain in the abdomen associated with nausea, vomiting, restlessness, and even abdominal distention is often interpreted by patients as a sign of "indigestion," resulting in self-medication with antacids, and it may suggest an acute abdominal process to the physician. Right-sided heart failure, characterized by hepatomegaly and a positive abdominojugular reflux, is unusual in patients with acute left ventricular infarction but does occur in patients with severe and prolonged left ventricular failure or right ventricular infarction.

EXTREMITIES.

Coronary atherosclerosis is often associated with systemic atherosclerosis, and it is therefore common for patients with AMI to have a history of intermittent claudication and to demonstrate physical findings of peripheral vascular disease. Thus, diminished peripheral arterial pulses, loss of hair, and atrophic skin in the lower extremities are noted frequently in patients with coronary artery disease. Peripheral edema is a manifestation of right ventricular failure and, like congestive hepatomegaly, is unusual in patients with acute left ventricular infarction. Cyanosis of the nailbeds is common in patients with severe left ventricular failure and is particularly striking in patients with cardiogenic shock.

NEUROPSYCHIATRIC FINDINGS.

Except for the altered mental status that occurs in patients with AMI who have a markedly reduced cardiac output and cerebral hypoperfusion, the neurological examination is normal unless the patient has suffered cerebral embolism secondary to a mural thrombus. Indeed, an underlying MI is common in patients with cerebral embolic stroke. The coincidence between these two conditions may be explained by systemic hypotension due to MI precipitating a cerebral infarction and the converse, as well as by mural emboli from the left ventricle causing cerebral emboli.

Patients with AMI often exhibit alterations of the emotional state, including intense anxiety, denial, and depression. Medical staff caring for AMI patients must be sensitive to changes in the patient's emotional state: a calm, professional atmosphere, with thorough explanations of equipment and prognosis, can help alleviate the distress associated with AMI.

LABORATORY EXAMINATIONS

Markers of Cardiac Damage

The classic World Health Organization (WHO) criteria for the diagnosis of AMI require that at least two of the following three elements be present: (1) a history of ischemic-type chest discomfort, (2) evolutionary changes on serially obtained ECG tracings, and (3) a rise and fall in serum cardiac markers.[105] There is considerable variability in the pattern of presentation of AMI with respect to these three elements, as exemplified by the following statistics. ST segment elevation and Q waves on the ECG, two features that are highly indicative of AMI, are seen in only about half of AMI cases on presentation. Approximately one third of patients with AMI do not present with classic chest pain,[98A] and the event would go unrecognized unless an ECG were recorded fortuitously in temporal proximity to the infarction or permanent pathological Q waves were are seen on later tracings. Nondiagnostic ECGs are recorded in approximately half of patients presenting to emergency departments with chest pain suggestive of MI who ultimately are shown to have an AMI. Among patients admitted to the hospital with a chest pain syndrome, fewer than 20 percent are subsequently diagnosed as having had an AMI. Therefore, in the majority of patients, clinicians must obtain serum cardiac marker measurements at periodic intervals to either establish or exclude the diagnosis of AMI; such measurements may also be useful for a rough quantitation of the size of infarction.[106] The availability of new serum cardiac markers with markedly enhanced sensitivity for myocardial damage enables clinicians to diagnose AMI in about an additional one third of patients who would not have fulfilled criteria for AMI in the past.[107] The increased use of more sensitive biomarkers of AMI combined with more precise imaging techniques has necessitated establishment of new criteria for AMI (Table 35-2) .

As myocytes become necrotic, the integrity of the sarcolemmal membrane is compromised and intracellular macromolecules (serum cardiac markers) begin to diffuse into the cardiac interstitium and ultimately into the microvasculature and lymphatics in the region of the infarct[60] (Fig. 35-14 and Table 35-3) . The rate of appearance of these macromolecules in the peripheral circulation depends on several factors, including intracellular location, molecular weight, local blood and lymphatic flow, and the rate of elimination from the blood.[60] [108] [109]

Given the accelerated pace of decision-making in patients with acute coronary syndromes and emphasis on reduction of length of hospital stay, there is considerable interest in evaluating new serum cardiac markers,[60] shortening assay time in the central chemistry laboratory,[110] and designing rapid whole blood bedside assays.[111] For optimal specificity, a serum marker of MI should be present in high concentration in the myocardium and be absent from nonmyocardial tissue and serum.[60] [108] For optimal sensitivity it should be rapidly released into the blood after myocardial injury, and there should be a stoichiometric relationship between the plasma level of the marker and the extent of myocardial injury. For ease of clinical use, the marker should persist in blood for an appropriate length of time to provide a convenient diagnostic time window (see Table 35-3) . Finally, the assay methodology should be inexpensive and easy to perform.

CREATINE KINASE (CK).

Serum CK activity exceeds the normal range within 4 to 8 hours after the onset of AMI and declines to normal within 2 to 3 days (see Fig. 35-14) .

TABLE 35-2 -- CRITERIA FOR THE DIAGNOSIS OF ACUTE MYOCARDIAL INFARCTION (AMI)

INCREASED BIOMARKERS PLUS ONE OR MORE OF THE FOLLOWING	PATHOLOGICAL FINDINGS OF AMI	TYPICAL SYMPTOMS OF AMI PLUS ONE OF THE FOLLOWING	PROCEDURAL MYOCARDIAL DAMAGE
Typical symptoms of myocardial ischemia	No other findings required	ST segment elevation in the ECG	Increased levels of cardiac biomarkers to prespecified levels; symptoms may be absent; ECG changes may be absent or nonspecific
Q waves in the ECG		Increased levels of cardiac biomarkers	
ST segment elevation or depression in the ECG			

Modified from Alpert J, Thygesen K, et al: Towards a new definition of myocardial infarction for the 21st century. J Am Coll Cardiol 2000, in press.

Figure 35-14 Plot of the appearance of cardiac markers in blood versus time after onset of symptoms. Peak A, early release of myoglobin or CK-MB isoforms after AMI; peak B, cardiac troponin after

AMI; peak C, CK-MB after AMI; peak D, cardiac troponin after unstable angina. Data are plotted on a relative scale, where 1.0 is set at the AMI cutoff concentration. *(From Wu AH, Apple FS, Gibler WB, et al: National Academy of Clinical Biochemistry Standards of Laboratory Practice: Recommendations for the use of cardiac markers in coronary artery diseases. Clin Chem 45:1104-1121, 1999.)*

Although the peak CK occurs on average at about 24 hours, peak levels occur earlier in patients who have had reperfusion as a result of the administration of thrombolytic therapy or mechanical recanalization (as well as in patients with early spontaneous thrombolysis). Because the time-activity curve of serum CK is influenced by reperfusion, and because reperfusion itself influences infarct size, reperfusion interferes with estimation of infarct size by enzyme analysis.[60] [112]

Although elevation of the serum CK is a sensitive enzymatic detector of AMI that is routinely available in most hospitals,[60] important drawbacks include false-positive results in patients with muscle disease, alcohol intoxication, diabetes mellitus, skeletal muscle trauma, vigorous exercise, convulsions, intramuscular injections, thoracic outlet syndrome, and pulmonary embolism.[60] [109] [113]

CK ISOENZYMES.

Three isoenzymes of CK (MM, BB, and MB) have been identified by electrophoresis. Extracts of brain and kidney contain predominantly the BB isoenzyme, skeletal muscle contains principally MM but does contain some MB (1 to 3 percent), and both MM and MB isoenzymes are present in cardiac muscle. The MB isoenzymes of CK may also be present in minor quantities in the small intestine, tongue, diaphragm, uterus, and prostate. Strenuous exercise, particularly in trained long-distance runners or professional athletes, may cause elevation of both total CK and CK-MB.[114] Because CK-MB can be detected in the blood of healthy subjects, the cutoff value for abnormal elevation of CK-MB is usually set a few units above the end of the reference (normal) range for a given laboratory. Despite the fact that small quantities of CK-MB isoenzyme are found in tissues other than the heart, elevated levels of CK-MB may be considered, for practical purposes, to be the result of AMI (except in the case of trauma or surgery on the aforementioned organs).

Earlier CK-MB assay methods that were in common use included radioimmunoassay and agarose gel electrophoresis techniques; these have now been largely supplanted by highly sensitive and specific enzyme immunoassays that use monoclonal antibodies directed against CK-MB.[115] Mass assays report results in nanograms per milliliter rather than units per milliliter and have been confirmed to be more accurate than CK-MB activity assays, especially in patients presenting within 4 hours of the onset of AMI. It has been

TABLE 35-3 -- MOLECULAR MARKERS USED OR PROPOSED FOR USE IN THE DIAGNOSIS OF ACUTE MYOCARDIAL INFARCTION

MARKER	MW (D)	RANGE OF TIMES TO INITIAL ELEVATION (hr)	MEAN TIME TO PEAK ELEVATIONS (NONTHROMBOLYSIS)	TIME TO RETURN TO NORMAL RANGE	MOST COMMON SAMPLING SCHEDULE
hFABP	14,000-15,000	1.5	5-10 hr	24 hr	On presentation, then 4 hr later
Myoglobin	17,800	1-4	6-7 hr	24 hr	Frequent; 1-2 hr after CP
MLC	19,000-27,000	6-12	2-4 d	6-12 d	Once at least 12 hr after CP
cTnI	23,500	3-12	24 hr	5-10 d	Once at least 12 hr after CP
cTnT	33,000	3-12	12 hr-2 d	5-14 d	Once at least 12 hr after CP
MB-CK	86,000	3-12	24 hr	48-72 hr	Every 12 hr×3*
MM-CK tissue isoform	86,000	1-6	12 hr	38 hr	60-90 min after CP
MB-CK tissue isoform	86,000	2-6	18 hr	Unknown	60-90 min after CP
Enolase	90,000	6-10	24 hr	48 hr	Every 12 hr×3
LD	135,000	10	24-48 hr	10-14 d	Once at least 24 hr after CP
MHC	400,000	48	5-6 d	14 d	Once at least >2 d after CP

hFABP=heart fatty acid binding proteins; MLC=myosin light chain; cTnI=cardiac troponin I; cTnT=cardiac troponin T; MB-CK=MB isoenzyme of creatinine kinase (CK); MM-CK=MM isoenzyme of CK; LD=lactate dehydrogenase; MHC=myosin heavy chain; CP=chest pain

*-Increased sensitivity can be achieved with sampling every 6 or 8 hours.

proposed that a ratio (relative index) of CK-MB mass/CK activity of about 2.5 is indicative of a myocardial rather than a skeletal source of the CK-MB elevation. Although this ratio may be satisfied by many patients with AMI, it is inaccurate in several circumstances: (1) when high levels of total CK are present because of skeletal muscle injury (a large quantity of CK-MB must be released from the myocardium to satisfy criteria); (2) chronic skeletal muscle injury releases large amounts of CK-MB; and (3) total CK measurements are within the normal reference range for the laboratory and CK-MB is elevated (possibly indicating that a microinfarction has occurred). Patients with minimally elevated CK-MB and normal CK levels have a prognosis that is generally worse than that for patients with suspected MI but no CK-MB elevation. Elevation of CK-MB after percutaneous coronary artery revascularization is associated with increased late (1-3 years) cardiac mortality.[116]

Clinicians should not rely on measurements of CK and CK-MB at a single point in time but instead should evaluate the temporal rise and fall of serially obtained values; skeletal muscle release of CK-MB generally remains elevated for a longer time than myocardial release of CK-MB and produces a "plateau" pattern of CK-MB values over several days, in contrast to the shorter time course of skeletal muscle CK-MB elevation, as depicted in Figure 35-7 (Figure Not Available) . Of note, since the cardiac-specific troponin I and T (cTnI and cTnT) (see Fig. 35-14 and Tables 35-2 and 35-3) accurately distinguish skeletal from cardiac muscle damage, the troponins are now considered the preferred biomarkers for diagnosing AMI.[117]

In addition to AMI secondary to coronary obstruction, other forms of injury to cardiac muscle--such as those resulting from myocarditis, trauma, cardiac catheterization, shock, and cardiac surgery--may also produce elevated serum CK-MB levels.[114] These latter causes of elevation of serum CK-MB values can usually be readily distinguished from AMI by the clinical setting.

CK ISOFORMS.

Isoforms of the MM and MB isoenzymes have been identified.[118] These are subtypes of the individual isoenzymes and are formed in the circulation when the enzyme carboxypeptidase cleaves lysine residues from the carboxy terminus of the myocardial form of the enzyme (CK-MM3 and CK-MB2), producing isoforms with a different electrophoretic mobility (CK-MM2, CK-MM1, and CK-MB1). Certain isoforms appear to be released into the blood quite rapidly, perhaps as soon as 1 hour, after the onset of infarction. An absolute level of CK-MB2 isoform greater than 1.0 U/liter or a ratio of CK-MB2/CK-MB1 greater than 2.5 has a sensitivity for diagnosing AMI of 46.4 percent at 4 hours and of 91.5 percent at 6 hours.[119] A rapid high-voltage electrophoretic assay for these isoforms is available, and results in experienced research laboratories suggest it may permit early identification of patients with AMI and early detection of successful reperfusion (peak CK-MB2/CK-MB1 > 3.8 at 2 hours).[120]

MYOGLOBIN.

This low-molecular-weight heme protein is released into the circulation from injured myocardial cells and can be detected within a few hours after the onset of infarction (see Fig. 35-14 and Table 35-3) . Peak levels of serum myoglobin are reached considerably earlier (1 to 4 hours) than peak values of serum CK.[120] Because of its lack

of cardiac specificity, an isolated measurement of myoglobin within the first 4 to 8 hours after onset of chest discomfort in patients with a nondiagnostic ECG should not be relied on to make the diagnosis of AMI but should be supplemented by a more cardiac-specific marker such as cTnI or cTnT.[117]

In contrast to CK, myoglobin is readily excreted into the urine. A more rapid rise in serum myoglobin has been observed after reperfusion, and its measurement has been suggested as a useful index of successful reperfusion[120] (Fig. 35-15) and even infarct size. In patients presenting less

Figure 35-15 Receiver operator curves (ROC) of the 60-min value of myoglobin, CK-MB and cardiac troponin-I (cTnI), for noninvasive prediction of occlusion after thrombolysis. than 6 hours from symptoms and with ST segment elevation where the diagnosis of AMI is not in doubt, an elevated myoglobin level is associated with an increased risk of mortality.[121] The adverse prognostic significance of an elevated myoglobin level at presentation is probably due to a combination of a large amount of myocardial damage and a delay of at least several hours from onset of symptoms to blood sampling.

CARDIAC-SPECIFIC TROPONINS.

The troponin complex consists of three subunits that regulate the calcium-mediated contractile process of striated muscle. These include troponin C, which binds Ca^{2+} ; troponin I (TnI), which binds to actin and inhibits actin-myosin interactions; and troponin T (TnT), which binds to tropomyosin, thereby attaching the troponin complex to the thin filament (see Chap. 14) . Although the majority of TnT is incorporated in the troponin complex, approximately 6 percent is dissolved in the cytosol; about 2 to 3 percent of TnI is found in a cytosolic pool.

Although both TnT and TnI are present in cardiac and skeletal muscle, they are encoded by different genes and the amino acid sequence differs.[122] This permits the production of antibodies that are specific for the cardiac form (cTnT and cTnI) and has led to the development of quantitative assays for cTnT and cTnI that have been approved by the Food and Drug Administration (FDA) for clinical use[117] (see Fig. 35-14 and Table 35-3) . Several studies have confirmed the reliability of these new quantitative assays for detecting myocardial injury, and measurement of cTnT or cTnI is now at the center of a new diagnostic criterion for AMI.[52] [123] [123A] Qualitative, rapid, bedside assays for cTnT and cTnI have also been approved for diagnosing AMI.[124]

When interpreting the results of assays for cTnT or cTnI, clinicians must be cognizant of several analytical issues.[124A] The first-generation assay for cTnT exhibited some nonspecific binding to skeletal muscle troponin, but this was corrected in subsequent generations of assays. The cTnT assays are produced by a single manufacturer, leading to relative uniformity of cutoffs, whereas multiple manufacturers produce cTnI assays. The majority of cTnI released into the bloodstream in AMI is complexed with cardiac troponin C.[125] Variations in the cutoff concentration for abnormal levels of cTnI in the clinically available immunoassays may be due in part to different specificities of the antibodies used for detecting free and complexed cTnI.[125] Thus, when using the measurement of cTnI for diagnosing AMI, clinicians

should apply the cutoff values for the particular assay used in their laboratory. For both cTnT and cTnI, the definition of an abnormally increased level is a value exceeding that of 99 percent of a reference control group.[123]

Because cTnT or cTnI is not detected in the peripheral circulation under normal circumstances, the cutoff value for these analytes may be set only slightly above the "noise" level of the assay.[109] Furthermore, whereas CK-MB usually increases 10- to 20-fold above the upper limit of the reference range, cTnT and cTnI typically increase more than 20 times above the reference range. These features of the cardiac-specific troponin assays provide an improved signal-to-noise ratio, enabling the detection of even minor degrees of myocardial necrosis.[52A] [111] In patients with AMI, cTnT and cTnI first begin to rise above the upper reference limit by 3 hours from the onset of chest pain. Due to a continuous release from a degenerating contractile apparatus in necrotic myocytes, elevations of cTnI may persist for 7 to 10 days after AMI; elevations of cTnT may persist for up to 10 to 14 days. The prolonged time course of elevation of cTnT and cTnI is advantageous for the late diagnosis of AMI.

Patients with AMI who undergo successful recanalization of the infarct-related artery have a rapid release of cardiac troponins that may be useful as an indicator of reperfusion, although myoglobin appears slightly more efficient in this regard.[126] [127]

Troponins vs. CK-MB.

When comparing the diagnostic efficiency of the cardiac troponins versus CK-MB for AMI, it is important to bear in mind that the troponin assays are probably capable of detecting episodes of myocardial necrosis that are below the detection limit of the current CK-MB assays, leading to a number of "false-positive" cases of troponin elevations if CK-MB is used as the gold standard.[52A] The somewhat vague terms "*minor myocardial damage*" and "*microinfarction*" have been used to describe the pathological process in patients who have a chest pain syndrome and elevated cardiac troponin but in whom CK-MB is in the normal range.[128] From a clinical perspective, it is desirable to have diagnostic tests for AMI with increased sensitivity to increase the number of AMI cases identified and increased specificity to reduce the number of cases incorrectly diagnosed and treated for AMI. In addition, cardiac troponin measurements have been shown to have prognostic value for identifying patients with an acute coronary syndrome at risk for adverse clinical outcomes and who also exhibit enhanced responsiveness to new therapies such as glycoprotein (GP) IIb/IIIa inhibitors and low-molecular-weight heparins.[129] The prognostic value of the troponins is independent of other risk factors, such as age and ECG abnormalities, as well as the measurement of classic biomarkers such as CK-MB. The exact mechanism(s) by which troponins convey adverse prognostic potential is not clearly established. They may provide a more accurate reflection of the amount of myocardial necrosis sustained by the patient, but they may also reflect an increased propensity for thromboembolization from an unstable coronary plaque.

Interpretation of Elevated Troponin.

Both cTnI and cTnT have been detected in the blood of patient with end-stage heart failure, including those with a nonischemic cardiomyopathy.[130] Observations such as these emphasize that the troponins detect myocyte damage regardless of the cause.

Balanced against the advantages of the troponins for improved detection of AMI and prognostication of risk are the epidemiological, social, and health care delivery implications of assigning a diagnosis of AMI to a larger cohort of patients than was the case in an earlier era (see Table 35-2) . Revised criteria for AMI impact on the ability to monitor trends in the incidence of AMI and draw comparisons with previous observations, the psychological status of the patient, ability to obtain driving and pilot licenses, disability applications, and hospital reimbursement.[123] There is no clear solution to the issues just cited. It has been proposed that two decision limits are needed for optimal interpretation of troponin tests: a low abnormal value indicating myocardial damage and a higher value indicating the diagnosis of AMI according to traditional criteria.[128] There is a quantitative relationship between the amount of cardiac troponin released into the blood and the risk for adverse clinical outcomes.[5] We consider patients without elevation of cTnI or cTnT not to have had an AMI, those with elevated troponin but normal CK-MB to have microinfarction and a slight increase in risk compared with patients without troponin elevations, and those with elevation of both troponin and CK-MB to fulfill the "classic" definition of AMI with a larger amount of myocardial infarction and the greatest risk of adverse outcome.

LACTATE DEHYDROGENASE (LDH).

The activity of this enzyme exceeds the normal range by 24 to 48 hours after the onset of AMI, reaches a peak 3 to 6 days after the onset of pain, and returns to normal levels 8 to 14 days after the infarction. LDH comprises five isoenzymes, which are numbered in the order of the rapidity of their migration toward the anode of an electrophoretic field. LDH_1 moves most rapidly, whereas LDH_5 is the slowest. Fractionation of the serum LDH into its five isoenzymes increases diagnostic accuracy because the heart contains principally LDH_1 . However, LDH isoenzyme analysis for the diagnosis of AMI is no longer recommended because it has been superseded by newer, more cardiac-specific late markers such as cTnT or cTnI (see Table 35-3) . [117]

OTHER SERUM CARDIAC MARKERS.

Other promising serum cardiac markers that are under development include heart fatty acid binding proteins (hFABP), myosin light chains (MLC), myosin heavy chains (MHC), and glycogen phosphorylase isoenzyme BB (GPBB).[113] These markers offer the potential for earlier diagnosis (hFABP, GPBB) and a longer diagnostic window (ML*C*, MHC), but their relative roles compared with traditional markers such as CK-MB and newer markers such as CK-MB isoforms, cTnT, or cTnI remain to be

defined and we do not recommend their routine use for diagnosing AMI.[117]

RECOMMENDATIONS FOR MEASUREMENT OF SERUM MARKERS.

It seems reasonable for clinicians to measure either cTnT or cTnI in patients with suspected AMI. From a cost-effectiveness perspective, it is unnecessary to measure both a cardiac-specific troponin and CK-MB at all time points.[131] Routine diagnosis of AMI can be accomplished within 12 hours using CK-MB, cTnT, or cTnI by obtaining measurements approximately every 8 to 12 hours (see Table 35-2) . Retrospective diagnosis or diagnosis of AMI in the presence of skeletal muscle injury is more readily accomplished with cTnT or cTnI. Future directions for research with the cardiac troponins involve evaluating their ability to aid in the diagnosis of AMI that occurs after cardiac and noncardiac surgery[132] and interventional catheterization procedures and in identifying myocardial injury from conditions other than AMI, such as myocarditis.

Although serum cardiac markers have been used successfully to stratify patients for risk of cardiac events when the presenting ECG does not show ST segment elevation, bedside assays for troponin or myoglobin either alone or in combination with the ECG also are useful for stratifying risk in patients with STEMI.[121] [133]

OTHER LABORATORY MEASUREMENTS

Numerous nonspecific manifestations may be recognized in patients with AMI. Although they are not generally employed in establishing the diagnosis, awareness of their coexistence with infarction is important to avoid misinterpretation or erroneous diagnosis of other disorders.

SERUM LIPIDS.

These are often determined in patients with AMI. However, the results may be misleading because numerous factors that can alter the values are operating at the time of the patient's admission to the hospital. Serum triglycerides are affected by caloric intake, intravenous glucose, and recumbency.

During the first 24 to 48 hours after admission, total cholesterol and high-density lipoprotein (HDL) cholesterol remain at or near baseline values but generally fall precipitously after that. The fall in HDL cholesterol after AMI is greater than the fall in total cholesterol; thus, the ratio of total cholesterol to HDL cholesterol is no longer useful for risk assessment early after MI. A lipid profile should be obtained

---

on all AMI patients who are admitted within 24 to 48 hours of symptoms. Based on the success of lipid-lowering therapy in primary and secondary prevention studies and evidence that hypolipidemic therapy improves endothelial function and inhibits thrombus formation,[134] [135] it has been argued that early management of serum lipids in patients hospitalized for AMI is advisable.[136] For patients admitted beyond 24 to 48 hours, more accurate determinations of serum lipid levels are obtained about 8 weeks after the infarction has occurred.

HEMATOLOGICAL MANIFESTATIONS.

The elevation of the white blood cell count usually develops within 2 hours after the onset of chest pain, reaches a peak 2 to 4 days after infarction, and returns to normal in 1 week; the peak white blood cell count usually ranges between 12 and 15×10^3 /mm^3 but occasionally rises to as high as 20×10^3 /mm^3 in patients with large transmural AMI. Often there is an increase in the percentage of polymorphonuclear leukocytes and a shift of the differential count to band forms.

The erythrocyte sedimentation rate (ESR) is usually normal during the first 1 or 2 days after infarction, even though fever and leukocytosis may be present. It then rises to a peak on the fourth or fifth day and may remain elevated for several weeks. The increase in the ESR is secondary to elevated plasma $alpha_2$ -globulin fibrinogen, but the peak does not correlate well with the size of the infarction or with the prognosis. The hematocrit often increases during the first few days after infarction as a consequence of hemoconcentration.

Electrocardiographic Findings (See also Chap. 5)

In the majority of patients with AMI, some change can be documented when serial ECGs are compared. However, many factors limit the ability of the ECG to diagnose and localize MI: the extent of myocardial injury, the age of the infarct, its location, the presence of conduction defects, the presence of previous infarcts or acute pericarditis, changes in electrolyte concentrations, and the administration of cardioactive drugs. Changes in the ST segment and T wave are quite nonspecific and may occur in a variety of conditions, including stable and unstable angina pectoris, ventricular hypertrophy, acute and chronic pericarditis, myocarditis, early repolarization, electrolyte imbalance, shock, and metabolic disorders and after the administration of digitalis. Serial ECGs may be of considerable aid in differentiating these conditions from AMI. Transient changes favor angina or electrolyte disturbances, whereas persistent changes argue for infarction if other causes, such as shock, administration of digitalis, and persistent metabolic disorders, can be eliminated. Nevertheless, serial standard 12-lead ECGs remain a potent and extremely clinically useful method for the detection and localization of MI.[55] [137] [138] Analysis of the constellation of ECG leads showing ST segment elevation may also be useful for identifying the site of occlusion in the infarct artery.[139] [140] The extent of ST deviation on the ECG, location of infarction, and QRS duration correlate with risk of adverse outcomes.[56] [141] Even when left bundle branch block is present on the ECG, MI can be diagnosed when striking ST segment deviation is present beyond that which can be explained by the conduction defect.[142] In addition to the diagnostic and prognostic information contained within the 12-lead ECG, it also provides valuable noninvasive information about the success of reperfusion for STEMI.

Although general agreement exists on ECG and vectorcardiographic criteria for the recognition of infarction of the anterior and inferior myocardial walls, less agreement is found on criteria for lateral and posterior infarcts[143] ; here even the terminology may be confusing. It has been reported that patients with an abnormal R wave in V_1 (0.04 second in duration and/or R/S ratio
1 in the absence of preexcitation or right ventricular hypertrophy) with inferior or lateral Q waves have an increased incidence of isolated occlusion of a dominant left circumflex coronary artery without collateral circulation; such patients have a lower ejection fraction, increased end-systolic volume, and higher complication rate than patients with inferior infarction due to isolated occlusion of the right coronary artery.

More sophisticated forms of ECG recordings including high-resolution ECG, body surface potential mapping of ST segments, and continuous vectorcardiography have all been reported in small series of patients to augment the 12-lead ECG in diagnosing AMI, but the lack of ready availability of equipment and the special expertise required limit the use of these techniques.

Although most patients continue to demonstrate the ECG changes from an infarction for the rest of their lives, particularly if they evolve Q waves, in a substantial minority the typical changes disappear, Q waves can regress, and the ECG can even return to normal after a number of years. Under many circumstances Q-wave patterns may simulate MI. Conditions that may mimic the ECG features of MI by producing a pattern of "pseudoinfarction" include ventricular hypertrophy, conduction disturbances, preexcitation, primary myocardial disease, pneumothorax, pulmonary embolus, amyloid heart disease, primary and metastatic tumors of the heart, traumatic heart disease, intracranial hemorrhage, hyperkalemia, pericarditis, early repolarization, and cardiac involvement with sarcoidosis. Normalization of negative T waves on serial ECGs is a useful marker of recovery of regional ventricular function after AMI.[143A]

Q-WAVE AND NON-Q-WAVE INFARCTION.

As noted earlier (see p. 1116), the presence or absence of Q waves on the surface ECG does not reliably predict the distinction between transmural and nontransmural (subendocardial) AMI.[39] Q waves on the ECG signify abnormal electrical activity but are not synonymous with irreversible myocardial damage. Also, the absence of Q waves may simply reflect the insensitivity of the standard 12-lead ECG, especially in the posterior zones of the left ventricle. True pathological subendocardial AMI, as recognized at autopsy, is seen with ST segment depression and/or T wave changes only about 50 percent of the time.[144] Angiographic studies in AMI patients without ST segment elevation show a higher incidence of subtotal occlusion of the culprit coronary vessel and greater collateral flow to the infarct zone. Observational data suggest that AMI without ST segment elevation is seen more commonly in elderly patients and patients with a prior MI.

ISCHEMIA AT A DISTANCE.

Patients with new Q waves and ST segment elevation diagnostic for AMI in one territory often have ST segment depression in other territories. These additional ST segment changes may be caused either by ischemia in a territory other than the area of infarction, termed "ischemia at a distance," or by reciprocal electrical phenomena. A good deal of attention has been directed to associated ST segment depression in the anterior leads when it occurs in patients with acute inferior MI.

However, despite the clinical importance of differentiation among causes of anterior ST segment depression in such patients--including anterior ischemia, posterior wall infarction, and true reciprocal changes--such a differentiation cannot be made reliably by ECG or even vectorcardiographic techniques. Although precordial ST segment depression is more commonly associated with extensive infarction of the posterior, lateral, or inferior septal segments--rather than anterior wall subendocardial ischemia--imaging techniques such as two-dimensional echocardiography are necessary to ascertain whether an anterior wall motion abnormality is present.[145] [146] Regardless of whether the anterior ST segment changes reflect anterior wall ischemia or are reciprocal to changes elsewhere, this finding, as with ischemia at a distance, implies a poorer prognosis than if such changes are not present.[147]

RIGHT VENTRICULAR INFARCTION.

ST segment elevation in right precordial leads (V_1 , V_3 R-V_6 R) is a relatively sensitive and specific sign of right ventricular infarction.[63A] [148] Occasionally, ST segment elevation in leads V_2 and V_3 may be due to acute right ventricular infarction; this appears to occur only when the injury to the left inferior wall is minimal.[149]

Usually, the concurrent inferior wall injury suppresses this anterior ST segment elevation resulting from right ventricular injury. Likewise, right ventricular infarction appears to reduce the anterior ST segment depression often observed with inferior wall MI. A QS or QR pattern in leads V_3 R and/or V_4 R also suggests right ventricular myocardial necrosis but has less predictive accuracy than ST segment elevation in these leads.[52]

ATRIAL INFARCTION.

The most common ECG patterns are depression or elevation of the PR segment, alterations in the contour of the P wave, and abnormal atrial rhythms, including atrial flutter, atrial fibrillation, wandering atrial pacemaker, and atrioventricular (AV) nodal rhythm.

Imaging

ROENTGENOGRAPHY.

The initial chest roentgenogram in patients with AMI is almost invariably a portable film obtained in the emergency department or the CCU. When present, prominent pulmonary vascular markings on the roentgenogram reflect elevated left-ventricular end-diastolic pressure, but significant temporal discrepancies may occur because of what have been termed diagnostic lags and post-therapeutic lags. Up to 12 hours may elapse before pulmonary edema accumulates after ventricular filling pressure has become elevated. The posttherapeutic phase lag represents a longer time interval; up to 2 days are required for pulmonary edema to resorb and the radiographic signs of pulmonary congestion to clear after ventricular filling pressure has returned toward normal. The degree of congestion and the size of the left side of the heart on the chest film are useful for defining groups of patients with AMI who are at increased risk of dying after the acute event.[150]

Echocardiography (See Figs. 7-104 , 7-105 , and 7-106)

TWO-DIMENSIONAL ECHOCARDIOGRAPHY.

The relative portability of echocardiographic equipment makes this technique ideal for the assessment of patients with AMI hospitalized in the CCU or even in the emergency department before admission. In patients with chest pain compatible with AMI but with a nondiagnostic ECG, the finding on echocardiography of a distinct region of disordered contraction can be helpful diagnostically because it supports the diagnosis of myocardial ischemia. Echocardiography is also useful in evaluating patients with chest pain and a nondiagnostic ECG who are suspected of having an aortic dissection. The identification of an intimal flap consistent with an aortic dissection is a crucial observation because it represents a major contraindication to thrombolytic therapy (see Chap. 40) .

Areas of abnormal regional wall motion are observed almost universally in patients with AMI, and the degree of wall motion abnormality can be categorized with a semiquantitative wall motion score index. Of note, abnormal wall motion is less often noted echocardiographically when the infarction is small and the age of regional wall motion abnormality cannot always be determined.[52] Left ventricular function estimated from two-dimensional ECGs correlates well with measurements from angiography and is useful in establishing prognosis after AMI.[145] Furthermore, the early use of echocardiography can aid in the early detection of potentially viable but stunned myocardium (contractile reserve), residual provocable ischemia, patients at risk for the development of congestive heart failure after AMI, and mechanical complications of AMI.[145]

Whereas transthoracic imaging is adequate in most patients, occasional patients have poor echo windows, especially if they are undergoing mechanical ventilation. In such patients transesophageal echocardiography can be safely performed and can be useful in evaluating ventricular septal defects and papillary muscle dysfunction.[146]

DOPPLER ECHOCARDIOGRAPHY (see Fig. 7-28) .

This technique allows for assessment of blood flow in the cardiac chambers and across cardiac valves. Used in conjunction with two-dimensional echocardiography, it is helpful in detecting and assessing the severity of mitral or tricuspid regurgitation after AMI. Identification of the site of acute ventricular septal rupture, as well as quantification of shunt flow across the resulting defect, is also possible.[146]

Other Imaging Modalities

NUCLEAR IMAGING.

Radionuclide angiography, perfusion imaging, infarct-avid scintigraphy, and positron-emission tomography have been used to evaluate patients with AMI. Nuclear cardiac imaging techniques (see Figs. 9-15 and 9-16) can be useful for detecting AMI; assessing infarct size, collateral flow, and jeopardized myocardium; determining the effects of the infarct on ventricular function; and establishing prognosis of patients with AMI.[151] However, the necessity of moving a critically ill patient from the CCU to the nuclear medicine department limits their practical application unless a portable gamma camera is available. Cardiac radionuclide imaging for the diagnosis of MI should be restricted to special, limited situations in which the trial of clinical history, ECG findings, and serum marker measurements is unavailable or unreliable.[52]

COMPUTED TOMOGRAPHY (CT) (see Chap. 10) .

This technique can provide useful cross-sectional information in patients with MI. In addition to the assessment of cavity dimensions and wall thickness, left ventricular aneurysms may be detected and, of particular importance in AMI, intracardiac thrombi can be identified. Although cardiac CT is a less convenient technique, it probably is more sensitive for thrombus detection than is echocardiography.

MAGNETIC RESONANCE IMAGING (MRI) (see Fig. 10-9) .

In addition to localizing and sizing the area of infarction, MRI techniques are capable of early recognition of MI and of providing an assessment of the severity of the ischemic insult.[152] This modality is attractive because of its ability to assess perfusion of infarcted and noninfarcted tissue as well as of reperfused myocardium; to identify areas of jeopardized but not infarcted myocardium; to identify myocardial edema, fibrosis, wall thinning, and hypertrophy; to assess ventricular chamber size and segmental wall motion; and to identify the temporal transition between ischemia and infarction[153] but has limited practical application because of the need to transport patients with AMI to the MRI facility.

ESTIMATION OF INFARCT SIZE

ELECTROCARDIOGRAPHY.

Interest in limiting infarct size, in large part because of the recognition that the quantity of myocardium infarcted has important prognostic implications, has focused attention on the accurate determination of MI size. The sum of ST segment elevations measured from multiple precordial leads correlates with the extent of myocardial

injury in patients with anterior MI.[154] QRS scoring systems and planar or vectorcardiographic techniques to estimate infarct size have also been developed. Although they demonstrate good correlations with infarct size at autopsy and with enzymatic estimates, formal sizing of infarcts by ECG technique is not necessary in most patients. Of note, however, there is a relationship between the number of ECG leads showing ST segment elevation and mortality: patients with 8 or 9 of 12 leads with ST segment elevation have three to four times the mortality of those with only 2 or 3 leads with ST segment elevation. The duration of ischemia time as estimated from continuous ST segment monitoring is correlated with infarct size, the ratio of infarct size to area at risk, and the extent of regional wall motion abnormality observed at 7 days and 30 days after AMI.[154]

CARDIAC MARKER METHODS.

To estimate infarct size by analysis of serum cardiac marker levels, it is necessary to account for the quantity of the marker lost from the myocardium, its volume of distribution, and its release ratio.[60] Serial measurements of proteins released by necrotic myocardium are helpful in determining AMI size. Clinically, the peak CK or CK-MB provides an approximate estimate of infarct

size and is widely used prognostically. In the prethrombotic era, quantification of the cumulative release of CK or CK-MB correlated with other techniques for estimating infarct size in vivo as well as with the area of necrosis at autopsy. However, coronary artery reperfusion dramatically changes the washout kinetics of CK and other markers from myocardium, resulting in early and exaggerated peak levels and limiting the usefulness of such curves as a measure of infarct size.

NONINVASIVE IMAGING TECHNIQUES.

Echocardiography (see Chap. 7) , radionuclide scintigraphy[52] (see Chap. 9) , CT (see Chap. 10) , and MRI (see Chap. 10) have all been used for the clinical and experimental assessment of infarct size. Infarct-avid scintigraphy and myocardial perfusion imaging have been used to quantify infarct size. Estimation of infarct size by quantitative tomographic technetium-99m (^{99m} Tc)-sestamibi imaging appears to be less limited by ventricular geometry and can distinguish small infarcts and ischemia from infarcted myocardium more readily than other noninvasive methods.[155] Tomography has improved on planar techniques employing ^{99m} Tc pyrophosphate to image AMI (see Chap. 9) .[156] Contrast medium-enhanced MRI has been helpful in demonstrating the regional heterogeneity of infarction patterns in patients with persistently occluded infarct arteries versus those with successfully reperfused vessels.

Management

PREHOSPITAL CARE

The prehospital care of patients with suspected AMI is a crucial element bearing directly on the likelihood of survival. Most deaths associated with AMI occur within the first hour of its onset and are usually due to ventricular fibrillation[157] (see also Chap. 26) . Accordingly, the importance of the immediate implementation of definitive resuscitative efforts and of rapidly transporting the patient to a hospital cannot be overemphasized.[52] Major components of the delay from the onset of symptoms consistent with AMI to reperfusion include the following[157] : (1) the time for the patient to recognize the seriousness of the problem and seek medical attention; (2) prehospital evaluation, treatment, and transportation; (3) the time for diagnostic measures and initiation of treatment in the hospital (e.g., "door-to-needle" time for patients receiving a thrombolytic and "door-to-balloon" time for patients undergoing a catheter-based reperfusion strategy); and (4) the time from initiation of treatment to restoration of flow (Fig. 35-16) (Figure Not Available) .

Patients with previously diagnosed coronary heart disease have the same delay times (median of 2.0 hours) as those without prior AMI or coronary heart disease.[158] [159] Therefore, patients must be educated to seek immediate medical attention should they develop manifestations of AMI. Patient-related factors that correlate with longer decision to seek medical attention include older age; female gender; African-American race; low socioeconomic status; low emotional or somatic awareness; history of angina, diabetes, or both; consulting a spouse or other relative; and consulting a physician.[159] [160]

Health care professionals should heighten the level of awareness of patients at risk for AMI (e.g., those with hypertension, diabetes, history of angina pectoris).[158] They should review and reinforce with patients and their families the need for seeking urgent medical attention for a

Figure 35-16 (Figure Not Available) Major components of time delay between onset of infarction and restoration of flow in the infarct-related artery. Plotted sequentially from left to right are shown the time for patients to recognize symptoms and seek medical attention, transportation to the hospital, in-hospital decision-making and implementation of reperfusion strategy, and time for restoration of flow once the reperfusion strategy has been initiated. The time to initiate thrombolytic therapy is the "door-to-needle" (D-N) time; this is followed by the period of time required for pharmacological restoration of flow. More time is required to move the patient to the catheterization laboratory for a percutaneous coronary interventional (PCI) procedure, referred to as the "door-to-balloon" (D-B) time, but restoration of flow in the epicardial infarct-related artery occurs promptly after PCI. At the bottom are shown a variety of methods for speeding the time to reperfusion along with the goals for the time intervals for the various components of the time delay. *(Cannon CP, Antman EM, Walls R, Braunwald E: Time as an adjunctive agent to thrombolytic therapy. J Thromb Thrombol 1:27-34, 1994.)*

pattern of symptoms including chest discomfort, extreme fatigue, and dyspnea, especially if accompanied by diaphoresis, lightheadedness, palpitations, or a sense of impending doom[52] (see Fig. 35-16) (Figure Not Available) . Although many patients shun such discussions and tend to minimize the likelihood of ever needing emergency cardiac treatment, emphasis should be placed on the prevention and treatment of potentially fatal arrhythmias as well as salvage of the jeopardized myocardium by reperfusion, for which time is crucial.[161] Patients should also be instructed in the proper use of sublingual nitroglycerin, which should be taken as one tablet at the onset of ischemic-type discomfort and repeated at 5-minute intervals for a total of three doses. If the symptoms have not dissipated within 15 minutes, the patient should be rapidly transported to a medical facility that has the capability of recording and interpreting an ECG, providing advanced cardiac life support and cardiac monitoring, and initiating reperfusion therapy with either thrombolysis or angioplasty if indicated. Primary care physicians play an important role in helping implement strategies to facilitate early treatment. [158]

THE NATIONAL HEART ATTACK ALERT PROGRAM.

This program has stressed the importance of community-wide planning for strategies allowing rapid recognition and triage of patients potentially suffering from AMI[162] (see Fig. 35-16) (Figure Not Available) . Well-equipped ambulances and helicopters staffed by personnel trained in the acute care of the infarction victim (mobile CCUs) allow definitive therapy to commence while the patient is being transported to the hospital[163] (Table 35-4) (Table Not Available) . To be used effectively, they must be placed strategically within a community, and excellent radio communication systems must be available. These units should be equipped with battery-operated monitoring equipment, a direct-current defibrillator, oxygen, endotracheal tubes and suction apparatus, and commonly used cardiovascular drugs. Radiotelemetry systems that allow transmission of the ECG signal to the hospital are highly desirable and are becoming increasingly available in many communities (see Fig. 35-16) (Figure Not Available) . The effectiveness of such a prehospital system depends on the competency of paramedics,[160] [164] transmission distances, and the availability of expert consultation on the receiving end.[165] Observations of simple variables such as heart rate and blood pressure permit initial classification of patients into high- or low-risk subgroups[166] because those patients initially presenting with hypotension have a mortality in excess of 30 percent, whereas young patients with isolated sinus bradycardia and a normal or elevated blood pressure appear to have a mortality that is under 5 percent.[15]

In addition to prompt defibrillation, the efficacy of prehospital care appears to depend on several factors, including early relief of pain with its deleterious physiological sequelae, reduction of excessive activity of the autonomic nervous system, and abolition of prelethal arrhythmias, such as ventricular tachycardia. However, these efforts must not inhibit rapid transfer to the hospital.[52]

PREHOSPITAL THROMBOLYSIS.

The potential benefits of prehospital thrombolysis have been evaluated in several

TABLE 35-4 -- CHEST PAIN CHECKLIST FOR USE BY EMT/PARAMEDIC FOR DIAGNOSIS OF ACUTE MYOCARDIAL INFARCTION AND THROMBOLYTIC THERAPY SCREENING

(Not Available)

Adapted from the Seattle/King County EMS Medical Record. From 1999 Updated ACC/AHA AMI Guideline (Web version), p 16.

randomized trials.[167] Although none of the individual trials showed a significant reduction in mortality with prehospital-initiated thrombolytic therapy, there was a generally consistent observation of benefit from earlier treatment, and meta-analyses of all the available trials demonstrate a significant 17 percent reduction in mortality.[167] [167A]

Several factors must be weighed when communities consider whether their ambulances and emergency transport vehicles should have capabilities of initiating thrombolytic therapy. The greatest reduction in mortality is observed when reperfusion can be initiated within 60 to 90 minutes of the onset of symptoms.[15] [168] It has been suggested that the streamlining of emergency department triage practices so that treatment can be started within 30 minutes, when coupled with the 15- to 30-minute transport time that is common in most urban centers, may be more cost-effective than equipping all ambulances to administer prehospital thrombolytic therapy[52] (see Fig. 35-16) (Figure Not Available) . The latter would require extensive training of personnel (see Table 35-4) (Table Not Available) , installation of

computer-assisted electrocardiographs or systems for radio transmission of the ECG signal to a central station, and stocking of medicine kits with the necessary drug supplies[165] [169] [170] [171] (see Fig. 35-16) (Figure Not Available) . However, in selected communities where transport delays may be 60 to 90 minutes or longer and experienced personnel or physicians are available on ambulances, prehospital thrombolytic therapy is probably beneficial.[52] [172] [173]

MANAGEMENT IN THE EMERGENCY DEPARTMENT

Physicians evaluating patients in the emergency department must confront the difficult task of rapidly identifying patients who require urgent reperfusion therapy, triaging lower risk patients to the appropriate facility within the hospital, and not discharging patients home inappropriately while avoiding unnecessary admissions.[157] [168] [174] [174A] [174B] As emphasized in Figure 35-17 , a history of ischemic-type discomfort and the initial 12-lead ECG (Fig. 35-18) are the primary tools for screening patients with acute coronary syndromes in the emergency department. ST segment elevation on the ECG of a patient with a history compatible with AMI is highly suggestive of thrombotic occlusion of an epicardial coronary artery,[61] and its presence should serve as the trigger for a well-rehearsed sequence of rapid assessment of the patient for contraindications to thrombolysis and initiation of a reperfusion strategy[157] [168] [175] [176] [177] (see Fig. 35-17) .

Because lethal arrhythmias can occur suddenly in patients with an acute coronary syndrome, all patients should have a 12-lead ECG performed immediately while a brief targeted history is taken[157] [168] (see Fig. 35-17) . Patients should then be attached to a bedside ECG monitor and intravenous access obtained for infusion of 5 percent dextrose in water. If the initial ECG shows ST segment elevation of 1 mm or more in at least two contiguous leads (see Fig. 35-18) or a new or presumably new bundle branch block, the patient should be screened immediately for any contraindications to thrombolysis (Table 35-5) (Table Not Available) to help facilitate expeditious initiation of reperfusion therapy. [178] The National Heart Attack Alert Program recommends that emergency departments strive for a goal of treating eligible AMI patients with thrombolytic therapy within 30 minutes[157] [168] [177] (see Figs. 35-16 (Figure Not Available) and 35-17) . As door-to-needle times increase beyond 30 minutes, there is a progression in mortality and the likelihood of developing an ejection fraction less than 40 percent.[179] Evidence exists that for patients undergoing primary PTCA for AMI, delays in door-to-balloon times in excess of 2 hours are associated with increased mortality, emphasizing the need for expeditious transfer to the catheterization laboratory if primary PTCA is selected as the reperfusion strategy.[179A]

The available data fail to show a benefit of thrombolysis in AMI patients who do not present with ST segment elevation[15] [180] (see Fig. 35-17) . Patients with an initial ECG that reveals new or presumably new ST segment depression and/or T wave inversion, while not considered candidates for thrombolytic therapy, should be treated as though they are suffering from AMI without ST segment elevation or unstable angina (a distinction to be made subsequently after scrutiny of serial ECGs and cardiac marker measurements) (see Figs. 35-2 and 35-14 and Chap. 36) .

Management of the AMI patient without ST segment elevation is an important problem because 40 to 50 percent of patients with AMI are not considered candidates for thrombolysis on the basis of an initial ECG that does not show ST segment elevation.[5] Some patients without ST segment elevation on the initial ECG may subsequently experience a worsening of ischemic discomfort, develop ST segment elevation (presumably when a subtotal occlusion of the culprit coronary artery progresses to total occlusion), and become candidates for reperfusion therapy (see Table 35-5) (Table Not Available) . Therefore, patients whose ECG is highly suggestive of myocardial ischemia should be admitted to a hospital unit with facilities for continuous monitoring of the ECG (either the CCU or intermediate care unit) that will alert the staff if arrhythmias or ST segment elevation occurs.[181] [182] Arrangements should be made for 12-lead ECGs to be obtained approximately every 8 hours for the first 24 hours, or more frequently if ischemic discomfort recurs.

Patients with a history suggestive of AMI (see p. 1128) and an initial nondiagnostic ECG (i.e., no obvious ST segment deviation or T wave inversion) should have serial tracings obtained while being evaluated in the emergency department for AMI (see Fig. 35-17) . Emergency department staff may be alerted to the sudden development of ST segment elevation by periodic visual inspection of the bedside ECG monitor, by continuous ST segment recording, or by auditory alarms when the ST segment deviation exceeds programmed limits. Decision aids such as computer-based diagnostic algorithms, identification of high-risk clinical indicators, rapid determination of cardiac serum markers,[111] two-dimensional echocardiographic screening for regional wall motion abnormalities, and myocardial perfusion imaging are of greatest clinical utility when the ECG is nondiagnostic. In an effort to improve the cost-effectiveness of care of patients with a chest pain syndrome, nondiagnostic ECG, and low suspicion of AMI but in whom the diagnosis has not been entirely excluded, many medical centers have developed critical pathways that involve a coronary observation unit with a goal of ruling out AMI in less than 12 hours (see Fig. 35-17) . [183] [184]

General Treatment Measures

ASPIRIN.

This agent is effective across the entire spectrum of acute coronary syndromes (see Fig. 35-2) and now forms part of the initial management strategy of patients with suspected AMI (see Fig. 35-17) . The pharmacology of aspirin is presented in Chapter 62 . The goal of aspirin treatment is to quickly block formation of thromboxane A_2 in platelets by cyclooxygenase inhibition. Because low doses (40 to 80 mg) take several days to achieve full antiplatelet effect, at least 160 to 325 mg should be administered acutely in the emergency department.[52] To achieve therapeutic blood levels rapidly, the patient should chew the tablet, thus promoting buccal absorption rather than absorption through the gastric mucosa.

CONTROL OF CARDIAC PAIN.

Analgesia is an important element of management of AMI patients in the emergency department. Often there is a tendency to underdose the

Figure 35-17 Algorithm for management of patients with suspected acute coronary syndrome in emergency department. All patients with possible ischemic-type discomfort should be rapidly evaluated and have a 12-lead electrocardiogram (ECG) performed. If the ECG is diagnostic of an acute coronary syndrome, patients should receive aspirin (ASA), beta blockers (in the absence of contraindications), and an antithrombin. Patients with ST segment elevation should be considered candidates for reperfusion, whereas those without ST segment elevation whose ECG and clinical history are strongly suspicious for ischemia should be admitted for initiation of antiischemic therapy. Patients with a nondiagnostic ECG should undergo further evaluation in the emergency department or short-term observation unit with ultimate disposition based on the results of serial serum cardiac marker levels and echocardiographic findings. Patients with ST segment elevation treated within 12 hours who are eligible for thrombolytics should expeditiously receive thrombolytic therapy or be considered for primary percutaneous coronary intervention (PCI). Primary PCI should be supported by an intravenous glycoprotein IIb/IIIa inhibitor and stent as needed. Primary PCI is also to be considered when thrombolytic therapy is contraindicated. Individuals treated after 12 hours should receive the initial medical therapy noted earlier and on an individual basis and may be candidates for angiotensin-converting enzyme (ACE) inhibitors (particularly if left ventricular function is impaired). Routine blood tests that should be obtained in all patients admitted by means of the algorithm include a complete blood cell count (CBC), lipid profile, and electrolyte levels. After discharge, all patients should receive aspirin and a beta blocker (in the absence of contraindications). Dietary modifications and, if needed, treatment to reduce low-density lipoprotein cholesterol and elevated high-density lipoprotein cholesterol are strongly encouraged, as is life style modification (including regular physical exercise and cessation of cigarette smoking).

Figure 35-18 This 12-lead ECG was obtained from a middle-aged man admitted with an extensive anterior AMI. (Note pathological Q waves in the precordial leads and marked repolarization abnormalities in the anterior and lateral leads.) A five-beat salvo of nonsustained ventricular tachycardia is seen extending over the transition between leads III and aV_f . *(From Antman EM, Rutherford JD: Coronary Care Medicine. Boston, Martinus Nijhoff Publishing, 1986, p 81.)*

TABLE 35-5 -- CONTRAINDICATIONS AND CAUTIONS FOR THROMBOLYTIC USE IN MYOCARDIAL INFARCTION

(Not Available)
From 1999 Updated ACC/AHA AMI Guideline (Web version), p 38.

patient for fear of obscuring response to antiischemic or reperfusion therapy. This should be avoided because pain contributes to the heightened sympathetic activity that is particularly prominent during the early phase of AMI. Control of cardiac pain is typically accomplished with a combination of nitrates, analgesics (e.g., morphine), oxygen, and beta-adrenoceptor blockers. Similar pharmacological principles apply in the CCU, where many of the therapies discussed in this section are continued after initial dosing in the emergency department. Because the pain associated with MI is related to ongoing ischemia, many interventions that act to improve the oxygen supply-demand relationship (by either increasing supply or decreasing demand) may lessen the pain associated with AMI.

Analgesics.

Although a wide variety of analgesic agents has been used to treat the pain associated with AMI, including meperidine, pentazocine, and morphine, the last one remains the drug of choice, except in patients with well-documented morphine hypersensitivity. Four to 8 mg of morphine should be administered intravenously and doses of 2 to 8 mg repeated at intervals of 5 to 15 minutes until the pain is relieved or evident toxicity (i.e., hypotension, depression of respiration, or severe vomiting) precludes further administration of the drug. In some patients, remarkably large cumulative doses of morphine (2 to 3 mg/kg) may be required and are usually tolerated.[185]

The reduction of anxiety resulting from morphine diminishes the patient's restlessness and the activity of the autonomic nervous system, with a consequent reduction of the heart's metabolic demands. The beneficial effect of morphine in patients with pulmonary edema is unequivocal and may relate to several factors, including peripheral arterial and venous dilatation (particularly among patients with excessive sympathoadrenal activity), reduction of the work

of breathing, and slowing of heart rate secondary to combined withdrawal of sympathetic tone and augmentation of vagal tone.[185]

Hypotension after the administration of nitroglycerin and morphine can be minimized by maintaining the patient in a supine position and elevating the lower extremities if systolic arterial pressure declines below 100 mm Hg. Obviously, such positioning is undesirable in the presence of pulmonary edema, but morphine rarely produces hypotension under these circumstances. The concomitant administration of atropine in doses of 0.5 to 1.5 mg intravenously may be helpful in reducing the excessive vagomimetic effects of morphine, particularly when hypotension and bradycardia are present before it is administered.[52] Respiratory depression is an unusual complication of morphine in the presence of severe pain or pulmonary edema, but as the patient's cardiovascular status improves, impairment of ventilation may supervene and should be watched for. It can be treated with naloxone, in doses of 0.1 to 0.2 mg intravenously initially, repeated after 15 minutes if necessary. Nausea and vomiting may be troublesome side effects of large doses of morphine and may be treated with a phenothiazine.

NITRATES.

By virtue of their ability to enhance coronary blood flow by coronary vasodilation and to decrease ventricular preload by increasing venous capacitance, sublingual nitrates are indicated for most patients with an acute coronary syndrome. At present, the only groups of patients with AMI in whom sublingual nitroglycerin should *not* be given are those with inferior MI and suspected right ventricular infarction[63] [63A] or marked hypotension (systolic pressure < 90 mm Hg), especially if accompanied by bradycardia.

Once it is ascertained that hypotension is not present, a sublingual nitroglycerin tablet should be administered and the patient observed carefully for improvement in symptoms or change in hemodynamics. If an initial dose is well tolerated and appears to be of benefit, further nitrates should be administered, with careful monitoring of the vital signs. Even small doses may produce sudden hypotension and bradycardia, a reaction that can be life threatening but can usually be easily reversed with intravenous atropine if it is recognized quickly. Long-acting oral nitrate preparations should be avoided in the very early course of AMI because of the frequently changing hemodynamic status of the patient. In patients with a prolonged period of waxing and waning chest pain, intravenous nitroglycerin may be of benefit in controlling symptoms and correcting ischemia, but frequent monitoring of blood pressure is required.[185]

BETA-ADRENOCEPTOR BLOCKERS.

These drugs relieve pain, reduce the need for analgesics in many patients, and reduce infarct size.[186] Patients most suited for the use of beta blockers early in the course of AMI are those who also have sinus tachycardia and hypertension because beta blockers lower both the heart rate and arterial blood pressure, thereby lowering myocardial oxygen demand. A popular and relatively safe protocol for the use of a beta blocker in this situation is as follows:

1. Patients with heart failure (rales >10 cm up from diaphragm), hypotension (BP<90 mm Hg), bradycardia (heart rate<60 beats/min), or heart block (PR >0.24 sec) are first excluded.[187]
2. Metoprolol is given in three 5-mg boluses.
3. Patients are observed for 2 to 5 minutes after each bolus, and if the heart rate falls below 60 beats/min or systolic blood pressure falls below 100 mm Hg, no further drug is given; a total of three intravenous doses (15 mg) is administered.
4. If hemodynamic stability continues, 15 minutes after the last intravenous dose, the patient is begun on oral metoprolol, 50 mg every 6 hours for 2 days, then switched to 100 mg twice daily. An infusion of an extremely short-acting beta blocker, esmolol (50 to 250 mg/kg/min), may be useful in patients with relative contraindications to beta blockade in whom heart rate slowing is considered highly desirable.[188]

OXYGEN.

Hypoxemia may occur in patients with AMI and is usually secondary to ventilation-perfusion abnormalities that are sequelae of left ventricular failure; pneumonia and intrinsic pulmonary disease are additional causes of hypoxemia. It is common practice to treat all patients hospitalized with AMI with oxygen for at least 24 to 48 hours, based on the empirical assumption of hypoxia and evidence that increased oxygen in the inspired air may protect ischemic myocardium.[189] However, this practice may not be cost-effective. Augmentation of the fraction of oxygen in the inspired air does not elevate oxygen delivery significantly in patients who are not hypoxemic. Furthermore, it may increase systemic vascular resistance and arterial pressure and thereby lower cardiac output slightly.

In view of these considerations, arterial oxygen saturation may be estimated by pulse oximetry (an increasingly available technology), and oxygen therapy may be omitted if it is normal. On the other hand, oxygen should be administered to patients with AMI when arterial hypoxemia is clinically evident or can be documented by measurement (e.g., Sa_{O_2} < 90%).[52] In these patients, serial arterial blood gas measurements may be employed to follow the efficacy of oxygen therapy.

In general, the delivery of 2 to 4 liters/min of 100 percent oxygen by mask or nasal prongs for 6 to 12 hours is satisfactory for most patients with mild hypoxemia. If arterial oxygenation is still depressed on this regimen, the flow rate may have to be increased and other causes for hypoxemia should be sought. In patients with pulmonary edema, endotracheal intubation and positive-pressure controlled ventilation may be necessary.

Limitation of Infarct Size

Infarct size is an important determinant of prognosis in patients with AMI. Patients who succumb from cardiogenic shock generally exhibit either a single massive infarct or a small to moderate-sized infarct superimposed on multiple prior infarctions.[190] Survivors with large infarcts frequently exhibit late impairment of ventricular function, and the long-term mortality rate is higher than that for survivors with small infarcts, who tend not to develop cardiac decompensation.[78] [191]

In view of the prognostic importance of infarct size, the concept that modification of infarct size is possible has attracted a great deal of experimental and clinical attention[192] (see Fig. 35-17) . Efforts to limit the size of the infarct have been divided among several different (sometimes overlapping) approaches: (1) early reperfusion,[193] (2) reduction of myocardial energy demands, (3) manipulation of sources of energy production in the myocardium, and (4) prevention of reperfusion injury. Although early reperfusion ("time-dependent effect of reperfusion") has been the major focus of modern management strategies for AMI, it is important to note that in addition to the limitation of infarct size, even late reperfusion of ischemic myocardium conveys several benefits that contribute to mortality reduction ("time-independent effect of reperfusion")[74] (see Fig. 35-17) .

THE DYNAMIC NATURE OF INFARCTION.

AMI is a dynamic process that does not occur instantaneously but evolves over hours (see Fig. 35-5) . The fate of jeopardized, ischemic tissue may be affected favorably by interventions that restore myocardial perfusion, reduce microvascular damage in the infarct zone, reduce myocardial oxygen requirements, inhibit accumulation of or facilitate washout

of noxius metabolites, augment the availability of substrate for anaerobic metabolism,[84] [194] or blunt the effects of mediators of injury (e.g., calcium overload or oxygen free radicals)[84] [194] [195] [196] [197] that compromise the structure and function of intracellular organelles and constituents of cell membranes. Strong evidence in experimental animals and suggestive evidence in patients indicate that ischemic preconditioning, a form of endogenous protection against AMI, before sustained coronary occlusion decreases infarct size and is associated with a more favorable outcome and with decreased risk of extension of infarction and recurrent ischemic events.[198] Brief episodes of ischemia in one coronary vascular bed may precondition myocardium in a remote zone, attenuating the size of infarction in the latter when sustained coronary occlusion occurs.[199] Intriguing data have been reported that the expression of angiogenesis factors early after the onset of AMI may also contribute to the limitation of infarct size by promoting neovascularization in the infarct zone.[199A]

The perfusion of the myocardium in the infarct zone appears to be reduced maximally immediately after coronary occlusion. Up to one third of patients may develop spontaneous recanalization of an occluded infarct-related artery beginning at 12 to 24 hours. This delayed spontaneous reperfusion has been associated with improvement of left ventricular function because it improves healign of infarcted tissue, prevents ventricular remodeling, and reperfuses hibernating myocardium. However, in order to *maximize* the amount of myocardium salvaged by *accelerating* the process of reperfusion and also implementing it in those patients who would otherwise have an occluded infarct-related artery, the strategies of pharmacologically induced and catheter-based reperfusion of the infarct vessel have been developed (see page 1145).

Additional factors that may contribute to limitation of infarct size in association with reperfusion include relief of coronary spasm, prevention of damage to the microvasculature, improved systemic hemodynamics (augmentation of coronary perfusion pressure and reduced LV-EDP), and development of collateral circulation. The prompt implementation of measures designed to protect ischemic myocardium and support myocardial perfusion may provide sufficient time for the development of anatomical and physiological compensatory mechanisms that limit the ultimate extent of infarction (see Figs. 35-10 (Figure Not Available) and 35-12) . It is possible that interventions designed to protect ischemic myocardium during the initial event may also reduce the incidence of extension of infarction or early reinfarction.

ROUTINE MEASURES FOR INFARCT SIZE LIMITATION.

Whereas reperfusion of ischemic myocardium is the most important technique for limiting infarct size, several routine measures to accomplish this goal are applicable to all patients with AMI, whether or not reperfusion therapy is prescribed. The treatment strategies discussed in this section may be initiated in the emergency department (see Fig. 35-17) and then continued in the CCU.

It is important to maintain an optimal balance between myocardial oxygen supply and demand so that as much as possible of the jeopardized zone of the myocardium surrounding the most profoundly ischemic zones of the infarct can be salvaged. During the period before irreversible injury has occurred, myocardial oxygen consumption should be minimized by maintaining the patient at rest, physically and emotionally, and by using mild sedation and a quiet atmosphere, which may lower heart rate, a major determinant of myocardial oxygen consumption. If the patient was receiving a beta-adrenoceptor blocking agent at the time the clinical manifestations of the infarction began, the drug should be continued unless a specific contraindication develops, such as left ventricular systolic failure or bradyarrhythmia. Marked sinus bradycardia (heart rate less than approximately 50 beats/min) and the frequently coexisting hypotension should be treated with postural maneuvers (the Trendelenburg position) to increase central blood volume and atropine and electrical pacing, but not with isoproterenol. On the other hand, the routine administration of atropine, with the resultant increase in heart rate, to patients without serious bradycardia is contraindicated. All forms of tachyarrhythmias require prompt treatment because they increase myocardial oxygen needs.[52]

Congestive heart failure should be treated promptly. Given their multiple beneficial actions in AMI patients, ACE inhibitors are the first line of drugs indicated in the treatment of congestive heart failure associated with AMI unless the patient is hypotensive (see p. 1169).[199B] Drugs such as isoproterenol that increase myocardial oxygen consumption should be avoided.

As discussed earlier, arterial oxygenation should be restored to normal in patients with hypoxemia, such as occurs in patients with chronic pulmonary disease, pneumonia, or left ventricular failure. Oxygen-enriched air should be administered to patients with hypoxemia, and bronchodilators and expectorants should be used when indicated. Severe anemia, which can also extend the area of ischemic injury, should be corrected by the cautious administration of packed red cells, accompanied by a diuretic if there is any evidence of left ventricular failure. Associated conditions, particularly infections and the accompanying tachycardia, fever, and elevated myocardial oxygen needs, require immediate attention.

Systolic arterial pressure should not be allowed to deviate by more than approximately 25 to 30 mm Hg from the patient's usual level unless marked hypertension had been present before the AMI. It is likely that each patient has an optimal range of arterial pressure; as coronary perfusion pressure deviates from this level, the unfavorable balance between oxygen supply (which is related to coronary perfusion pressure) and myocardial oxygen demand (which is related to ventricular wall tension) that ensues increases the extent of ischemic injury.

REPERFUSION OF MYOCARDIAL INFARCTION

GENERAL CONCEPTS.

Although reperfusion occurs spontaneously in some patients, persistent thrombotic occlusion is present in the majority of patients with STEMI while the myocardium is undergoing necrosis.[62] Timely reperfusion of jeopardized myocardium represents the most effective way of restoring the balance between myocardial oxygen supply and demand. The extent of protection appears to be related directly to the rapidity with which reperfusion is implemented after the onset of coronary occlusion[166] [193] [200] (see Fig. 35-7) (Figure Not Available) . Preliminary data exist suggesting that after thrombolytic therapy more rapid reperfusion (and smaller infarcts) occurs in patients with AMI preceded by unstable angina compared with those without preinfarction angina.[201]

In some patients, particularly those with cardiogenic shock, tissue damage occurs in a "stuttering" manner rather than abruptly, a condition that might more properly be termed subacute infarction. This concept of the nature of the infarction process, as well as the observation that the incidence of complications of AMI in both the early and late postinfarction periods is a function of infarct size, underscores the need for careful history-taking to ascertain whether the patient appears to have had repetitive cycles of spontaneous reperfusion and reocclusion. "Fixing" the time of onset of the infarction process in such patients can be difficult. In such patients with waxing and waning ischemic discomfort, a rigid time interval from the first episode of pain should not be used when determining whether a patient is "outside the window" for benefit from acute reperfusion therapy.

PATHOPHYSIOLOGY OF MYOCARDIAL REPERFUSION.

Prevention of cell death by the restoration of blood flow depends on the severity and duration of preexisting ischemia. Substantial experimental and clinical evidence exists indicating that recovery of left ventricular systolic function, improvement in diastolic function, and reduction in overall mortality are more favorably influenced the earlier that blood flow is restored[15] [193] (see Fig. 35-7) (Figure Not Available) . Collateral coronary vessels also appear to play a role in the successful left ventricular function after reperfusion.[67] They provide sufficient perfusion of myocardium to retard cell death and are probably of greater importance in patients having reperfusion later rather than 1 to 2 hours after coronary occlusion.

Even after successful reperfusion and despite the absence of irreversible myocardial damage, a period of postischemic contractile dysfunction can occur--a phenomenon referred to as *myocardial stunning*[202] (see Chap. 34) . Animal data suggest that selective proteolysis of troponin I may contribute to myocardial stunning.[202A] Periods of myocardial stunning are well described in experimental animals but have also been confirmed in AMI patients by Gerber and coworkers using positron emission tomography after PTCA to measure myocardial blood flow and oxygen consumption.[203]

Reperfusion Injury

The process of reperfusion, although beneficial in terms of myocardial salvage, may come at a cost owing to a process known as *reperfusion injury*[204] [204A] (see Fig. 35-9) . Kloner and Przyklonk have summarized the data on the four types of reperfusion injury that have been observed in experimental animals.[205] These consist of (1) lethal reperfusion injury--a term referring to reperfusion-induced death of cells that were still viable at the time of restoration of coronary blood flow; (2) vascular reperfusion injury--progressive damage to the microvasculature such that there is an expanding area of no reflow and loss of coronary vasodilatory reserve[206] [207] ; (3) stunned myocardium--salvaged myocytes display a prolonged period of contractile dysfunction after restoration of blood flow owing to abnormalities of intracellular biochemistry leading to reduced energy production[196] (see Chap. 34) (see Fig. 35-9) ; and (4) reperfusion arrhythmias--bursts of ventricular tachycardia and, on occasion, ventricular fibrillation that occur within seconds of reperfusion. The available evidence suggests that vascular reperfusion injury, stunning, and reperfusion arrhythmias can all occur in patients with AMI. The concept of lethal reperfusion injury of potentially salvageable myocardium remains controversial, both in

experimental animals and in patients.[57] [205] [208]

Reperfusion increases the cell swelling that occurs with ischemia. Reperfusion of the myocardium in which the microvasculature is damaged leads to the creation of a hemorrhagic infarct (see Fig. 35-9) . Thrombolytic therapy appears more likely to produce hemorrhagic infarction than reperfusion by mechanical means. Although concern has been raised that this hemorrhage may lead to extension of the infarct, this does not appear to be the case. Histological study of patients not surviving in spite of successful reperfusion has revealed hemorrhagic infarcts, but this hemorrhage usually does not extend beyond the area of necrosis.[57]

The loss of magnesium with ischemia, followed during reperfusion by the sudden exposure of severely ischemic cells to both calcium and oxygen on restoration of flow, has been observed to affect the severity of ischemic damage in several animal species.[195] [196] [209] Toxicity from oxygen-derived free radicals mediated at least in part by stimulated leukocytes has attracted considerable attention for its possible role in extending myocardial injury and contributing to calcium overload and inability to regulate cell volume. It has been proposed that necrotic myocytes expose cardiac antigens that lead to T-cell activation and generation of cytokines such as interferon gamma, interleukin-3, and granulocyte-monocyte colony stimulating factor.[210] These cytokines ultimately increase the expression of integrins such as Mac-1 on monocytes promoting adhesion to the endothelium in the ischemic territory and microvascular plugging (i.e., no-reflow phenomenon). Interest has therefore arisen in development of antibodies that interrupt leukocyte-leukocyte and leukocyte-endothelium interactions in patients with AMI.[210] Experimental models of AMI have revealed a consistent message: interventions that attenuate reperfusion injury exert their maximal beneficial effect if blood levels (and presumably myocardial tissue concentrations) are elevated at the time reperfusion occurs.[204A] [211] The effectiveness of agents such as superoxide dismutase and magnesium rapidly declines the later they are administered after reperfusion; eventually no beneficial effect is detectable in animal models after 45 to 60 minutes of reperfusion has elapsed.[208] Drugs such as beta-adrenoceptor blockers, which delay the death of ischemic cells, may, if administered prophylactically to patients at high risk of occlusion (or reocclusion) or in the earliest phases of the development of an AMI, enhance the quantity of myocardium salvaged by early reperfusion.[212] [213]

Ischemic Preconditioning

Brief periods of experimental coronary occlusion and reperfusion before a more sustained period of occlusion result in marked reduction in the amount of necrosis that develops has led to the concept of *ischemic preconditioning*[198] [214] (see Chap. 14) . Data suggest that during the period of brief coronary occlusion adenosine receptors are activated that initiate a cascade of intracellular events culminating in phosphorylation of a membrane protein that is responsible for the protective effect. The leading candidate is the mitochondrial adenosine triphosphate (ATP)-dependent potassium channel that, when activated, causes a decrease in calcium influx, a reduction in contractile force generation, and thereby an energy-sparing effect.[215] The implications of ischemic preconditioning, including a possible modification of the severity of MI, are profound and have stimulated interest in ATP-dependent potassium channel openers such as nicorandil, bimakalim, and other "preconditioning mimetic" agents for potential use in patients with AMI.[198] [216] A second window of protection after preconditioning has been described.[198] It may be mediated by such processes as molecular adaptation leading to the production of heat shock protein or antioxidant enzymes, augmentation of inducible NO synthase, and opening of mitochondrial ATP-sensitive potassium channels.[215] Preconditioning appears to be associated with a more oxidized cellular redox state, which may contribute to protection against subsequent bouts of ischemia. In experimental animals the infarct size-limiting effect of ischemic preconditioning is blunted by hypercholesterolemia but is restored by treatment with pravastatin.[217]

Clinical observations consistent with the concept of ischemic preconditioning include the "warm-up phenomenon" reported by many angina patients (i.e., angina early in exercise necessitating a brief rest period followed by a resumption of exercise without angina) and a lower 30-day cardiac event rate (mortality, recurrent MI, congestive heart failure, or shock) in AMI patients who have a history of angina within the 48-hour period that precedes infarction. [218] A history of preinfarction angina in patients with a first Q-wave MI has been reported to be associated with lower peak CK activity, lower in-hospital incidence of sustained ventricular tachycardia (VT) and ventricular fibrillation, and a lower incidence of pump failure and cardiac mortality. Of interest, in patients with a first anterior MI, a history of preinfarction angina was associated with a

greater degree of recovery of left ventricular function.[219] The greater protective effect of a longer time interval between angina pectoris and AMI suggests that the beneficial effect of prior angina is due to a delayed response to preconditioning.[219]

Reperfusion Arrhythmias

Transient sinus bradycardia occurs in many patients with inferior infarcts at the time of acute reperfusion; it is most often accompanied by some degree of hypotension. This combination of hypotension and bradycardia with a sudden increase in coronary flow has been ascribed to the activation of the Bezold-Jarisch reflex. Premature ventricular contractions, accelerated idioventricular rhythm, and nonsustained VT are also seen commonly after successful reperfusion. In experimental animals with AMI, ventricular fibrillation occurs shortly after reperfusion, but this arrhythmia is not as frequent in patients as in the experimental setting. Although some investigators have postulated that early afterdepolarizations participate in the genesis of reperfusion ventricular arrhythmias, Vera and colleagues have shown that early afterdepolarizations are present both during ischemia and during reperfusion and are therefore unlikely to be involved in the development of reperfusion VT or ventricular fibrillation.

When present, rhythm disturbances may actually be a marker of successful restoration of coronary flow. However, although reperfusion arrhythmias have a high sensitivity for detecting successful reperfusion, the high incidence of identical rhythm disturbances in patients without successful coronary artery reperfusion limits their specificity for detection of restoration of coronary blood flow. In general, clinical features are poor markers of reperfusion, with no single clinical finding or constellation of findings being reliably predictive of angiographically demonstrated coronary artery patency.[220]

Although reperfusion arrhythmias may show a temporal clustering at the time of restoration of coronary blood flow in patients with successful thrombolysis, the overall incidence of such arrhythmias appears to be similar in patients not receiving a thrombolytic agent who may develop these arrhythmias as a consequence of spontaneous coronary artery reperfusion or the evolution of the infarct process itself. These considerations, as well as the fact that the brief "electrical storm" occurring at the time of reperfusion is generally innocuous, indicate that no prophylactic antiarrhythmic therapy is necessary when thrombolytics are prescribed.[221]

Late Establishment of Patency of the Infarct Vessel

It has been suggested that improved survival and ventricular function after successful reperfusion are not due entirely to limitation of infarct size.[74] [222] Both experimental and clinical evidence indicates that the benefits of a patent artery include a favorable effect on ventricular remodeling (improved healign of infarcted tissue and prevention of infarct expansion),[72] [78] [191] [223] enhancement of collateral flow, improvement in diastolic and systolic function, increased electrical stability, and reduced long-term mortality.[224] [225] Late reperfusion of the artery perfusing an infarction provides a vascular scaffolding in the infarct zone and increases the influx of inflammatory cells that participate in the formation of a mature fibrous scar. The vascular scaffold and firmer myocardial scar prevent infarct segment lengthening and decrease the tendency toward infarct expansion and aneurysm formation.[222] Poorly contracting or noncontracting myocardium in a zone that is supplied by a stenosed infarct-related artery with slow antegrade perfusion may still contain viable myocytes. This situation is referred to as *hibernating* myocardium[204] (see Chap. 37) , and its function can be improved by PTCA to augment flow in the infarct-related artery.[226] Late reperfusion of the infarct-related artery by thrombolysis or late restoration of flow by PTCA enhances the electrical stability of the infarcted zone and is probably related to the reduced incidence of ventricular fibrillation and automatic firing of implantable cardioverter-defibrillator devices.[227] [228] The beneficial effect of late reperfusion of the infarct-related artery is independent of left ventricular function and other mortality-reducing therapies such as ACE inhibitors.[224] Several clinical trials are under way testing the benefits of late reperfusion of an occluded infarct artery in asymptomatic patients (OAT, ACTOR).

Summary of Effects of Myocardial Reperfusion

As illustrated in Figure 35-13 , rupture of an unstable plaque in the culprit vessel produces complete occlusion of the infarct-related coronary artery. AMI occurs with the ensuing development of left ventricular dilatation and ultimate death through a combination of pump failure and electrical instability. Early reperfusion (i.e., thrombolysis, primary PTCA) shortens the duration of coronary occlusion, minimizes the degree of ultimate LV dysfunction and dilatation, and reduces the probability that the AMI patient will develop pump failure or malignant ventricular tachyarrhythmias. Late reperfusion may favorably affect the process of infarct healign and minimize LV remodeling and the ultimate development of pump dysfunction and electrical instability.

CORONARY THROMBOLYSIS

Many years elapsed between the first report of intracoronary clot lysis in an experimental animal and the widespread use of thrombolytic agents in AMI. With publication of the first Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico (GISSI) trial of over 11,000 patients in 1986,[229] in which intravenous streptokinase was shown to result in a significant reduction in mortality in patients treated within 6 hours of the onset of symptoms, the routine use of thrombolytic therapy in AMI was established. It is now clear that thrombolysis recanalizes thrombotic occlusion associated with AMI (see Fig. 35-10) (Figure Not Available) and that

restoration of coronary flow reduces infarct size and improves myocardial function and survival over both the short and the long term.[230] [231] The majority of the mortality benefit seen at 10-year follow-up in the GISSI trial was obtained before hospital discharge because no survival difference was seen in thrombolysed and control patients discharged alive except for those treated within the first hour after symptoms.[230]

INTRACORONARY THROMBOLYSIS.

Clinical investigation of pharmacological reperfusion of ischemic myocardium initially focused on intracoronary thrombolysis in the early hours of AMI.[193] [232] [233] The fact that viability could be maintained in a portion of the successfully reperfused myocardium was reflected in studies showing the restoration of contractile activity.[234] Most reported experience with intracoronary thrombolysis has not been in randomized controlled trials, largely because it has been thought difficult to withhold thrombolytic therapy once a thrombotic coronary artery occlusion has been visualized angiographically and because it has not been considered ethical to catheterize patients if randomization to no thrombolytic therapy were possible for a portion of the patients. Because of the delay involved in catheterizing patients with AMI, current consensus is that intracoronary administration of thrombolytic therapy should be reserved for patients who develop coronary thrombosis during the course of an angiographic procedure and in whom either a coronary catheter is already in place or such placement is easily and rapidly achieved.

INTRAVENOUS THROMBOLYSIS.

This form of thrombolytic therapy has several important advantages over intracoronary use. Because only the placement of a peripheral intravenous line is required, therapy may be initiated early, in a variety of locations (home, ambulance, helicopter,

Figure 35-19 Correlation of Thrombolysis in Myocardial Infarction (TIMI) flow grade and mortality. A pooled analysis of data from 5498 patients in several angiographic trials of reperfusion for ST segment elevation MI showed a gradient of mortality when the angiographic findings were stratified by TIMI flow grade. Patients with TIMI 0 or TIMI 1 flow had the highest mortality; TIMI 2 flow was associated with an intermediate mortality; lowest mortality was observed in patients with TIMI 3 flow. *(Personal communication, Dr. Michael Gibson, 2000.)*

emergency department) and at relatively low cost. The subject of intravenous thrombolysis has perhaps been one of the most rapidly evolving areas in the management of patients with AMI, especially over the past decade.

To provide a level of standardization for comparison of the various regimens, most investigators describe the flow in the infarct vessel according to the TIMI grading system:

Grade 0 = complete occlusion of the infarct-related artery.

Grade 1 = some penetration of the contrast material beyond the point of obstruction but without perfusion of the distal coronary bed.

Grade 2 = perfusion of the entire infarct vessel into the distal bed but with delayed flow compared with a normal artery.

Grade 3 = full perfusion of the infarct vessel with normal flow.[235] [236]

When evaluating reports of angiographic studies of thrombolytic agents, it must be kept in mind that only in studies in which a pretreatment coronary arteriogram documents occlusion of the culprit vessel can the term *recanalization* be applied if flow is restored. If the status of the culprit vessel is not known before treatment, the only fact that can be stated with certainty is the *patency rate* of the vessel at the moment contrast medium is injected. This snapshot in time does not reflect the fluctuating status of flow in the infarct vessel that characteristically undergoes repeated cycles of patency and reocclusion, as has been documented angiographically and by continuous ST segment monitoring.

Figure 35-20 Relationship between coronary blood flow and mortality in AMI. *(From Gibson CM: Primary angioplasty, rescue angioplasty, and new devices. In Hennekens CH (ed): Clinical Trials in Cardiovascular Disease: A Companion to Braunwald's Heart Disease. Philadelphia, WB Saunders, 1999, p 194.)*

Issues of the fluctuating nature of patency of the infarct-related artery notwithstanding, the majority of angiographic studies of reperfusion regimens for STEMI used an assessment of the TIMI flow grade at 90 minutes as the primary endpoint of the trial. With an increasing number of angiographers being able to perform diagnostic catheterizations in patients with AMI more expeditiously than in the past, investigators have now focused on the TIMI grade flow assessed at 60 minutes. Evidence exists that differences between reperfusion regimens with respect to the rate and extent of thrombolysis can be discriminated better at 60 rather than 90 minutes after initiation of therapy: earlier opening of infarct-related arteries is expected to reduce infarct size further and translate into a reduction in mortality.[237]

Initially, combined TIMI grade 2 and grade 3 flow was lumped into the favorable category of coronary patency that was compared with a combined TIMI grade 0 and grade 1 flow into an unfavorable category of persistent occlusion. However, TIMI grade 2 flow should not be lumped with grade 3 flow because it has been recognized that TIMI grade 3 flow is far superior to grade 2 flow in terms of infarct size reduction and both short-term[238] and long-term [239] mortality benefit. Therefore, TIMI grade 3 flow should be considered to be the goal of reperfusion therapy[240] [241] (Fig. 35-19) . In an effort to provide a more quantitative statement of the briskness of coronary blood flow in the infarct artery and also to account for differences in the size and length of vessels (e.g., left anterior descending artery vs. right coronary artery) and interobserver variability, Gibson and coworkers have developed the *TIMI frame count*--a simple count of the number of angiographic frames elapsed until the contrast medium arrives in the distal bed of the vessel of interest. The TIMI frame count, an objective and quantitative index of coronary blood flow, is an independent predictor of in-hospital mortality from AMI and also discriminates patients with TIMI grade 3 flow into low- and high-risk groups.[242] [243] The TIMI frame count can also be used to quantitate coronary blood flow (milliliters per second) calculated at 21/(observed TIMI frame count) × 1.7 (based on Doppler velocity wire data showing normal flow equals 1.7 cm^3 /sec, which is proportional to 21 frames). The relationship between calculated coronary perfusion and mortality for patients treated with thrombolytics and primary PTCA is illustrated in Figure 35-20 .

MYOCARDIAL PERFUSION.

Despite the intense interest in development of reperfusion regimens that normalize flow in the epicardial infarct-related artery, the real goal of reperfusion in STEMI is to improve myocardial perfusion in the infarct zone. Of course, myocardial perfusion cannot be improved adequately without restoration of flow in the occluded infarct-related artery (Fig. 35-21) . However, even patients with TIMI grade 3 flow may not achieve adequate myocardial perfusion.[207] [244] The two major impediments to normalization of myocardial perfusion are microvascular damage[245] (see Fig. 35-21) and reperfusion injury. Obstruction of the distal microvasculature in the downstream bed of the infarct-related artery is caused by platelet microemboli and thrombi. Microembolization of platelet aggregates may actually be exacerbated by thrombolysis by means of the exposure of clot-bound thrombin, an extremely potent platelet agonist. Spasm may also occur in the microvasculature owing to the release of substances from activated platelets such as serotonin and thromboxane A_2 (see Fig. 35-3) . Reperfusion injury, discussed earlier (see p. 1144), results in cellular edema, free radical formation, and calcium overload. In addition, cytokine activation leads to neutrophil accumulation and inflammatory mediators that contribute to tissue injury.

Several techniques have been used to evaluate the adequacy of myocardial perfusion. ST segment resolution on the ECG is a strong predictor of outcome in AMI patients (Fig. 35-22) ; its absence is a better predictor of an occluded rather than patent infarct-related artery.[207] [246] [247] [248] [249] [250] Absence of early ST segment resolution after angiographically successful primary PTCA identifies patients with a higher risk of left ventricular dysfunction and mortality, presumably because of microvascular damage in the infarct zone.[251] [252] Thus, the 12-lead ECG can serve as a clinically useful marker of the biological integrity of myocytes in the infarct zone and can reflect inadequate myocardial perfusion even in the presence of TIMI 3 flow.[207] Given the dynamic nature of coronary occlusion, it has been proposed that continuous ST segment monitoring is more informative than static 12-lead ECG recordings, but practical limitations have prevented continuous ST segment monitoring from

Figure 35-21 Patterns of response to thrombolysis. *A,* Failure of epicardial reperfusion can occur owing to failure to induce a lytic state or to mechanical factors at the site of occlusion. Failure of microvascular reperfusion is due to a combination of platelet microthrombi followed by endothelial swelling and myocardial edema ("no reflow"). *B,* Thrombolysis may fail owing to persistent occlusion of the epicardial infarct-related artery (TIMI 0 and 1), patency of an epicardial artery in the presence of impaired (TIMI 2) flow, or microvascular occlusion in the presence of angiographically normal flow (TIMI 3). Successful reperfusion requires a patent artery with an intact microvascular network. Conversely, reperfusion may occur despite an occluded epicardial artery due to the presence of collateral vessels. *(From Davies CH, Ormerod OJ: Failed coronary thrombolysis. Lancet 351:1191-1196, 1998.)*

Figure 35-22 Relationship between ST segment resolution and 30-day mortality. Patients with complete (> 70 percent) ST segment resolution have the lowest 30-day mortality followed by patients with partial (30-70 percent) and no (< 30 percent) ST segment resolution. The gradient of mortality stratified by ST segment resolution is evident at both 90 minutes and 180 minutes after initiation of thrombolytic therapy. *(Adapted from data in Schroder R, et al: Comparison of the predictive value of ST segment elevation resolution at 90 and 180 min after start of streptokinase in acute myocardial infarction: A substudy of the Hirudin for Improvement of Thrombolysis [HIT]-4 study. Eur Heart J 20:1563-1571, 1999.*

widespread clinical application.[253] [254] Defects in perfusion patterns seen with myocardial contrast echocardiography correlate with regional wall motion abnormalities[255] and lack of myocardial viability on dobutamine stress echocardiography.[256] A practical limitation to myocardial contrast echocardiography is the need for intracoronary injection of echo contrast medium, although this may be circumvented

Figure 35-23 Myocardial perfusion in AMI. *A,* ^{99m}Tc-sestamibi SPECT before reperfusion; vertical long-axis slice; reduced tracer uptake of basal inferior left ventricular myocardium (arrows). *B,* ^{99m}Tc-sestamibi SPECT 7 days after stenting of left circumflex coronary artery; nearly normal tracer uptake of basal inferior left ventricular myocardium. by the availability of new echo contrast agents that may be injected intravenously.[257] [257A] Doppler flow wire studies, MRI, and nuclear imaging with positron emission tomography (Fig. 35-23) have also been used to define abnormalities of myocardial perfusion.[245] [258] [259] [260]

A new angiographic method for assessing myocardial perfusion has also been introduced by Gibson and colleagues--the TIMI myocardial perfusion grade (Fig. 35-24) . Abnormalities of increasing myocardial perfusion as assessed by the TIMI myocardial perfusion grade correlate with mortality risk even after adjusting for the presence of TIMI grade 3 flow or a normal TIMI frame count.[261]

A variety of treatments have been tested for increasing myocardial perfusion. A generally consistent theme is that myocardial protective agents should be administered either before or concurrent with efforts at restoration of flow in the epicardial infarct-related artery to minimize damage that may occur as a consequence of reperfusion strategies. Administration of adenosine in the Acute Myocardial Infarction Study of Adenosine (AMISTAD) trial was associated with a reduction in infarct size in patients with an anterior wall MI.[262] Efforts to treat vasospasm with vasodilators such as nicorandil, papavarine, verapamil, and trimetazidine have been associated with improvement in myocardial perfusion in several small series.[216] The most promising intervention to date for treating obstruction of the microvasculature is the administration of an intravenous GPIIb/IIIa inhibitor either in conjunction with a reduced dose of thrombolytic or in association with a catheter-based reperfusion strategy.

Figure 35-24 Relationship between TIMI myocardial perfusion grade and mortality. TIMI myocardial perfusion (TMP) grade 0 or no perfusion of the myocardium is associated with the highest mortality. If the stain of the myocardium is present (grade 1), mortality is also high. A reduction in mortality is seen if the dye enters the microvasculature but is still persistent at the end of the washout phase (grade 2). The lowest mortality is observed in those patients with normal perfusion (grade 3) in whom the dye is minimally persistent at the end of the washout phase. *(From Gibson CM, et al: Circulation 101:125-130, 2000. Copyright 2000, American Heart Association.)*

With the exception of intravenous GPIIb/IIIa inhibitors, no intervention can be recommended definitively for the specific purposes of improving myocardial perfusion, although this situation may change as more data become available.

Effect on Mortality

There is no doubt that early intravenous therapy and thrombolytic drugs improve survival in patients with AMI[15] [52] (Fig. 35-25) . Mortality varies considerably depending on patients included for study and adjunctive therapies employed. The benefit of thrombolytic therapy appears to be greatest when agents are administered as early as possible, with the most dramatic results when the drug is given less than 1 to 2 hours after symptoms begin.[166] [263] [264] The Fibrinolytic Therapy Trialists' (FTT) collaborative group has performed a comprehensive overview of nine trials of thrombolytic therapy, each of which enrolled more than 1000 patients[15] (Fig. 35-26) . The data base for the FTT overview consisted of a total of 58,600 patients, including 6,177 (10.5 percent) who died, 564 (1.0 percent) who sustained a stroke, and 436 (0.7 percent) who sustained major noncerebral hemorrhages. The absolute mortality rates for the control and fibrinolytic groups stratified by presenting features are shown in Figure 35-26 . The overall results indicated an 18 percent reduction in short-term mortality, but as much as a 25 percent reduction in mortality for the subset of 45,000 patients with ST segment elevation or bundle branch block. Two trials, Late Assessment

Figure 35-25 Cumulative vascular mortality (deaths from cardiac, cerebral, hemorrhagic, or other known vascular disease, or unknown causes) in days 0 to 35 of the Second International Study of Infarct Survival (ISIS-2). The four curves describe mortality for patients allocated (i) active streptokinase only, (ii) active aspirin only, (iii) both active treatments, and (iv) neither. Note that individually aspirin and streptokinase have a favorable effect of similar magnitudes and together the benefits appear additive. *(From ISIS-2 [Second International Study of Infarct Survival] Collaborative Group: Randomized trial of intravenous streptokinase, oral aspirin, both, or neither among 17,187 cases of suspected acute myocardial infarction: ISIS-2. Lancet 2:349, 1988.)*

of Thrombolytic Efficacy (LATE) and Estudio Multicentrico Estreptquinasa Republicas de America del Sur (EMERAS), viewed together provide evidence that a mortality reduction may still be observed in patients treated with thrombolytics between 6 and 12 hours from the onset of ischemic symptoms.[265] [266] The data from LATE and EMERAS and the FTT overview form the basis for extending the "window" of treatment with thrombolytics up to 12 hours from the onset of symptoms. Boersma and colleagues pooled the trials in the FTT overview, 2 smaller studies with data on time to randomization, and 11 additional trials of more than 100 patients. Patients were divided into six time categories from symptom onset to randomization. A regression analysis revealed there was a nonlinear relationship of treatment benefit to time.

MORTALITY REDUCTIONS IN SUBGROUPS.

The mortality effect of thrombolytic therapy in elderly patients is of considerable interest and controversy.[23A] [23B] Whereas patients older than the age of 75 were initially excluded from randomized trials of thrombolytic therapy, they now constitute about 15 percent of the patients studied in recent megatrials of thrombolysis and are being analyzed in registries of AMI patients.[19] [267] [268] Barriers to initiation of therapy in older patients with AMI include a protracted period of delay in seeking medical care, a lower incidence of ischemic discomfort and greater incidence of atypical symptoms and concomitant illnesses, and an increased incidence of nondiagnostic ECGs.[158] Younger patients with AMI achieve a slightly greater relative reduction in mortality compared with elderly patients, but the higher absolute mortality in the elderly results in similar absolute mortality reductions. Thus, as seen in Figure 35-26 , there was a 26 percent decrease in mortality in patients who were younger than 55 years of age (11 lives saved per 1000 with thrombolytic therapy) and a 4 percent reduction in mortality in patients older than age 75 (10 lives saved per 1000 treated). Observational data from the Cooperative Cardiovascular Project (CCP) have raised concern about increased mortality in patients over age 75 years.[23A] However, such observations should not be considered definitive given the nonrandomized nature of the dataset.[23B] Nevertheless clinicians should consider the risks of thrombolysis, especially intracranial hemorrhage, when selecting a reperfusion strategy for elderly patients.[23B]

Other important baseline characteristics that have an impact on the mortality effect of thrombolytic therapy include the vital signs at presentation and the presence of diabetes mellitus (see Fig. 35-26) . For example, there was an 18 percent decrease in mortality for patients presenting with a systolic pressure less than 100 mm Hg (62 lives saved per 1000 treated), compared with a 12 percent reduction in mortality for patients with a systolic pressure of 175 mm Hg or more (10 lives saved per 1000 treated). Patients with a history of diabetes mellitus experienced a mortality reduction of 21 percent (37 lives saved per 1000 treated), compared with a mortality

reduction of 15 percent (15 lives saved per 1000 treated) in patients without a history of diabetes.

A number of models have been developed to integrate the many clinical variables that affect a patient's mortality risk before administration of thrombolytic therapy. In the TIMI II trial, patients were classified as low risk if they *lacked* any of the following: age of 70 years or older, previous infarction, atrial fibrillation, anterior infarction, rales in more than one third of the lung fields, hypotension and sinus tachycardia, female gender, and diabetes mellitus (see Table 35-4) (Table Not Available) . A more comprehensive, convenient, bedside, simple risk-scoring system for predicting 30-day mortality at presentation for fibrinolytic-eligible patients with ST-elevation MI was developed by Morrow et al using the InTIME-2 trial database[268A] (Fig. 35-27) . However, modeling of mortality risk cannot cover all clinical scenarios and should not substitute for clinical judgment in individual cases. For

Figure 35-26 Mortality differences during days 0 to 35 subdivided by presentation features in a collaborative overview of results from nine trials of thrombolytic therapy. The absolute mortality rates are shown for fibrinolytic and control groups in the center portion of the figure for each of the clinical features at presentation listed on the left side of the figure. The odds ratio for death in the fibrinolytic group to that in the control group is shown for each subdivision (colored square), along with its 99 percent confidence interval (horizontal line). The summary odds ratio at the bottom of the figure corresponds to an 18 percent proportional reduction in 35-day mortality and is highly statistically significant. This translates to a reduction of 18 deaths per 1000 patients treated with thrombolytic agents. *(From Fibrinolytic Therapy Trialists' [FTT] Collaborative Group: Indications for fibrinolytic therapy in suspected acute myocardial infarction: Collaborative overview of mortality and major morbidity results from all randomized trials of more than 1000 patients. Lancet 343:311, 1994.)*

example, patients with inferior MI who might otherwise be considered to have a low risk of mortality and for whom many physicians have questioned the benefits of thrombolytic therapy might be in a much higher mortality risk subgroup if their inferior infarction is associated with right ventricular infarction, precordial ST segment depression, or ST segment elevation in the lateral precordial leads. The Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) I investigators developed a regression model to illustrate the relative importance of clinical characteristics on 30-day mortality in contemporary thrombolytic-treated patients.[269] Much greater proportions of the risk of mortality are contributed by the systolic blood pressure and heart rate at presentation than precisely which thrombolytic agent is selected.

CLINICAL BENEFIT.

As a result of greater patency of the infarct vessel in patients treated with thrombolytic agents, the clinical benefits that appear to accrue and contribute to the reduction in mortality include reductions in left ventricular failure, malignant arrhythmias,[270] and serious complications of AMI such as septal rupture and cardiogenic shock.[270] [271] [272] The short-term survival benefit enjoyed by patients who receive thrombolytic therapy is maintained over the 1- to 10-year follow-up that has been reported in a number of studies.[230] However, room for improvement remains, given reports of reocclusion rates of the infarctrelated artery as high as 10 percent in hospital and up to 30 percent by 3 months[273] and reinfarction rates as high as 5 percent in hospital and 7 percent within the first year in thrombolytic-treated patients.

Comparison of Thrombolytic Agents (See also Chap. 62)

There has been considerable controversy regarding the efficacy of various thrombolytic agents[274] (Table 35-6) . In the GUSTO I trial, 41,021 patients were randomized into one of four treatment arms: streptokinase,

Figure 35-27 TIMI Risk Score for STEMI for predicting 30-day mortality. STE=ST elevation; LBBB=left bundle branch block; h/o=history of; HTN=hypertension. *(From Morrow DA, Antman EM, Charlesworth A, et al: The TIMI risk score for ST elevation myocardial infarction: A convenient, bedside, clinical score for risk assessment at presentation: An InTIME II substudy. Circulation, in press.)*

1.5 MU over 60 minutes with immediate intravenous heparin to a target activated partial thromboplastin time of 60 to 85 seconds; accelerated t-PA with immediate intravenous heparin; a combination arm of intravenous t-PA (1 mg/kg over 60 minutes) and streptokinase (1.0 MU over 60 minutes); and streptokinase, 1.5 MU over 60 minutes with subcutaneous heparin. The 30-day mortality for the accelerated t-PA group was 6.3 percent; streptokinase plus subcutaneous heparin, 7.2 percent; streptokinase plus intravenous heparin, 7.4 percent; and streptokinase plus t-PA combination plus intravenous heparin, 7.0 percent.

In the GUSTO angiographic substudy involving 2431 patients, those with TIMI grade 0 or 1 flow had a 30-day mortality of 9.8 percent that was reduced to 7.9 percent in patients with TIMI grade 2 flow and to 4.3 percent in those with TIMI grade 3 flow.[238] The 90-minute patency rates for the infarct-related artery in the four treatment arms were as follows: accelerated t-PA, 81 percent (54 percent grade 3 flow); combination t-PA plus streptokinase, 73 percent (38 percent grade 3 flow); streptokinase plus intravenous heparin, 60 percent (32 percent grade 3 flow); and streptokinase plus subcutaneous heparin, 54 percent (29 percent grade 3 flow). This early gradient in patency rates favoring t-PA was no longer apparent beyond 180 minutes, presumably because of a "catch-up" phenomenon whereby late patency rates with streptokinase approach those of front-loaded t-PA, albeit beyond a time when as much myocardial salvage is possible as with t-PA. A related observation on early arterial patency was made in the TIMI 4 trial that randomized patients with AMI presenting within 6 hours to receive front-loaded t-PA, anistreplase (APSAC, anisoylated plasminogen streptokinase activator complex), or a combination of a reduced dose of both t-PA and anistreplase.[275] The 90-minute patency rate for front-loaded t-PA was 84 percent (60 percent grade 3); anistreplase, 73 percent (43 percent grade 3); and the combination, 68 percent (45 percent grade 3). A mortality trend favoring t-PA compared with both of the other treatment regimens was seen at 1 year.[275]

TISSUE PLASMINOGEN ACTIVATOR.

The t-PA molecule contains the following five domains: finger, epidermal growth factor, kringle 1 and kringle 2, and serum protease[276] (Fig. 35-28) . In the absence of fibrin, t-PA is a weak plasminogen activator; fibrin provides a scaffold on which t-PA and plasminogen are held in such a way that the catalytic efficiency for plasminogen activation of t-PA is increased manyfold. Plasma clearance of t-PA is mediated to a varying degree by residues in each of the domains except the serine protease domain, which is responsible for the enzymatic activity of t-PA. The accelerated dose regimen of t-PA over 90 minutes produces more rapid thrombolysis than the standard 3-hour infusion of t-PA. A double-bolus regimen of t-PA was not shown to be equivalent to the accelerated dose regimen[277] [278] [279] and was associated with a slightly higher rate of intracranial hemorrhage; the double-bolus regimen has not been recommended for clinical use.

Modifications of the basic t-PA structure have been made to yield a group of third-generation fibrinolytics (see Fig. 35-28 and Table 35-6) . A common feature among the third-generation fibrinolytics is prolonged plasma clearance, allowing them to be administered as a bolus rather than the

SK=streptokinase; t-PA=recombinant tissue-type plasminogen activator (alteplase); SAK=recombinant staphylokinase; TNK-tPA=TNK variant of tissue-type plasminogen activator; r-PA=reteplase.

*Most frequently used/tested.

With the exception of SK and t-PA, the need for concomitant heparin has not been formally tested.

Figure 35-28 Molecular structure of alteplase (t-PA), lanoteplase (n-PA), reteplase (r-PA), and tenecteplase. Streptokinase is the least fibrin-specific thrombolytic agent in clinical use; the progressive increase in relative fibrin specificity for the various thrombolytics is shown at the bottom. *(Modified from Brener SJ, Topol EJ: Third-generation thrombolytic agents for acute myocardial infarction. In Topol EJ [ed]: Acute Coronary Syndromes. New &York, Marcel Dekker, Inc., 1998, p. 169.)*

bolus and double infusion technique by which accelerated dose t-PA is administered.[276]

RETEPLASE (rPA).

This is a recombinant deletion mutant form of t-PA lacking the finger, epidermal growth factor, and kringle 1 domains as well as the carbohydrate side chains (see Fig. 35-28 and Table 35-6) . After a series of four phase II angiographic trials were performed (GRECO,[280] GRECO-DB,[281] Recombinant Plasminogen Activator Angiographic Phase II International Dose Finding Study [RAPID]-1,[282] RAPID-2[283]), it was determined that the optimum dose and administration schedule for reteplase was 10 + 10 units delivered as two separate intravenous boluses separated by 30 minutes. The TIMI 3 flow rate with a 10 + 10-unit regimen of reteplase was 51.2 percent at 60 minutes and 59.5 percent at 90 minutes compared with 37.4 percent and 45.2 percent at 60 and 90 minutes, respectively, for 100 mg of accelerated dose t-PA.[283]

The International Joint Efficacy Comparison of Thrombolytics (INJECT) trial was the first equivalence trial in the field of thrombolytic therapy for STEMI.[284] A total of 6010 patients were randomized to a double bolus 10 + 10-unit reteplase regimen given 30 minutes apart or 1.5 million units of streptokinase over 60 minutes. Mortality at 35 days was 9.02 percent in the reteplase group and 9.53 percent in the streptokinase group. The 95 percent confidence intervals of the differences in mortality range from -1.98 percent to 0.96 percent, satisfying the prespecified definition for equivalence between reteplase and streptokinase. The intracranial hemorrhage rate with reteplase was 0.77 percent compared with 0.37 percent for streptokinase.

The GUSTO III trial compared the 10 + 10-unit regimen of reteplase with accelerated t-PA in 15,059 patients.[20] The 30-day mortality rate was 7.47 percent in the reteplase group and 7.24 percent in the t-PA group, corresponding to an absolute difference of 0.23 percent, with a 95 percent confidence interval of -0.66 percent to +1.1 percent (Fig. 35-29) . The results of GUSTO III did not demonstrate superiority of reteplase over t-PA; using a 1 percent absolute difference as a boundary for equivalence, the mortality results also do not formally demonstrate equivalence. [278] [279] The intracranial hemorrhage rate was 0.91 percent with reteplase and 0.87 percent with t-PA. The secondary composite endpoint of net clinical benefit (death or disabling stroke) was 7.89 percent with reteplase and 7.91 percent with accelerated t-PA.

Although GUSTO III did not fulfill formal criteria for equivalence of reteplase and t-PA, many clinicians consider the two agents to be therapeutically similar and consider the double bolus method of administration of reteplase to be an advantage over t-PA.

LANOTEPLASE.

Lanoteplase (nPA, novel plasminogen activator) is a mutant of t-PA lacking the finger and epidermal growth factor domains and also containing an amino acid substitution in the kringle 1 domain, leading to deletion of a glycosylation site (see Fig. 35-28 and Table 35-6) . The phase II dose-ranging angiographic trial InTIME I suggested that lanoteplase at a dose of 120 kU/kg was superior to accelerated dose t-PA in that the TIMI 3 flow rate at 90 minutes was 57.1 percent with lanoteplase versus 46.4 percent with t-PA.[285] InTIME II was a phase III double-blind equivalence trial in 15,078 patients comparing 120 kU/kg of lanoteplase with 100 mg of accelerated dose t-PA. The 30-day mortality was 6.61 percent in the t-PA group and 6.75 percent in the lanoteplase group[21] (relative risk 1.02; $p = 0.075$ for equivalence) (Fig. 35-29) . The intracranial hemorrhage rate was 0.64 percent for t-PA and 1.12 percent for lanoteplase ($p = 0.004$).

TENECTEPLASE.

Tenecteplase (TNK-t-PA) is a mutant of t-PA with specific amino acid substitutions in the kringle 1 domain and protease domain introduced to decrease plasma clearance, increase fibrin specificity, and reduce sensitivity to PAI-1[286] (see Fig. 35-28 and Table 35-6) . The phase II angiographic dose-ranging studies TIMI 10A and TIMI 10B defined the optimum dose of tenecteplase with respect to efficacy.[287] [288] A single bolus of 40 mg of tenecteplase over 5 to 10 seconds was associated with a 63 percent rate of TIMI 3 flow at 90 minutes; 50 mg of tenecteplase

Figure 35-29 Mortality rates in trials of bolus thrombolytics. A 30-day mortality rate was similar in patients receiving the bolus thrombolytics in the trials shown compared with patients receiving the accelerated dose regimen of tissue plasminogen activator. *(Adapted from data in [1] The Global Use of Strategies to Open Occluded Coronary Arteries [GUSTO III] Investigators. N Engl J Med 337:1118-1123, 1997. [2] Neuhaus KL: InTIME-2 results. Presented at the Scientific Sessions of the American College of Cardiology, New Orleans, March 9, 1999; and [3] Assessment of the Safety and Efficacy of a New Thrombolytic [ASSENT-2] Investigators. Lancet 354:716-722, 1999.)*

produced a 66 percent TIMI 3 flow rate. An analysis comparing the weight-adjusted dose of tenecteplase compared with TIMI 3 flow indicated that a dose of 0.53 mg/kg was optimal for achieving high rates of TIMI 3 flow.[288]

The safety of tenecteplase was evaluated in both TIMI 10B and another large phase II clinical trial called ASSENT 1.[289] Initially, tenecteplase doses of 30, 40, and 50 mg were tested in ASSENT 1, but the 50-mg dose was discontinued and replaced by the 40-mg dose because of increased bleeding observed in the TIMI 10B study. An overall rate of intracranial hemorrhage of 0.77 percent was observed in the total ASSENT 1 study population. Observations made in the combined data set of TIMI 10B and ASSENT 1 suggested that a reduction in the dose of adjunctive unfractionated heparin was associated with a reduction in the risk of intracranial hemorrhage.

ASSENT 2 was a randomized double-blind phase III equivalence trial comparing single-bolus tenecteplase with accelerated dose t-PA in 16,949 patients.[22] The 30-day mortality rate with tenecteplase was 6.179 percent and with t-PA 6.151 percent ($p = 0.0059$ for equivalence) (see Fig. 35-29) . The rate of intracranial hemorrhage was 0.93 percent with tenecteplase and 0.94 percent with t-PA. Major bleeding occurred in 4.66 percent of tenecteplase-treated patients compared with 5.94 percent of t-PA-treated patients (peak was 0.0002). There was no specific subgroup of patients in whom tenecteplase or t-PA was significantly better, with the exception of patients treated after 4 hours from the onset of symptoms in whom the mortality rate was 7.0 percent with tenecteplase and 9.2 percent with t-PA ($p = 0.018$).

OTHER THROMBOLYTIC AGENTS.

SPB, a naturally occurring plasminogen activator, has been undergoing evaluation for treatment of AMI for at least three decades. Although it offers the potential advantage of less antigenicity than that with streptokinase, infarct artery patency rates are about the same as those achieved with streptokinase. Although it is prescribed in an intravenous regimen for AMI in some countries, given its high cost and lack of advantage over streptokinase, its use in the United States is almost

exclusively for intracoronary infusion (6000 IU/min to an average cumulative dose of 500,000 IU) to lyse intracoronary thrombi that are believed to be responsible for an evolving AMI. Anistreplase, usually administered in a dose of 30 mg over 2 to 5 minutes intravenously, has a side effect profile similar to that of streptokinase, a patency profile similar to that of conventional-dose t-PA, and a mortality benefit similar to that of streptokinase or t-PA (double-chain form, duteplase). The lack of any compelling advantages (other than bolus administration) and costs higher than streptokinase have relegated anistreplase to an extremely infrequently prescribed drug for AMI in the United States.

SPB (scuPA or prourokinase) has been produced both in nonglycosylated (e.g., saruplase) and glycosylated (e.g., Abbott-74187) forms. Angiographic studies of saruplase (PRIMI,[290] Saruplase and Urokinase in the Treatment of Acute Myocardial Infarction [SUTAMI][291] , Study in Europe with Saruplase and Alteplase in Myocardial Infarction [SESAMI][292]) have shown it to have thrombolytic efficacy similar to streptokinase, urokinase, and a 3-hour infusion of t-PA; and the Practical Applications of Saruplase Study (PASS) suggested it could be administered safely (intracranial hemorrhage rate of 0.5 percent in 1698 patients).[276] [293] In the Comparison Trial of Saruplase and Streptokinase (COMPASS), the 30-day mortality was 5.8 percent for saruplase versus 6.7 percent for streptokinase; intracranial hemorrhage occurred in 0.9 percent of saruplase patients and 0.3 percent of streptokinase patients.[294] In the Bolus versus Infusion in Rescuepase Development (BIRD) trial, single-bolus administration of saruplase, 80 mg, was found to be similar to a 1 hour infusion.[295]

Staphylokinase.

This is a highly fibrin-specific plasminogen activator that requires priming on the surface of a clot.[296] (see Table 35-6) . Recombinant forms of staphylokinase have shown high degrees of thrombolytic efficiency (STAR trial[297]), and dose-ranging studies are the ongoing Collaborative Angiographic Patency Trial of Recombinant Staphylokinase [CAPTORS].[298] Of concern is the fact that recombinant staphylokinase is highly antigenic, which may limit its use beyond a single administration unless pegilated variants with reduced immunogenicity prove to be clinically safe and effective.

Effect on Left Ventricular Function

Although precise measurements of infarct size would be an ideal endpoint for clinical reperfusion studies, such measures have been found to be impractical. Attempts to use LV ejection fraction as a surrogate for infarct size have not been productive because little difference is seen in ejection fraction between treatment groups that show a significant difference in mortality. Alternative methods of assessing left ventricular function, such as end-systolic volume[299] or quantitative echocardiography,[300] are more revealign because patients with smaller volumes and better-preserved ventricular shape have an improved survival.

As with survival, improvement in global LV function is related to the time of thrombolytic treatment, with greatest improvement occurring with earliest therapy. Greater improvement in left ventricular function has been reported with anterior than with inferior infarcts. Earlier trials failed to demonstrate any difference in global left ventricular function when streptokinase and t-PA were compared.[301] The angiographic substudy in GUSTO I reported detailed regional wall motion analyses stratified by thrombolytic regimen.[238] Patients who received the accelerated t-PA regimen had significantly less depression of regional wall motion in the ischemic zone, as evidenced by fewer abnormal chords when their ventricular silhouettes were subjected to segmental wall motion analysis. In addition, this patient group tended to have a slightly higher global ejection fraction and slightly reduced end-systolic volume index at 90 minutes after initiation of thrombolytic therapy. The totality of the data presented in the GUSTO angiographic substudy[238] is consistent with the hypothesis that more rapid and complete restoration of normal coronary blood flow in the infarct-related artery with t-PA was associated with an improvement in regional and global left ventricular function (presumably through greater myocardial salvage in the ischemic zone) and that this difference in function compared with that obtained with streptokinase may have contributed to the mortality differences observed at 30 days and beyond.

Complications of Thrombolytic Therapy

Recent (< 1 year) exposure to streptococci or streptokinase produces some degree of antibody-mediated resistance to streptokinase (and anistreplase) in most patients. Although this is of clinical consequence only rarely, it is recommended that patients not receive streptokinase for AMI if they have been treated with a streptokinase product within the past year. Bleeding complications are, of course, the most common and potentially the most serious. Most bleeding is relatively minor with all agents, with more serious episodes occurring in patients requiring invasive procedures.[302] [303] Overall, 70 percent of bleeding episodes occur at the site of vascular punctures.[302] [303] [304] Intracranial hemorrhage is the most serious complication of thrombolytic therapy[305] [306] ; its frequency varies with the clinical characteristics of the patient and the thrombolytic prescribed[306] [307] (Table 35-7) .

Collaborators from the European Cooperative Society Group (ECSG) and GISSI, TAMI, TIMI, and ISAM groups pooled their respective data bases on thrombolytic-treated patients with AMI to develop a statistical model for individual risk assessment for intracranial hemorrhage using a case-control format.[307] The following four clinical variables known at hospital admission were shown to predict an increased risk of intracranial hemorrhage: age older than 65 years (odds ratio for intracranial hemorrhage = 2.2), weight less than 70 kg (2.1), hypertension on presentation (2.0), and use of t-PA as opposed to streptokinase (1.6). Assuming an overall incidence of intracranial hemorrhage of 0.75 percent, the expected incidence of intracranial hemorrhage stratified by the number of risk factors would be 0.26 percent for no risk factors, 0.96 percent for one risk factor, 1.32 percent for two risk factors, and 2.17 percent for three risk factors. The incremental incidence of intracranial hemorrhage with thrombolysis appears to be at least partially

offset by a lower frequency of thrombotic strokes, so that the overall incidence of stroke is usually not much higher in patients receiving thrombolytic therapy than in control patients.[229] [305] [308] Gurwitz and colleagues analyzed 71,073 patients in the National Registry of Myocardial Infarction 2 who had received t-PA for AMI.[309] Multivariable analysis indicated the following patient characteristics were associated with an increased risk of intracranial hemorrhage: older age, female sex, black ethnicity, systolic blood pressure of 140 mm Hg or more, diastolic blood pressure of 100 mm Hg or more, history of stroke, t-PA dose more than 1.5 mg/kg, and a low body weight (Table 35-8) .

There have been reports of an "early hazard" with thrombolytic therapy, that is, an excess of deaths in the first 24 hours in thrombolytic-treated patients compared with controls (especially in elderly patients treated >12 hours).[15] However, this excess early mortality is more than offset by the deaths prevented beyond the first day, culminating in an 18 percent (13 to 23 percent) reduction in mortality by 35 days.[15] The mechanisms responsible for this early hazard are not clear but probably are multiple, including an increased risk of myocardial rupture (particularly in the elderly), fatal intracranial hemorrhage,[305] inadequate myocardial reperfusion resulting in pump failure and cardiogenic shock,[310] and possible reperfusion injury of reperfused myocardium.[205] Reports of more unusual complications such as splenic rupture, aortic dissection, and cholesterol embolization have also appeared.

Recommendations for Thrombolytic Therapy

NET CLINICAL BENEFIT OF THROMBOLYSIS.

Perhaps one of the most important messages from all of the available evidence is that thrombolytic therapy is underused in patients with AMI.[311] Hesitancy in prescribing a thrombolytic agent is often the result of uncertainty about the risk of bleeding, and analysis from GUSTO-1 shows that moderate to severe bleeding occurred more often in patients who were older, female, lighter, shorter, and of African ancestry and who underwent an invasive procedure.[312] The specific profile of patients at risk for intracranial hemorrhage was discussed previously. Patients with a higher baseline risk of mortality are more likely to benefit from thrombolytic therapy.

Against the mortality benefit associated with thrombolytic therapy must be weighed the excess risk of stroke. By using the net clinical benefit composite endpoint of 30-day mortality or nonfatal stroke, a small but statistically significant benefit is seen for accelerated dose t-PA compared with streptokinase. Given the data from the GUSTO-3 and Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT)-2 trials, it appears that the net clinical benefit of accelerated dose t-PA is similar to that obtained with reteplase or tenecteplase.[20] [22] Of interest, the rate of noncerebral major bleeding was lower with tenecteplase than t-PA in the ASSENT-2 trial, possibly due to the greater fibrin specificity of tenecteplase.[22]

CHOICE OF AGENT.

Analysis of the net clinical benefit and cost-effectiveness of t-PA versus streptokinase does not easily yield recommendations for treatment because clinicians must weigh the risk of mortality and risk of intracranial hemorrhage when confronting a thrombolytic-eligible patient with AMI; additional considerations may be the constraints placed on physicians' therapeutic decision-making

TABLE 35-8 -- ADJUSTED ODDS RATIOS RELATING PATIENT CHARACTERISTICS TO INTRACRANIAL HEMORRHAGE

Modified from Gurwitz JF, Gore JM, Goldberg RJ, et al: Risk for intracranial hemorrhage after tissue plasminogen activator treatment for acute myocardial infarction. Participants in the National Registry of Myocardial Infarction 2. Ann Intern Med 129:597-604, 1998.

by the health care system in which they are practicing.[313] We are in agreement with the general recommendations by Martin and Kennedy[193] and Simoons and Arnold[314] that categorize patients into those that are at high risk of death (advanced age, female gender, depressed left ventricular function, anterior MI, bundle branch block, total magnitude of ST segment elevation, diabetes, heart rate greater than 100 beats/min, systolic pressure less than 100 mm Hg, long delay since onset of ischemic discomfort),[193] [314] and high risk of intracranial hemorrhage. In the subgroup of patients presenting within 4 hours of symptom onset, the speed of reperfusion of the infarct vessel is of paramount importance, and a high-intensity thrombolytic regimen such as accelerated t-PA or tenecteplase is the preferred treatment, except in those individuals in whom the risk of death is low (e.g., a young patient with a small inferior MI) and the risk of intracranial hemorrhage is increased (e.g., acute hypertension), in whom streptokinase and accelerated t-PA are approximately equivalent choices. Of note, for those patients presenting between 4 and 12 hours from symptom onset with a low mortality risk but an increased risk of intracranial hemorrhage (e.g., elderly patients with inferior MI, blood pressure greater than 100 mm Hg, and heart rate less than 100 beats/min), streptokinase is probably preferable to t-PA because of cost considerations if thrombolytic therapy is prescribed at all in such a patient.

In those patients considered appropriate candidates for thrombolysis and in whom t-PA would have been selected as the agent of choice in the past, we believe clinicians should now consider using a bolus thrombolytic such as reteplase or tenecteplase. The rationale for this recommendation is that bolus thrombolysis has the advantage of ease of administration and a lower chance of medication errors (and the associated increase in mortality when such medication errors occur) and also offers the potential for prehospital thrombolysis.

LATE THERAPY.

No mortality benefit was demonstrated in the LATE and EMERAS trials when thrombolytics were routinely administered to patients between 12 and 24 hours,[265] [266] although we believe it is still reasonable to consider thrombolytic therapy in appropriately selected patients with persistent symptoms and ST segment elevation on ECG beyond 12 hours (see Fig. 35-17) . Persistent chest pain late after the onset of symptoms correlates with a higher incidence of collateral or antegrade flow in the infarct zone and is therefore a marker for patients with viable myocardium that might be salvaged.[315] Because elderly patients treated with thrombolytics more than 12 hours after the onset of symptoms are at increased risk of cardiac rupture, it is our practice to restrict late thrombolytic administration to younger patients (<65 years) with ongoing ischemia, especially those with large anterior infarctions. The elderly patient with ongoing ischemic symptoms but presenting late (>12 hours) is probably

better managed with direct (primary) PTCA (discussed subsequently) than with thrombolytic therapy.

Before the institution of thrombolytic therapy, consideration should be given to the patient's need for intravascular catheterization, as would be required for the placement of an arterial pressure monitoring line, a pulmonary artery catheter for hemodynamic monitoring, or a temporary transvenous pacemaker. If any of these are required, ideally they should be placed as expeditiously as possible *before* infusion of the thrombolytic agent. If such procedures require an additional delay of more than 30 minutes, they should be deferred as long as possible after thrombolytic therapy is begun. In the early hours after institution of thrombolytic therapy, such catheterization should be performed only if crucial to survival, and then sites where excessive bleeding can be controlled should be chosen (e.g., subclavian vein catheterization should be avoided).

As noted earlier, all patients with suspected AMI should receive aspirin (160 to 325 mg) regardless of the thrombolytic agent prescribed. Aspirin should be continued indefinitely. The issues surrounding antithrombin therapy as an adjunct to thrombolysis are complex and are discussed in detail in a subsequent section (see p. 1162).

CATHETER-BASED REPERFUSION (See also Chap. 38)

It is now established that reperfusion can be achieved by emergency percutaneous coronary intervention (PCI). By using a guidewire and balloon catheter, it is technically easier to cross a total occlusion consisting of a fresh thrombus than to cross a long-standing occlusion of a coronary artery. Thus, wire-guided balloon angioplasty can be useful to achieve reperfusion in two quite different circumstances: (1) in lieu of thrombolytic therapy where it is referred to as *direct* or *primary angioplasty*[316] and (2) as adjunctive therapy with thrombolysis or as a management strategy in the subacute phase of AMI (days 2 to 7) in patients who do not receive thrombolysis. Several clinical scenarios have been described that represent different categories of use of PCI when it is not selected as the primary reperfusion strategy. When thrombolysis has failed to reperfuse the infarct vessel or a severe stenosis is present in the infarct vessel, a *rescue PCI* may be performed as soon as possible. Alternatively, strategies of empirical *immediate* (i.e., performed urgently within a few hours) or *deferred* (i.e., performed within the first week) PCI have been proposed for all patients with residual critical stenosis (> 70 percent of lumen diameter) who receive thrombolysis. Finally, a more conservative approach of *elective* PCI may be used to manage AMI patients only when spontaneous or exercise-provoked ischemia occurs whether or not they have received a previous course of thrombolytic therapy.

Catheter-based strategies for reperfusion of the occluded infarct-related artery in patients with AMI is a rapidly evolving field. Coronary artery stenting, originally introduced for elective percutaneous procedures, was originally withheld in patients with AMI because of concerns over acute stent thrombosis. However, with advances in stent deployment (high pressure inflations, intravascular ultrasound guidance), improvements in antiplatelet therapy (GPIIb/IIIa inhibitors) and operator experience have fueled interest in primary coronary artery stenting as a new catheter-based strategy for reperfusion.[316] [317]

Primary Angioplasty

ADVANTAGES.

An important advantage of primary PCI in AMI is the ability to achieve reperfusion of the infarct vessel without the risk of bleeding associated with thrombolytic therapy. In addition, primary PCI (performed predominantly in experienced centers) as compared with thrombolytic therapy has been shown in several randomized trials and registries to yield higher patency rates of the infarct vessel both at 90 minutes (85 to 90 percent for PCI vs. 65 percent for thrombolysis).[238] [273] [318] Systematic overviews of trials of primary PTCA versus thrombolysis collectively enrolling 2635 patients revealed lower 30-day and 6-month mortality rates for patients treated with primary PTCA versus thrombolysis[319] [320] (Fig. 35-30) . The rate of recurrent infarction was also lower for patients treated with primary PTCA[320] (see Fig. 35-30) . Primary PTCA was also associated with significant reductions in total stroke and hemorrhagic stroke. Thus, primary PCI appears to be superior to thrombolytic therapy when it is performed in experienced

Figure 35-30 Comparison of mortality and reinfarction in AMI patients treated with thrombolysis vs. primary percutaneous transluminal coronary angioplasty (PTCA). Pooled data from 11 randomized trials revealed significant reductions in the 30-day and 6-month rates of mortality and reinfarction in patients treated with primary PTCA. *(Adapted from Grines CL, Ellis SG, Jones M, et al: Primary coronary angioplasty vs. thrombolytic therapy for acute myocardial infarction (MI): Long term follow-up of ten randomized trials. Circulation [Suppl] I-499, 1999.)*

centers with a well-staffed invasive angiography team. It is also associated with a shorter length of hospital stay and reduced costs because of fewer patients with recurrent ischemia and recurrent MI when treated with primary PCI.[321] [322]

Primary PCI appears to have a particular advantage over thrombolysis for the management of high-risk AMI patients such as diabetics and the elderly.[323] [324] In an analysis of Medicare patients in the Cooperative Cardiovascular Project data base, primary PCI was associated with improved 30-day survival (hazard ratio 0.74, 95 percent confidence interval 0.63-0.88) and also 1-year survival (hazard radio 0.88, 95 percent confidence intervals 0.73-0.94).[325] The benefits of primary PCI in the elderly persisted after stratification by the volume of AMI patients cared for at individual hospitals and the presence of on-site angiography.

Why have these dramatic differences favoring primary PCI over thrombolytic therapy been observed? In addition to the high level of technical expertise in the dedicated centers that have reported promising results with primary PCI, differences in the adequacy of reperfusion and responses of ischemic myocardium to restoration of flow by thrombolysis and mechanical means should be considered. Early patency of the infarct-related artery is higher with direct PCI, full reperfusion (TIMI grade 3 flow) is higher, the degree of residual stenosis is less, reocclusion rates are lower,[273] and collateral flow to non-infarct-related myocardial zones is probably increased--all features that promote better healign in the infarct zone, less left ventricular dilatation, and reduced morbidity and mortality.[326] [327] [328] Mechanical recanalization of the infarct vessel does not produce the interstitial edema, contraction band necrosis, and microvascular hemorrhage seen with thrombolytic therapy (see Figs. 35-8 and 35-9) .

OBSTACLES TO IMPLEMENTATION.

The clinical trial results and intriguing experimental observations cited earlier must be placed in perspective when one considers implementing primary PCI as a treatment strategy for the majority of patients with AMI. Because PCI is performed only in patients with suitable angiographic anatomy, a bias may have been introduced in the available data bases excluding patients at higher risk of events from being treated by PCI.[329] The MITRA Registry of 54 university and community hospitals in Germany found that in clinical practice patients treated with primary PTCA are more often given beta blockers and ACE inhibitors than patients treated with thrombolytics, drug treatment practices that could contribute to a reduction in mortality that is not a direct result of PTCA.[330] Although reports from individual community hospitals replicating the results in randomized trials can be found in the literature, fewer than 20 percent of hospitals in the United States and less than 10 percent of hospitals in Europe can perform primary PCI, and an even smaller proportion are capable of performing it on an emergency basis 24 hours a day, 7 days a week.[331]

It remains to be determined whether lower-volume PCI centers with less-experienced investigators can replicate the encouraging results reported to date. In addition, it is unclear whether on-site cardiac surgical backup is a necessary component of a primary PCI strategy for AMI.[332] The problem of lack of on-site surgical backup is being evaluated in studies such as Air PAMI in which patients who present to a community hospital that does not perform primary PCI and who are thrombolytically eligible with at least one high-risk criterion are randomized to either immediate intravenous thrombolysis or emergency transfer for PCI.[333] The randomized population in Air PAMI will be compared with a separate registry of Air PAMI-eligible patients who have PCI performed in hospitals with catheterization laboratories but no on-site surgery (No S.O.S. Registry).[333] Preliminary results from the No S.O.S. Registry are encouraging in that the in-hospital death rate was 2.7 percent and the stroke rate was 2.7 percent in 500 patients.[332] The PRAGUE study compared the incidence of death/MI/stroke at 30 days in a randomized trial of aspirin plus streptokinase with management in a community hospital (Group A); aspirin plus streptokinase with transfer to a nearby interventional center (Group B); and aspirin plus heparin (10,000 U) with transfer to a nearby interventional center (Group C). All patients received fraxiparine for 3 days and ticlopidine for 1 month.[334] There were no deaths during or within 30 minutes of transport. The primary composite endpoint occurred in 23 percent of group A, 15 percent of group B, and 8 percent of group C patients, respectively ($p < 0.02$), indicating that interhospital transport for primary PCI is feasible and safe and may be associated with a lower event rate after AMI. The potential cost implications of offering primary PCI to all eligible patients with AMI are staggering and have been the subject of considerable ongoing debate in several countries.[316]

Primary Stenting

Although it has been agreed that primary PTCA has an advantage over thrombolysis in AMI patients with a prior CABG, observations from the National Registry of Myocardial Infarction (NRMI)-2 suggest the outcome is similar to the two reperfusion strategies.[335] Interventionalists have begun to embrace new strategies such as stenting and intravenous GPIIb/IIIa inhibitors (see Chap. 38) to improve on results with PTCA in AMI. Experience gained with elective coronary stenting (see Chap. 38)

led to a series of reports of implantation of coronary stents in AMI patients.[336] A high procedural success rate was reported and the subacute thrombosis rate was low (< 3 percent), largely due to aggressive use of antiplatelet therapy with aspirin and ticlopidine. Table 35-9 summarizes major randomized trials of primary stenting versus primary PTCA in AMI. In general, the procedural success rate was high with both stenting and PTCA. Of interest, in the largest of the trials, PAMI-STENT, a slightly lower rate of TIMI grade 3 flow was seen with stenting compared with PTCA, raising the possibility of embolization of platelet aggregates at the time of stent deployment.[337] Mortality rates were generally low, with

From Every NR: Thrombolysis and Interventional Therapy in Acute Myocardial Infarction. Presented at the George Washington University 15th International Workshop on Thrombolysis and Interventional Therapy in Acute Myocardial Infarction, November 6, 1999, Atlanta, GA.

*All differences in mortality are nonsignificant.

slight nonsignificant trends favoring stenting. The major benefit of stenting was seen in a significant reduction in the incidence of the subsequent target vessel revascularization.[337]

Angioplasty as an Adjunct to Thrombolysis

Ellis and associates have summarized the heterogeneous outcomes reported in observational series of *rescue* PTCA after failed thrombolysis. Although procedural success was obtained in about 80 percent of patients, the average rate of reocclusion was 18 percent and the average mortality was 10.6 percent. The RESCUE trial focused on the subset of AMI patients with an anterior infarction and reported a reduction in the composite endpoint of death or congestive heart failure by 30 days in the PTCA group.[338]

After thrombolytic therapy, the majority of patients are found to have a significant residual stenosis.[338A] Even in patients who clinically appear to have reperfused, PTCA, whether applied immediately or deferred, has the theoretical benefit of further opening of a stenosed coronary artery to increase flow, perhaps enhancing myocardial recovery and diminishing the possibility of reocclusion. Several trials have compared immediate, early (within several hours to a few days), or deferred (delayed for 4 days) PTCA versus no PTCA, whereas others have compared immediate versus deferred PTCA or immediate versus deferred versus no PTCA. A summary of the design features and main findings of 16 trials that collectively enrolled about 6200 patients in these categories has been published along with meta-analysis of the mortality results.[339] Although none of the individual comparisons of strategies achieved conventional statistical significance, a consistent theme was observed--the *routine empirical* use of PTCA (either immediate or delayed) after thrombolysis was associated with a trend toward *increased* mortality. [339] In addition, there were higher rates of abrupt reclosure of the infarct-related coronary artery and complications, including reinfarction and the need for urgent CABG while providing no benefit in terms of recovery of ventricular function.[340] [341] Possible explanations for the increased hazard associated with PTCA soon after thrombolysis include exacerbation of platelet activation and thrombosis at the site of plaque rupture and increased bleeding, including hemorrhagic dissections of the target vessel.[212] [340] [342] [343]

There is also no evidence to support *empirically deferred* PCI in patients without evidence of recurrent or provocable ischemia. The TOPS trial randomized patients with a negative exercise test several days after thrombolysis to either medical therapy or medical therapy plus PCI. There was no benefit in terms of rest or exercise ejection fraction, but there were disturbing trends toward a higher rate of abrupt vessel closure and non-Q-wave MI acutely and a lower rate of infarct-free survival at 1-year follow-up in the PTCA-treated patients.

Because many of the previous trials of PCI early after full-dose thrombolytics were undertaken during the thrombolytic infusion or shortly thereafter, which potentially contributed to a lower success rate of PCI, higher bleeding, and a trend toward higher rates of adverse outcomes, the Plasminogen-activator Angioplasty Compatibility Trial (PACT) was undertaken.[344] After aspirin and heparin, 606 AMI patients were randomized within 6 hours of symptoms to a 50-mg bolus of t-PA over 3 minutes or placebo followed by angiography and rescue PTCA for less than TIMI 3 flow. Patency of the infarct artery was 61 percent (TIMI 3 = 33 percent, TIMI 2 = 28 percent) in the t-PA group versus 34 percent (TIMI 3 = 15 percent, TIMI 2 = 19 percent) in the placebo group (p = 0.001) before PCI (median of 98 minutes from pharmacological reperfusion). Rescue PCI was successful in over 90 percent of patients in both groups as was left ventricular ejection fraction at 5 to 7 days. However, left ventricular function was significantly higher in those patients achieving TIMI 3 flow by the time of diagnostic angiography and those patients who had rescue PCI within 1 hour of the bolus of the study drug. The rates of major bleeding and reinfarction were similar in the t-PA and placebo groups. Thus, PACT reaffirmed the time-dependent nature of the open artery hypothesis with greater preservation of left ventricular function in patients with earlier attainment of TIMI 3 flow. This trial also showed that a tailored combination of reduced dose lytic and rescue PCI as needed could be performed safely.[345] However, only 26 percent of patients in PACT underwent stenting, and GPIIb/IIIa inhibitors were used in only 5 percent of patients.[344] [346] Whether the improved equipment available now for PTCA, the use of stents,[347] and modified pharmacological reperfusion regimens such as reduced-dose thrombolytics, intravenous GPIIb/IIIa inhibitors, or the combination of reduced dose thrombolytics and GPIIb/IIIa inhibitors (see p. 1164) would swing the evidence in favor of routine angiography followed by catheter-based reperfusion as needed after MI is an intriguing

question that needs to be addressed.

Recommendations for Catheter-Based Reperfusion in AMI

It appears that primary PCI, when carried out by experienced interventional cardiologists in high-volume angiography laboratories, is superior to thrombolytic therapy. It is our practice to refer thrombolytic-ineligible patients to primary PCI and also to select primary PCI as the reperfusion method of choice if the patient is at relatively high risk of intracerebral hemorrhage consequent to thrombolytic therapy (see p. 1153), or if the anticipated time to placement of angioplasty catheters is less than 1 hour from the patient's presentation to the emergency department. In the special circumstances of cardiogenic shock, provided no other life-threatening comorbidities are present, we refer patients for revascularization (see p. 1179).

Patients in whom thrombolytic therapy fails to achieve reperfusion represent candidates for rescue PCI, and in such patients this can usually be safe and effective. The practical issue is the difficulty in reliably identifying patients who fail to reperfuse after thrombolytic therapy using noninvasive indices either alone or in combination.[127] [348] [348A] Therefore, until there are better ways to recognize patients who might benefit from "rescue PCI," the question of optimal treatment of thrombolytic failure remains unresolved. However, we consider patients with evolving chest pain and ST segment elevations that persist for 90 minutes after the onset of administration of a thrombolytic agent to be candidates for emergency catheterization and, if the infarct-related vessel is occluded, for rescue PCI. Elective PCI can be considered for most patients receiving thrombolytic therapy in whom ischemia develops at rest, during ambulation in the hospital, or during a prehospital discharge exercise test.[349] We do not consider it necessary to carry out routine coronary arteriography on asymptomatic patients with negative prehospital discharge exercise tests to identify patients who have severe obstruction in whom PCI can be performed.

Although some reports suggested that prophylactic intraaortic balloon counterpulsation may be useful to maintain vessel patency after PCI, subsequent randomized trials in high-risk patients showed that balloon counterpulsation did not decrease the rates of infarct-related artery reocclusion or reinfarction, promote myocardial recovery, or

improve overall clinical outcome.[350] We believe that intraaortic balloon pumping should be reserved for hemodynamically unstable patients.[351]

SURGICAL REPERFUSION

There have been extensive improvements in intraoperative myocardial preservation with cardioplegia and hypothermia and in surgical techniques. These have allowed surgical reperfusion in patients with AMI to be carried out at quite low short- and long-term mortality rates--approximately 2 percent in hospital and 25 percent 10-year mortality rates in selected centers. This has kept alive the concept of emergency coronary revascularization as a possible measure to protect jeopardized myocardium in patients suffering AMI.[352] As appears to be the case for all methods designed to limit infarct size, salvage of myocardium is most successful if surgery is performed within the first 4 to 6 hours of the onset of the acute event. In the usual patient who develops an AMI outside the hospital, it is logistically almost impossible to bring the patient to the hospital, carry out a clinical evaluation, outline the coronary anatomy by arteriography, assemble the surgical team, commence operation, and place the patient on cardiopulmonary bypass in less than 4 to 6 hours after the onset of the event. It is therefore unlikely that surgical reperfusion can or will be applied in the *routine* treatment of AMI. Indeed, the operation is contraindicated in patients with uncomplicated transmural infarcts more than 6 hours after the onset of the event. When carried out at this time, surgical reperfusion appears to produce marked hemorrhage into the area of infarction. In some patients with AMI, including some with cardiogenic shock, infarction appears to occur in a stuttering manner over an interval of several days.[353] Revascularization carried out more than 6 hours after the onset of the event might be of benefit in this group, but this has yet to be rigorously established.

Ten to 20 percent of AMI patients are currently referred for CABG for one of the following indications: persistent or recurrent chest pain despite thrombolysis or PCS, high-risk coronary anatomy (e.g., left main artery stenosis) discovered at catheterization, or a complication of AMI such as ventricular septal rupture or severe mitral regurgitation due to papillary muscle dysfunction. Patients with AMI with continued severe ischemic and hemodynamic instability are likely to benefit from emergency revascularization. PCI with stenting as needed is the preferable technique when revascularization is needed in the first 48 to 72 hours after AMI; surgery should be reserved for those in whom PCI has been unsuccessful or whose anatomy dictates the need for CABG, such as patients with left main or extensive multivessel coronary artery disease.

Patients undergoing successful thrombolysis but with important residual stenoses, who on anatomical grounds are more suitable for surgical revascularization than for PCI, have undergone CABG with quite low mortality (about 4 percent) and morbidity *provided* that they are operated on more than 24 hours after AMI; those patients requiring urgent or emergency CABG within 24 to 48 hours of AMI have mortality rates between 15 and 20 percent.[352] When surgery is performed under urgent conditions with active and ongoing ischemia or cardiogenic shock, operative mortality rises steeply. At autopsy, such patients have extensive myocardial necrosis that is often hemorrhagic. Patients who are referred urgently for CABG within 6 to 12 hours of receiving a thrombolytic should receive aprotinin and fresh-frozen plasma to correct their coagulation system deficit and minimize the requirements for blood transfusion (see Chap. 60) . Although postoperative chest tube drainage with relatively minor bleeding occurs more commonly than after elective bypass surgery, this problem is not of major concern.

ANTITHROMBOTIC AND ANTIPLATELET THERAPY (See also Chap. 62)

Antithrombotic Therapy

Despite more than 30 years of active clinical investigation, the use of antithrombotic agents after AMI remains controversial. The rationale for administering heparin acutely in AMI includes prevention of deep venous thrombosis, pulmonary embolism, ventricular thrombus formation, and cerebral embolization. In addition, establishing and maintaining patency of the infarct-related artery, whether or not a patient receives thrombolytic therapy, is another common rationale for heparin therapy in AMI.

EFFECT ON MORTALITY.

Randomized trials in AMI conducted in the prethrombolytic era (between 1969 and 1973) showed that the risks of pulmonary embolism, stroke, and reinfarction were reduced in patients who received intravenous heparin. This formed the basis for the use of heparin in AMI patients not treated with thrombolytic therapy. With the introduction of the thrombolytic era and importantly after the publication of the Second International Study of Infarct Survival (ISIS-2),[308] the situation became more complicated because of strong evidence of a substantial mortality reduction with aspirin alone and confusing and conflicting data regarding the risk-benefit ratio of heparin used as an adjunct to aspirin or in combination with aspirin and a thrombolytic agent (Table 35-10) .

In the SCATI trial of streptokinase for AMI, in which patients were randomized to receive either delayed subcutaneous heparin or placebo as the *sole* adjunctive therapy (i.e., no aspirin), there was a trend toward lower mortality in the heparin group. In the combined data set of GISSI-2 and ISIS-3 (totalign over 62,000 patients), the 35-day mortality was 10.0 percent in the patients receiving subcutaneous heparin versus 10.2 percent in the patients not receiving any subcutaneous heparin. In addition, in the GUSTO study, no difference was seen in the 35-day mortality rate in patients receiving streptokinase plus subcutaneous heparin (7.2 percent) or intravenous heparin (7.4 percent).[19] Nonrandomized subgroup analyses from the LATE trial of 2821 patients who received t-PA showed a 35-day mortality of 7.6 percent when intravenous heparin was administered, compared with 10.4 percent when no heparin was given.[265] Thus, the available information suggests that intravenous heparin is probably of no benefit in patients receiving streptokinase but may be helpful in patients receiving t-PA.[274] Heparin was administered as adjunctive therapy in randomized trials of reteplase and tenecteplase under the supposition that those agents were more fibrin specific than streptokinase and required concomitant use of heparin.[289] [354]

EFFECT ON PATENCY OF INFARCT ARTERY

A number of angiographic studies have examined the role of heparin in establishing and maintaining patency of the infarct-related artery in patients with AMI. Comparison of these trials is difficult because of potentially important differences in study design, including whether aspirin was administered along with heparin, the thrombolytic agent that was administered, and variations in the time of diagnostic coronary arteriography. The Bleich and coworkers[355] and HART[356] studies showed a higher infarct-related artery patency rate in AMI patients treated with t-PA plus heparin than t-PA plus placebo (71 to 82 percent

TABLE 35-10 -- EFFECTS OF HEPARIN IN THE ABSENCE AND IN THE PRESENCE OF ASPIRIN: OVERVIEW OF 26 RANDOMIZED TRIALS

	TRIALS WITH ROUTINE ASPIRIN (68,000 PATIENTS: 93%ALSO HAD FIBRINOLYTIC AGENT)

vs. 43 to 52 percent infarct-related artery patency at 7 to 72 hours). The European Cooperative Study Group performed angiograms relatively late (i.e., 48 to 120 hours after t-PA) and still showed a somewhat greater patency rate of the infarct-related artery in the heparin-treated patients.[357] The TAMI-3 study suggested that in patients receiving aspirin plus t-PA no patency benefit was achieved by the immediate intravenous administration of heparin and that it could therefore be delayed for at least 60 to 90 minutes after thrombolysis.

Although a slightly better 90-minute infarct-related artery patency rate was observed in the OSIRIS (streptokinase plus aspirin) study in patients who received heparin versus placebo (82 percent patency vs. 72 percent), the GUSTO angiographic substudy[238] showed no benefit of intravenous heparin versus subcutaneous heparin in patients who received streptokinase plus aspirin with respect to 90-minute infarct-related artery patency (60 percent vs. 54 percent). Although preliminary observations suggested that extremely high doses of intravenous unfractionated heparin (300 U/kg) alone were associated with an increase in patency rates of the infarct-related artery, this was not confirmed on follow-up in a larger trial.[358] [359]

EFFECT ON LEFT VENTRICULAR THROMBUS.

Anticoagulant therapy significantly reduces the incidence of echocardiographically documented left ventricular thrombi.[360] These benefits are observed most prominently in patients with anterior MI, particularly those with a large area of wall motion abnormality. In the thrombolytic era, the incidence of left ventricular thrombi is reduced.[361] Although coadministration of heparin does not appear to affect the incidence of left ventricular thrombus formation in patients who receive thrombolytic therapy, the thrombi protrude less into the ventricular cavity when heparin is administered.

COMPLICATIONS OF ANTITHROMBOTIC THERAPY

Although heparin may induce thrombocytopenia through an immunological mechanism, this is seen only rarely, probably occurring in only 2 to 3 percent of patients.[362] The most serious complication of antithrombotic therapy is bleeding (especially intracranial hemorrhage) when thrombolytic agents are prescribed. Major hemorrhagic events occur more frequently in patients of low body weight, advanced age, female gender, marked prolongation of the activated partial thromboplastin time (> 90 to 100 seconds), and the performance of invasive procedures.[302] [303] [312] [363] Frequent monitoring of the activated partial thromboplastin time (facilitated by use of a bedside testing device) reduces the risk of major hemorrhagic complications in patients treated with heparin. However, during the first 12 hours after thrombolytic therapy, the activated partial thromboplastin time may be elevated from the thrombolytic agent alone (particularly if streptokinase is administered), making it difficult to accurately interpret the effects of a heparin infusion on the patient's coagulation status.

The optimal dose of unfractionated heparin as an adjunct to thrombolysis and its potential causative role in intracranial hemorrhage is unclear. Giugliano and associates examined the data from four sets of trials: (1) TIMI trials studying accelerated t-PA and intravenous heparin, (2) studies with t-PA and intravenous unfractionated heparin in which the heparin regimen was changed during the course of the trial, (3) phase III trials with accelerated dose t-PA and intravenous unfractionated heparin, and (4) trials of new single-bolus thrombolytics.[364] The intracranial hemorrhage rate in the angiographic TIMI trials was nearly double that in the nonangiographic TIMI trials (1.42 percent vs. 0.76 percent). Lower rates of intracranial hemorrhage were observed among studies of t-PA that reduced the dose of unfractionated heparin midtrial (TIMI 9A-9B, 1.87 percent-1.07 percent; GUSTO IIA-IIb, 0.92 percent-0.7 percent; TIMI 10B, 2.80 percent-1.16 percent). The rates of intracranial hemorrhage with accelerated-dose t-PA gradually increased from GUSTO I (0.72 percent) conducted in 1990-1993 to ASSENT 2 (0.94 percent) conducted in 1997-1998. Potential explanations for the increase in intracranial hemorrhage rates over time include enrollment of higher-risk patients and greater ascertainment of intracranial hemorrhage due to increased availability of imaging modalities such as CT and MRI. This trend in intracranial hemorrhage with t-PA was reversed in the InTIME-II trial, which used the lowest dose of heparin and most aggressive activated partial thromboplastin time monitoring and observed an intracranial hemorrhage rate of 0.64 percent. Observations regarding the benefit of a reduction in the dose of intravenous unfractionated heparin with t-PA also were extended to tenecteplase and laneteplase.

NEW ANTITHROMBOTIC AGENTS

Potential disadvantages of unfractionated heparin include dependency on antithrombin III for inhibition of thrombin activity, sensitivity to platelet factor 4, inability to inhibit clot-bound thrombin, marked interpatient variability in therapeutic response, and the need for frequent activated partial thromboplastin time monitoring.[365] In an effort to circumvent these disadvantages of unfractionated heparin, there has been interest in the development of novel antithrombotic compounds.

HIRUDIN.

The prototypical direct antithrombin hirudin was compared with heparin in several phase III trials: TIMI 9A, GUSTO IIA, and r-Hirudin for Improvement of Thrombolysis (HIT) III.[302] [303] [366] A feature common to all three trials was that they were stopped prematurely because of unacceptable rates of serious bleeding, particularly intracranial hemorrhage. This excessive rate of bleeding appeared to be attributable to high levels of anticoagulation in both the heparin and hirudin groups. Possible explanations for the unexpectedly high rates of bleeding were low estimates of the hemorrhagic risk of the doses of hirudin infused owing to the relatively small number of patients previously evaluated in phase II studies and attempts to push the heparin dose to achieve activated partial thromboplastin time levels in an effort to prevent reocclusion of successfully reperfused vessels.[302] After downward modification of the dose of antithrombins, the TIMI 9B and GUSTO IIb trials were initiated.[354] [367] The results of a prospectively planned meta-analysis of the TIMI 9B and GUSTO IIB data are shown in Table 35-11 .[368] Mortality rates were similar at 30 days in both trials. A generally consistent reduction in the rate of reinfarction was seen in the two trials, but this was of borderline statistical significance in the pooled data set: no statistically significant reduction

TABLE 35-11 -- GUSTO-TIMI METAANALYSIS: EVENTS WITHIN 30 DAYS

GROUP	NO.	MORTALITY		
		Heparin (%)	**Hirudin (%)**	**OR (95% CI)**

Modified from Antman EM, Bittl JA: Direct thrombin inhibitors. In Hennekens CH [ed]: Clinical Trials in Cardiovascular Disease: A Companion to Braunwald's Heart Disease. Philadelphia, WB Saunders, 1999, p 155.

was seen in the composite endpoint of death and nonfatal reinfarction.

By inhibiting the coagulation cascade upstream from thrombin, heparin has an advantage over the direct antithrombins because of its additional ability to decrease thrombin generation along with its ability to inhibit thrombin activity. Hirudin has a greater ability than heparin to decrease thrombin activity, but once the thrombin inhibitory capacity is exceeded (by virtue of the local concentration of hirudin), free thrombin may be generated in an explosive fashion. The net result of this balance of actions is that use of heparin or the direct antithrombins in a dose that is safe results in an equivalent decrement in thrombus formation in the infarct-related artery.

EFEGATRAN.

Efegatran, another direct antithrombin, was compared with unfractionated heparin as an adjunct to streptokinase in the ESCALAT study.[369] Efegatran was not superior to heparin in achieving coronary patency and was associated with high rates of bleeding.

HIRULOG.

It has been argued by the Hirulog Early Reperfusion/Occlusion (HERO) trial investigators that in order to truly expose the benefits of a direct antithrombin, it must be administered before a thrombolytic.[370] The ongoing HERO II trial is comparing hirulog with unfractionated heparin for reduction in mortality in patients receiving streptokinase.[371]

LOW-MOLECULAR-WEIGHT HEPARINS.

These are formed by controlled enzymatic or chemical depolymerization producing chains of glycosaminoglycans of varying length but with a mean molecular weight of approximately 5000 daltons.[365] Advantages of low-molecular-weight heparins include a stable, reliable anticoagulant effect, high bioavailability permitting administration by means of the subcutaneous route, and a high anti-factor Xa:anti-factor IIa ratio producing blockade of the coagulation cascade in an upstream location resulting in a marked decrement in thrombin generation. Preliminary observations suggest that low-molecular-weight heparins facilitate thrombolysis and prevent recurrent ischemic events.[372] [373] [374] Low-molecular-weight heparin preparations are now being examined in AMI patients both in the presence (AMISK, HART-2, ENTIRE-TIMI 23) and absence (TETAMI) of thrombolytic therapy.

Recommendations for Antithrombin Therapy

Given the pivotal role played by thrombin in the pathogenesis of AMI, antithrombotic therapy remains an important therapeutic intervention. All patients with an acute coronary syndrome should receive antiplatelet therapy (aspirin remains the recommended agent at this time). For patients who do *not* receive thrombolytic therapy, overviews of the available data indicate that heparin reduces mortality and morbidity from serious complications such as reinfarction and thromboembolism.[52] Therefore, in the absence of contraindications to anticoagulation we routinely use antithrombin therapy in *all* AMI patients presenting with ST segment elevation who are not candidates for thrombolysis and also prescribe it for AMI patients presenting without ST segment elevation. Although intravenous unfractionated heparin for 48 to 72 hours is an acceptable choice, given the greater ease of use we prefer subcutaneous injections of a low-molecular-weight heparin instead of either subcutaneous or intravenous unfractionated heparin for such patients.[375] In view of its superiority over unfractionated heparin[376] in patients with an acute coronary syndrome presenting without ST segment elevation, we prefer to prescribe enoxaparin, 1 mg/kg twice daily, for the duration of the hospitalization.[376] In patients at high risk for systemic emboli (large or anterior MI, atrial fibrillation, previous embolus, known left ventricular thrombus), intravenous unfractionated heparin is the preferred form of anticoagulation because of insufficient data to formulate recommendations for treatment with a low-molecular-weight heparin.

For patients receiving thrombolytic therapy with either streptokinase or anistreplase, there is no apparent mortality benefit of immediate intravenous heparin, and we do not recommend its use if those thrombolytics are prescribed. The only exception to this are patients who have another compelling indication for anticoagulation, such as a large anterior MI with a significant wall motion abnormality[360] or atrial fibrillation; in this case we generally use intravenous heparin administered to a target activated partial thromboplastin time of 50 to 70 seconds. The relative benefits of routine use of delayed (4 to 12 hours), high-dose (12,500 IU twice daily) subcutaneous heparin in patients receiving streptokinase remain unresolved.[377]

On the basis of the principle that t-PA is a more fibrin-specific lytic agent and the evidence that infarct-related artery patency rates are higher in patients receiving intravenous heparin adjunctively with t-PA, it is commonly recommended that with t-PA, intravenous heparin should be administered.[360] A similar line of reasoning can be applied to reteplase and tenecteplase. Nevertheless, the dose of heparin in thrombolytic-treated patients remains controversial. Lessons learned from clinical trials over the past 5 to 10 years suggest that the target activated partial thromboplastin time values should be lower than was previous practice; the current recommendation is an activated partial thromboplastin time of 50 to 70 seconds.[312] In addition, unfractionated heparin should be administered using a weight-based regimen with lower total maximum doses than was previous practice. An initial 60-unit/kg bolus (maximum 4000 units) should be followed by a maintenance infusion of 12 units/kg/hr (maximum 1000 units/hr).[52] It is important to emphasize that it is difficult to provide a heparin adjustment nomogram that is universally applicable because of varying responsiveness of the thromboplastin reagent used in local laboratories for measuring the activated partial thromboplastin time. The appropriate therapeutic range must be established for each local laboratory reagent, with nomograms developed corresponding to the defined therapeutic range. Whereas for patients with venous thrombosis or pulmonary embolism, the target activated partial thromboplastin time should be equivalent to a heparin level of 0.3 to 0.7 unit/ml by anti-factor Xa heparin levels, the therapeutic range should be lower in patients receiving thrombolytics and/or GPIIb/IIIa inhibitors. Although no large-scale studies are available, we are in agreement with the recommendation of Hochman and coworkers, who proposed a therapeutic range corresponding to anti-factor Xa levels of 0.14 to 0.34 unit/ml.[378]

Because of concern about the possibility of a rebound increase in thrombin generation and recurrent ischemia after cessation of heparin therapy, some clinicians have suggested a tapering of heparin infusions rather than abrupt discontinuation together with continued aspirin.[379]

Antiplatelet Therapy

As discussed earlier (see p. 1116), platelets play a major role in the thrombotic response to rupture of a coronary artery plaque[380] (see Fig. 35-3) . Platelets are activated in response to thrombolysis and platelet-rich thrombi are also more resistant to thrombolysis than are fibrin and erythrocyte-rich thrombi[381] (Fig. 35-31) . Thus, there is a sound scientific basis for inhibiting platelet aggregation in *all* AMI patients, regardless of whether a thrombolytic agent is prescribed. Comprehensive overviews of randomized trials of antiplatelet therapy have summarized the overwhelming evidence of the benefit of antiplatelet therapy for a wide range of vascular disorders.[14] [382] [383] [384] In patients at risk for AMI, patients with a documented prior AMI, and patients in the acute phase of an AMI, dramatic reductions (between 25 to 50 percent in relative risk) in mortality, nonfatal reduction of recurrent infarction, and nonfatal stroke are achieved by antiplatelet therapy[14] (Fig. 35-32) . Not unexpectedly, the *absolute* benefits are greatest in those patients at highest baseline risk.[14] Although several antiplatelet regimens have been evaluated, the agent most extensively tested has been aspirin, and this also is the drug for which the most compelling evidence of benefit exists.[274]

The ISIS-2 study was the largest trial of aspirin in AMI and provides the single strongest piece of evidence that aspirin reduces mortality in AMI[308] (see Fig. 35-25) . Of

interest, in contrast to the observations of a time-dependent mortality effect of thrombolytic therapy, the mortality reduction with aspirin was similar in patients treated within 4 hours (25 percent reduction in mortality), between 5 and 12 hours (21 percent reduction), and between 13 and 24 hours (21 percent reduction). There was an overall 23 percent reduction in mortality from aspirin in ISIS-2 that was largely additive to the 25 percent reduction in mortality from streptokinase, so that patients receiving both therapies experienced a 42 percent reduction in mortality.[308] The mortality reduction was as high as 53 percent in those patients who received both aspirin and streptokinase within 6 hours of symptoms. Of particular interest was the finding that the combination of streptokinase and aspirin reduced mortality from 23.8 to 15.8 percent (34 percent reduction) *without* increasing the risk of stroke or hemorrhage. Fibrinogen bound to the GPIIb/IIIa receptor on platelets interacts with leukocytes by means of the CD116/CD18 (Mac-1) receptor, providing a link between platelet activation and inflammatory processes in AMI.[385] [386]

Obstructive arterial thrombi that are platelet rich are resistant to thrombolysis and have an increased tendency to produce reocclusion after initial successful reperfusion in patients with ST segment elevation AMI.[47] [51A] [387] Despite the inhibition of cyclooxygenase by aspirin, platelet activation continues to occur through thromboxane A2-independent pathways, leading to platelet aggregation and increased thrombin formation. Activation of platelets by a variety of agonists results in the expression of functional receptors for fibrinogen and other ligands on the platelet surface--the GPIIb/IIIa receptor.[388] GPIIb/IIIa inhibition accelerates thrombolysis and prevents reocclusion in several animal species with experimentally induced platelet-rich coronary thromboses.[237] [389] Potential mechanistic explanations for the beneficial effects of GPIIb/IIIa inhibition when combined with thrombolytics center around important interactions between thrombolytics and platelets (see Fig. 35-31) . Platelets can be stimulated by thrombolytics (e.g., by the exposure of clot-bound thrombin). A narrowed lumen and a highly stenosed infarct-related artery generate high shear forces, a potent stimulus to platelet activation. Activated platelets may inhibit thrombolysis through the release of substances such as PAI-1, alpha$_2$ -plasminogen inhibitor, and factor XIII, which stabilize the clot and also enhance clot retraction, all features that make the clot more resistant to thrombolysis. Observations such as those just noted served as the foundation for testing the hypothesis that GPIIb/IIIa inhibition is a potent and safe addition to thrombolytic regimens and introduced the concept of *combination reperfusion* for STEMI.[390]

GPIIb/IIIa INHIBITION.

Reperfusion in AMI represents a potent stimulus for platelet activation and aggregation as well as activation of the coagulation cascade. Thus, GPIIb/IIIa inhibition has also been used to support PCI and stenting in AMI patients with the hopes of decreasing the risk of acute thrombotic occlusion of the infarct artery and also reducing the risk of death and cardiac ischemic events.[390]

Aspirin only partially inhibits platelet aggregation by inhibiting the thromboxane A_2 pathway. Thienopyridines such as ticlopidine and clopidogrel inhibit binding to the adenosine diphosphate receptor and also block adenosine diphosphate-dependent pathways for platelet activation. Platelet inhibition by aspirin and the thienopyridines blocks only a limited number of the pathways of platelet activation. Irrespective of the stimulus for platelet activation, the final common pathway is expression of the GPIIb/IIIa receptor on the platelet surface.[47] Therefore, direct inhibition of the GPIIb/IIIa receptor with intravenous agents such as abciximab, tirofiban, and eptifibatide has been studied in patients with AMI[391] (see Fig. 35-31) .

Figure 35-31 Pharmacological dissolution of thrombus in infarct-related artery. The three panels shown in this figure are schematic views of a longitudinal section of an infarct-related artery at the level of the obstructive thrombus. *A,* After rupture of a vulnerable plaque (bottom center), the coagulation cascade is activated, ultimately leading to the deposition of fibrin strands (black curvilinear arcs); platelets are activated and begin to aggregate (transition from flat discs representing inactive platelets to spiked ball elements representing activated and aggregating platelets). The mesh of fibrin strands and platelet aggregates obstructs flow (normally moving from left to right) in the infarct-related artery; this would correspond to TIMI grade 0 on angiography. Pharmacological reperfusion is a multipronged approach consisting of thrombolytics that digest fibrin, antithrombins that prevent the formation of thrombin and inhibit the activity of thrombin that is formed, and antiplatelet therapy. *B,* Full-dose thrombolysis results in incomplete reperfusion in about 50 percent of patients because of persistent platelet aggregates and fibrin strands. On angiography, this would correspond to TIMI flow grade 2. *C,* Combination reperfusion therapy with an intravenous glycoprotein IIb/IIIa inhibitor and reduced dose thrombolytic facilitates the rate and extent of thrombolysis. Prevention of platelet aggregates allows deeper penetration of the thrombolytic into the weakened clot structure, and full reperfusion (TIMI flow grade 3) is achieved. *(Courtesy of Luke Welles, The Exeter Group.)*

Figure 35-32 Antiplatelet therapy in myocardial infarction. Pooled data from randomized control trials (RCTs) of acute myocardial infarction indicate reductions in the rate of reinfarction, stroke (cerebrovascular accident [CVA]), and death in patients receiving antiplatelet therapy compared with control. Similarly, reductions in reinfarction, CVA, and death are seen in the pooled data from trials of secondary prevention with antiplatelet therapy after AMI. Based on the absolute event rates and the treatment effect for each endpoint, the benefit per 1000 patients treated with an antiplatelet agent can be calculated. *(Adapted from data in Antiplatelet Trialists' Collaboration: Collaborative overview of randomised trials of antiplatelet therapy: I. Prevention of death by myocardial infarction and stroke by prolonged antiplatelet therapy in various categories of patients. BMJ 308:81-106, 1994.)*

Pharmacological Reperfusion with Thrombolytic and GPIIb/IIIa Inhibition

Several clinical studies evaluated the combination of GPIIb/IIIa inhibitors and thrombolytics. The first series of trials combined full doses of thrombolytic agents with GPIIb/IIIa inhibitors. TAMI-8 was a dose-ranging study that demonstrated that 80 percent or more inhibition of platelet aggregation with the murine Fab fragments of a monoclonal antibody against the GPIIb/IIIa receptor (m7E3) could be accomplished safely.[392] TIMI grade 2 or 3 flow was seen in the infarct-related artery at follow-up angiography at day 5 in 56 percent of 9 control patients and 92 percent of 37 patients receiving m7E3 (p = 0.02). The IMPACT AMI trial demonstrated that patients receiving doses of eptifibatide achieving 50 to 60 percent of platelet aggregation in combination with full-dose t-PA showed an increased rate of TIMI grade 3 flow at 90 minutes (66 percent compared with 39 percent in the placebo group).[393] The streptokinase-eptifibatide trial combined full-dose streptokinase with ascending doses of eptifibatide. Although increased rates of TIMI grade 3 flow were observed in the combination arms, unacceptably high rates of major hemorrhage were also observed, leaving the investigators to conclude that eptifibatide could not be safely combined with full doses of streptokinase.[394] The Platelet Aggregation Receptor Antagonist Dose Investigation and Reperfusion Gain in Myocardial Infarction (PARADIGM) investigators compared different doses of lamifiban with either t-PA or streptokinase at standard doses.[395] Lamifiban was associated with improved ST segment resolution on continuous ECG monitoring, suggesting improved myocardial perfusion.

The combination of a reduced dose thrombolytic agent and GPIIb/IIIa inhibitor was tested in a subsequent series of trials. The TIMI 14 trial demonstrated that abciximab facilitated the rate and extent of thrombolysis, producing early, marked increases in TIMI 3 flow when combined with half the usual dose of t-PA (50 mg) (Fig. 35-33) (Figure Not Available) . [237] The improvement in epicardial reperfusion with reduced-dose t-PA occurred without an increase in major bleeding. Although modest improvements in TIMI 3 flow were seen when abciximab was combined with reduced doses of streptokinase, there was an increased risk of bleeding suggesting that even reduced doses of streptokinase could not be safely combined with a GPIIb/IIIa inhibitor.[237] In multivariate logistic regression analyses, after adjusting for infarct location and time from symptom onset to administration of the reperfusion regimen when compared with a full-dose thrombolytic, use of abciximab with a reduced-dose thrombolytic was associated with a significant increase

Figure 35-33 (Figure Not Available) Abciximab (Abx) facilitates the rate and extent of thrombolysis. Compared with patients receiving full-dose t-PA (100 mg), patients receiving abciximab and reduced-dose t-PA (50 mg) had a significantly higher rate of TIMI grade 3 flow at 60 minutes after initiation of reperfusion therapy. A significantly greater proportion of patients treated with the combination reperfusion regimen had lower frame counts (i.e., faster flow).

Figure 35-34 Improved myocardial perfusion with combination therapy. Abciximab in combination with reduced-dose thrombolytics increased the proportion of patients achieving complete ST segment resolution at 90 minutes and TIMI myocardial perfusion grade 2 or 3 at 90 minutes. TMPG = TIMI myocardial perfusion grade. *(Modified from data in de Lemos JA, Antman EM, Gibson CM, et al: Circulation. 2000;101:239-43 and Antman EM, Gibson CM, de Lemos JA, et al: Combination reperfusion therapy with abciximab and reduced dose reteplase: Results from TIMI 14. Eur Heart J, 2000, in press.)*

in the probability of achieving TIMI 3 flow and complete ST segment resolution at 90 minutes.[396] Improvement in ST segment resolution and TIMI myocardial perfusion grade was observed even among patients with normal epicardial flow, indicating that abciximab improves not only epicardial flow but also myocardial perfusion (Fig. 35-34) . [396A] Combination reperfusion therapy for STEMI is being studied in GUSTO IV, a large phase III trial that will provide data on the impact of abciximab with reduced doses of reteplase on clinical outcome.

The Strategies for Patency Enhancement in the Emergency Department (SPEED) and INTRO-AMI trials evaluated abciximab with low-dose reteplase and eptifibatide with low-dose t-PA, respectively.[397] [398] Both studies showed that combination therapy with intravenous GPIIb/IIIa inhibitors and reduced doses of lytics increased the proportion of patients achieving TIMI 3 flow by 60 to 90 minutes and also facilitated rescue PTCA procedures.

GPIIb/IIIa Inhibition to Support Catheter-Based Reperfusion

Interest in the use of intravenous GPIIb/IIIa inhibitors to support primary PTCA for AMI began with a small series of patients studied by Gold and colleagues and a subset of patients in the EPIC trial.[399] [400] Promising observations included improvements in TIMI 3 flow and a reduction in the primary composite endpoint of death, MI, or urgent revascularization in patients treated with abciximab and primary PTCA. Neumann and colleagues reported that improvement in papaverine-induced peak flow velocities and wall motion indices was seen in patients undergoing stenting for AMI when the procedure was supported by abciximab[260] (Fig. 35-35) . Schomig and associates reported that in patients with AMI, coronary stenting plus abciximab led to a greater degree of myocardial salvage and a better clinical outcome than did fibrinolysis with t-PA.[260A]

Abciximab given in the emergency department in patients awaiting primary angioplasty increases the probability of achieving TIMI grade 3 flow before the procedure. Compared with an 8 percent incidence of TIMI 3 flow in the GUSTO IIB trial in patients receiving heparin and aspirin, a time-dependent increase in the proportion of patients with TIMI 3 flow was seen with 18 percent in the Glycoprotein Receptor Antagonist Patency Evaluation (GRAPE) trial (45 minutes), 23 percent in the SPEED trial (60 minutes), and 32 percent in TIMI 14 (90 minutes).[401] The ReoPro and Primary PTCA Organization and Randomized Trial (RAPPORT) was a double-blind comparison of abciximab versus placebo.[402] The composite endpoint of death, MI, or urgent target vessel revascularization was reduced from 17.8 percent in the placebo group to 11.6 percent in the abciximab group, the benefit being driven almost entirely by a 64 percent reduction in the odds of requiring urgent target vessel revascularization when abciximab was used. Major bleeding occurred significantly more frequently in the abciximab group (16.6 percent vs. 9.5 percent, $p = 0.02$) mostly at the arterial access site. The Abciximab before Direct angioplasty and stenting in Myocardial Infarction Regarding Acute and Long-term follow-up (ADMIRAL) investigators randomized AMI patients with 12 hours of symptoms to either abciximab or placebo, which was administered in the ambulance, emergency department, or catheterization

Figure 35-35 Effect of abciximab on myocardial flow and contractile function. *A,* Plot of differences between 14-day follow-up and initial postinterventional study in basal flow velocity and papaverine-induced flow velocity in patients treated with primary percutaneous intervention for acute MI. The columns represent mean differences. *B,* Plot of differences between 14-day follow-up and initial postinterventional study in wall motion index and in number of cords with an infarct region. *(From Neumann FJ, Blasini R, Schmitt C, et al: Effect of glycoprotein IIb/IIIa receptor blockade on recovery of coronary flow and left ventricular function after the placement of coronary-artery stents in acute myocardial infarction. Figure 35-36 Glycoprotein IIb/IIIa receptor antagonists for failed rescue angioplasty. *A,* Before balloon angioplasty there is acute inferior MI with hampered flow and cardiogenic shock. A thrombus is seen in the middle of the right coronary artery (arrow). *B,* After balloon angioplasty, there is no reflow. Although proximal coronary artery is patent, smaller distal vessels are occluded (arrow). *C,* Approximately 10 minutes after abciximab administration (0.25-mg/kg bolus and a 10-mug/min infusion), coronary artery flow is restored to TIMI 3 flow. *(Reproduced from Ronner E, et al: IIb/IIIa receptor antagonists for failed rescue angioplasty. Circulation 101:214-215, 2000. Copyright 2000, American Heart Association.)*

laboratory as soon as AMI was diagnosed and before sheath insertion. The incidence of death/recurrent MI/urgent target vessel revascularization at 30 days was reduced by 46.5 percent with abciximab from 20.0 percent in the placebo group to 10.7 percent in the abciximab group ($p < 0.03$). [403] As was observed in the RAPPORT trial, the major benefit of abciximab was in reducing urgent target vessel revascularization.

The CADILLAC trial was designed to compare in a 2 × 2 factorial fashion the effects of balloon angioplasty (with or without abciximab) and stenting (with or without abciximab) in AMI patients presenting within 12 hours of symptoms. TIMI 3 flow was obtained after PTCA in about 95 percent of patients both with and without abciximab treatment. There was a slight reduction in the rate of TIMI 3 flow to 92.1 percent in the stent group without abciximab, which rose to 96.7 percent in patients receiving a stent in combination with abciximab. Use of abciximab was associated with reductions in target vessel revascularization and recurrent ischemia both in patients undergoing primary PTCA without stenting and those patients undergoing primary stenting.[404]

Recommendations for Antiplatelet Therapy

Some uncertainty about the optimal dose of aspirin for acute treatment of AMI remains. In general, high doses of aspirin are not more effective than lower doses but are more likely to provoke gastrointestinal side effects. However, adequate cyclooxygenase inhibition (and reduction in thromboxane A_2 production) takes several days to accomplish with less than 75 mg of aspirin, and loading doses of 160 to 325 mg (preferably chewed) are therefore recommended for all AMI patients without a history of aspirin allergy whether they present with ST segment elevation or not and whether they undergo reperfusion with thrombolytics or PTCA or are treated with a more conservative medical regimen (see Fig. 35-17) . Active peptic ulcer disease is a relative contraindication to antiplatelet therapy. For patients with severe nausea and vomiting, aspirin suppositories (325 mg) can be used. Aspirin should be continued indefinitely in patients with AMI.

In patients with AMI who cannot tolerate aspirin, clopidogrel, 75 mg orally, is an acceptable alternative. Administration of intravenous GPIIb/IIIa inhibitors cannot be recommended as a routine measure after full-dose thrombolytic therapy has been given. However, as reviewed earlier they are useful to support primary PCI (Fig. 35-36) .[405] [406] [407]

Hospital Management

CORONARY CARE UNITS

Deaths from primary ventricular fibrillation in AMI have been prevented because the CCU allows continuous monitoring of cardiac rhythm by highly trained nurses with the authority to initiate immediate treatment of arrhythmias in the absence of physicians and because of the specialized equipment (defibrillators, pacemakers) and drugs available. Although all of these benefits can be achieved for patients scattered throughout the hospital, the clustering of patients with AMI in the CCU has greatly improved the efficient use of the trained personnel, facilities, and equipment. In recent years, with increasing emphasis on hemodynamic monitoring and treatment of the serious complications of AMI with such modalities as thrombolytic therapy, afterload reduction, and intraaortic balloon counterpulsation, the CCU has assumed even greater importance.[185] Improvements in the 30-day survival of elderly patients with AMI can be traced to advances in therapy delivered in CCUs.[408] As interventional strategies including thrombolytic therapy and acute coronary angioplasty are used more routinely in AMI patients, facilities in which patients may undergo diagnostic and therapeutic angiographic procedures are being integrated into the CCU structure.

At the same time, the value of CCUs for patients with uncomplicated AMI has been questioned and restudied.[185] With increasing attention directed to the limitation of resources and to the economic impact of intensive care, there have been efforts to select patients for whom hospitalization in a CCU would likely be of benefit. The ECG, on presentation, particularly in conjunction with previous tracings[409] and an immediate general clinical assessment, can be useful both for predicting which patients will have the diagnosis of AMI confirmed and identifying low-risk patients who may require less intensive care.[55] Among patients with a history of typical chest pain but with a normal ECG in the emergency department, less than 20 percent ultimately have an AMI on that admission, and less than 1 percent develop any significant complication. Thus, a patient with a normal ECG may not require admission to a full-fledged CCU. Careful analysis of the quality of pain may help identify such low-risk patients as well. Patients without a history of angina pectoris or MI presenting with pain that is sharp or stabbing and pleuritic, positional, or reproduced by palpation of the chest wall are extremely unlikely to have an AMI. Computer-guided decision protocols are being developed to aid clinicians in identifying those AMI patients who require admission to the CCU as opposed to a less intensive hospital ward.[174]

Contemporary CCUs typically have equipment available

for noninvasive monitoring of single or multiple ECG leads, cardiac rhythm, ST segment deviation, arterial pressure, and arterial oxygen saturation. Computer algorithms for detection and analysis of arrhythmias are superior to visual surveillance by skilled CCU staff. However, even the most sophisticated ECG monitoring systems are susceptible to artifacts due to patient movement or noise on the signal from poor skin preparation when monitoring electrodes are applied.[185] Noninvasive monitoring of arterial blood pressure using a sphygmomanometric cuff that undergoes cycles of inflation and deflation at programmed intervals is suitable for the majority of patients admitted to a CCU. Invasive arterial monitoring is preferred in patients with a low output syndrome under circumstances in which inotropic therapy is initiated for severe left ventricular failure.[185]

The CCU remains the appropriate hospital unit for patients with complicated infarctions (e.g., hemodynamic instability, recurrent arrhythmias) and those patients requiring intensive nursing care for devices such as an intraaortic balloon pump.[44] For patients with a low risk of mortality from AMI (Fig. 35-27) , the clinician should consider admission to an intermediate care facility (see later) equipped with simple ECG monitoring and resuscitation equipment.[52] This strategy has been shown to be cost-effective and may reduce CCU utilization by one third, shorten hospital stays, and have no deleterious effect on patients' recovery. Intermediate-care units for low-risk AMI patients may also be appealign to patients who stand to gain little benefit from the high staffing, intense activity, and elaborate technology available in current CCUs (with their attendant high costs) and who may be disturbed by that activity and equipment.[410] [411]

RECOMMENDATIONS FOR ADMISSION TO THE CCU.

The following should be considered:

1. Patients with clear-cut AMI, presenting within 12 to 24 hours of symptoms, should, in general, be admitted to a CCU. A possible exception are patients who are taken directly from the emergency department to the catheterization laboratory where they undergo a successful and uncomplicated revascularization procedure. Such patients may be considered for admission to an intermediate-care unit rather than the CCU.
2. Patients with severe unstable angina should also be admitted to the CCU, particularly if episodes of chest pain occur at rest, high doses of intravenous nitroglycerin (e.g.,
   300 mg/min) are required to relieve chest pain, or frequent adjustments of intravenous nitroglycerin infusions are required because of fluctuating symptoms and hemodynamic status (see Chap. 36) .
3. Once an AMI is ruled out (ideally by 12 hours) and symptoms are controlled with oral or topical pharmacological agents, discharge from the CCU should be considered.
4. AMI patients with an uncomplicated status, such as those without a history of previous infarction, persistent ischemic-type discomfort, congestive heart failure, hypotension, heart block, or hemodynamically compromising ventricular arrhythmias, may be safely transferred out of the CCU within 24 to 36 hours.
5. In patients with a complicated AMI, the duration of the CCU stay should be dictated by the need for "intensive" care, that is, hemodynamic monitoring, close nursing supervision, intravenous vasoactive drugs, and frequent changes in the medical regimen.

General Measures for Management of AMI

The CCU staff must be sensitive to patient concerns about mortality, prognosis, and future productivity. A calm, quiet atmosphere and the "laying on of hands" with a gentle but confident touch help allay anxiety and reduce sympathetic tone, ultimately leading to a reduction in hypertension, tachycardia, and arrhythmias.[185] To reduce the risk of nausea and vomiting early after infarction and to reduce the risk of aspiration, during the first 4 to 12 hours after admission patients should receive either nothing by mouth or a clear liquid diet (Table 35-12) (Table Not Available) . Subsequently, a diet with 50 to 55 percent of calories from complex carbohydrates and up to 30 percent from mono- and unsaturated fats should be given. The diet should be enriched in foods that are high in potassium, magnesium, and fiber but low in sodium (see Table 35-12) (Table Not Available) .

The results of laboratory tests obtained in the CCU should be scrutinized for any derangements potentially contributing to arrhythmias, such as hypoxemia, hypovolemia, disturbances of acid-based balance or of electrolytes, and drug toxicity. Oxazepam, 15 to 30 mg orally four times a day, is useful to allay the anxiety that is common in the first 24 to 48 hours (see Table 35-12) (Table Not Available) . Delirium may be provoked by medications frequently used in the CCU, including antiarrhythmic drugs, histamine-2 blockers, narcotics, and beta blockers. Potentially offending agents should be discontinued in patients with an abnormal mental status. Haloperidol, a butyrophenone, may be used safely in patients with AMI beginning with a dose of 2 mg intravenously for mildly agitated patients and 5 to 10 mg for progressively more agitated patients. Hypnotics, such as temazepam, 15 to 30 mg, or an equivalent, should be provided as needed for sleep. Dioctyl sodium sulfosuccinate, 200 mg daily, or another stool softener should be used to prevent constipation and straining (see Table 35-12) (Table Not Available) .

"Coronary precautions" that do *not* appear to be supported by evidence from clinical research include the avoidance of iced fluids,[412] hot beverages, caffeinated

beverages, rectal examinations, back rubs, and assistance with eating.[185]

PHYSICAL ACTIVITY.

In the absence of complications, patients with AMI need not be confined to bed for more than 12 hours and, unless they are hemodynamically compromised, they may use a bedside commode shortly after admission (see Table 35-12) (Table Not Available) . Progression of activity should be individualized depending on the patient's clinical status, age, and physical capacity.

In patients without hemodynamic compromise, early ambulation (including dangling feet on the side of the bed,

TABLE 35-12 -- SAMPLE ADMITTING ORDERS

(Not Available)

From 1999 Updated ACC/AHA AMI Guidelines (Web version), p 54. Severe chronic obstructive pulmonary disease

sitting in a chair, standing, and walking around the bed) does not cause important changes in heart rate, blood pressure, or pulmonary wedge pressure. Although heart rate increases slightly (usually by less than 10 percent), pulmonary wedge pressures fall slightly as the patient assumes the upright posture for activities. Early ambulatory activities are rarely associated with any symptoms; when symptoms do occur, they generally are related to hypotension. Thus, when Levine and Lown proposed the "armchair" treatment of AMI in 1952, they were undoubtedly correct that stress to the myocardium is less in the upright position.[413] As long as blood pressure and heart rate are monitored carefully, early ambulation offers considerable psychological and physical benefit without any clear medical risk.

The Intermediate Coronary Care Unit

AMI patients are at risk for late in-hospital mortality from recurrent ischemia or infarction, hemodynamically significant ventricular arrhythmias, and severe congestive heart failure after discharge from the CCU. Therefore, continued surveillance in intermediate CCUs (also called step-down units) is justifiable. Risk factors for mortality in the hospital after discharge from the CCU include significant congestive heart failure, evidenced by persistent sinus tachycardia for more than 2 days and rales greater than one third of the lung fields; recurrent VT and ventricular fibrillation; atrial fibrillation or flutter while in the CCU; intraventricular conduction delays or heart block; anterior location of infarction; and recurrent episodes of angina with marked ST segment abnormalities at low activity levels. Although it has not been shown rigorously, it is likely that a reduction in late hospital mortality can be achieved with the use of intermediate CCUs, which permits prolonged continuous monitoring of the ECG and prompt, effective treatment of ventricular fibrillation and other serious arrhythmias.

The availability of intermediate care units may also be helpful in identifying those patients who remain free of complications and are suitable candidates for early discharge from the hospital. Aggressive reperfusion protocols with angioplasty or thrombolytics can reduce length of hospital stay.[322] In patients who are believed to have undergone successful reperfusion, the *absence* of early sustained ventricular tachyarrhythmias, hypotension, or heart failure, coupled with a well-preserved LV ejection fraction, predicts a low risk of late in-hospital complications.[414] Such patients are suitable candidates for discharge from the hospital in less than 5 days from the onset of symptoms,[410] although decisions regarding the length of stay must also factor in the need to optimize medication dosages and the patient's psychological state and support systems at home.[411]

After AMI, patients are often eager for information, in need of reassurance, confused by misinformation and prior impressions, capable of counterproductive denial, and simply frightened.[185] Intermediate care facilities provide ideal settings and ample opportunities to begin the rehabilitation process.[52] [414b] The capacity for the early detection of problems after AMI and the social and educational benefits of grouping such patients together strongly argue for continued utilization of intermediate CCUs. Furthermore, the economic advantage of grouping such patients together for sharing of skilled personnel and resources outweighs any questions raised by the lack of a clear consensus regarding reduced mortality. An additional potential advantage is the facilitation of patient education in a group setting with lectures and audiovisual programs.

PHARMACOLOGICAL THERAPY

The rationale and recommendations for initiation of several pharmacological measures to treat AMI in the emergency department have been reviewed previously (see p. 1139 ; see Fig. 35-18) . The early use of beta blockers, ACE inhibitors, calcium antagonists, nitrates, and other therapies such as magnesium and glucose-insulin-potassium is discussed in this section. Secondary prevention with some of these agents is discussed subsequently (see p. 1203).

Beta Blockers

The effects of beta blockers on AMI can be divided into those that are immediate, when the drug is given very early in the course of infarction, and long term (secondary prevention), when the drug is initiated sometime after infarction. The intravenous administration of beta-adrenoceptor blockers reduces cardiac index, heart rate, and blood pressure.[186] The net effect is a reduction in myocardial oxygen consumption per minute and per beat. Favorable effects of acute intravenous administration of beta-adrenoceptor blockers on the balance of myocardial oxygen supply and demand are reflected in reductions in chest pain, in the proportion of patients with threatened infarction who actually evolve AMI, and in the development of ventricular arrhythmias.[415] Because beta-adrenoceptor blockade diminishes circulating levels of free fatty acids by antagonizing the lipolytic effects of catecholamines and because elevated levels of fatty acids augment myocardial oxygen consumption and probably increase the incidence of arrhythmias, these metabolic actions of beta-blocking agents may also be beneficial to the ischemic heart.

Objective evidence of beneficial effects of beta blockers in AMI has been reported using the precordial ST segment mapping technique. Acute beta blockade probably reduces infarct size in AMI. Reduction in release of cardiac enzymes with beta blockade[416] is suggestive of a smaller infarct, as is the preservation of R waves and reduction in the development of Q waves.

At least 29 randomized beta blocker trials involving more than 28,970 patients have been undertaken. Intravenous, followed by oral, beta-blocker therapy is associated with about a 13 percent relative reduction in the risk of mortality[417] (Fig. 35-37) . Although antagonism of sympathetic stimulation to the heart might be expected to exacerbate pulmonary edema in patients with occult heart failure, usually only small changes in pulmonary capillary wedge pressure occur when the drug is used in patients with AMI. Thus, in appropriately selected patients (Table 35-13) (Table Not Available) the

Figure 35-37 Effect of beta blockers on mortality in myocardial infarction. The relative risk of mortality is reduced with beta blockers both during the acute phase of treatment and when prescribed as secondary prevention after acute myocardial infarction. *(Adapted from data in Chae CU, Hennekens CH: Beta blockers. In Hennekens CH [ed]: Clinical Trials in Cardiovascular Disease: A Companion to Braunwald's Heart Disease. Philadelphia, WB Saunders, 1999, p 84.)*

TABLE 35-13 -- CONTRAINDICATIONS TO BETA-ADRENOCEPTOR BLOCKER THERAPY IN ACUTE MYOCARDIAL INFARCTION

(Not Available)

From 1999 Updated ACC/AHA AMI Guidelines (Web version), p 109.

benefits just noted occur at a cost of about a 3 percent incidence of provocation of congestive heart failure or complete heart block and a 2 percent incidence of the development of cardiogenic shock.

Because reduction of infarct size in AMI patients treated with beta blockers is likely to occur only with early treatment (4 hours from the onset of pain), investigators have sought other explanations for the reduction in the mortality in the acute phase that has been observed. Intriguing observations from the ISIS-1 trial raise the

possibility that a reduction in the development of cardiac rupture or electromechanical dissociation during the first day is achieved with early beta blockade.[418]

In the TIMI-II trial the addition of a beta blocker (metoprolol) to thrombolytic therapy was studied.[349] Although recurrent ischemia and reinfarction were reduced by immediate intravenous versus delayed use of metoprolol, mortality was not reduced nor was ventricular function improved. Thus, immediate intravenous beta blockade, although clinically beneficial, may not enhance salvage of myocardium in the setting of early reperfusion but may confer clinical benefit by means of its antiischemic effect.[213]

Substantial proportions of elderly patients who are hospitalized with AMI and are ideal candidates for early beta blocker therapy do not receive this treatment.[419] Compared with elderly patients who receive early beta blockade in AMI, those who do not receive beta blockade are older, more likely to be women, and less likely to be white. Elderly patients who receive early beta-blocker therapy have significantly lower in-hospital mortality rates than those who do not receive beta blockers (5.1 percent compared with 8.1 percent; *p*
0.001).

RECOMMENDATIONS.

Given the overwhelming evidence of benefits of early blockade in AMI, patients without a contraindication who can be treated within 12 hours of the onset of infarction, irrespective of administration of concomitant thrombolytic therapy or performance of primary angioplasty, should receive beta blockers. We do not draw a distinction between AMI patients presenting with ST segment elevation and those presenting without ST segment elevation and therefore consider early beta blockade applicable across the entire spectrum of acute coronary syndromes. For patients presenting within 12 hours of the onset of symptoms or for those presenting with overactivity of the sympathetic nervous system, we prefer to begin beta-blocker therapy intravenously. For patients presenting after 12 hours, especially if there is little sympathetic overactivity, it is our practice to begin beta-blocker therapy orally. Beta blockers are especially helpful in patients in whom infarction is complicated by persistent or recurrent ischemic pain, by progressive or repetitive serum enzyme elevations suggestive of infarct extension, or by tachyarrhythmias early after the onset of infarction. If adverse effects of beta blockers develop or if patients present with complications of infarction that are contraindications to beta blockade such as heart failure or heart block, the beta blocker should be withheld. Unless there are contraindications (see p. 1243), beta blockade probably should be continued in patients who develop AMI.

Selection of Beta Blocker.

Favorable effects have been reported with atenolol, timolol, and alprenolol; these benefits probably occur with propranolol and with esmolol, an ultra-short-acting agent, as well. In the absence of any favorable evidence supporting the benefit of agents with intrinsic sympathomimetic activity, such as pindolol and oxprenolol, and with some unfavorable evidence for these agents in secondary prevention,[420] beta blockers with intrinsic sympathomimetic activity probably should not be chosen for treatment of AMI. Occasionally, the clinician may wish to proceed with beta-blocker therapy even in the presence of relative contraindications, such as a history of mild asthma, mild bradycardia, mild heart failure, or first-degree heart block. In this situation, a trial of esmolol may help determine whether the patient can tolerate beta blockade.[188] [420] Because the hemodynamic effects of this drug, with a half-life of 9 minutes, disappear in less than 30 minutes, it offers considerable advantage over longer-acting agents when the risk of a beta blocker complication is relatively high.

ACE Inhibitors

In 1992, with the publication of the Survival and Ventricular Enlargement (SAVE) trial,[421] ACE inhibitors were established as an important addition to the list of treatments for AMI. The rationale for their use includes experimental and clinical evidence of a favorable impact on ventricular remodeling, improvement in hemodynamics, and reductions in congestive heart failure.[78] [191] There is now unequivocal evidence from randomized, placebo-controlled mortality trials that ACE inhibitors reduce death from AMI.[199B] These trials may be grouped into two categories. The first *selected* AMI patients for randomization, based on features indicative of increased mortality such as left ventricular ejection fraction less than 40 percent,[421] clinical signs and symptoms of congestive heart failure,[422] anterior location of infarction,[423] and abnormal wall motion score index[424] (Fig. 35-38) . The second group were *unselective* trials that randomized all patients with AMI provided they had a minimum systolic pressure of approximately 100 mm Hg (ISIS-4,[425] GISSI-3,[426] Cooperative North Scandinavian Enalapril Survival Study [CONSENSUS] II,[427] and Chinese Captopril Study[428]) (Fig. 35-39) . With the exception of the Survival

Figure 35-38 Effect of angiotensin-converting enzyme inhibitors on mortality after myocardial infarction: Results from the long-term trials. *(From Flather MD, Pfeffer MA: Angiotensin-converting enzyme inhibitors. of Myocardial Infarction Long-term Evaluation (SMILE) trial,[423] all of the selective trials initiated ACE inhibitor therapy between 3 and 16 days after AMI and maintained it for 1 to 4 years, whereas the unselective trials all initiated treatment within the first 24 to 36 hours and maintained it for only 4 to 6 weeks.

A consistent survival benefit was observed in all of the trials already noted, except for CONSENSUS II, the only study that used an intravenous preparation early in the course of AMI.[427] Estimates of the mortality benefit of ACE inhibitors in the unselective, short duration of therapy trials was 5 per 1000 patients treated.[429] [430] Analysis of these unselective short-term trials indicates that approximately one third of the lives saved occurred within the first 1 to 2 days. Certain subgroups such as those with anterior infarction showed proportionately greater benefit from early administration (11 lives saved/1000) of ACE inhibitors. Not unexpectedly, greater survival benefits of 42 to 76 lives saved per 1000 patients treated were obtained in the *selective,* long duration of therapy trials. Of note, there was generally a 20 percent reduction in the risk of death attributable to ACE inhibitor treatment in the selective trials. The mortality reduction with ACE inhibitors is accompanied by significant reductions in the development of congestive heart failure, supporting the underlying pathophysiological rationale for administering this class of drugs in AMI.[421] [422] [424] [426] In addition, some data suggest that ischemic events, including recurrent infarction and the need for coronary revascularization, can also be reduced by chronic administration of ACE inhibitors after an AMI.[431]

The mortality benefits of ACE inhibitors are additive to those achieved with aspirin and beta blockers.[421] [426] Thus, ACE inhibitors should not be considered a substitute for these other therapies with proven benefit in AMI patients.[199B] The benefits of ACE inhibition appear to be a class effect because mortality and morbidity have been reduced by several agents. However, to replicate these benefits in clinical practice, physicians should select a specific agent and prescribe the drug according to the protocols used in the successful clinical trials reported to date.

The major *contraindications* to the use of ACE inhibitors in AMI include hypotension in the setting of adequate preload, known hypersensitivity, and pregnancy. Adverse reactions include hypotension, especially after the first dose, and intolerable cough with chronic dosing; much less commonly angioedema can occur (see Chap. 18) .

The benefits of an alternative method of pharmacological inhibition of the renin-angiotensin system by angiotensin-II receptor antagonists is being evaluated in the VALIANT[431A] and Optimal Therapy in Myocardial Infarction with the Angiotensin II Antagonist Losartan, (OPTIMAAL) trials.[432]

RECOMMENDATIONS.

After administration of aspirin and initiating reperfusion strategies and, where appropriate, beta blockade, *all* AMI patients should be considered for ACE inhibition therapy. Although there is little disagreement that high-risk AMI patients (elderly, anterior infarction, prior infarction, Killip class II or greater, and asymptomatic patients with evidence of depressed global ventricular function on an imaging study) should receive life-long treatment with ACE inhibitors,[191] [433] therapy to a broader group of patients has also been proposed based on the pooled results of the unselective mortality trials.[425] Considering all the available data, we favor a strategy of an initial trial of oral ACE inhibitors in all AMI patients with congestive heart failure as well as in hemodynamically stable patients with ST segment elevation or left bundle branch block, commencing within the first 24 hours.[430] [434] Recommendations for chronic use of ACE inhibitors are discussed on p. 1203 .

Nitrates

Sublingual nitroglycerin very rarely opens occluded coronary arteries. However, in patients with AMI the potential for reductions in ventricular filling pressures, wall

tension, and cardiac work coupled with improvement in coronary blood flow, especially in ischemic zones, and antiplatelet effects make nitrates a logical and attractive pharmacological intervention in AMI.[435] [436]

In patients with AMI, the administration of nitrates reduces pulmonary capillary wedge pressure and systemic arterial pressure, left ventricular chamber volume, infarct size, and the incidence of mechanical complications. As with other interventions to spare ischemic myocardium in AMI, intravenous nitroglycerin appears to be of greatest benefit in patients treated earliest after the onset of symptoms.

CLINICAL TRIAL RESULTS.

In the prethrombolytic era, 10 randomized trials of acute administration of intravenous nitroglycerin (or nitroprusside, another nitric oxide donor) collectively enrolled 2042 patients. A meta-analysis of these trial results showed a reduction in mortality of 35 percent associated with nitrate therapy.

In the thrombolytic era two megatrials of nitrate therapy have been conducted--GISSI-3[426] and ISIS-4.[425] In GISSI-3, there was no independent effect of nitrates on short-term mortality.[426] Similarly, in ISIS-4, no effect of a mononitrate on 35-day mortality was observed. A pooled analysis of over 80,000 patients treated with nitrate-like preparations intravenously or orally in 22 trials revealed a mortality rate of 7.7 percent in the control group, which was reduced to 7.4 percent in the nitrate group. These data are consistent with a small treatment effect of nitrates on mortality such that three to four fewer deaths would occur for every 1000 patients treated.[425]

NITRATE PREPARATIONS AND MODE OF ADMINISTRATION.

Intravenous nitroglycerin can be administered safely to patients with evolving MI as long as the dose is titrated carefully to avoid induction of reflex tachycardia or systemic arterial hypotension. Patients with inferior wall infarction are particularly sensitive to an excessive fall in preload, particularly if concurrent right ventricular infarction is present.[52] In such cases nitrate-induced venodilatation could impair cardiac output and reduce coronary block flow, thus worsening myocardial oxygenation rather than improving it.

A useful regimen employs an initial infusion rate of 5 to 10 mug/min with increases of 5 to 20 mug/min until the mean arterial blood pressure is reduced by 10 percent of its baseline level in normotensive patients and by 30 percent for hypertensive patients, but in no case below a systolic pressure of 90 mm Hg. Alternatively, nitroglycerin may be administered as a sustained-release oral preparation (30 to 60 mg/d) or as an ointment (1 to 3 inches every 6 to 8 hours for patients with a systolic pressure greater than 120 mm Hg). Nitroglycerin can also be given sublingually at doses of 0.3 to 0.6 mg. This route may be more hazardous because the rate of absorption is difficult to control and arterial pressure may decline precipitously.

ADVERSE EFFECTS.

Clinically significant methemoglobinemia has been reported to occur during administration of intravenous nitroglycerin. Although uncommon, this problem is seen when unusually large doses of nitrates are administered. It is important not only for its potential to cause symptoms of lethargy and headache but also because elevated methemoglobin levels can impair the oxygencarrying capacity of blood, potentially exacerbating ischemia. Dilatation of the pulmonary vasculature supplying poorly ventilated lung segments may produce a ventilation-perfusion mismatch.

Tolerance to intravenous nitroglycerin (as manifested by increasing nitrate requirements) develops in many patients, often as soon as 12 hours after the infusion is started. Despite the theoretical and demonstrated benefit of sulfhydryl agents in diminishing tolerance, their use has not become widespread.

RECOMMENDATIONS.

Nitroglycerin is indicated for the relief of persistent pain and as a vasodilator in patients with infarction associated with left ventricular failure. In the absence of recurrent angina or congestive heart failure, we do not routinely prescribe them in AMI patients. Higher-risk patients such as those with large transmural infarctions, especially of the anterior wall, have the most to gain from nitrates in terms of reduction of ventricular remodeling, and we therefore routinely use intravenous nitrates for 24 to 48 hours in such patients. There is no clear benefit to empirical long-term cutaneous or oral nitrates in the asymptomatic patient, and we therefore do not prescribe nitrates beyond the first 48 hours unless angina or ventricular failure is present.

Calcium Antagonists

Despite sound experimental and clinical evidence of an antiischemic effect, calcium antagonists have *not* been found to be helpful in the acute phase of AMI; concern has been raised in several systematic overviews about an increased risk of mortality when they are prescribed on a routine basis to AMI patients.[186] [437] [438] Perhaps in response to the lack of compelling data showing a beneficial effect and concerns about the risk of excess mortality coupled with more convincing evidence of benefit from aspirin and beta blockers, many clinicians have decreased their use of calcium antagonists in the setting of AMI.[26] [439] A distinction should be made between the dihydropyridine type of calcium antagonists (e.g., nifedipine) and the nondihydropyridine calcium antagonists (e.g., verapamil and diltiazem).[437]

NIFEDIPINE.

In multiple trials involving a total of over 5000 patients, the immediate-release preparation of nifedipine has not shown any reduction in infarct size, prevention of progression to infarction, control of recurrent ischemia, or lowering of mortality. When trials of the immediate-release form of nifedipine are pooled in a meta-analysis, evidence suggests a dose-related increased risk of in-hospital mortality (especially above 80 mg of nifedipine),[438] [440] although post-hospital mortality does not appear to be increased in nifedipine-treated patients.[441] Nifedipine does not appear to be helpful in conjunction with either thrombolytic therapy or beta blockade.[442] A potential mechanism by which the immediate-release form of nifedipine may be harmful in AMI is coronary hypoperfusion due to an abrupt fall in systolic pressure from peripheral vasodilatation. The abrupt fall in arterial pressure may also provoke a reflex action of the renin-angiotensin system and sympathetic discharge that produces tachycardia. Thus, we do not recommend use of immediate-release nifedipine early in the treatment of AMI. No trials of the sustained-release preparations of nifedipine in AMI have been reported to date.

VERAPAMIL AND DILTIAZEM.

When administered during the acute phase of AMI, these drugs have not had any demonstrated favorable effect on infarct size or other important endpoints in patients with AMI, with the exception of control of supraventricular arrhythmias.[443] Although the possibility has been raised that verapamil and diltiazem in the first few days after AMI may be helpful in preventing reinfarction in patients with non-Q-wave infarction,[443] [444] [445] the data supporting this contention are not statistically robust and require further evaluation in future studies. Subgroup analyses of the Multicenter Diltiazem Postinfarction Trial (MDPIT) and the Danish Verapamil Infarction Trial (DAVIT)-II with both diltiazem and verapamil have suggested that mortality is reduced in patients free of heart failure in the CCU.[446] [447] These subgroup analyses must be interpreted with caution because in the MDPIT study about 50 percent of patients in the placebo and diltiazem groups were also receiving beta blockers that may have contributed to the observed mortality reduction[446] ; in the DAVIT-II study patients with an indication for beta blockers were excluded from the trial.[447] Furthermore, both the MDPIT and DAVIT-II studies were conducted in an era when aspirin, ACE inhibitors, and early use of coronary angiography for recurrent ischemia were not as common as they are now. The Incomplete Infarction Trial of European Research Collaborators Evaluating Prognosis Post-Thrombolysis (INTERCEPT) trial is testing the hypothesis that sustained-release diltiazem will decrease death and cardiac ischemic events in patients receiving thrombolytic therapy for a first AMI.[448]

RECOMMENDATIONS.

Based on the available data, we do *not* recommend the routine use of either verapamil or diltiazem in AMI regardless of whether it is believed that the patient is suffering from a Q-wave or non-Q-wave infarction.[449] Verapamil and diltiazem may be given for relief of ongoing ischemia or slowing of a rapid ventricular response in atrial fibrillation in patients for whom beta blockers are ineffective or contraindicated.[52] Their use should be avoided in patients with Killip class II or greater hemodynamic findings.

MAGNESIUM

Patients with AMI may have a total body deficit of magnesium because of a low dietary intake, advanced age, or prior diuretic use. They may also acquire a functional deficit of available magnesium due to trapping of free magnesium in adipocytes, because soaps are formed when free fatty acids are released by catecholamine-induced lipolysis with the onset of infarction. Myocardial and urinary losses of magnesium that occur during AMI may increase a patient's magnesium

requirement. The magnesium cation serves as a critical cofactor in over 300 intracellular enzymatic processes, including several that are integrally involved in mitochondrial function, energy production, maintenance of trans-sarcolemmal ionic gradients, cell volume control, and resting membrane potential.[450] Experimental models of AMI in at least four different animal species have shown that supplemental administration of magnesium before coronary occlusion, during occlusion, coincident with reperfusion, or for a short time interval (15 to 45 minutes) after reperfusion reduces infarct size and prevents myocardial stunning due to reperfusion injury.[208] However, delayed administration of magnesium beyond a very short interval (15 to 60 minutes) after reperfusion is no longer effective in reducing myocardial damage.[208]

Since 1984, several trials of routine supplemental administration of intravenous magnesium in patients with suspected AMI have been conducted. Synthesis of all the trials published before ISIS-4 suggests that the treatment effect of magnesium is greatest in patients at highest risk of mortality and decreases progressively as the mortality risk in the control population decreases.[208] Despite its large sample size, the negative results for magnesium in ISIS-4 do not conclusively exclude benefits of magnesium in AMI. The control group mortality was 7.2 percent in ISIS-4 compared with 7.6 percent in the magnesium group.[425] Given the low control group mortality rate in ISIS-4, the lack of a beneficial effect of magnesium was not unexpected. In addition, ISIS-4 required that acute phase treatment for MI, including lytic therapy, be administered before randomization and that study drugs such as magnesium be administered beyond the "early" lytic phase (e.g., first hour). Because the time for randomization to actual administration of magnesium was not recorded in ISIS-4, the actual relationship between reperfusion and timing of administration of magnesium cannot be determined with certainty but the available information suggests that magnesium was administered relatively late in ISIS-4--a second feature that may have biased ISIS-4 toward a null effect of magnesium. In contrast, Shechter and associates reported a reduction in mortality with magnesium in a high-risk population of patients who were considered unsuitable for thrombolysis.[451] Because of the trivial cost of magnesium, its ease of administration, widespread availability, and the fact that it has the potential to reduce mortality in high-risk AMI patients, another large-scale randomized multicenter trial (Magnesium in Coronaries [MAGIC]) is underway to define more explicitly the role of magnesium in AMI.[452]

RECOMMENDATIONS.

Because of the risk of cardiac arrhythmias when electrolyte deficits are present in the early phase of infarction, all patients with AMI should have a serum magnesium measurement on admission. We advocate repleting magnesium deficits to maintain a serum magnesium level of 2.0 mEq/liter or more. In the presence of hypokalemia (< 4.0 mEq/liter) during the course of treatment of AMI, the serum magnesium level should be rechecked and repleted if necessary because it is often difficult to correct a potassium deficit in the presence of a concurrent magnesium deficit. Episodes of torsades de pointes should be treated with 1 to 2 gm of magnesium delivered as a bolus over about 5 minutes. Although routine early (ideally < 6 hours from the onset of chest pain) supplemental magnesium administration may be helpful in certain high-risk patients such as the elderly or those for whom reperfusion therapy is contraindicated,[52] additional data are needed before definite recommendations regarding patient selection and dosing can be made. There does not appear to be any benefit to routine late (> 6 hours) administration of magnesium to patients with uncomplicated AMI who do not have electrolyte deficits.

Because it may cause vasodilation and hypotension, magnesium infusions should not be administered in patients with a systolic pressure less than 80 to 90 mm Hg. Patients with renal failure may not excrete magnesium normally and should not be considered candidates for supplemental magnesium infusions.

Other Approaches

GLUCOSE-INSULIN-POTASSIUM.

Administration of a solution of glucose-insulin-potassium (300 gm of glucose, 50 units of insulin, and 80 mEq of KCl in 1000 ml of water administered at a rate of 1.5 ml/kg/hr) lowers the concentration of plasma free fatty acids and improves ventricular performance, as reflected in systolic arterial pressure, cardiac output, and stroke work at any level of left ventricular filling pressure; also the frequency of VPBs decreases.[453] Fath-Ordoubadi and Beatt reported in a meta-analysis of nine studies conducted between 1965 and 1987 enrolling a cumulative total of 1932 patients that the mortality rate was reduced from 21 percent in the placebo group to 16.1 percent in the glucose-insulin-potassium group (OR 0.72, 95 percent CI 0.57-0.90; $p = 0.004$).[454] Subsequently, the Estudios Cardiologicos Latinoamerica (ECLA) group performed a randomized trial of AMI patients treated within 24 hours of onset of symptoms.[455] Mortality was reduced from 15.2 percent in the control group to 5.2 percent in the glucose-insulin-potassium group for the subset of patients who received thrombolysis (OR 0.34; 95 percent CI 0.15-0.77; $p = 0.01$). The findings from the ECLA study raise the possibility that therapeutic metabolic manipulation in AMI patients may be a fruitful avenue of investigation, particularly in specific patient subgroups such as those with left ventricular hypertrophy and those for whom there is a delay until the performance of a primary catheter-based reperfusion procedure.[456] [457]

The Diabetes Mellitus Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study reported a significant 30 percent relative decrease in mortality at 1 year in diabetics with AMI who received a strict regimen of an insulin-glucose infusion for 24 hours, followed by 3 months of subcutaneous injections of insulin four times daily as compared with standard therapy[458] (Fig. 35-40) . Thus, "infusions of glucose-insulin-potassium (GIK) may provide necessary metabolic support for the ischemic myocardium; this may be particularly important in patients with large anterior infarcts and cardiogenic shock."[84]

INTRAAORTIC BALLOON COUNTERPULSATION. (See also Chap. 19.)

From a theoretical standpoint, intraaortic balloon counterpulsation might be expected to limit infarct size for several reasons. In experimental animals, intraaortic balloon counterpulsation decreases preload, increases coronary blood flow, and improves cardiac performance. No definitive information is available, indicating that intraaortic balloon counterpulsation alters the prognosis in patients with relatively uncomplicated infarction. The Second Primary Angioplasty in Myocardial Infarction (PAMI-II) investigators randomized high-risk patients undergoing primary PTCA to 36 to 48 hours of intraaortic balloon counterpulsation treatment versus traditional care. There was no significant difference in the predefined composite endpoint of death, reinfarction, infarct-related artery reocclusion, stroke, or new-onset heart failure/hypotension in patients treated with an intraaortic balloon counterpulsation versus those treated conservatively.[350] Intraaortic balloon counterpulsation also did not result in enhanced myocardial recovery after PTCA.

Given the relatively frequent rate of complications after intraaortic balloon insertion and the absence of convincing data for infarct size reduction, intraaortic balloon pumping should be reserved for hemodynamically compromised patients and for those with refractory ischemia. Although noninvasive external forms of counterpulsation have been developed, these approaches have not been rigorously studied in patients with AMI.

OTHER AGENTS.

Oxygen-derived free radicals are abundant in ischemic tissue and may contribute to myocardial injury, particularly after

Figure 35-40 Actuarial mortality curves in patients receiving insulin-glucose infusion and in control subjects of the Diabetes Mellitus Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study during 1 year of follow-up. Numbers below graph indicate the number of patients at different times of observation. Active = patients receiving infusion. *(From Malmberg K, Ryden L, Efendic S, et al: Randomized trial of insulin glucose infusion followed by subcutaneous insulin treatment in diabetic patients with acute myocardial infarction (DIGAMI Study): Effects on mortality at 1 year. J Am Coll Cardiol 26:57, 1995.)*

reperfusion (see Chap. 34) . Although evidence from studies in animals suggested that the extent of myocardial necrosis and postischemic dysfunction can be affected favorably by treatment with oxygen free radical scavengers such as superoxide dismutase,[195] initial results in patients have not been encouraging. Given the important role that nitric oxide (NO) plays in regulating platelet activation, interest has arisen in developing techniques for increasing NO production or providing exogenous NO donors in the setting of AMI other than the nitrates discussed earlier. Adenosine, a widely used pharmacological stress agent for detection of coronary artery disease, has been shown in animal models of reperfusion injury to decrease infarct size. The AMISTAD trial tested the hypothesis that a 3-hour infusion of adenosine as an

adjunct to thrombolysis would reduce myocardial infarct size.[262] Although there was a reduction in infarct size as determined by single-photon emission computed tomographic cardiac imaging, this observation was restricted to patients with an anterior infarction. Despite the reduction in left ventricular infarct size in the adenosine group, in-hospital clinical outcomes were similar between the two treatment groups.

Previous studies suggested that poloxamer 188 (RheothRx) reduces infarct size and improves left ventricular function. However, the Collaborative Organization for RheothRx Evaluation (CORE) trial showed no effect on the composite endpoint of mortality, reinfarction, or cardiogenic shock but did increase the risk of renal failure in patients with AMI.[459] The HALT-AMI trial tested whether a humanized IgG4 monoclonal antibody that binds to CD11b/CD18 receptors on leukocytes, would reduce MI size in patients treated with primary angioplasty.[460] Although the study drug was well tolerated when given just before angioplasty, no significant reduction in infarct size or major cardiac adverse events was seen.

Hemodynamic Disturbances

HEMODYNAMIC ASSESSMENT

In patients with clinically uncomplicated AMI, invasive hemodynamic monitoring is *not* necessary because the status of the circulation can be assessed by careful clinical evaluation. This ordinarily consists of monitoring of heart rate and rhythm, repeated measurement of systemic arterial pressure by cuff, obtaining chest roentgenograms to detect heart failure, careful and repeated auscultation of the lung fields for pulmonary congestion, measurement of urine flow, examination of the skin and mucous membranes for evidence of the adequacy of perfusion, and arterial sampling for P_{O_2} , P_{CO_2} , and pH when hypoxemia or metabolic acidosis is suspected.

In contrast, in patients with AMI whose ventricular contractile performance is not normal, it is important to assess the degree of hemodynamic compromise to initiate therapy with drugs such as vasodilators and diuretics. In the past, central venous or right atrial pressure was used to gauge the degree of left ventricular failure in patients with AMI. However, this technique is fraught with error because central venous pressure actually reflects right rather than left ventricular function. Right ventricular function and therefore systemic venous pressure may be normal or nearly so in patients with significant left ventricular failure. Conversely, patients with right ventricular failure due to right ventricular infarction or pulmonary embolism may exhibit elevated right atrial and central venous pressures despite normal left ventricular function. Low values for right atrial and central venous pressures imply hypovolemia, whereas elevated right atrial pressures usually result from right ventricular failure secondary to left ventricular failure, pulmonary hypertension, or right ventricular infarction or less commonly from tricuspid regurgitation or pericardial tamponade.

Major advances in the management of AMI have resulted from the hemodynamic monitoring that has become widespread in CCUs[461] [462] (Table 35-14) (Table Not Available) . This often consists of both an intraarterial catheter and a pulmonary artery catheter for measurement of pulmonary artery, pulmonary artery occlusive (equivalent to pulmonary wedge) and right atrial pressures, and cardiac output by thermodilution. In patients with hypotension, a Foley catheter provides accurate and continuous measurement of urine output.

NEED FOR INVASIVE MONITORING.

The use of invasive hemodynamic monitoring is based on the following principal factors:

1. Difficulty of interpreting clinical and radiographic findings of pulmonary congestion because of phase lags, such as those occurring after diuretic therapy. Severe depression of cardiac index and/or elevation of left ventricular filling pressure may be unsuspected in as many as 15 percent of patients when estimates are based exclusively on clinical criteria.
2. Need for identifying noncardiac causes of arterial hypotension, particularly hypovolemia.
3. Possible contribution of reduced ventricular compliance to impaired hemodynamics, requiring judicious adjustment of intravascular volume to optimize left ventricular filling pressure.
4. Difficulty in assessing the severity and sometimes even determining the presence of lesions such as mitral regurgitation and ventricular septal defect when the cardiac output or the systemic pressures are depressed.
5. Establishing a baseline of hemodynamic measurements and guiding therapy in patients with clinically apparent pulmonary edema or cardiogenic shock.
6. Underestimation of systemic arterial pressure by the cuff method in patients with intense vasoconstriction.

The prognosis and the clinical status are related to both the cardiac output and the pulmonary artery wedge pressure. Patients with normal cardiac output after AMI have an extremely low expected mortality; prognosis worsens as cardiac output declines. Patients with intraventricular conduction defects, AV block, or both after anterior infarction have lower cardiac indices and higher pulmonary capillary wedge pressures than do patients without these conduction disturbances. On the other hand, patients with these conduction defects and inferior MI usually do not demonstrate such hemodynamic abnormalities.

PULMONARY ARTERY PRESSURE MONITORING.

Patients most likely to benefit from pulmonary artery catheter monitoring

TABLE 35-14 -- INDICATIONS FOR HEMODYNAMIC MONITORING OF ACUTE MYOCARDIAL INFARCTION

(Not Available)

From Gore JM, Zwernet PL: Hemodynamic monitoring of acute myocardial infarction. In Francis GS, Alpert JS (eds): Modern Coronary Care. Boston, Little, Brown & Co, 1990, p 138.

include those whose AMI is complicated by (1) hypotension that is not easily corrected by fluid administration; (2) hypotension in the presence of congestive heart failure; (3) hemodynamic compromise severe enough to require intravenous vasopressors or vasodilators or intraaortic balloon counterpulsation; (4) mechanical lesions (or suspected ones) such as cardiac tamponade, severe mitral regurgitation, and a ruptured ventricular septum; and (5) right ventricular infarction.[63] Other indications for hemodynamic monitoring include assessment of the effects of mechanical ventilation, differentiating pulmonary disease from left ventricular failure as the cause of hypoxemia, and management of septic shock[185] (see Table 35-14) (Table Not Available) .

Before inserting a pulmonary artery catheter into a patient with an AMI, the physician must decide that the potential benefit of the information to be obtained outweighs any potential risks. Major complications from pulmonary artery catheters are relatively rare (3 to 5 percent of cases), but severe problems can occur, including sepsis, pulmonary infarction, and pulmonary artery rupture. By minimizing the duration of catheterization and by strict adherence to aseptic techniques, risk can be diminished.[462A] Catheter-related bloodstream infections can also be reduced by using antiseptic-impregnated catheters.[463]

Accurate determination of hemodynamics by clinical assessment is difficult in critically ill patients. The use of a pulmonary artery catheter often leads to important changes in therapy that would not have occurred if the hemodynamic information had not been available. Of note, reports exist that complications and mortality may be higher in patients who undergo pulmonary artery catheterization, although such patients are often at higher risk initially. These observations emphasize the importance of patient selection, meticulous technique, and correct interpretation of the data obtained.

Hemodynamic Abnormalities

In 1976, Swan, Forrester, and their associates measured the cardiac output and wedge pressure simultaneously in a large series of patients with AMI and identified four major hemodynamic subsets of patients (Table 35-15) : (1) patients with normal perfusion and without pulmonary congestion (normal cardiac output and normal wedge pressure), (2) patients with normal perfusion and pulmonary congestion (normal cardiac output and elevated wedge pressure), (3) patients with decreased

perfusion but without pulmonary congestion (reduced cardiac output and normal wedge pressure), and (4) patients with decreased perfusion and pulmonary congestion (reduced cardiac output and elevated wedge pressure). This classification, which overlaps with a crude clinical classification proposed earlier by Killip and Kimball (see Table 35-15) , has proved to be quite useful, but it should be noted that patients frequently pass from one category to another with therapy and sometimes apparently even spontaneously.

HEMODYNAMIC SUBSETS.

These are usually reflected in the patient's clinical status. Hypoperfusion usually becomes evident clinically when the cardiac index falls below approximately 2.2 liters/min/m^2 , whereas pulmonary congestion is noted when the wedge pressure exceeds approximately 20 mm Hg. However, approximately 25 percent of patients with cardiac indices less than 2.2 liters/min/m^2 and 15 percent of patients with elevated pulmonary capillary wedge pressures are not recognized clinically. Discrepancies in hemodynamic and clinical classification of patients with AMI arise for a variety of reasons. Patients may exhibit "phase lags" as clinical pulmonary congestion develops or resolves, symptoms secondary to chronic obstructive pulmonary disease may be confused with those resulting from pulmonary congestion, or longstanding left ventricular dysfunction may mask signs of hypoperfusion secondary to compensatory vasoconstriction.[69]

The hemodynamic findings shown in Tables 35-15 and 35-16 allow for rational approaches to therapy. The goals of hemodynamic therapy are to maintain ventricular performance, support blood pressure, and protect jeopardized myocardium. Because these goals occasionally may be at cross-purposes, recognition of the hemodynamic profile, as assessed clinically or as available from hemodynamic monitoring, is required before optimal therapeutic interventions can be designed along the lines discussed here.

Hypotension in the Prehospital Phase

During the prehospital phase of AMI, invasive hemodynamic monitoring is not feasible; during this period, therapy should be guided by frequent clinical assessment and measurement of arterial pressure by cuff, with the recognition that intense vasoconstriction can provide a falsely low pressure measured by this method. Hypotension associated with bradycardia often reflects excessive vagotonia. Relative or absolute hypovolemia is often present when hypotension occurs with a normal or rapid heart rate, particularly among patients receiving diuretics just before the occurrence of infarction. Marked diaphoresis, reduction of fluid intake, or vomiting during the period preceding and accompanying the onset of AMI may all contribute to the development of hypovolemia. Even if the effective vascular volume is normal, relative hypovolemia may be present because ventricular compliance is reduced in AMI and a left ventricular filling pressure as high as 20 mm Hg may be needed to provide an optimal preload.

MANAGEMENT.

In the absence of rales involving more than one third of the lung fields, the patient should be put in the reverse Trendelenburg position, and in those with

sinus bradycardia and hypotension, atropine should be administered (0.3 to 0.6 mg intravenously repeated at 3- to 10-minute intervals up to 2.0 mg). If these measures do not correct the hypotension, normal saline should be administered intravenously, beginning with a bolus of 100 ml followed by 50-ml increments every 5 minutes. The patient should be carefully observed and the infusion stopped when the systolic pressure returns to approximately 100 mm Hg, if the patient becomes dyspneic, or if pulmonary rales develop or increase. Because of the poor correlation between LV filling pressure and mean right atrial pressure, assessment of systemic (even central) venous pressure is of limited value as a guide to fluid therapy.

Administration of cardiotonic agents is indicated during the prehospital phase if systemic hypotension persists despite correction of hypovolemia and excessive vagotonia. In the absence of invasive hemodynamic monitoring, assessment of peripheral vascular resistance must be based on clinical observations. If cutaneous vasoconstriction is present, therapy with dobutamine, which stimulates cardiac contractility without unduly accelerating heart rate and which does not increase the impedance to ventricular outflow, may be helpful (see Chap. 18) . In hypotensive patients with AMI with clinical evidence of vasodilatation, an uncommon circumstance, phenylephrine hydrochloride, is preferable, although this agent, which increases coronary as well as peripheral vascular tone, should be used with caution.

Hypovolemic Hypotension

Recognition of hypovolemia is of particular importance in hypotensive patients with AMI because of the hazard it poses and because of the improvement in circulatory dynamics that can be achieved so readily and safely by augmentation of vascular volume. Because hypovolemia is often occult, it is frequently overlooked in the absence of invasive hemodynamic monitoring. Hypovolemia may be absolute, with low LV filling pressure (8 mm Hg), or relative, with normal (8 to 12 mm Hg) or even modestly increased (13 to 18 mm Hg) left ventricular filling pressures. Because of the reduction of left ventricular compliance that occurs with acute ischemia and infarction (see Chap. 34) , LV filling pressures between 13 and 18 mm Hg, although above the upper limits of normal, may actually be suboptimal.

Exclusion of hypovolemia as the cause of hypotension requires the documentation of a reduced cardiac output despite left ventricular filling pressure exceeding 18 mm Hg. If, in a hypotensive patient, the pulmonary capillary wedge pressure (ordinarily measured as the pulmonary artery occlusive pressure) is below this level, fluid challenge should be carried out as described previously. If hypovolemia is documented or suspected, the fluid replaced should resemble the fluid lost. Thus, when a low hematocrit complicates AMI, infusion of packed red blood cells or whole blood is the treatment of choice. On the other hand, crystalloid or colloid solutions should be administered when the hematocrit is normal or elevated.

Hypotension caused by right ventricular infarction may be confused with that caused by hypovolemia because both are associated with a low, normal, or minimally elevated LV filling pressure. The findings and management of right ventricular infarction are discussed on page 1180 .

The Hyperdynamic State

When infarction is not complicated by hemodynamic impairment, no therapy other than general supportive measures and treatment of arrhythmias is necessary. However, if the hemodynamic profile is of the hyperdynamic state (i.e., elevation of sinus rate, arterial pressure, and cardiac index, occurring singly or together in the presence of a normal or low LV filling pressure) and if other causes of tachycardia such as fever, infection, and pericarditis can be excluded, treatment with beta-adrenoceptor blockers is indicated. Presumably, the increased heart rate and blood pressure are the result of inappropriate activation of the sympathetic nervous system, possibly secondary to augmented release of catecholamines, pain and anxiety, or some combination of these.

LEFT VENTRICULAR FAILURE

Even in the thrombolytic era, left ventricular dysfunction remains the single most important predictor of mortality after AMI (Fig. 35-41) .[20] [22] In patients with AMI, heart failure is characterized either by systolic dysfunction alone or by both systolic and diastolic dysfunction. Left ventricular diastolic dysfunction leads to pulmonary venous hypertension and pulmonary congestion, whereas systolic dysfunction is principally responsible for a depression of cardiac output and of the ejection fraction. Clinical manifestations of left ventricular failure become more common as the extent of the injury to the left ventricle increases. In addition to infarct size, other important predictors of the development of symptomatic left ventricular dysfunction include advanced age and diabetes.[464] Mortality increases in association with the severity of the hemodynamic deficit.[69]

THERAPEUTIC IMPLICATIONS.

Classification of patients with AMI by hemodynamic subsets has therapeutic relevance. As already noted, patients with normal wedge pressures and hypoperfusion often benefit from infusion of fluids, because the peak value of stroke volume is usually not attained until LV filling pressure reaches 18 to 24 mm Hg. However, a low level of left ventricular filling pressure

Figure 35-41 Impact of left ventricular function on survival after myocardial infarction. The curvilinear relationship between left ventricular ejection fraction (LVEF) for patients treated in the thrombolytic era is shown. Among patients with an LVEF below 40 percent, mortality is markedly increased at 6 months. Thus, interventions such as thrombolysis, aspirin, and angiotensin-converting enzyme (ACE) inhibitors should be of considerable benefit in patients with acute myocardial infarction to minimize the amount of left ventricular damage and interrupt the neurohumoral activation seen with congestive heart failure. *(Adapted from Volpi A, De VC, Franzosi MG, et al: Determinants of 6-month mortality in survivors of myocardial infarction after thrombolysis: Results of the GISSI-2 data base. The Ad Hoc Working Group of the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI)-2 Data Base. Circulation 88:416-429, 1993. Copyright 1993, American Heart Association.)*

does not imply that left ventricular damage is necessarily slight. Such patients may be relatively hypovolemic and/or may have suffered a right ventricular infarct with or without severe left ventricular damage.

The relation between ventricular filling pressure and cardiac index when preload is increased by an infusion of saline or dextran can provide valuable hemodynamic information, in addition to that obtained from baseline measurements. For example, the ventricular function curve rises steeply (marked increase in cardiac index, small increase in filling pressure) in patients with normal left ventricular function and hypovolemia, whereas the curve rises gradually or remains flat in those patients with a combination of hypovolemia and depressed cardiac function.

Invasive hemodynamic monitoring is essential to guide therapy for patients with severe left ventricular failure (pulmonary capillary wedge pressure > 18 mm Hg *and* cardiac index < 2.5 liters/min/m^2).

AVOIDANCE OF HYPOXEMIA.

Patients whose AMI is complicated by congestive heart failure characteristically develop hypoxemia due to a combination of pulmonary vascular engorgement (and in some cases pulmonary interstitial edema), diminished vital capacity, and respiratory depression from narcotic analgesics. Hypoxemia can impair the function of ischemic tissue at the margin of the infarct and thereby contribute to establishing or perpetuating the vicious circle (see Fig. 35-11) . The ventilation-perfusion mismatch that results in hypoxemia requires careful attention to ventilatory support. Increasing fractions of inspired oxygen (F_{IO_2}) via face mask should be used initially, but if the oxygen saturation of the patient's blood cannot be maintained above 85 to 90 percent on 100 percent F_{IO_2} , strong consideration should be given to endotracheal intubation with positive-pressure ventilation. The improvement of arterial oxygenation and hence myocardial oxygen supply may help to restore ventricular performance. Positive end-expiratory pressure (PEEP) may diminish systemic venous return and reduce effective left ventricular filling pressure. This may require reduction in the amount of PEEP, normal saline infusions to maintain LV filling pressure, adjustment of the rate of infusion of vasodilators such as nitroglycerin, or some combination. Because myocardial ischemia frequently occurs during the return to unsupported spontaneous breathing, the weaning process should be accompanied by observation for signs of ischemia and is potentially facilitated by a period of intermittent mandatory ventilation or pressure support ventilation before extubation. Continuous ST segment monitoring has been recommended for these patients.

When wheezing complicates pulmonary congestion, bronchodilators that act primarily on $beta_2$ -adrenoceptors, such as metaproterenol, given as an aerosol, or terbutaline, are more desirable than conventional bronchodilators such as isoproterenol or epinephrine. The latter act primarily on $beta_1$ -receptors, which, by increasing myocardial oxygen consumption, can increase ischemia. Racemic $beta_2$ agonists are composed of a 50:50 mixture of R and S isomers. The R isomers exhibit virtually all the bronchodilation, whereas the S isomers enhance bronchial reactivity to methacholine, eosinophil activation, and histamine-induced influx of fluid, proteins, and neutrophils into the airspaces. As suggested by Handley, use of pure R isomers of $beta_2$ -adrenoceptor agonists may permit bronchodilation with few beta-adrenoceptor-mediated side effects.[465]

Although positive inotropic agents may be useful, they do not represent the initial therapy of choice in patients with AMI. Instead, heart failure is managed most effectively first by reduction of ventricular preload and then, if possible, by lowering afterload. Arrhythmias may contribute to hemodynamic compromise and should be treated promptly in patients with left ventricular failure.

DIURETICS. (See also Chap. 18.)

Mild heart failure in patients with AMI frequently responds well to diuretics such as furosemide, administered intravenously in doses of 10 to 40 mg, repeated at 3- to 4-hour intervals if necessary. The resultant reduction of pulmonary capillary pressure reduces dyspnea, and the lowering of LV wall tension that accompanies the reduction of LV diastolic volume diminishes myocardial oxygen requirements and may lead to improvement of contractility and augmentation of the ejection fraction, stroke volume, and cardiac output. The reduction of elevated LV filling pressure may also enhance myocardial oxygen delivery by diminishing the impedance to coronary perfusion attributable to elevated ventricular wall tension. It may also improve arterial oxygenation by reducing pulmonary vascular congestion.

The intravenous administration of furosemide reduces pulmonary vascular congestion and pulmonary venous pressure within 15 minutes, before renal excretion of sodium and water has occurred; presumably this action results from a direct dilating effect of this drug on the systemic arterial bed. It is important not to reduce left ventricular filling pressure much below 18 mm Hg, the lower range associated with optimal left ventricular performance in AMI, because this may reduce cardiac output further and cause arterial hypotension. Excessive diuresis may also result in hypokalemia, with its attendant risk of digitalis intoxication.

AFTERLOAD REDUCTION. (See also Chap. 18.)

Myocardial oxygen requirements depend on LV wall stress, which in turn is proportional to the product of peak developed left ventricular pressure, volume, and wall thickness. Vasodilator therapy is recommended in patients with AMI complicated by (1) heart failure unresponsive to treatment with diuretics, (2) hypertension, (3) mitral regurgitation, or (4) ventricular septal defect. In these patients, treatment with vasodilator agents increases stroke volume and may reduce myocardial oxygen requirements and thereby lessen ischemia. Hemodynamic monitoring of systemic arterial and, in many cases, pulmonary capillary wedge (or at least pulmonary artery) pressure and cardiac output in patients treated with these agents is important. Improvement of cardiac performance

and energetics requires three simultaneous effects: (1) reduction of LV afterload, (2) avoidance of excessive systemic arterial hypotension in order to maintain effective coronary perfusion pressure, and (3) avoidance of excessive reduction of ventricular filling pressure with consequent diminution of cardiac output. In general, pulmonary capillary wedge pressure should be maintained at approximately 20 mm Hg and arterial pressure above 90/60 mm Hg in patients who were normotensive before developing the AMI.

Vasodilator therapy is particularly useful when AMI is complicated by mitral regurgitation or rupture of the ventricular septum. In such patients, vasodilators alone or in combination with intraaortic balloon counterpulsation can sometimes serve as a "holding maneuver" and provide hemodynamic stabilization to permit definitive catheterization and angiographic studies to be carried out and to prepare the patient for early surgical intervention. Because of the precarious state of patients with complicated infarction and the need for meticulous adjustment of dosage, therapy is best initiated with agents that can be administered intravenously and that have a short duration of action, such as nitroprusside, nitroglycerin, or isosorbide dinitrate. After initial stabilization, the medication of choice is generally an ACE inhibitor, but long-acting nitrates given by mouth, sublingually, or by ointment may also be useful.

Nitroglycerin. (See also Chap. 36.)

This drug has been shown in animal experiments to be less likely than nitroprusside to produce a "coronary steal" (i.e., to divert blood flow from the ischemic to the nonischemic zone). Therefore, apart from consideration of its routine use in AMI patients discussed earlier (see p. 1170), it may be a particularly useful vasodilator in patients with AMI complicated by left ventricular failure. Ten to 15 mug/min is infused, and the dose is increased by 10 mug/min every 5 minutes until (1) the desired effect (improvement of hemodynamics or relief of ischemic chest pain) is achieved or (2) a decline in systolic arterial pressure to 90 mm Hg, or by more than 15 mm Hg, has occurred. Although both nitroglycerin and nitroprusside lower systemic arterial pressure, systemic vascular resistance, and the heart rate/systolic blood pressure product, the reduction of LV filling pressure is more prominent with nitroglycerin because of its relatively greater effect than nitroprusside on venous capacitance vessels. Nevertheless, in patients with severe left ventricular failure, cardiac output often increases despite the reduction in LV filling pressure produced by nitroglycerin.

Oral Vasodilators.

The use of oral vasodilators in the treatment of chronic congestive heart failure is discussed in Chapter 21 . In patients with AMI and persistent heart failure, long-term treatment with a converting enzyme inhibitor should be carried out. This reduced ventricular load decreases the remodeling of the left ventricle that occurs commonly in the period after MI and thereby reduces the development of heart failure and risk of death.[72]

DIGITALIS. (See also Chap. 18.)

Although digitalis increases the contractility and the oxygen consumption of normal hearts, when heart failure is present the diminution of heart size and wall tension frequently results in a net reduction of myocardial oxygen requirements. In animal experiments it fails to improve ventricular performance immediately after experimental coronary occlusion, but salutary effects are elicited when it is administered several days later. The absence of early beneficial effects may be due to the inability of ischemic tissue to respond to digitalis or the already maximal stimulation of contractility of the normal heart by circulating and neuronally released catecholamines.

Although the issue is still controversial, arrhythmias may be increased by digitalis glycosides when they are given to patients in the first few hours after the onset of MI, particularly in the absence of hypokalemia. Also, undesirable peripheral systemic and coronary vasoconstriction may result from the rapid intravenous administration of rapidly acting glycosides such as ouabain.

Administration of digitalis to patients with AMI in the hospital phase should generally be reserved for the management of supraventricular tachyarrhythmias such as atrial flutter and fibrillation and of heart failure that persists despite treatment with diuretics, vasodilators, and beta-adrenoceptor agonists. There is no indication for its use as an inotropic agent in patients without clinical evidence of left ventricular dysfunction, and it is too weak an inotropic agent to be relied on as the principal cardiac stimulant in patients with overt pulmonary edema or cardiogenic shock. It may, however, be useful as a supplement to vasodilator agents and in the maintenance phase of treatment for persistent or recurrent left ventricular failure.[466]

Cardiac glycosides appear to become progressively more effective in the treatment of heart failure as the interval from onset of infarction lengthens; that is, they are more effective in the treatment of chronic than of acute heart failure secondary to ischemic heart disease. Of note, in a direct comparison of captopril versus digoxin for prevention of left ventricular remodeling and dysfunction after AMI, patients in whom captopril therapy was initiated 7 to 10 days after onset of infarction had less left ventricular remodeling and better preserved global left ventricular function than patients receiving digitalis. In addition, the possibility that continued administration of digitalis might contribute to late mortality in the 2 years after AMI has been raised[467] [468] [469] and debated.[470] [471] Although it is clear that mortality is greater in patients treated with digoxin after AMI, it is not clear that this increase in mortality is due to digoxin itself or to confounding variables that correlate with use of digoxin.[471] At this time, digoxin appears to be indicated in AMI patients only if they exhibit supraventricular tachyarrhythmias or overt heart failure that is not adequately controlled by ACE inhibitors and diuretics.

BETA-ADRENOCEPTOR AGONISTS.

When left ventricular failure is severe, as manifested by marked reduction of cardiac index (< 2 liters/min/m^2), and pulmonary capillary wedge pressure is at optimal (18 to 24 mm Hg) or excessive (> 24 mm Hg) levels despite therapy with diuretics, beta-adrenoceptor agonists are indicated. Although isoproterenol is a potent cardiac stimulant and improves ventricular performance, it should be avoided in AMI patients. It also causes tachycardia and augments myocardial oxygen consumption and lactate production; in addition, it reduces coronary perfusion pressure by causing systemic vasodilation and in animal experiments it increases the extent of experimentally induced infarction. Norepinephrine also increases myocardial oxygen consumption because of its peripheral vasoconstrictor as well as positive inotropic actions.

Dopamine and dobutamine (see Chap. 18) may be particularly useful in patients with AMI and reduced cardiac output, increased left ventricular filling pressure, pulmonary vascular congestion, and hypotension. Fortunately, the potentially deleterious alpha-adrenergic vasoconstrictor effects exerted by dopamine occur only at higher doses than those required to increase contractility. Its vasodilating actions on renal and splanchnic vessels and its positive inotropic effects generally improve hemodynamics and renal function. In patients with AMI and severe left ventricular failure, this drug should be administered at a dose of 3 mug/kg/min while monitoring pulmonary capillary wedge and systemic arterial pressures as well as cardiac output. The dose may be increased stepwise to 20 mug/kg/min, to reduce pulmonary capillary wedge pressure to approximately 20 mm Hg and elevate cardiac index to exceed 2 liters/min/m^2 . However, it must be recognized that doses exceeding 5 mug/kg/min activate peripheral alpha receptors and cause vasoconstriction.

Dobutamine has a positive inotropic action comparable to that of dopamine but a slightly less positive chronotropic effect and less vasoconstrictor activity. In patients

with AMI, dobutamine improves left ventricular performance without augmenting enzymatically estimated infarct size.[472] It may be administered in a starting dose of 2.5 mug/kg/min and increased stepwise to a maximum of 30 mug/kg/min. Both dopamine and dobutamine must be given carefully and with constant monitoring of the ECG, systemic arterial pressure, and pulmonary artery or pulmonary artery occlusive pressure and, if possible, with frequent measurements of cardiac output. The dose must be reduced if the heart rate exceeds 100 to 110 beats/min, if supraventricular or ventricular tachyarrhythmias are precipitated, or if ST segment changes increase.

OTHER POSITIVE INOTROPIC AGENTS.

Milrinone is a noncatecholamine, nonglycoside, phosphodiesterase inhibitor with inotropic and vasodilating action (see Chap. 18) . It is useful in selected patients whose heart failure persists despite treatment with diuretics, who are not hypotensive, and who are likely to benefit from both an enhancement in contractility and afterload reduction. Milrinone should be given as a loading dose of 50 mug/kg over 10 minutes, followed by a maintenance infusion of 0.375 to 0.75 mug/kg/min.

CARDIOGENIC SHOCK

This severest clinical expression of left ventricular failure is associated with extensive damage to the left ventricular myocardium (about 40 percent) in more than 80 percent of AMI patients in whom it occurs; the remainder have a mechanical defect such as ventricular septal or papillary muscle rupture or predominant right ventricular infarction.[473] [473A] In the past, cardiogenic shock has been reported to occur in up to 20 percent of patients with AMI,[474] but estimates from recent large randomized trials of thrombolytic therapy and observational data bases report an incidence rate in the range of 7 percent.[192] [475] About 10 percent of patients with cardiogenic shock present with this condition at the time of admission, whereas 90 percent develop it during hospitalization. This low-output state is characterized by elevated ventricular filling pressures, low cardiac output, systemic hypotension, and evidence of vital organ hypoperfusion (e.g., clouded sensorium, cool extremities, oliguria, acidosis).[190] Patients with cardiogenic shock due to AMI are more likely to be older, to have a history of a prior MI or congestive heart failure, and to have sustained an anterior infarction at the time of development of shock.[190] [475A] Of note, although the incidence of cardiogenic shock in AMI has been relatively stable since the mid 1970s, the short-term mortality decreased from 70 to 80 percent in the 1970s to 50 to 60 percent in the 1990s.[475] Cardiogenic shock is the cause of mortality in about 60 percent of patients dying after thrombolysis for AMI.[476]

PATHOLOGICAL FINDINGS.

At autopsy, more than two thirds of patients with cardiogenic shock demonstrate stenosis of 75 percent or more of the luminal diameter of all three major coronary vessels, usually including the left anterior descending coronary artery. Almost all patients with cardiogenic shock are found to have thrombotic occlusion of the artery supplying the major region of recent infarction with loss of about 40 percent of the left ventricular mass.[473] Other causes of cardiogenic shock in AMI include mechanical defects such as rupture of the ventricular septum, a papillary muscle, or a free wall with tamponade; right ventricular infarction[473] ; or marked reduction of preload due to conditions such as hypovolemia.[477]

Patients who die as a consequence of cardiogenic shock often have "piecemeal" necrosis, that is, progressive myocardial necrosis from marginal extension of their infarct into an ischemic zone bordering on the infarction. This is generally associated with persistent elevation of CK-MB. Early deterioration in left ventricular function secondary to apparent extension of infarction may, in some cases, result from expansion of the necrotic zone of myocardium without actual extension of the necrotic process (Fig. 35-42) . Shear forces that develop during ventricular systole can disrupt necrotic myocardial muscle bundles, with resultant expansion and thinning of the akinetic zone of myocardium, which in turn results in deterioration of overall left ventricular function.

At autopsy, patients with cardiogenic shock consistently demonstrate marginal extension of recent areas of infarction. Additionally, focal areas of necrosis are frequently found in regions of the left and right ventricles that are not adjacent to the major area of recent infarction. Such extensions and focal lesions are probably in part the result of the shock state itself, because they can also be found in the hearts of patients dying of noncardiogenic shock. Infarction of the ischemic periinfarction zone can be precipitated by a number of factors that adversely affect the supply of oxygen or the metabolic demand in this zone of myocardium. These include a reduction of coronary perfusion pressure that causes impaired myocardial perfusion in the presence of atherosclerotic obstructions of the nonculprit artery. An augmentation of myocardial oxygen demand resulting from the local release of catecholamines from ischemic adrenergic nerve endings in the heart as well as from circulating

Figure 35-42 Infarct expansion after transmural anterior myocardial infarction. *(From Tice FD, Kisslo J: Echocardiographic assessment and monitoring of the patient with AMI: Prospects for the thrombolytic era. In Califf RM, Mark DB, Wagner GS (eds): Acute Coronary Care. St. Louis, Mosby-Year Book, 1995, p 496.)*

endogenous or infused catecholamines may also play a role. Patients with shock due to a mechanical defect often have smaller infarcts than do those with cardiogenic shock secondary to ventricular failure without a mechanical lesion. The prognosis is better in such patients because the smaller infarct allows their left ventricle to support the circulation if the mechanical defect has been corrected surgically.

PATHOPHYSIOLOGY.

The shock state in patients with AMI appears to be the result of a vicious circle, demonstrated in Figure 35-11 (see p. 1124).[190] According to this formulation, coronary obstruction leads to myocardial ischemia, which impairs myocardial contractility and ventricular performance. This, in turn, reduces arterial pressure and therefore coronary perfusion pressure, leading to further ischemia and extension of necrosis until the left ventricle has insufficient contracting myocardium to sustain life. The progressive nature of the myocardial insult in this syndrome is reflected in the stuttering and progressive evolution of elevations in the plasma enzyme-time activity curves of markers specific for myocardial injury. Consideration of the vicious circle also points to the hazard of hypovolemic hypotension in patients with AMI but without cardiogenic shock. Hypotension, whatever its cause, reduces coronary perfusion, especially of myocardium in the territory of obstructive arteries, and thereby may enhance necrosis.

DIAGNOSIS.

Cardiogenic shock is characterized by marked and persistent (>30 min) hypotension with systolic arterial pressure less than 80 mm Hg and a marked reduction of cardiac index (generally<1.8 liters/mm/m^2) in the face of elevated LV filling pressure (pulmonary capillary wedge pressure>18 mm Hg). Spurious estimates of LV filling pressure based on measurements of the pulmonary artery wedge pressure can occur in the presence of marked mitral regurgitation, in which the tall v wave in the left atrial (and pulmonary artery wedge) pressure tracing elevates the mean pressure above LV end-diastolic pressure. Accordingly, mitral regurgitation and other mechanical lesions, such as ventricular septal defect, ventricular aneurysm, and pseudoaneurysm, must be excluded before the diagnosis of cardiogenic shock due to impairment of left ventricular function can be established. Mechanical complications should be suspected in any patient with AMI in whom circulatory collapse occurs.[190] Immediate hemodynamic, angiographic, and echocardiographic evaluations are necessary in patients with cardiogenic shock. It is important to exclude mechanical complications because primary therapy of such lesions usually requires immediate operative treatment with intervening support of the circulation by intraaortic balloon counterpulsation.

Medical Management

When the aforementioned mechanical complications are not present, cardiogenic shock is due to impairment of left ventricular function. Although dopamine or dobutamine usually improves the hemodynamics in these patients, unfortunately neither appears to improve hospital survival significantly. Similarly, vasodilators have been used in an effort to elevate cardiac output and to reduce left ventricular filling pressure. However, by lowering the already markedly reduced coronary perfusion pressure, myocardial perfusion can be compromised further, accelerating the vicious circle illustrated in Figure 35-11 . Vasodilators may nonetheless be used in conjunction with intraaortic balloon counterpulsation and inotropic agents in an effort to increase cardiac output while sustaining or elevating coronary perfusion pressure.[190]

The systemic vascular resistance is usually elevated in patients with cardiogenic shock, but occasionally resistance is normal and in a few cases vasodilation actually predominates. When systemic vascular resistance is not elevated (i.e., <1800 dyne-sec/cm^5) in patients with cardiogenic shock, norepinephrine, which has both alpha- and beta-adrenoceptor agonist properties (in doses ranging from 2 to 10 g/min), may be employed to increase diastolic arterial pressure, maintain coronary perfusion, and improve contractility. Norepinephrine should be used only when other means, including balloon counterpulsation, fail to maintain arterial diastolic pressure above 50 to 60 mm Hg in a previously normotensive patient. The use of alpha-adrenoceptor agents such as phenylephrine and methoxamine is contraindicated in patients

with cardiogenic shock (unless systemic vascular resistance is inordinately low).

Intraaortic Balloon Counterpulsation (See also Chap. 19)

INDICATIONS.

Intraaortic balloon counterpulsation is used in the treatment of AMI in three groups of patients[478] : (1) those whose conditions are hemodynamically unstable and in whom support of the circulation is required for the performance of cardiac catheterization and angiography carried out to assess lesions that are potentially correctable surgically or by angioplasty; (2) those with cardiogenic shock that is unresponsive to medical management; and (3) rarely, those with persistent ischemic pain that is unresponsive to treatment with inhalation of 100 percent oxygen, beta-adrenoceptor blockade, and nitrates. Unfortunately, among patients with cardiogenic shock, improvement is often only temporary and "balloon dependence" commonly develops. Patients with cardiogenic shock treated with this modality can be successfully weaned from the supporting system only occasionally. Counterpulsation alone does not improve overall survival in patients either with or without a surgically remediable mechanical lesion.

COMPLICATIONS.

These occur infrequently but include damage to or perforation of the aortic wall, ischemia distal to the site of insertion of the balloon in the femoral artery, thrombocytopenia, hemolysis, renal emboli, and mechanical failure such as rupture of the balloon. Those at highest risk include patients with peripheral vascular disease, the elderly, and women, particularly if they are small. These factors should be taken into consideration before an attempt is made to institute intraaortic balloon counterpulsation. Because of the potential for vascular bleeding complications, there has been reluctance to use intraaortic pumps in patients who have undergone thrombolytic therapy. However, despite the increased bleeding risk, because of the poor outcome among patients with shock after thrombolysis (usually ineffective thrombolysis), this modality should be considered in selected patients who are candidates for an aggressive approach to revascularization.

Revascularization

Reversal of cardiogenic shock by acute reperfusion has been reported, usually with thrombolytic therapy, emergency PTCA, or a combination of these measures.[190] In uncontrolled reports, the mortality of patients with cardiogenic shock appears to have been reduced by about 30 percent by early angioplasty or coronary artery bypass surgery.[479] Encouraging evidence favoring early angiography and revascularization has been reported in a cardiogenic shock registry. Another small retrospective series reported that patients with cardiogenic shock who underwent a successful angioplasty had a better 1-year survival than either those who did not undergo a successful angioplasty or those who received only medical therapy. These promising results must be interpreted cautiously because selection bias due to exclusion of elderly and moribund patients may have inflated the estimate of the beneficial effect of angioplasty.

Of the five therapies frequently used to treat patients with cardiogenic shock (vasopressors, intraaortic balloon counterpulsation, thrombolysis, angioplasty, and CABG), the first two are useful temporizing maneuvers. Surgical

Figure 35-43 (Figure Not Available) Effect of early revascularization in cardiogenic shock. The 6-month mortality is lower in patients with cardiogenic shock from myocardial infarction who were randomized to early revascularization in the SHOCK trial. Subgroups of patients that showed a particular benefit from early revascularization include those patients younger than age 75, a history of prior myocardial infarction, and randomization in less than 6 hours from the onset of symptoms. *(Adapted from data in Hochman JS, Sleeper LA, Webb JG, et al: Early revascularization in acute myocardial infarction complicated by cardiogenic shock. SHOCK Investigators. Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock. N Engl J Med 341:625-634, 1999.)*

treatment in cardiogenic shock (aside from correcting mechanical abnormalities) may involve bypassing occluded as well as severely obstructed nonoccluded vessels. Occlusion of one major vessel may cause left ventricular dysfunction and hypotension, which can then lead to hypoperfusion and ischemia of myocardium subserved by the other diseased vessels. Left ventricular function may be improved by relief of this ischemia with revascularization.

The SHOCK study evaluated early revascularization for the treatment of patients with AMI complicated by cardiogenic shock. Patients with shock due to left ventricular failure complicating MI were randomized to emergency revascularization (n = 152), accomplished by either CABG or angioplasty, or initial medical stabilization (n = 150). In 86 percent of patients in both groups, intraaortic balloon counterpulsation was performed. The primary endpoint was all-cause mortality at 30 days; a secondary endpoint was mortality at 6 months. At 30 days, overall mortality was 46.7 percent in the revascularization group, not significantly different from the 56.0 percent mortality rate observed in the medical-therapy group ($p = 0.11$). However, 6-month mortality was significantly lower in the revascularization group than in the medical-therapy group, with rates of 50.3 percent versus 63.1 percent, respectively ($p = 0.027$). [480] Subgroups of patients in the SHOCK trial that showed particular benefit from the early revascularization strategy (i.e., reduced 6-month mortality) were those who were younger than 75 years of age, had a prior AMI, and were randomized in less than 6 hours from onset of infarction (see Fig. 35-43) (Figure Not Available) .

RECOMMENDATIONS.

We recommend assessment of patients on an individualized basis to determine their desire for aggressive care and overall candidacy for further treatment (e.g., age, mental status, comorbidities). Patients who are potential candidates for revascularization should then rapidly receive intraaortic balloon counterpulsation and be referred for coronary arteriography. Those with suitable anatomy should be revascularized with angioplasty or CABG. In appropriately selected patients, emergency cardiac transplantation has also been used successfully to manage cardiogenic shock.

RIGHT VENTRICULAR INFARCTION

A characteristic hemodynamic pattern (Table 35-17) has been observed in patients with right ventricular infarction, which frequently accompanies inferior left ventricular infarction or rarely occurs in isolated form. Right-sided heart filling pressures (central venous, right atrial, and right ventricular end-diastolic pressures) are elevated, whereas left ventricular filling pressure is normal or only slightly raised; right ventricular systolic and pulse pressures are decreased, and cardiac output is often markedly depressed. Rarely,

TABLE 35-17 -- FEATURES OF RIGHT VENTRICULAR MYOCARDIAL INFARCTION

Clinical Findings
Normal or depressed right ventricular function
Shock
Tricuspid regurgitation
Ruptured ventricular septum
Hemodynamic Measurements
Abnormally elevated right atrial pressure
Normal right ventricular and pulmonary artery systolic pressures
Increased ratio of right ventricular to left ventricular filling presure
Depressed right ventricular function curve
Scintigraphy
Uptake in right ventricular free wall
Increased right ventricular dimensions and decreased wall motion
Echocardiography
Increased right ventricular dimension
Absence of pericardial effusion
Cardiac Enzymes

Increased magnitude of enzyme values relative to degree of left ventricular dysfunction
Cardiac Catheterization
Involvement of right (usually) or left (rarely) circumflex coronary arteries
Right ventricular akinesis
Differential Diagnosis
Hypotension with acute myocardial infarction
Pericardial tamponade
Constrictive pericarditis
Pulmonary embolus
Modified from Rackley CE, Russell RO Jr, Mantle JA, et al: Right ventricular infarction and function. Am Heart J 101:215, 1981.

this disproportionate elevation of right-sided filling pressure causes right-to-left shunting through a patent foramen ovale. This possibility should be considered in patients with right ventricular infarction who have unexplained systemic hypoxemia. The finding of an elevation in atrial natriuretic factor in this condition has led to the suggestion that abnormally high levels of this peptide might be in part responsible for the hypotension seen in right ventricular infarction. Of note, the same protective effect of ischemic preconditioning that has been described in infarction of the left ventricle has also been reported in patients with infarction of the right ventricle.[481] [482]

Diagnosis

Right ventricular infarction is common among patients with inferior left ventricular infarction. Therefore, otherwise unexplained systemic arterial hypotension or diminished cardiac output or marked hypotension in response to small doses of nitroglycerin in patients with inferior infarction should lead to the prompt consideration of this diagnosis.

Many patients with the combination of normal left ventricular filling pressure and depressed cardiac index have right ventricular infarcts (with accompanying inferior left ventricular infarcts). The hemodynamic picture may superficially resemble that seen in patients with acute pericarditis (see Chap. 50) . It includes elevated right ventricular filling pressure; steep, right atrial *y* descent; and an early diastolic drop and plateau (square root sign) in the right ventricular pressure tracing. Moreover, Kussmaul's sign (an increase in jugular venous pressure with inspiration, see Chap. 4) and pulsus paradoxus (a fall in systolic pressure of greater than 10 mm Hg with inspiration, see Chap. 4) may be present in patients with right ventricular infarction.[52] In fact, Kussmaul's sign in the setting of inferior wall AMI is highly predictive of right ventricular involvement.

ELECTROCARDIOGRAPHY.

The ECG may provide the first clue that right ventricular involvement is present in the patient with inferior wall MI (see Chap. 5) . Most patients with right ventricular infarction have ST segment elevation in lead V_4 R (right precordial lead in V_4 position). [63A] [482] Transient elevation of the ST segment in any of the right precordial leads may occur with right ventricular MI, and the presence of ST segment elevation of 0.1 mV or more in any one or combination of leads V_4 R, V_5 R, and V_6 R in patients with the clinical picture of acute MI is highly sensitive and specific for the diagnosis of right ventricular MI.[483] Wellens has emphasized that, in addition, noting the presence or absence of convex upward ST segment elevation in V_4 R, clinicians should determine if the T wave is positive or negative; such distinctions help distinguish proximal versus distal occlusion of the right coronary artery versus occlusion of the left circumflex artery[140] (Fig. 35-44) . Elevation of the ST segments in leads V_1 through V_4 due to right ventricular infarction can be confused with that due to anteroseptal infarction. Although the elevated ST segments are oriented anteriorly in both cases, it is the frontal plane that provides important clues--the ST segments are oriented to the right in right ventricular infarction (e.g. +120 degrees) whereas they are oriented to the left in anteroseptal infarction (e.g. -30 degrees).[484]

ECHOCARDIOGRAPHY AND RADIONUCLIDE ANGIOGRAPHY.

Echocardiography is helpful in the differential diagnosis because in right ventricular infarction, in contrast to pericardial tamponade, no significant quantities of pericardial fluid are seen. On two-dimensional echocardiography, abnormal wall motion of the right ventricle as well as right ventricular dilatation and depression of right ventricular ejection fraction are noted.[52] Gated equilibrium radionuclide angiography is also useful for recognizing right ventricular MI. Serial studies have shown that some degree of recovery of an initially depressed right ventricular ejection fraction is the rule with right ventricular MI,[424] whereas this is less apparent in left ventricular ejection fraction.

HEMODYNAMICS.

Loss of atrial transport in patients with right ventricular infarction can result in marked reductions in stroke volume and arterial blood pressure. As already noted, disproportionate elevation of the right-sided filling pressure is the hemodynamic hallmark of right ventricular infarction. Therefore, ventricular pacing may fail to increase cardiac output, and atrioventricular sequential pacing may be required.

Management

Because of their ability to reduce preload, medications routinely prescribed for left ventricular infarction may produce profound hypotension in patients with right ventricular in

Figure 35-44 ST segment and T wave configurations in lead V_4 R in inferoposterior myocardial infarction. Proximal occlusion of the right coronary artery is characterized by ST segment elevation of at least 1 mm and a positive T wave. Distal occlusion of the right coronary artery is characterized by a positive T wave but no ST segment elevation. Occlusion of the circumflex coronary artery is characterized by a negative T wave and ST segment depression of at least 1 mm. *(Reproduced with permission from Wellens HJ: The value of the right precordial leads of the electrocardiogram. In patients with hypotension due to right ventricular MI, hemodynamics may be improved by a combination of expanding plasma volume to augment right ventricular preload and cardiac output and, when left ventricular failure is present, arterial vasodilators[63] (Table 35-18) (Table Not Available) . The initial therapy for hypotension in patients with right ventricular infarction should almost always be volume expansion. However, if hypotension has not been corrected after one or more liters of fluid has been administered briskly, consideration should be given to hemodynamic monitoring with a pulmonary artery catheter, because further volume infusion may be of little use and may produce pulmonary congestion.[485] Vasodilators reduce the impedance to left ventricular outflow and, in turn, left ventricular diastolic, left atrial, and pulmonary (arterial) pressures, thereby lowering the impedance to right ventricular outflow and enhancing right ventricular output (see Table 35-18) (Table Not Available) .

In view of the importance of atrial transport, patients requiring pacing should have atrial or AV sequential pacing. Successful reperfusion of the right coronary artery significantly improves right ventricular mechanical function and lowers in-hospital mortality in patients with right ventricular infarction.[64] Replacement of the tricuspid valve and repair of the valve with annuloplasty rings have been carried out in the treatment of severe tricuspid regurgitation secondary to right ventricular infarction.

MECHANICAL CAUSES OF HEART FAILURE

Free Wall Rupture

The most dramatic complications of AMI are those that involve tearing or rupture of acutely infarcted tissue[486] (Fig. 35-45). The clinical characteristics of these lesions vary considerably and depend on the site of rupture, which may involve the papillary muscles, the interventricular septum, or the free wall of either ventricle. The overall incidence of these complications is hard to assess because clinical and autopsy series differ considerably.[487] [488] However, as a group they are probably responsible for about 15 percent of all deaths from AMI.[486] [489] In general, patients with rupture of a cardiac structure during AMI have a greater delay to hospital admission and are more likely to have engaged in sustained physical activity after the onset of AMI compared

Figure 35-45 Cardiac rupture syndromes complicating acute myocardial infarction. *A,* Anterior myocardial rupture in an acute infarct (arrow). *B,* Rupture of the ventricular septum (arrow). *C,* Complete rupture of a necrotic papillary muscle. (From Schoen FJ: The heart. *In* Cotran RS, Kumar V, Collins T [eds]: Pathologic Basis of Disease. 6th ed. Philadelphia, WB Saunders, 1999, p 562.)

with those AMI patients who do not experience cardiac rupture.[490] The comparative clinical profile of these complications, as gathered from different studies, is shown in Table 35-19 . The incidence of myocardial rupture has increased since the late 1960s.[487] The prior use of corticosteroids or nonsteroidal antiinflammatory agents has been implicated as predisposing to rupture as a result of impaired healign. Controversy remains about the actual relationship between the use of such agents and the frequency of rupture, with several series suggesting a correlation of rupture with their use[491] and others not.[488] Conversely, the early use of thrombolytic therapy appears to reduce the incidence of cardiac rupture, an effect that is responsible in part for improved survival with effective thrombolysis. Late thrombolytic therapy may actually *increase* the risk of cardiac rupture despite improving overall survival.

Rupture of the free wall of the infarcted ventricle (see Fig. 35-45) occurs in up to 10 percent of patients dying in the hospital of AMI.[486] Thinness of the apical wall, marked intensity of necrosis at the terminal end of the blood supply, poor collateral flow, the shearing effect of muscular contraction against an inert and stiffened necrotic area, and aging of the myocardium with laceration of the myocardial microstructure have all been proposed as the local factors that lead to rupture.

CLINICAL FEATURES.

The following are some features that characterize this serious complication of AMI:

1. It occurs more frequently in the elderly and possibly more frequently in women than in men with infarction.[492]
2. It appears to be more common in hypertensive than in normotensive patients.
3. It occurs more frequently in the left than the right ventricle and seldom occurs in the atria.
4. It usually involves the anterior or lateral walls[486] of the ventricle in the area of the terminal distribution of the left anterior descending coronary artery.
5. It is usually associated with a relatively large transmural infarction involving at least 20 percent of the left ventricle.
6. It occurs between 1 day and 3 weeks, but most commonly 1 to 4 days, after infarction.
7. It is usually preceded by infarct expansion (i.e., thinning and a disproportionate dilatation within the softened necrotic zone).
8. Most commonly it results from a distinct tear in the myocardial wall or a dissecting hematoma that perforates a necrotic area of myocardium (see Fig. 35-45).
9. It usually occurs near the junction of the infarct and the normal muscle.
10. It occurs less frequently in the center of the infarct, but when rupture occurs here, it is usually during the second rather than the first week following the infarct.
11. It rarely occurs in a greatly thickened ventricle or in an area of extensive collateral vessels.
12. It most often occurs in patients *without* previous infarction.[488]
13. There is no evidence that the intensity of anticoagulation influences the occurrence of rupture.[492]

Rupture of the free wall of the left ventricle usually leads to hemopericardium and death from cardiac tamponade. Occasionally, rupture of the free wall of the ventricle occurs as the first clinical manifestation in patients with undetected or silent MI, and then it may be considered a form of "sudden cardiac death."

TABLE 35-19 -- CLINICAL PROFILE OF MECHANICAL COMPLICATIONS OF MYOCARDIAL INFARCTION

VARIABLE	VENTRICULAR SEPTAL DEFECT	FREE WALL RUPTURE	PAPILLARY MUSCLE RUPTURE
Age (mean, years)	63	69	65
Days post-MI	3-5	3-6	3-5
Anterior MI	66%	50%	25%
New murmur	90%	25%	50%
Palpable thrill	Yes	No	Rare
Previous MI	25%	25%	30%

Surgical	50%	Case reports	40-90%

MI=myocardial infarction; LA=left atrium; PA=pulmonary artery; RV=right ventricle; PCW=pulmonary capillary wedge.

Modified from Labovitz AJ, et al: Mechanical complications of acute myocardial infarction. Cardiovasc Rev Rep 5:948, 1984.

The course of rupture varies from catastrophic, with an acute tear leading to immediate death, to subacute, with nausea, hypotension, and pericardial type of discomfort being the major clinical clues to its presence.[486] Survival depends on the recognition of this complication, on hemodynamic stabilization of the patient (usually with inotropic agents and/or intraaortic balloon pump), and, most importantly, on prompt surgical repair.

PSEUDOANEURYSM.

Incomplete rupture of the heart may occur when organizing thrombus and hematoma, together with pericardium, seal a rupture of the left ventricle and thus prevent the development of hemopericardium (Fig. 35-46) . With time, this area of organized thrombus and pericardium can become a pseudoaneurysm (false aneurysm) that maintains communication with the cavity of the left ventricle. In contrast to true aneurysms, which always contain some myocardial elements in their walls, the walls of pseudoaneurysms are composed of organized hematoma and pericardium and lack any elements of the original myocardial wall. Pseudoaneurysms can become quite large, even equalign the true ventricular cavity in size, and they communicate with the left ventricular cavity through a narrow neck. Frequently, pseudoaneurysms contain significant quantities of old and recent thrombus, superficial portions of which can cause arterial emboli. Pseudoaneurysms can drain off a portion of each ventricular stroke volume exactly as do true aneurysms. The diagnosis of pseudoaneurysm can usually be made by two-dimensional echocardiography (see Chap. 7)

and contrast angiography, although at times differentiation between true aneurysm and pseudoaneurysm may be difficult by any imaging technique.

DIAGNOSIS.

The rupture usually is first suggested by the development of sudden profound shock, often rapidly leading to electromechanical dissociation due to pericardial tamponade. Immediate pericardiocentesis confirms the diagnosis and relieves the pericardial tamponade, at least momentarily. If the patient's condition is relatively stable, echocardiography may help in establishing the diagnosis of tamponade.[52] Under the most favorable conditions, cardiac catheterization can be carried out, not necessarily to confirm the diagnosis of rupture but to delineate the coronary anatomy. This is helpful so that, in addition to ventricular repair, CABG can be performed in patients in whom high-grade obstructive lesions are present. In patients in whom hemodynamics are critically compromised, establishment of the diagnosis should be followed immediately by surgical resection of the necrotic and ruptured myocardium with primary reconstruction (Fig. 35-47) . When rupture is subacute and a pseudoaneurysm is suspected or present, prompt elective surgery is indicated because rupture of the pseudoaneurysm occurs relatively frequently.

Rupture of the Interventricular Septum

Although rupture of the interventricular septum previously was reported in up to 11 percent of autopsied cases and 2 percent of AMI patients in the prethrombolytic era, it occurs in 0.2 percent of patients in recent thrombolytic trials.[486] [493] [494] Clinical features associated with an increased risk of rupture of the interventricular septum include lack of development of a collateral network, advanced age, hypertension, anterior location of infarction, and possibly thrombolysis.[493] [494] Patients who develop a rupture of the

Figure 35-46 Differences between a pseudoaneurysm and a true aneurysm. *(From Shah PK: Complications of acute myocardial infarction. In Parmley W, Chatterjee K [eds]: Cardiology. Philadelphia, JB Lippincott, 1987.)*

Figure 35-47 Management of free wall rupture. Typically, the rupture site is within a larger area of necrotic muscle *(A).* After debridement, pledgeted sutures are placed inside the ventricle and through a tailored prosthetic patch *(B).* The patch is then secured to the free wall *(C).(Courtesy of Dr. David Adams, Division of Cardiac Surgery, Brigham and Women's Hospital.)*

interventricular septum after AMI have a higher 30-day mortality (74 percent) compared with those patients who do not develop this complication (7 percent).[493]

The perforation may range in length from one to several centimeters (see Fig. 35-45). It may be a direct through-and-through opening, or it may be more irregular and serpiginous. The size of the defect determines the magnitude of the left-to-right shunt and the extent of hemodynamic deterioration, which in turn affects the likelihood of survival.[486] As in rupture of the free wall of the ventricle, transmural infarction underlies rupture of the ventricular septum. Rupture of the septum with an anterior infarction tends to be apical in location, whereas inferior infarctions are associated with perforation of the basal septum and with a worse prognosis than those in an anterior location. In contrast to rupture of the free wall, rupture of the ventricular septum is more likely (20 to 30 percent of cases) to be associated with complete heart block, right bundle branch block, and atrial fibrillation.[495] Virtually all patients have multivessel coronary artery disease, with the majority exhibiting lesions in all of the major vessels. The likelihood of survival depends on the degree of impairment of ventricular function and the size of the defect.[496]

A ruptured interventricular septum is characterized by the appearance of a new harsh, loud holosystolic murmur that is heard best at the lower left sternal border and that is usually accompanied by a thrill.[52] Biventricular failure generally ensues within hours to days. The defect can also be recognized by two-dimensional echocardiography with color flow Doppler imaging or insertion of a pulmonary artery balloon catheter to document the left-to-right shunt. Catheter placement of an umbrella-shaped device within the ruptured septum has been reported to stabilize the conditions of critically ill patients with acute septal rupture after AMI.

Papillary Muscle Rupture

Partial or total rupture of a papillary muscle is a rare but often fatal complication of transmural MI[486] (see Fig. 35-45). Inferior wall infarction can lead to rupture of the posteromedial papillary muscle,[497] which occurs more commonly than rupture of the anterolateral muscle, a consequence of anterolateral MI. Rupture of a right ventricular papillary muscle is rare but can cause massive tricuspid regurgitation and right ventricular failure. Complete transection of a left ventricular papillary muscle is incompatible with life because the sudden massive mitral regurgitation that develops cannot be tolerated. Rupture of a portion of a papillary muscle, usually the tip or head of the muscle, resulting in severe, although not necessarily overwhelming, mitral regurgitation, is much more frequent and is not immediately fatal. Unlike rupture of the ventricular septum, which occurs with large infarcts, papillary muscle rupture occurs with a relatively small infarction in approximately one half of the cases seen. The extent of coronary artery disease in these patients sometimes is modest as well.

In a small number of patients, rupture of more than one cardiac structure is noted clinically or at postmortem examination; all possible combinations of rupture of the free left ventricular wall, the interventricular septum, and the papillary muscles have been described.[495]

Figure 35-48 Surgical management of mitral regurgitation due to ruptured papillary muscle. Acute papillary muscle rupture results in severe mitral regurgitation due to leaflet and commissural prolapse *(A).* Mitral valve replacement is usually necessary. Mitral debridement with retention of the unruptured commissural and leaflet segment is performed to preserve partial annular papillary continuity *(B).* Mitral valve replacement is then performed *(C).* Occasionally, mitral valve repair can be performed by transfer of a papillary head to a nonrupture segment *(D).(Courtesy of Dr. David Adams, Division of Cardiac Surgery, Brigham and Women's Hospital.)*

As with patients who have a ruptured ventricular septal defect, those with papillary muscle rupture manifest a new holosystolic murmur and develop increasingly severe heart failure. In both conditions the murmur may become softer or disappear as arterial pressure falls. Mitral regurgitation due to partial or complete rupture of a papillary muscle may be promptly recognized echocardiographically.[498] Color flow Doppler imaging is particularly helpful in distinguishing acute mitral regurgitation from a ventricular septal defect in the setting of AMI (Table 35-19) .[499] Therefore, an echocardiogram should be obtained immediately on any patient in whom the diagnosis is suspected, because hemodynamic deterioration can ensue rapidly. Echocardiography also often permits differentiation of papillary muscle rupture from other, generally less severe forms of mitral regurgitation that occur with AMI.

Differentiation Between Ventricular Septal Rupture and Mitral Regurgitation

It may be difficult, on clinical grounds, to distinguish between acute mitral regurgitation and rupture of the ventricular septum in patients with AMI who suddenly develop a loud systolic murmur. This differentiation can be made most readily by color flow Doppler echocardiography. In addition, a right-heart catheterization with a balloon-tipped catheter can readily distinguish between these two complications. As already noted, patients with ventricular septal rupture demonstrate a "step-up" in oxygen saturation in blood samples from the right ventricle and pulmonary artery compared with those from the right atrium. Patients with acute mitral regurgitation lack this step-up; they may demonstrate tall c-v waves in both the pulmonary capillary wedge and pulmonary arterial pressure tracings.

Invasive monitoring, which is essential in these patients, also allows for the critically important assessment of ventricular function.[52] Right and left ventricular filling pressures (right atrial pressure and pulmonary capillary wedge pressure) dictate fluid administration or the use of diuretics, whereas measurements of cardiac output and mean arterial pressure are obtained for calculation of systemic vascular resistance as a guide for vasodilator therapy. Unless systolic pressure is below 90 mm Hg, this therapy, generally using nitroglycerin or nitroprusside, should be instituted as soon as possible once hemodynamic monitoring is available. This may be critically important for stabilizing the patient's condition in preparation for further diagnostic studies and surgical repair. If vasodilator therapy is not tolerated or if it fails to achieve hemodynamic stability, intraaortic balloon counterpulsation should be rapidly instituted.

Surgical Treatment

Operative intervention is most successful in patients with AMI and circulatory collapse when a surgically correctable mechanical lesion such as ventricular septal defect

or mitral regurgitation can be identified and repaired.[493] In such

Figure 35-49 Repair of ischemic ventricular septal defect. The infarct typically involves a free wall and septum (*A* and *B*). Repair of the defect is performed through an incision in the ventricular wall infarct. The septal defect is closed with a prosthetic patch, and a second patch is used to close the incision in the free wall *(C).(Courtesy of Dr. David Adams, Division of Cardiac Surgery, Brigham and Women's Hospital.)*

patients the circulation should at first be supported by intraaortic balloon pulsation and a positive inotropic agent such as dopamine or dobutamine in combination with a vasodilator, unless the patient is hypotensive. Operation should not be delayed in patients with a correctable lesion who agree to an aggressive management strategy and require pharmacological and/or mechanical (counterpulsation) support.[494] Such patients frequently develop a serious complication (infection, adult respiratory distress syndrome, extension of the infarct, or renal failure) if operation is delayed. Surgical survival is predicted by early operation, short duration of shock, and mild degrees of right and left ventricular impairment.[494] When the hemodynamic status of a patient with one of these mechanical lesions complicating an AMI remains stable after the patient has been weaned from pharmacological and/or mechanical support, it may be possible to postpone operation for 2 to 4 weeks to allow some healign of the infarct to occur. Surgical repair may involve correction of mitral regurgitation, insertion of a prosthetic mitral valve repair, or closure of a ventricular septal defect, usually accompanied by coronary revascularization (Figs. 35-48 and 35-49) .[52]

Arrhythmias

The genesis, diagnosis, and treatment of cardiac arrhythmias are presented in Chapters 22 to 26 . The role of arrhythmias in complicating the course of patients with AMI and the prevention and treatment of these arrhythmias in this setting are discussed here and summarized in Table 35-20 .

The incidence of arrhythmias is higher in those patients seen earlier after the onset of symptoms. Many serious arrhythmias develop before hospitalization, even before the patient is monitored.[500] Some abnormality of cardiac rhythm also occurs in the majority of patients with AMI treated in CCUs.[501] When patients are seen very early during the course of MI, they almost invariably exhibit evidence of increased activity of the autonomic nervous system. Thus, sinus bradycardia, sometimes associated with AV block, and hypotension reflect augmented vagal activity.

MECHANISM OF ARRHYTHMIAS IN MYOCARDIAL INFARCTION.

Owing to the difficulty of studying cardiac arrhythmias

TABLE 35-20 -- CARDIAC ARRHYTHMIAS AND THEIR MANAGEMENT DURING ACUTE MYOCARDIAL INFARCTION

CATEGORY	ARRHYTHMIA	OBJECTIVE OF TREATMENT	THERAPEUTIC OPTIONS
1. Electrical instability	Ventricular premature beats	Correction of electrolyte deficits and increased sympathetic tone	Potassium and magnesium solutions, beta blocker
	Ventricular tachycardia	Prophylaxis against ventricular fibrillation, restoration of hemodynamic stability	Antiarrhythmic agents; cardioversion/defibrillation
	Ventricular fibrillation	Urgent reversion to sinus rhythm	Defibrillation; bretylium tosylate
	Accelerated idioventricular rhythm	Observation unless hemodynamic function is compromised	Increase sinus rate (atropine, atrial pacing); antiarrhythmic agents
	Nonparoxysmal atrioventricular junctional tachycardia	Search for precipitating causes (e.g., digitalis intoxication); suppress arrhythmia only if hemodynamic function is compromised	Atrial overdrive pacing; antiarrhythmic agents; cardioversion relatively contraindicated if digitalis intoxication present
2. Pump failure/excessive sympathetic stimulation	Sinus tachycardia	Reduce heart rate to diminish myocardial oxygen demands	Antipyretics; analgesics; consider beta blocker unless congestive heart failure present; treat latter if present with anticongestive measures (diuretics, afterload reduction)
	Atrial fibrillation and/or atrial flutter	Reduce ventricular rate; restore sinus rhythm	Verapamil, digitalis glycosides; anticongestive measures (diuretics, afterload reduction); cardioversion; rapid atrial pacing (for atrial flutter)
	Paroxysmal supraventricular tachycardia	Reduce ventricular rate; restore sinus rhythm	Vagal maneuvers; verapamil, cardiac glycosides, beta-adrenergic blockers; cardioversion; rapid atrial pacing
3. Bradyarrhythmias and conduction disturbances	Sinus bradycardia	Acceleration of heart rate only if hemodynamic function is compromised	Atropine; atrial pacing
	Junctional escape rhythm	Acceleration of sinus rate only if loss of atrial "kick" causes hemodynamic compromise	Atropine; atrial pacing
	Atrioventricular block and intraventricular block		Insertion of pacemaker

Modified from Antman EM, Rutherford JD (eds): Coronary Care Medicine: A Practical Approach. Boston, Martinus Nijhoff Publishing, 1986, p 78.

in patients with acute myocardial ischemia and infarction, investigators have resorted to animal models of coronary occlusion and release in an attempt to elucidate the causes of arrhythmias in the clinical setting and identify potential therapeutic targets.[502] [503] Animal models have generally been divided into arrhythmias occurring during the early phase of MI (first 30 minutes after coronary occlusion) and arrhythmias occurring during later phases in the infarction process (occurring hours to days and even weeks after infarction).[504] When interpreting animal models to draw correlations to clinical arrhythmias, several factors must be considered: the mode of coronary artery occlusion (thrombotic occlusion versus coronary ligation), number of successive coronary occlusions (e.g., preconditioning), the size of the myocardial ischemic zone, the level of activity of the autonomic nervous system, and the presence or absence of collateral vessels.[505] Electrophysiological disturbances during the acute phase of coronary occlusion in experimental animals that are probably relevant in patients with AMI include a loss of transmembrane resting potential, alterations in refractoriness and excitability, slowing of conduction, and the emergence of abnormal mechanisms of automatic impulse formation. A leading hypothesis for a major mechanism of arrhythmias in the acute phase of coronary occlusion is micro-reentry due to inhomogeneity of the electrical characteristics of ischemic myocardium. Cells at the center of the ischemic zone have a relatively uniform increase in extracellular potassium concentration, whereas cells in the border zone between the ischemic region and normal myocardium are only partially depolarized and therefore have action potentials with a larger amplitude. Slowing of impulse conduction and block occurs in markedly depressed areas leading to arrhythmias such as polymorphic VT and ventricular fibrillation.[506]

The cellular electrophysiological mechanisms for reperfusion arrhythmias appear to include washout of various ions such as lactate and potassium and toxic metabolic substances that have accumulated in the ischemic zone. Cells in reperfused myocardial zones can exhibit action potentials of the slow response type.[504] In animal models in which reperfusion does not take place and a permanent occlusion of the infarct artery occurs, delayed afterdepolarizations and triggered automaticity have been demonstrated. It is unclear whether such phenomena also occur in patients with AMI.

The treatment of tachyarrhythmias involves not only the use of antiarrhythmic drugs but also correction of abnormalities of plasma electrolyte concentrations, acid-base balance disturbances, hypoxemia, anemia, and digitalis intoxication. In addition, it is essential to treat pericarditis, pulmonary emboli, and pneumonia or other infections, which may give rise to sinus tachycardia or other supraventricular tachyarrhythmias.

Arrhythmias occurring in patients with AMI require aggressive treatment when they (1) impair hemodynamics, (2) compromise myocardial viability by augmenting

oxygen requirements, or (3) predispose to malignant ventricular arrhythmias (i.e., VT, ventricular fibrillation, or asystole). Evidence indicates that both the diminished threshold to ventricular fibrillation[507] and the incidence of malignant ventricular arrhythmias associated with infarction are affected by the extent of the underlying infarction.[508]

HEMODYNAMIC CONSEQUENCES.

Patients with significant left ventricular dysfunction have a relatively fixed stroke volume and depend on changes in heart rate to alter cardiac output. However, there is a narrow range of heart rate over which the cardiac output is maximal, with significant reductions occurring at both faster and slower rates. Thus, all forms of bradycardia and tachycardia may depress the cardiac output in patients with AMI. Although the optimal rate insofar as cardiac output is concerned may exceed 100 beats/min, it is important to consider that heart rate is one of the major determinants of myocardial oxygen consumption and that at more rapid heart rates myocardial energy needs can be elevated to levels that adversely affect ischemic myocardium. Therefore, in patients with AMI, the optimal rate is usually lower, in the range of 60 to 80 beats/min.

A second factor to consider in assessing the hemodynamic consequences of a particular arrhythmia is the loss of the atrial contribution to ventricular preload. Studies in patients without AMI have demonstrated that loss of atrial transport decreases left ventricular output by 15 to 20 percent.[509] However, in patients with reduced diastolic left ventricular compliance of any cause (including AMI), atrial systole is of greater importance for left ventricular filling. In patients with AMI, atrial systole boosts end-diastolic volume by 15 percent, end-diastolic pressure by 29 percent, and stroke volume by 35 percent.

VENTRICULAR ARRHYTHMIAS (See also Chap. 25)

Ventricular Premature Beats

Before the widespread use of reperfusion therapy, aspirin, beta blockers, and intravenous nitrates in the management of AMI, it was believed that frequent VPB (more than five per minute), VPBs with multiform configuration, early coupling (the "R-on-T" phenomenon), and repetitive patterns in the form of couples or salvos presaged ventricular fibrillation. However, it is now clear that such "warning arrhythmias" are present in as many patients who do not develop fibrillation as those who do. Several reports have shown that primary ventricular fibrillation (see later) occurs without antecedent warning arrhythmias and may even develop in spite of suppression of warning arrhythmias. [510] On the other hand, frequent and complex VPBs and R-on-T beats are commonly observed in patients with AMI who never develop ventricular fibrillation.[510] Both primary ventricular fibrillation and VPBs, especially R-on-T beats, occur during the early phase of AMI when considerable heterogeneity of electrical activity is present. Although R-on-T beats expose this heterogeneity and can precipitate ventricular fibrillation in a small minority of patients, the ubiquitous nature of VPBs in AMI and the extremely infrequent nature of ventricular fibrillation in the current era of AMI management produce unacceptably low sensitivity and specificity of ECG patterns observed on monitoring systems for identifying patients at risk of ventricular fibrillation.

MANAGEMENT.

Because the incidence of ventricular fibrillation in AMI seen in CCUs over the past three decades appears to be declining, the prior practice of prophylactic suppression of VPBs with antiarrhythmic drugs is no longer necessary and there is the possibility that its use may actually be associated with an increased risk of fatal bradycardic and asystolic events.[511] [512] [513] [514] [515] Therefore, we pursue a conservative course when VPBs are observed in AMI and do not routinely prescribe antiarrhythmic drugs but instead determine whether recurrent ischemia or electrolyte (Fig. 35-50) or metabolic disturbances are present.[510]

When, at the very inception of an infarction, VPBs are encountered in the presence of sinus tachycardia, augmented sympathoadrenal stimulation is often a contributing factor and may be treated by beta-adrenoceptor blockade. In fact, early administration of an intravenous beta blocker is effective in reducing the incidence of ventricular fibrillation in evolving MI.[516] [517]

Accelerated Idioventricular Rhythm

Commonly defined as a ventricular rhythm with a rate of 60 to 125 beats/min, and frequently called "slow ventricular tachycardia," this arrhythmia is seen in up to 20 percent of patients with AMI. It occurs frequently during the first 2 days, with about equal frequency in anterior and inferior infarctions, and probably results from enhanced automaticity of Purkinje fibers. Most episodes are of short duration, and the arrhythmia may terminate abruptly, slow gradually before termination, or be overdriven by acceleration of the basic cardiac rhythm. Variation of the rate is common.

Accelerated idioventricular rhythm is often observed shortly after successful reperfusion has been established.[518] However, the frequent occurrence of these rhythms in patients without reperfusion limits their reliability as markers of restoration of patency of the infarct-related coronary artery.[519] In contrast to rapid ventricular tachycardia, accelerated idioventricular rhythms are thought not to affect prognosis. There is no definitive evidence that this arrhythmia, when left untreated, increases the incidence of either ventricular fibrillation or death. Therefore, we do not routinely treat accelerated idioventricular rhythms. In the rare patient with clear-cut hemodynamic compromise or recurrent angina related to accelerated idioventricular rhythms, we attempt to accelerate the sinus rate with atropine or atrial pacing; suppressive antiarrhythmic therapy with lidocaine or procainamide is usually not used unless there is unequivocal precipitation of more serious ventricular tachyarrhythmias.

Ventricular Tachycardia

Nonsustained ventricular tachycardia (VT) is usually defined as three or more consecutive ventricular ectopic beats (at a rate > 100 beats/min and lasting < 30 seconds; see Fig. 35-18); sustained VT refers to similar rhythms that last longer than 30 seconds or cause hemodynamic compromise *that requires intervention.* (Although most brief runs of VT

Figure 35-50 Importance of electrolyte deficits, as shown in this study in which the risk for ventricular fibrillation was strikingly increased in patients who presented to the critical care unit (CCU) with hypokalemia. *(From Nordrehaug JE, van der Lippe G: Hypokalemia and ventricular fibrillation in acute myocardial infarction. Br Heart J 50:525, 1983.)*

cause some reduction in blood pressure that is observed on arterial line pressure tracings, the majority of such episodes are not recognized by the patient). Additional descriptive features of note for sustained VT are whether the ECG appearance is monomorphic or polymorphic.[520] This may be of importance because the former is more likely to be due to a myocardial scar and require aggressive strategies to prevent its recurrence and the latter may be more responsive to measures directed against ischemia. When continuous ECG recordings during the first 12 hours of AMI are analyzed, nonsustained paroxysms of monomorphic or polymorphic VT may be seen in up to 67 percent of patients.[521] These *nonsustained* runs of ventricular tachycardia do not appear to be associated with an increased mortality risk, either during hospitalization or over the first year. Data from the GUSTO-I trial indicate that in the thrombolytic era, sustained VT occurs in 3.5 percent of patients, ventricular fibrillation in 4.1 percent of patients, and a combination of sustained VT and ventricular fibrillation in 2.7 percent of patients.[522] Patients who experience sustained VT either in isolation or in combination with ventricular fibrillation have larger infarcts than patients who do not experience sustained VT or ventricular fibrillation. Not unexpectedly, the larger infarcts in patients with sustained VT are associated with a significantly higher risk of congestive heart failure, cardiogenic shock, and atrial fibrillation. The in-hospital mortality rate for patients experiencing only sustained VT is 18.6 percent, whereas those experiencing both sustained VT and ventricular fibrillation have a 44 percent in-hospital mortality.[522] Patients with sustained VT or both VT and ventricular fibrillation who survive to 30 days have a higher 1-year mortality rate (approximately 7 percent) compared with patients who do not experience either arrhythmia (approximately 3 percent).[522]

VT occurring late in the course of AMI is more common in patients with transmural infarction and left ventricular dysfunction, is likely to be sustained, usually induces marked hemodynamic deterioration, and is associated with both an increased hospital mortality and long-term mortality.

MANAGEMENT.

Because hypokalemia may increase the risk of developing VT,[523] low serum potassium levels should be identified quickly after a patient's admission for AMI and should be treated promptly. The serum potassium level should be maintained above 4.5 mEq/liter, and the serum magnesium level should be above 2 mEq/liter.[185]

Rapid abolition of sustained VT in patients with AMI is mandatory because of its deleterious effect on pump function and because it frequently deteriorates into ventricular fibrillation. When the ventricular rate is rapid (150 beats/min) and/or there is a decline in arterial pressure, a single attempt at "thumpversion" (i.e., striking a sharp blow to the precordium) is indicated. Rapid polymorphic VT should be managed similar to ventricular fibrillation, with an unsynchronized discharge of 200 J, whereas monomorphic VT should be treated with a synchronized discharge of 50 to 100 J.[52] Occasionally, lower-energy (10 to 20 J) synchronized discharges can terminate monomorphic VT.

When the ventricular rate is slower than approximately 150 beats/min and the arrhythmia is well tolerated hemodynamically, antiarrhythmic therapy with one of the following regimens should be attempted[52] :

1. *Lidocaine*--initial bolus of 1.0 to 1.5 mg/kg followed by supplemental boluses of 0.5 to 0.75 mg/kg every 5 to 10 minutes as needed to a maximum of 3 mg/kg. A maintenance infusion of 20 to 50 mug/kg/min (1 to 4 mg/min) may then be started. The metabolism of lidocaine is slowed not only in patients with heart failure or hypotension but also in those with diminution of hepatic blood flow due to effects of pharmacological agents such as propranolol. The rate of infusion should be lower in patients with renal failure. Therefore, careful titration is needed to avoid toxicity, manifested primarily by central nervous system hyperactivity, as well as by depression of intraventricular and atrioventricular conduction and cardiac contractility. Saturation of an extravascular pool normally occurs after a continuous infusion of approximately 3 hours, at which time blood levels increase despite maintenance of a constant infusion rate. At this time, it may be desirable to reduce the rate of administration by about 25 percent.
2. *Procainamide*--loading infusion of 12 to 17 mg/kg over about 20 to 30 minutes, followed by a maintenance infusion of 1 to 4 mg/min (see also Chap. 23) .
3. *Amiodarone*--loading infusion of 150 mg, followed by a constant infusion of 1.0 mg/min for up to 6 hours and then a maintenance infusion at 0.5 mg/min (see also Chap. 23) .

After reversion to sinus rhythm, every effort should be made to correct underlying abnormalities such as hypoxia, hypotension, acid-base or electrolyte disturbances, and digitalis excess. Although no definitive data are available, it is a common clinical practice to continue maintenance infusions of antiarrhythmic drugs for several days after an index episode of VT and to discontinue the drug and either observe the patient for recurrence or perform a diagnostic electrophysiology study. Patients with recurrent or refractory VT should be considered for specialized procedures such as implantation of antitachycardia devices or surgery (see Chap. 24) . Occasionally, urgent attempts at revascularization with angioplasty or CABG may help control refractory VT.[520]

Ventricular Fibrillation

This arrhythmia may occur in three settings in hospitalized patients with AMI. (Its occurrence as a mechanism of sudden death is discussed in Chapter 26.) *Primary* ventricular fibrillation occurs suddenly and unexpectedly in patients with no or few signs or symptoms of left ventricular failure.[520A] Although primary ventricular fibrillation occurred in up to 10 percent of patients hospitalized with AMI several decades ago, analyses suggest that its incidence has declined.[511] [524] Approximately 60 percent of episodes occur within 4 hours and 80 percent within 12 hours of the onset of symptoms.[521] *Secondary* ventricular fibrillation, on the other hand, is often the final event of a progressive downhill course with left ventricular failure and cardiogenic shock. So-called *late* ventricular fibrillation develops more than 48 hours after AMI and frequently but not exclusively occurs in patients with large infarcts and ventricular dysfunction. Patients with intraventricular conduction defects and anterior wall infarction, patients with persistent sinus tachycardia, atrial flutter, or fibrillation early in the clinical course, and those with right ventricular infarction who require ventricular pacing are at higher risk for suffering late in-hospital ventricular fibrillation than are patients without these features.

PROGNOSIS.

The effect of primary ventricular fibrillation on prognosis continues to be debated.[515] The MILIS study, conducted in the prethrombolytic era, suggested that it does not have an adverse effect on hospital mortality, whereas the GISSI investigators, reporting observations in large cohorts of thrombolytic-treated patients, suggest that there is an excess mortality due to primary ventricular fibrillation during the hospital phase but not thereafter.[525] Observations from the GUSTO I trial indicate that the in-hospital mortality of patients with early (within the first 48 hours) ventricular fibrillation is 19.8 percent but survivors to 30 days have a 1-year mortality of 2.7 percent, similar to the 1-year mortality of 30-day survivors who do not experience ventricular fibrillation or VT during the initial hospitalization for AMI.[522] On the other hand, secondary ventricular fibrillation occurring in association with marked left ventricular

failure or cardiogenic shock, an arrhythmia that typically occurs late (>48 hours) after presentation with AMI, entails a poor prognosis, with an in-hospital mortality rate of 40 to 60 percent.[521] [526] With the availability of amiodarone and new antitachycardia devices, the prognosis of late ventricular fibrillation is improving and is probably driven more by residual ventricular function and recurrent ischemia than the arrhythmic risk per se.[510]

PROPHYLAXIS.

In the early years of MI care in CCUs, concern about the risk of primary ventricular fibrillation led to aggressive monitoring for "warning" ventricular arrhythmias and the initiation of antiarrhythmic therapy when they appeared. Later, when it was shown that warning arrhythmias could not be relied on to predict the risk of ventricular fibrillation, arrhythmia prophylaxis became routine.[527] [528] Lidocaine has been studied most extensively in this regard and has been shown to reduce the incidence of ventricular fibrillation,[529] leading to its widespread routine use in CCUs in patients with known or suspected AMI. However, we no longer endorse that CCU practice for the following reasons:

1. As already noted, the incidence of ventricular fibrillation in patients hospitalized for AMI is decreasing so that the risk for the arrhythmia is now much lower than it was several decades ago (probably under 5 percent). The reasons for this reduction in ventricular fibrillation are not clear but probably include general improvements in the care of AMI patients, greater use of beta blockers, aggressive repletion of electrolytes, prompt treatment of ischemia and congestive heart failure, and reduction in infarct size from reperfusion strategies.[511]
2. There is no evidence that prophylaxis with lidocaine actually reduces mortality in hospitalized patients with AMI because they can almost always be promptly defibrillated.[515] Furthermore, there appear to be trends to excess mortality risk when lidocaine is used on a routine prophylactic basis.[512] [513] [514] [529]
3. Beta-adrenoceptor blockers, which should be administered promptly to the majority of patients with AMI (see p. 1168), have been shown to reduce not only ventricular fibrillation[517] but also mortality from AMI.[510] [530]
4. There is an association between hypokalemia and the risk of ventricular fibrillation in the CCU.[531] [532] (see Fig. 35-50)

Although it has not been conclusively shown that correction of hypokalemia to a level of 4.5 mEq/liter actually reduces the incidence of ventricular fibrillation, our experience suggests that this probably is protective and of little risk. The data on magnesium and the risk of ventricular fibrillation are incomplete at present. Despite the fact that no consistent relationship between hypomagnesemia and ventricular fibrillation has been observed,[532] magnesium deficits may still be involved in the risk of ventricular fibrillation because intracellular magnesium levels are reduced in AMI and are not adequately reflected by serum measurements. For these reasons, plus the fact that it is often difficult to repair a potassium deficit without administering supplemental magnesium, we routinely replete magnesium to a level of 2 mEq/liter.

The only situation in which we might consider prophylactic lidocaine (bolus of 1.5 mg/kg followed by 20 to 50 mug/kg/min) would be the unusual circumstance in which a patient within the first 12 hours of an AMI must be managed in a facility where cardiac monitoring is not available and equipment for prompt defibrillation is not readily accessible.

MANAGEMENT. (See also Chap. 25.)

The likelihood of successful restoration of an effective cardiac rhythm declines rapidly with time after the onset of uncorrected ventricular fibrillation. Irreversible brain damage may occur within 1 to 2 minutes, particularly in elderly patients. The treatment of ventricular fibrillation is an unsynchronized electrical countershock with at least 200 to 300 J, implemented as rapidly as possible.[52] This interrupts fibrillation and restores an effective cardiac rhythm in patients under direct medical observation in the CCU. When ventricular fibrillation occurs outside an intensive care unit, resuscitative efforts are much less likely to be successful, primarily because the time interval between the onset of the episode and the institution of definitive therapy tends to be prolonged. Because closed-chest cardiopulmonary resuscitation with external cardiac compression provides only a marginal cardiac output even under optimal circumstances, countershock could be implemented as soon as possible after

the detection of ventricular fibrillation rather than deferred under the mistaken impression that adequate circulatory and respiratory support can be maintained in the interim. Failure of electrical countershock to restore an effective cardiac rhythm is due almost always to rapidly recurrent VT or ventricular fibrillation, to electromechanical dissociation, or, very rarely, to electrical asystole.

Ventricular fibrillation often recurs rapidly and repeatedly when the metabolic milieu of the heart has been compromised by severe or prolonged hypoxemia, acidosis, electrolyte abnormalities, or digitalis intoxication. Under these conditions, continued cardiopulmonary resuscitation, prompt implementation of pharmacological and ventilatory maneuvers designed to correct these abnormalities, and rapidly repeated attempts with electrical countershock may be effective. Even though repeated shocks with excessive energy may damage the myocardium and elicit arrhythmias, speed is essential and prompt efforts with high-intensity shocks (generally 300 to 400 watt-seconds) are justified. When ventricular fibrillation persists without documented interruption by electrical countershock, administration of epinephrine either by the intracardiac route (up to 10 ml of a 1:10,000 concentration) or intravenous route (1 mg initially) may facilitate a subsequent defibrillation attempt.

Successful interruption of ventricular fibrillation or prevention of refractory recurrent episodes may also be facilitated by administration of bretylium tosylate, 5 mg/kg intravenously, repeated 5 to 20 minutes later if necessary, or amiodarone (75 to 150 mg bolus). When synchronous cardiac electrical activity is restored by countershock but contraction is ineffective (i.e., during electromechanical dissociation), the usual underlying cause is very extensive myocardial ischemia or necrosis or rupture of the ventricular free wall or septum. If rupture has not occurred, intracardiac administration of calcium gluconate or epinephrine may promote restoration of an effective heartbeat. We do *not* usually administer bicarbonate injections to correct acidosis because of the high osmotic load they impose and the fact that hyperventilation of the patient is probably a more suitable means of clearing the acidosis.

BRADYARRHYTHMIAS

Sinus Bradycardia

Sinus bradycardia is a common arrhythmia occurring during the early phases of AMI, and it is particularly frequent in patients with inferior and posterior infarction.[52] Observations in mobile CCUs indicate that 25 to 40 percent of patients with AMI have ECG evidence of sinus bradycardia within the first hour after the onset of symptoms; however, 4 hours after infarction commences the incidence of sinus bradycardia has declined to 15 to 20 percent.[500] Stimulation of cardiac vagal afferent receptors (which are more common in the inferoposterior than the anterior or lateral portions of the left ventricle), with resulting efferent cholinergic stimulation of the heart, produces vagotonia with resultant bradycardia and hypotension. This is a manifestation of the

Bezold-Jarisch reflex[533] that is mediated by the vagus nerves and occurs during reperfusion, particularly of the right coronary artery.[277] [308] [534] Often sinus bradycardia is a component of vasovagal or vasodepressor response, which may be intensified by severe pain as well as by morphine, and may be related to vasovagal syncope (see Chap. 27) . [535]

On the basis of data obtained in experimental infarction and from some clinical observations, it appears that the increased vagal tone that produces sinus bradycardia during the early phase of AMI may actually be protective, perhaps because it reduces myocardial oxygen demands.[536] Thus, the acute mortality rate appears to be as low in patients with sinus bradycardia as in patients without this arrhythmia.

MANAGEMENT.

Isolated sinus bradycardia, unaccompanied by hypotension or ventricular ectopy, should be observed rather than treated initially. In the first 4 to 6 hours after infarction, if the sinus rate is extremely slow (under 40 to 50 beats/min), administration of intravenous atropine in aliquots of 0.3 to 0.6 mg every 3 to 10 minutes (with a total dose not exceeding 2 mg) to bring heart rate up to approximately 60 beats/min often abolishes the VPBs commonly associated with this degree of sinus bradycardia.[537] Atropine often contributes to restoration of arterial pressure and hence coronary perfusion and should be employed if hypotension accompanying any degree of sinus bradycardia is present. The favorable effects of atropine may be accompanied by regression of ST segment elevation. Elevation of the lower extremities also often elevates arterial pressure by redistributing blood from the systemic venous bed to the thorax, thereby augmenting ventricular preload, cardiac output, and arterial pressure.

Sinus bradycardia occurring more than 6 hours after the onset of the AMI is often transitory, is caused by sinus node dysfunction or atrial ischemia rather than vagal hyperactivity, is usually not accompanied by hypotension, and does not usually predispose to ventricular arrhythmias. Treatment is not required unless ventricular performance is compromised or the administration of a beta-adrenoceptor blocker or high doses of antiarrhythmic drugs (which may slow the sinus rate further) is planned. When atropine is ineffective and the patient is symptomatic and/or hypotensive, electrical pacing is indicated.[52] In patients with depressed ventricular performance, who require the atrial contribution to ventricular filling, atrial pacing or atrioventricular sequential pacing is superior to simple ventricular pacing.

Atrioventricular and Intraventricular Block

Ischemic injury can produce conduction block at any level of the AV or intraventricular conduction system. Such blocks may occur in the AV node and the bundle of His, producing various grades of AV block; in either main bundle branch, producing right or left bundle branch block; and in the anterior and posterior divisions of the left bundle branch, producing left anterior or left posterior (fascicular) divisional blocks.[538] Disturbances of conduction can, of course, occur in various combinations. The mechanisms and recognition of intraventricular and AV conduction disturbances are discussed in Chapter 22 .

First-Degree AV Block

First-degree AV block occurs in less than 15 percent of patients with AMI admitted to CCUs. His bundle ECG studies have shown that almost all patients with first-degree AV block have disturbances in conduction above the bundle of His (i.e., intranodal). The localization of the site of block is important because development of complete heart block and ventricular asystole is restricted almost exclusively to those patients with first-degree block in whom the conduction disturbance is *below* the bundle of His; this occurs more commonly in patients with anterior infarction and those with associated bifascicular block.

First-degree AV block generally does not require specific treatment. However, if digitalis intoxication is suspected as the cause, this drug should be discontinued. Beta blockers and calcium antagonists (other than nifedipine) prolong AV conduction and may be responsible for first-degree AV block as well. However, discontinuation of these drugs in the setting of AMI has the potential to increase ischemia and ischemic injury. Therefore, it is our practice not to decrease the dosage of these drugs unless the PR interval is greater than 0.24 second. Only if higher-degree block or hemodynamic impairment occurs should these agents be stopped. If the block is a manifestation of excessive vagotonia and is associated with sinus bradycardia and hypotension, administration of atropine, as already outlined, may be helpful. Continued ECG monitoring is important in such patients in view of the possibility of progression to higher degrees of block.

Second-Degree AV Block

MOBITZ TYPE I OR WENCKEBACH AV BLOCK.

Mobitz type I block occurs in up to 10 percent of patients with AMI admitted to CCUs and accounts for about 90 percent of all patients with AMI and second-degree AV block. This type of block (1) generally occurs within the AV node, (2) is usually associated with narrow QRS complexes, (3) is presumably secondary to ischemic injury, (4) occurs more commonly in patients with inferior than anterior MI, (5) is usually transient and does not persist for more than 72 hours after infarction, (6) may be intermittent, and (7) rarely progresses to complete AV block (Table 35-21) . First-degree and type I second-degree AV blocks do not appear to affect survival, are most commonly associated with occlusion of the right coronary artery, and are caused by ischemia of the AV node.

Specific therapy is not required in patients with second-degree AV block of the Mobitz type I variety when the ventricular rate exceeds 50 beats/min and ventricular irritability, heart failure, and bundle branch block are absent. However, if these complications develop or if the heart rate falls below approximately 50 beats/min and the patient is symptomatic, immediate treatment with atropine (0.3 to 0.6 mg) is indicated; temporary pacing systems are almost never needed in the management of this arrhythmia.

MOBITZ TYPE II AV BLOCK.

This is a rare conduction defect after AMI, occurring in only 10 percent of all cases of second-degree block. Thus, the overall incidence of Mobitz type II block after

infarction is less than 1 percent. In contrast to Mobitz type I block, type II second-degree block (1) usually originates from a lesion in the conduction system below the bundle of His, (2) is associated with a wide QRS complex, (3) often but not invariably reflects trifascicular block with impaired conduction distal to the bundle of His, (4) often progresses suddenly to complete AV block, and (5) is almost always associated with anterior rather than inferior infarction (see Table 35-21) .

Because of its potential for progression to complete heart block, Mobitz type II second-degree AV block should be treated with a temporary external or transvenous demand pacemaker with the rate set at approximately 60 beats/min.[52]

Complete (Third-Degree) AV Block

The AV conduction system has a dual blood supply: the AV branch of the right coronary artery and the septal perforating branch from the left anterior descending coronary artery. Therefore, complete AV block can occur in patients

TABLE 35-21 -- ATRIOVENTRICULAR (AV) CONDUCTION DISTURBANCES IN ACUTE MYOCARDIAL INFARCTION

	LOCATION OF AV CONDUCTION DISTURBANCE	
	Proximal	**Distal**
Site of block	Intranodal	Infranodal
Site of infarction	Inferoposterior	Anteroseptal
Compromised arterial supply	RCA (90%), LCX (10%)	Septal perforators of LAD
Pathogenesis	Ischemia, necrosis, hydropic cell swelling, excess parasympathetic activity	Ischemia, necrosis, hydropic cell swelling
Predominant type of AV nodal block	First-degree (PR>200 msec)	Mobitz type II second-degree
	Mobitz type I second-degree	Third-degree
Common premonitory features of third-degree AV block	(a) First-second-degree AV block	(a) Intraventricular conduction block
	(b) Mobitz I pattern	(b) Mobitz II pattern
Features of escape rhythm following third-degree block		
(a) Location	(a) Proximal conduction system (His bundle)	(a) Distal conduction system (bundle branches)
(b) QRS width	(b) < 0.12/sec-*	(b) > 0.12/sec
(c) Rate	(c) 45-60/min but may be as low as 30/min	(c) Often < 30/min
(d) Stability of escape rhythm	(d) Rate usually stable; asystole uncommon	(d) Rate often unstable with moderate to high risk of ventricular asystole
Duration of high-grade AV block	Usually transient (2-3 days)	Usually transient but some form of AV conduction disturbance and/or intraventricular defect may persist
Associated mortality rate	Low unless associated with hypotension and/or congestive heart failure	High because of extensive infarction associated with power failure or ventricular arrhythmias
Pacemaker therapy		
(a) Temporary	(a) Rarely required; may be considered for bradycardia associated with left ventricular power failure, syncope, or angina	(a) Should be considered in patients with anteroseptal infarction and acute bifascicular block
(b) Permanent	(b) Almost never indicated because conduction defect is usually transient	(b) Indicated for patients with high-grade AV block with block in His-Purkinje system and those with transient advanced AV block and associated bundle branch block

RCA=right coronary artery; LCX=left circumflex coronary artery; LAD= left anterior descending coronary artery.

*Some studies suggest that a wide QRS escape rhythm (>0.12 sec) following high-grade AV block in inferior infarction is associated with a worse prognosis.

with either anterior or inferior infarction. Complete AV block occurs in about 5 percent of patients in the thrombolytic era, although the incidence may be higher in patients with right ventricular infarction.[63] [539] [540] As with other forms of AV block, the prognosis depends on the anatomical location of the block in the conduction system and the size of the infarction.[541]

Complete heart block in patients with inferior infarction usually results from an intranodal or supranodal lesion[542] and develops gradually, often progressing from first-degree or type I second-degree block (see Table 35-21) . The escape rhythm is usually stable without asystole and often junctional, with a rate exceeding 40 beats/min and a narrow QRS complex in 70 percent of cases and a slower rate and wide QRS in the others. This form of complete AV block is often transient, may be responsive to pharmacological antagonism of adenosine with methylxanthines,[543] [544] and resolves in the majority of patients within a few days. The mortality may approach 15 percent unless right ventricular infarction is present, in which case the mortality associated with complete AV block may be more than doubled.

In patients with anterior infarction, third-degree AV block often occurs suddenly, 12 to 24 hours after the onset of infarction, although it is usually preceded by intraventricular block and often Mobitz type II (not first-degree or Mobitz type I) AV block (see Table 35-20) . Such patients have unstable escape rhythms with wide QRS complexes and rates less than 40 beats/min; ventricular systole may occur quite suddenly. The mortality in this group of patients is extremely high, 70 to 80 percent.

PROGNOSIS.

This depends on the extent and secondarily on the anatomical site of the myocardial injury.[539] [545] Patients with inferior infarction often have concomitant ischemia or infarction of the AV node secondary to hypoperfusion of the AV nodal artery. However, the His-Purkinje system usually escapes injury in such individuals. Patients with inferior MI who develop AV block usually have lesions in both the right and left anterior descending coronary arteries. Likewise, patients with inferior MI and AV block have larger infarcts and more depressed right ventricular and left ventricular function than do patients with inferior infarct and no AV block. As already noted, junctional escape rhythms with narrow QRS complexes occur commonly in this setting. In patients with anterior infarction, AV block usually develops as a result of extensive septal necrosis that involves the bundle branches. The high mortality in this group of patients with slow idioventricular rhythm and wide QRS complexes is the consequence of extensive myocardial necrosis resulting in severe left ventricular failure and often shock.

Although data suggest that complete AV block is *not* an independent risk factor for mortality, whether temporary transvenous pacing per se improves survival of patients with anterior AMI remains controversial. Some investigators contend that ventricular pacing is useless when employed to correct complete AV block in patients with anterior infarction in view of the poor prognosis in this group

regardless of therapy. However, pacing may protect against transient hypotension with its attendant risks of extending infarction and precipitating malignant ventricular tachyarrhythmias. Also, pacing protects against asystole, a particular hazard in patients with anterior infarction and infranodal block. Improved survival with pacing probably occurs in only a small fraction of patients with complete AV block and anterior wall infarcts because the extensive destruction of the myocardium that almost invariably accompanies this condition results in a very high mortality rate, even in paced patients. Given these considerations, an extremely large series of patients would be required to demonstrate the small reduction of mortality that might be achieved by pacing. The absence of data supporting such an effect, however, by no means excludes the possibility that it may be present.

Pacing is not usually needed in patients with inferior wall infarction and complete AV block that is often transient in nature, but it is indicated if the ventricular rate is very slow (< 40 to 50 beats/min), if ventricular irritability or hypotension is present, or if pump failure develops; atropine is only rarely of value in these patients. Only when complete heart block develops in less than 6 hours after the onset of symptoms is atropine likely to abolish the AV block or cause acceleration of the escape rhythm. In such cases the AV block is more likely to be transient and related to increases in vagal tone than the more persistent block seen later in the course of MI, which generally requires cardiac pacing.

Intraventricular Block

In the prethrombolytic era, studies of intraventricular conduction disturbances, such as a block within one or more of the three subdivisions (fascicles) of the His-Purkinje system (the anterior and posterior divisions of the left bundle and the right bundle), had been reported to occur in 5 to 10 percent of patients with AMI.[532] [546] [547] Several series in the thrombolytic era suggest that intraventricular blocks occur in 2 to 5 percent of patients with AMI.[540] [548] The right bundle branch and the left posterior division have a dual blood supply from the left anterior descending and right coronary arteries, whereas the left anterior division is supplied by septal perforators originating from the left anterior descending coronary artery. Not all conduction blocks observed in patients with AMI can be considered to be complications of infarcts because almost half are already present at the time the first ECG is recorded, and they may represent antecedent disease of the conduction system.[547] [549] Compared with patients without conduction defects, AMI patients with bundle branch blocks have more comorbid conditions; are less likely to receive therapies such as thrombolytics, aspirin, and beta blockers; and have an increased in-hospital mortality rate.[550]

ISOLATED FASCICULAR BLOCKS.

Isolated left anterior divisional block is unlikely to progress to complete AV block.[546] [551] [552] Mortality is increased in these patients, although not as much as in patients with other forms of conduction block. The posterior fascicle is larger than the anterior fascicle, and, in general, a larger infarct is required to block it. As a consequence, mortality is markedly increased. Complete AV block is not a frequent complication of either form of isolated divisional block.[546] [551] [552]

RIGHT BUNDLE BRANCH BLOCK.

This defect alone occurs in approximately 2 percent of patients with AMI and may lead to AV block because it is often a new lesion, associated with anteroseptal infarction.[547] Isolated right bundle branch block is associated with an increased mortality risk in patients with anterior MI even if complete AV block does not occur, but this appears to be the case only if it is accompanied by congestive heart failure.[547] [551] [553]

BIFASCICULAR BLOCK.

The combination of right bundle branch block with either left anterior or posterior divisional block or the combination of left anterior and posterior divisional blocks (i.e., left bundle branch block) is known as bidivisional or bifascicular block. If a new block occurs in two of the three divisions of the conduction system, the risk of developing complete AV block is quite high. Mortality is also high because of the occurrence of severe pump failure secondary to the extensive myocardial necrosis required to produce such an extensive intraventricular block.[548] [552] Left bundle branch block occurs in 2 to 5 percent of patients with AMI. Although the latter defect progresses to complete AV block only half as frequently as does right bundle branch block, it is associated with as high a mortality as right bundle branch block and the other two forms of bifascicular block[551] and with a high late mortality. Patients with intraventricular conduction defects, particularly right bundle branch block, account for the majority of patients who develop ventricular fibrillation late in their hospital stay. However, the high mortality in these patients occurs even in the absence of high-grade AV block and appears to be related to cardiac failure and massive infarction rather than to the conduction disturbance.[550]

Preexisting bundle branch block or divisional block is less often associated with the development of complete heart block in patients with AMI than are conduction defects acquired during the course of the infarct.[551] Bidivisional block in the presence of prolongation of the PR interval (first-degree AV block) may indicate disease of the third subdivision rather than of the AV node. In such cases, termed "trifascicular block," nearly 40 percent progress to complete heart block, a risk that is considerably greater than the risk of complete heart block without first-degree AV block.[546]

Complete bundle branch block (either left or right), the combination of right bundle branch block and left anterior divisional (fascicular) block, and any of the various forms of trifascicular block are all more often associated with anterior than inferoposterior infarction. All these forms are more frequent with large infarcts and in older patients and have a higher incidence of other accompanying arrhythmias than is seen in patients without bundle branch block.

Asystole

This arrhythmia has been reported to occur in 1 to 14 percent of patients with AMI admitted to CCUs. This wide variation in incidence reflects differences in the definition of this event. The lower incidence rates include only patients who develop asystole either as a primary event or after abnormalities of AV or intraventricular conduction, whereas the higher rates include patients who develop asystole as a terminal complication. In either event, the mortality is very high.

The presence of apparent ventricular asystole on monitor displays of continuously recorded ECGs may be misleading, because the mechanism may in fact be fine ventricular fibrillation. Because of the predominance of ventricular fibrillation as the cause of cardiac arrest in this setting, initial therapy should include electrical countershock, even if definitive ECG documentation of this arrhythmia is not available. In the rare instance in which asystole can be documented to be the responsible electrophysiological disturbance, immediate transcutaneous pacing (or stimulation with a transvenous pacemaker if one is already in place) is indicated.[52]

Use of Pacemakers in AMI (See also Chap. 24)

TEMPORARY PACING.

Just as is the case for complete AV block, transvenous ventricular pacing has not resulted in statistically demonstrable improvement in prognosis among patients with AMI who develop intraventricular

---

conduction defects. However, temporary pacing is advisable in some of these patients because of the high risk of developing complete AV block. This includes patients with new bilateral (bifascicular) bundle branch block (i.e., right bundle branch block with left anterior or posterior divisional block and alternating right and left bundle branch block); first-degree AV block adds to this risk. Isolated new block in only one of the three fascicles even with PR interval prolongation and preexisting bifascicular block and normal PR interval poses somewhat less risk; these patients should be monitored closely, with insertion of a temporary pacemaker deferred unless higher-degree AV block occurs.

It has been proposed on the basis of results of an analysis of several large series of well-characterized patients that the risk of developing complete heart block after AMI can be predicted.[552] The presence (new or preexisting) of any of the following conduction disturbances is considered a risk factor: first-degree AV block, Mobitz type I second-degree AV block, Mobitz type II second-degree AV block, left anterior hemiblock, left posterior hemiblock, right bundle branch block, and left bundle branch block. Each risk factor was assigned a score of 1, and the risk score was calculated as the sum of these ECG risk factors. The incidence of complete heart block occurred as follows: risk score 0, 1.2 to 6.8 percent incidence; risk score 1, 7.8 to 10.4 percent incidence; risk score 2, 25.0 to 30.1 percent incidence; and risk score 3, 36 percent or greater incidence.[552] Some authorities have pointed out deficiencies in this scoring system in that Mobitz type II AV block is assigned a score of only 1 point but appears to carry more significance; also there is no differentiation between preexisting and newly appearing bundle branch block.

We believe that failure to demonstrate improved prognosis statistically does not belie the potential value of pacemaker therapy; it probably reflects the overriding impact on mortality of the extensive infarction responsible for the development of the conduction abnormality and the large number of patients required to permit statistical documentation of reduction of mortality.

In assessing the need for temporary pacing (see Table 35-21) , the clinician must keep in mind that between 10 and 20 percent of patients develop pacemaker-related complications. A pericardial friction rub develops in approximately 5 percent of patients but does not necessarily indicate cardiac perforation, nor is such a finding an indication for withdrawal of the pacemaker electrode. Arrhythmias requiring cardioversion, right ventricular perforation, and local infectious complications occur in 1 to 3 percent of cases. Pacemaker malfunction also occurs rather frequently and is, in part, related to the experience of the clinical team in managing the device and its insertion.

Although external temporary cardiac pacing was introduced in 1952, its widespread clinical use did not occur until relatively recently owing to technical refinements making the technique safe, quickly applicable, and relatively well tolerated. Noninvasive external temporary cardiac pacing is now possible routinely in conscious patients and is acceptable to many but not all patients because of the discomfort.[554] Used in a standby mode, it is virtually free of complications and contraindications and provides an important alternative to transvenous endocardial pacing.[52] Once it is clinically evident that continuous pacing is required, external pacing, which is generally not well tolerated for more than minutes to hours, should be replaced by a temporary transvenous pacemaker.

PERMANENT PACING.

The question of permanent pacing in survivors of AMI associated with conduction defects is still controversial (see Table 35-21) . Patients with inferior infarction with transient type II second-degree block or complete AV block without an associated intraventricular conduction defect do not appear to require permanent pacing. Some contend that prophylactic pacing makes little difference in the long-term survival of patients with AMI and bundle branch block complicated by transient high-degree block. On the other hand, in a retrospective multicenter study, survivors of AMI and bundle branch block who experienced transient high-degree (Mobitz type II second-degree or third-degree) block had a high incidence of recurrent high-degree AV block and sudden death, and this incidence was reduced by insertion of a permanent demand pacemaker.[546] [551] Thus, these findings suggest a role for prophylactic permanent pacing in patients with AMI and bundle branch block with transient high-degree AV block.

The question of the advisability of permanent pacemaker insertion is complicated by the fact that not all sudden deaths in this population are due to recurrent high-degree block. A high incidence of late in-hospital ventricular fibrillation occurs in CCU survivors with anteroseptal MI complicated by either right or left bundle branch block. If the propensity for this arrhythmia continued, ventricular fibrillation rather than asystole due to failure of AV conduction and of the infranodal pacemaker could be responsible for late sudden death.

Long-term pacing is often helpful when complete heart block persists throughout the hospital phase in a patient with AMI, when sinus node function is markedly impaired, or when Mobitz II second- or third-degree block occurs intermittently.[52] When high-grade AV block is associated with newly acquired bundle branch block or other criteria of impairment of conduction system function, prophylactic long-term pacing may be justified as well. Thus, despite the difficulty of proving that long-term pacing improves survival after MI because of the high mortality associated with extensive infarction frequently responsible for high degrees of heart block, prophylactic long-term pacing is prudent.

SUPRAVENTRICULAR TACHYARRHYTHMIAS (See also Chap. 25)

SINUS TACHYCARDIA.

This arrhythmia is typically associated with augmented sympathetic activity and may provoke transient hypertension or hypotension. Common causes are anxiety, persistent pain, left ventricular failure, fever, pericarditis, hypovolemia, pulmonary embolism, and the administration of cardioaccelerator drugs such as atropine, epinephrine, or dopamine; rarely it occurs in patients with atrial infarction. Sinus tachycardia is particularly common in patients with anterior infarction, especially if there is significant accompanying left ventricular dysfunction. It is an undesirable rhythm in patients with AMI because it results in an augmentation of myocardial oxygen consumption, as well as a reduction in the time available for coronary perfusion, thereby intensifying myocardial ischemia and/or external myocardial necrosis. Persistent sinus tachycardia may signify persistent heart failure and under these circumstances is a poor prognostic sign associated with an excess mortality.[52] An underlying cause should be sought and appropriate treatment instituted (e.g., analgesics for pain, diuretics for heart failure, oxygen, beta blockers and nitroglycerin for ischemia, and aspirin for fever or pericarditis.

Administration of beta-adrenoceptor blocking agents, may be helpful in the treatment of sinus tachycardia, particularly when this arrhythmia is a manifestation of hyperdynamic circulation, which is seen particularly in young patients with an initial MI without extensive cardiac damage. However, beta blockade is contraindicated in patients in whom the sinus tachycardia is a manifestation of hypovolemia or of pump failure, the latter reflected by a systolic arterial pressure below 100 mm Hg, rales involving more than one third of the lung fields, a pulmonary capillary wedge pressure exceeding 20 to 25 mm Hg, or a cardiac index below approximately 2.2 liters/min/m^2 . A possible exception to this is a patient in whom persistent ischemia is believed to be the cause or the result of tachycardia: cautious administration of an ultrashort-acting beta-adrenoceptor blocker such as esmolol (25 to 200 mug/kg/min) may be tried to ascertain the patient's response to slowing of the heart rate.[188]

ATRIAL PREMATURE CONTRACTIONS.

Atrial premature contractions, and the atrial tachyarrhythmias (paroxysmal supraventricular tachycardia, atrial flutter, and atrial fibrillation) that they often herald, may be caused by atrial distention secondary to increases in left ventricular diastolic pressure, by pericarditis with its associated atrial epicarditis, or, less commonly, by ischemic injury to the atria and sinus node. Atrial premature beats per se are not associated with an increase in

mortality, and cardiac output is unaffected. No specific therapy is needed, but it should be kept in mind that these beats may indicate excessive autonomic stimulation or the presence of overt or occult heart failure--conditions that may be assessed by physical examination, chest roentgenography, and echocardiography.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA.

This arrhythmia occurs in less than 10 percent of patients with AMI but requires aggressive management because of the rapid ventricular rate.[462] Augmentation of vagal tone by manual carotid sinus stimulation may restore sinus rhythm. The drug of choice for paroxysmal supraventricular tachycardia in the non-AMI patient is adenosine (6 to 12 mg).[462] Few data exist to guide therapy with adenosine in the AMI patient, but we believe that it can be used safely provided that hypotension (systolic pressure 100 mm Hg) is not present before its administration. Intravenous verapamil (5 to 10 mg), diltiazem (15 to 20 mg), and metoprolol (5 to 15 mg) are suitable alternatives in patients without significant left ventricular dysfunction. In the presence of congestive heart failure or hypotension, direct-current countershock or rapid atrial stimulation via a transvenous intraatrial electrode should be used. Although digitalis glycosides may be useful in augmenting vagal tone, thereby terminating the arrhythmia, their effect is often delayed.

ATRIAL FLUTTER AND FIBRILLATION.

Atrial flutter is the least common major atrial arrhythmia associated with AMI. Atrial flutter is usually transient, and in AMI it is typically a consequence of augmented sympathetic stimulation of the atria, often occurring in patients with left ventricular failure or pulmonary emboli in whom the arrhythmia intensifies hemodynamic deterioration.[500] [555]

Atrial fibrillation is far more common than flutter, occurring in 10 to 20 percent of patients with AMI.[556] [557] As with atrial premature contractions and atrial flutter, fibrillation is usually transient and tends to occur in patients with left ventricular failure but is also observed in patients with pericarditis and ischemic injury to the atria and right ventricular infarction.[63] [558] The increased ventricular rate and the loss of the atrial contribution to left ventricular filling result in a significant reduction in cardiac output. Atrial fibrillation during AMI is associated with increased mortality and stroke, particularly in patients with anterior wall infarction.[557] [559] However, because it is more common in patients with clinical and hemodynamic manifestations of extensive infarction and a poor prognosis, atrial fibrillation is probably a marker of poor prognosis, with only a small independent contribution to increased mortality.

Management.

Atrial flutter and fibrillation in patients with AMI are treated in a manner similar to these conditions in other settings (see Chap. 23) . Because of the possibility that the rapid ventricular rate and hypotension associated with these arrhythmias can increase infarct size and because of the important role played by atrial contraction in the support of cardiac output in patients with AMI, treatment must be prompt, especially when the ventricular rate exceeds 100 beats/min. When hemodynamic decompensation is prominent, electrical cardioversion is indicated, beginning with 25 to 50 J for atrial flutter and 50 to 100 J for atrial fibrillation, with gradual increase if the initial shock is not successful. For patients without hemodynamic compromise, the first maneuver should be to slow the ventricular rate. Ideally, a beta-adrenoceptor blocker (e.g., metoprolol in 5-mg intravenous boluses every 5 to 10 minutes to a total dose of 15 to 20 mg, followed by 25 to 50 mg orally every 6 hours) should be used because of the combined effects of ischemia and sympathetic tone that are usually present in patients with atrial fibrillation. If there is concern about the patient's ability to tolerate beta blockade, esmolol may be used. Intravenous doses of verapamil or diltiazem are attractive alternatives because of their ability to slow the ventricular rate promptly, but they should be used with caution if at all in patients with pulmonary congestion. In patients with congestive heart failure, digitalis is the principal agent used to slow the ventricular response, although the onset of its effect may be delayed for several hours. Digitalis may be supplemented by small intravenous doses of a beta blocker, which also prolongs the AV nodal refractory period: 1 to 4 mg of propranolol in divided doses is often quite effective in reducing the ventricular rate and is well tolerated, even in patients with mild heart failure and a rapid ventricular rate. An additional important option for the treatment of atrial flutter is the use of rapid atrial stimulation through a transvenous intraatrial electrode. Because of the increased risk of embolism in atrial fibrillation, intravenous anticoagulation with heparin should be instituted in the absence of any contraindications.

Attention should be directed to the management of the underlying cause (usually heart failure), and then a decision must be made about the advisability of antiarrhythmic therapy to restore and maintain sinus rhythm. In patients who have acute atrial flutter or fibrillation without a history of atrial fibrillation and in whom congestive symptoms are either absent or easily controlled, we usually administer intravenous procainamide (2 to 4 mg/min) for 24 to 48 hours. The goal is to achieve pharmacological cardioversion or secondarily to establish a therapeutic concentration of the drug in preparation for direct-current cardioversion.

In view of the mounting evidence of an increased risk of proarrhythmia from antiarrhythmic drugs prescribed for atrial fibrillation, as well as an adverse interaction between recurrent ischemia and antiarrhythmic drugs, we are reluctant to prescribe type I antiarrhythmic agents over the intermediate or long term in patients with AMI.[510] [560] Amiodarone appears to be an increasingly attractive antiarrhythmic drug for suppression of recurrences of atrial fibrillation. This drug is also useful for prevention of ventricular arrhythmias and can block the AV node should atrial fibrillation recur, both desirable features after AMI. It may be prescribed in a low dose (200 mg/d), thereby reducing the risk of toxicity. Although experience is limited, we believe that amiodarone is a logical choice for suppression of atrial fibrillation after AMI; often only a short course of treatment (6 weeks) is needed because the risk of atrial fibrillation decreases as time passes after infarction.

Patients with recurrent episodes of atrial fibrillation should be treated with oral anticoagulants (to reduce the risk of stroke), even if sinus rhythm is present at the time of hospital discharge, because no antiarrhythmic regimen can be relied on to be completely effective in suppressing atrial fibrillation. In the absence of contraindications, the majority of patients should receive a beta blocker after AMI; in addition to their several other beneficial effects in MI and post-MI patients, these agents are helpful in slowing the ventricular rate should atrial fibrillation recur.

JUNCTIONAL RHYTHMS.

These arrhythmias are often transient, occur during the first 48 hours of the infarction, typically develop and terminate gradually, and are characterized by QRS complexes that resemble those of normally conducted beats. Retrograde P waves may be evident, or AV dissociation may occur, with the junctional rate slightly in excess of the underlying sinus rate. Junctional rhythms fall into two categories:

1. AV junctional rhythm at a rate of 35 to 60 beats/min in which the AV junctional tissue simply assumes the role of the dominant pacemaker when the sinus node is depressed. This arrhythmia is generally a benign protective escape rhythm that is commonly seen among patients with a slow sinus rate in the presence of inferior MI. When there is hemodynamic impairment, transvenous sequential AV pacing may be required to facilitate ventricular performance and maintain adequate peripheral perfusion.
2. Accelerated junctional rhythm (nonparoxysmal junctional tachycardia) is less common and occurs when there is increased automaticity of the junctional tissue, which

usurps the role of pacemaker, usually appearing at a rate of 70 to 130 beats/min. This arrhythmia is seen more commonly with inferior than anterior AMI and may also appear in patients with digitalis intoxication. In studies conducted during the prethrombolytic era, the appearance of accelerated junctional rhythm in the setting of anterior infarction was associated with a poor prognosis, but this was not observed when it occurred in patients with inferior infarction.

OTHER COMPLICATIONS

Recurrent Chest Discomfort

Evaluation of postinfarction chest discomfort may be complicated by previous abnormalities on the ECG and a vague description of the discomfort by the patient who either may be exquisitely sensitive to fleeting discomfort or may deny a potential recrudescence of symptoms. The critical task for clinicians is to distinguish recurrent angina or infarction from nonischemic causes of discomfort that might be caused by infarct expansion, pericarditis, pulmonary embolism, and noncardiac conditions. Important diagnostic maneuvers include a repeat physical examination, repeat ECG, and assessment of the response to sublingual nitroglycerin, 0.4 mg. (The use of noninvasive diagnostic evaluation for recurrent ischemia in patients whose symptoms only appear with moderate levels of exertion is discussed on page 1199 .)

RECURRENT ISCHEMIA AND INFARCTION.

The incidence of postinfarction angina without reinfarction is between 20 and 30 percent.[349] It does not appear to be reduced by the use of thrombolytic therapy as the management strategy during the acute phase[19] but has been reported to be lower in patients who undergo primary PTCA for AMI, especially if stents are used.[337] When accompanied by ST segment and T wave changes in the same leads where Q waves have appeared, it may be due to occlusion of an initially patent vessel, reocclusion of an initially recanalized vessel, or coronary spasm.

Extension of the original zone of necrosis or *reinfarction* in a separate myocardial zone can be a difficult diagnosis, especially within the first 24 hours after the index event.[79] It is more convenient to refer to both extension and reinfarction collectively under the more general term *recurrent infarction.* Circulating cardiac markers may still be elevated from the initial infarction, and it may not be possible to distinguish the ECG changes that are part of the normal evolution after the index infarction from those due to recurrent infarction. Because the cardiac-specific troponins (see p. 1134) remain elevated for more than 1 week after the index event, they are of less value for diagnosing recurrent infarction than are more rapidly rising and falling markers such as CK-MB. Within the first 18 to 24 hours after the initial infarction, when serum cardiac markers may not have returned to the normal range, recurrent infarction should be strongly considered when there is repeat ST segment elevation on the ECG. Although pericarditis remains a possibility in such patients, the two can usually be distinguished by the presence of a rub and the lack of responsiveness to nitroglycerin in patients with pericardial discomfort.

Beyond the first 24 hours, cardiac markers such as CK-MB have usually returned to the normal range; thus, recurrent infarction may be diagnosed either by reelevation of the CK-MB above the upper limit of normal and increased by at least 50 percent of the previous value or by the appearance of new Q waves on the ECG.[52] Because of variations in patient populations and definitions of recurrent infarction, estimates of the incidence of this complication vary; recent large thrombolytic trials report reinfarction rates of 5 to 6 percent.[20] [22] Reinfarction is more common in patients with diabetes mellitus and those with a previous MI, but it cannot be predicted reliably from the angiographic appearance of the coronary artery early after infarction, at least when thrombolytic therapy has been given.

Regardless of whether postinfarction angina is persistent or limited, its presence is important because short-term morbidity is higher among such patients; mortality may be increased if the recurrent ischemia is accompanied by ECG changes and hemodynamic compromise.[52] [561] Recurrent infarction (due in many cases to reocclusion of the infarct-related coronary artery) carries serious adverse prognostic information because it is associated with a twofold to fourfold higher rate of in-hospital complications (congestive heart failure, heart block) and mortality. The mortality rate at 1 to 3 years after the initial infarction is higher in those patients who suffered from recurrent infarction during their index hospitalization.[562] Presumably, the higher mortality is related to the larger mass of myocardium whose function becomes compromised.

Of the standard therapies that are routinely prescribed during the acute phase of AMI, aspirin and beta blockers have been associated with a reduction in the incidence

of recurrent infarction.[52] [349] [563] The data on heparin are less convincing.

Management.

As with the acute phase of treatment of AMI, algorithms for management of patients with recurrent ischemic discomfort at rest center on the 12-lead ECG (Fig. 35-51) . Those patients with ST segment reelevation should either receive repeat thrombolysis[52] [564] or be referred for urgent catheterization and PTCA. Insertion of an intraaortic balloon pump may help stabilize the patient while other procedures are being arranged. For patients believed to have recurrent ischemia who do not have evidence of hemodynamic compromise, an attempt should be made to control symptoms with sublingual or intravenous nitroglycerin and intravenous beta blockade to slow the heart rate to 60 beats/min. When hypotension, congestive heart failure, or ventricular arrhythmias develop during recurrent ischemia, urgent catheterization and revascularization are indicated.

Pericardial Effusion and Pericarditis (See also Chap. 50.)

PERICARDIAL EFFUSION.

Effusions are generally detected echocardiographically, and their incidence varies with technique, criteria, and laboratory expertise. Effusions are more common in patients with anterior MI and with larger infarcts and when congestive heart failure is present.[565] The majority of pericardial effusions that are

Figure 35-51 Treatment of recurrent ischemic events. *(From Cannon CP, Ganz LI, Stone PH: Complicated myocardial infarction. In Rippe JM, Irwin RS, Fink MP, Cerra FB [eds]: Intensive Care Medicine. 3rd ed. Boston, Little, Brown & Co, 1995.)*

seen after AMI do not cause hemodynamic compromise; when tamponade occurs, it is usually due to ventricular rupture or hemorrhagic pericarditis.[99]

The reabsorption rate of a postinfarction pericardial effusion is slow, with resolution often taking several months. The presence of an effusion does not indicate that pericarditis is present; although they may occur together, the majority of effusions occur without other evidence of pericarditis.

PERICARDITIS.

When secondary to transmural AMI, pericarditis may produce pain as early as the first day and as late as 6 weeks after MI. The pain of pericarditis may be confused with that resulting from postinfarction angina, recurrent infarction, or both. An important distinguishing feature is the radiation of the pain to either trapezius ridge, a finding that is nearly pathognomonic of pericarditis and rarely seen with ischemic discomfort.[99] Transmural MI, by definition, extends to the epicardial surface and is responsible for local pericardial inflammation. An acute fibrinous pericarditis (pericarditis epistenocardica) occurs commonly after transmural infarction, but the majority of patients do not report any symptoms from this process.[99] Although transient pericardial friction rubs are relatively common among patients with transmural infarction within the first 48 hours, pain or ECG changes occur much less often. However, the development of a pericardial rub appears to be correlated with a larger infarct and greater hemodynamic compromise. The discomfort of pericarditis usually becomes worse during a deep inspiration, but it may be relieved or diminished when the patient sits up and leans forward.

Although anticoagulation clearly increases the risk for hemorrhagic pericarditis early after MI, this complication has not been reported with sufficient frequency during heparinization or after thrombolytic therapy to warrant absolute prohibition of such agents when a rub is present, but the detection of a pericardial effusion on an echocardiogram is usually an indication for discontinuation of anticoagulation.[99] In patients in whom continuation or initiation of anticoagulant therapy is strongly indicated (such as during cardiac catheterization or after coronary angioplasty), heightened monitoring of clotting parameters and observation for clinical signs of possible tamponade are needed. Late pericardial constriction due to anticoagulant-induced hemopericardium has been reported.

Treatment of pericardial discomfort consists of aspirin, but usually in higher doses than prescribed routinely after infarction: doses of 650 mg orally every 4 to 6 hours may be needed. Nonsteroidal antiinflammatory agents and corticosteroids should be avoided because they may interfere with myocardial scar formation.[566]

DRESSLER SYNDROME.

Also known as the postmyocardial infarction syndrome,[567] Dressler syndrome usually occurs 1 to 8 weeks after infarction. Its incidence is difficult to define because it often blends imperceptibly with the more common early post-MI pericarditis. Dressler cited an incidence of 3 to 4 percent of all AMI patients in 1957, but the incidence has decreased dramatically since that time. Clinically, patients with Dressler syndrome present with malaise, fever, pericardial discomfort, leukocytosis, an elevated ESR, and a pericardial effusion. At autopsy, patients with this syndrome usually demonstrate localized fibrinous pericarditis containing polymorphonuclear leukocytes.[567] The cause of this syndrome is not clearly established, although the detection of antibodies to cardiac tissue has raised the notion of an immunopathological process. Treatment is with aspirin, 650 mg, as often as every 4 hours. Glucocorticosteroids or nonsteroidal antiinflammatory agents are best avoided in patients with Dressler syndrome within 4 weeks of AMI because of their potential to impair infarct healign, to cause ventricular rupture,[568] and to increase coronary vascular resistance. Aspirin in large doses is effective. Four weeks after AMI, nonsteroidal antiinflammatory agents and in occasional patients corticosteroids are necessary to control what may be severe, recurrent symptoms.

Venous Thrombosis and Pulmonary Embolism

Almost all pulmonary emboli originate from thrombi in the veins of the lower extremities (see Chap. 52) ; much less commonly, they originate from mural thrombi overlying an area of right ventricular infarction. Bed rest and heart failure predispose to venous thrombosis and subsequent pulmonary embolism, and both of these factors occur commonly in patients with AMI, particularly those with large infarcts. Several decades ago, at a time when patients with AMI were routinely subjected to prolonged periods of bed rest, significant pulmonary embolism was found in more than 20 percent of patients with MI coming to autopsy, and massive pulmonary embolism accounted for 10 percent of deaths from AMI.[569] In recent years, with early mobilization and the widespread use of low-dose anticoagulant prophylaxis, especially using low-molecular-weight heparins, pulmonary embolism has become an uncommon cause of death in this condition. When pulmonary embolism does occur in patients with AMI, management is generally along the lines described for noninfarction patients.

Left Ventricular Aneurysm

The term *left ventricular aneurysm* (often termed *true aneurysm*) is generally reserved for a discrete, dyskinetic area of the left ventricular wall with a broad neck (to differentiate it from pseudoaneurysm due to a contained myocardial rupture). True left ventricular aneurysms probably develop in less than 5 to 10 percent of all patients with AMI and perhaps somewhat more frequently in patients with transmural infarction (especially anterior).[57] The wall of the true aneurysm is thinner than the rest of the left ventricle (Fig. 35-46) , and it is usually composed of fibrous tissue as well as necrotic muscle, occasionally mixed with viable myocardium. Aneurysm formation presumably occurs when intraventricular tension stretches the noncontracting infarcted heart muscle, thus producing infarct expansion; a relatively weak, thin layer of necrotic muscle; and fibrous tissue that bulges with each cardiac contraction. With the passage of time, the wall of the aneurysm becomes more densely fibrotic, but it continues to bulge with systole, causing some of the left ventricular stroke volume during each systole to be ineffective.

When an aneurysm is present after anterior MI, there is generally a total occlusion of a poorly collateralized left anterior descending coronary artery. An aneurysm is rarely seen with multivessel disease when there are either extensive collaterals or a nonoccluded left anterior descending artery. Aneurysms usually range from 1 to 8 cm in diameter. They occur approximately four times more often at the apex and in the anterior wall than in the inferoposterior wall. The overlying pericardium is usually densely adherent to the wall of the aneurysm, which may even become partially calcified after several years. True left ventricular aneurysms (in contrast to pseudoaneurysms) rarely rupture soon after development. Late rupture, when the true aneurysm has become stabilized by the formation of dense fibrous tissue in its wall, almost never occurs.

Mortality in patients with a left ventricular aneurysm is up to six times higher than in patients without aneurysms, even when compared with that in patients with comparable left ventricular ejection fraction.[570] Death in these patients is often sudden and presumably related to the high incidence of ventricular tachyarrhythmias that occur with aneurysms.[510]

The presence of persistent ST segment elevation in an ECG area of infarction, classically thought to suggest aneurysm formation, actually indicates a large infarct but does not necessarily imply an aneurysm. The diagnosis of aneurysm is best made noninvasively by an echocardiographic study by radionuclide ventriculography or at the time of cardiac catheterization by left ventriculography. With the loss of shortening from the area of the aneurysm, the remainder of the ventricle must be hyperkinetic in order to compensate. With relatively large aneurysms, complete compensation is impossible. The stroke volume falls or, if maintained, it is at the expense of an increase in end-diastolic volume, which in turn leads to increased wall

tension and myocardial oxygen demand. Heart failure may ensue, and angina may appear or worsen.

TREATMENT.

Aggressive management of AMI, including coronary thrombolysis, may diminish the incidence of ventricular aneurysms. Surgical aneurysmectomy (Fig. 35-52) generally is successful only if there is relative preservation of contractile performance in the nonaneurysmal portion of the left ventricle. In such circumstances, when the operation is performed for worsening heart failure or angina, operative mortality is relatively low and clinical improvement can be expected.[571]

Left Ventricular Thrombus and Arterial Embolism

Mural thrombi occur in approximately 20 percent of patients with AMI who do not receive anticoagulant therapy; the incidence rises to 40 percent with anterior infarction and to as high as 60 percent in patients with large anterior infarcts that involve the apex of the left ventricle.[346] The most convenient and accurate method for diagnosing left ventricular thrombosis is two-dimensional echocardiography (see Chap. 7) . It is hypothesized that endocardial inflammation during the acute phase of infarction provides a thrombogenic surface for clots to form in the left ventricle. With extensive transmural infarction of the septum, however, mural thrombi may overlie infarcted myocardium in both ventricles. Prospective studies have suggested that patients who develop a mural thrombus early (within 48 to 72 hours of infarction) have an extremely poor early prognosis,[494] with a high mortality from the complications of a large infarction (shock, reinfarction, rupture, and ventricular tachyarrhythmia), rather than emboli from the left ventricular thrombus.

Although a mural thrombus adheres to the endocardium overlying the infarcted myocardium, superficial portions of it can become detached and produce systemic arterial emboli. Although estimates vary based on patient selection, about 10 percent of mural thrombi result in systemic embolization.[346] Echocardiographically detectable features that suggest a given thrombus is more likely to embolize include increased mobility and protrusion into the ventricular chamber, visualization in multiple views, and contiguous zones of akinesis and hyperkinesis.

MANAGEMENT.

Over the past decade six randomized trials involving only 560 patients tested whether anticoagulant therapy reduced the incidence of *left ventricular thrombus formation.* [572] [573] Collectively, these smaller trials showed that anticoagulation (intravenous heparin or high-dose subcutaneous heparin) reduced the development of *thrombi* by 50 percent, but, because of the low event rate, it was not possible to demonstrate a reduction in the incidence of *systemic embolism.* Additional data from thrombolytic trials suggest that thrombolysis reduces the rate of thrombus formation and the character of the thrombi so that they are less protuberant. Of note, however, the data from thrombolytic trials are difficult to interpret because of the confounding effect of antithrombotic therapy with heparin.[573] Recommendations for anticoagulation vary considerably,[574] [575]

Figure 35-52 Surgical repair of ventricular aneurysm. In this case the aneurysm is located at the apex (*A*). and thrombolysis has precipitated fatal embolization. Nevertheless, anticoagulation for 3 to 6 months with warfarin is advocated for many patients with demonstrable mural thrombi.

Based on the available data, it is our practice to recommend anticoagulation (intravenous heparin to elevate the activated partial thromboplastin time one and one-half to two times control, followed by a minimum of 3 to 6 months of warfarin) in the following clinical situations: (1) an embolic event has already occurred or (2) the patient has a large anterior infarction whether or not a thrombus is visualized echocardiographically. We are also inclined to follow the same anticoagulation practice in patients with infarctions other than those in the anterior distribution if a thrombus or large wall motion abnormality is detected.

Aspirin, although probably not capable of affecting thrombus size in most patients, may prevent further platelet deposition on existing thrombi and also is protective against recurrent ischemic events. It should be prescribed in conjunction with warfarin to patients who are candidates for long-term anticoagulation therapy based on the indications discussed earlier.

Convalescence, Discharge, and Post-Myocardial Infarction Care

Prolonged hospitalization and enforced bed rest for any illness may lead to complications (particularly in elderly patients) such as constipation, decubitus ulcers, excessive resorption of bone with formation of renal calculi, atelectasis, thrombophlebitis, pulmonary emboli, urinary retention, mild anemia due to repetitive blood sampling for diagnostic tests, impaired oral intake of fluids, bleeding from the gastrointestinal tract due to stress ulcers, and deconditioning of cardiovascular reflex responses to postural changes. Because of the precarious status of the heart recovering from AMI, avoidance of such complications is of primary importance. For example, constipation may lead to straining,

---

transitory reduction of venous return and diminution of cardiac output, impaired coronary perfusion, and ventricular arrhythmias, occasionally culminating in ventricular fibrillation. Early use of a bedside commode, stool softeners, and a bed-chair regimen appear to be useful in avoiding many of the difficulties encountered previously among patients with AMI confined to bed for several weeks.

Although concern has been raised from studies in animals that early physical activity might unfavorably influence ventricular remodeling, perhaps by causing infarct extension, no evidence indicates that this concern is relevant to patients, and early mobilization appears to be warranted in most stable AMI patients. For the patient with an uncomplicated AMI, washing and personal care may begin within the first 12 to 24 hours. If the convalescence continues uneventfully, limited ambulation within the room can be begun on the second or third day (see Table 35-12) (Table Not Available) . Once early ambulatory activities are begun, advancement in the activity should depend on the patient's condition. A shower may be allowed some time after the third day.

TIMING OF HOSPITAL DISCHARGE.

The time of discharge from the hospital is variable. Patients who have undergone aggressive reperfusion protocols and have no significant ventricular arrhythmias, recurrent ischemia, or congestive heart failure have been safely discharged in less than 5 days. More commonly, discharge occurs 5 or 6 days after admission for patients who experience no complications, who can be followed readily at home, and whose family setting is conducive to convalescence. Most complications that would preclude early discharge occur within the first day or two of admission; therefore, patients suitable for early discharge can be identified early during the hospitalization. [410] [576] However, as noted previously, even if no complications have occurred by hospital day 3, many clinicians find it useful to keep the patient hospitalized for another 1 to 2 days to finalize the discharge prescriptions, provide additional patient education, and confirm the adequacy of the patient's support systems at home.[411]

For patients who have experienced a complication, discharge is deferred until their condition has been stable for several days and it is clear that they are responding appropriately to necessary medications such as antiarrhythmic agents, vasodilators, or positive inotropic agents or that they have undergone the appropriate work-up for recurrent ischemia.

COUNSELING.

Before discharge from the hospital, all patients should receive detailed instruction concerning physical activity. Initially, this should consist of ambulation at home but avoidance of isometric exercise such as lifting; several rest periods should be taken daily. In addition, the patient should be given fresh nitroglycerin tablets and instructed in their use and should receive careful instructions about the use of any other medications prescribed. As convalescence progresses, graded resumption of activity should be encouraged. Many approaches have been used, ranging from formal rigid guidelines to general advice advocating moderation and avoidance of any activity that evokes symptoms. Sexual counseling is often overlooked during recovery from MI and should also be included as part of the educational process. Such counseling should begin early after AMI and should include the recommendation that sexual activity be resumed after successful completion of either early submaximal or later symptom-limited exercise stress testing.[52]

Some evidence indicates that behavioral alteration is possible after recovery from MI and that this may improve prognosis. A cardiac rehabilitation program with supervised physical exercise and an educational component has been recommended for most MI patients after discharge. Although the overall clinical benefit of such programs continues to be debated, there is little question that most people derive considerable knowledge and psychological security from such interventions and they continue to be endorsed by experienced clinicians.[52] Meta-analyses of randomized trials of medically supervised rehabilitation programs versus usual care that were conducted in an era before the widespread use of beta-adrenoceptor blockers and thrombolytics have shown a reduction in cardiovascular death but no change in the incidence of nonfatal reinfarction.[577] Given the relationship between a history of depression and risk for AMI,[578] interest has arisen in psychosocial intervention programs in the convalescent phase of AMI.[579] [580] Psychosocial intervention programs alone have not been proven to be helpful, but they are a useful adjunct to standard cardiac rehabilitation programs after AMI.[581] [581A] More detailed information on physical and psychological aspects of rehabilitation of patients convalescing from AMI is discussed in Chapter 38 .

RISK STRATIFICATION

The process of risk stratification after AMI occurs in several stages: initial presentation, in-hospital course (CCU, intermediate care unit), and at the time of hospital discharge. The tools used to form an integrated assessment of the patient consist of baseline demographic information,[268A] serial ECGs and serum cardiac marker measurements, hemodynamic monitoring data, a variety of noninvasive tests, and, if performed, the findings at cardiac catheterization.[414] [582]

INITIAL PRESENTATION.

Certain demographic and historical factors are associated with a poor prognosis in patients with AMI, including female gender, age older than 70 years, a history of diabetes mellitus, prior angina pectoris, and previous MI.[414] Diabetes mellitus, in particular, appears to confer a threefold to fourfold increase in risk. Whether this is due to accelerated atherosclerosis or some other characteristic induced by the diabetic state (such as a larger infarct size) is unclear. (Surviving diabetic patients also experience a more complicated post-MI course, including a greater incidence of postinfarction angina, infarct extension, and heart failure.)[52]

In addition to playing a central role in the decision pathway for management of patients with AMI based on the presence or absence of ST segment elevation, the 12-lead ECG carries important prognostic information. Mortality is greater in patients experiencing anterior wall MI than after inferior MI, even when corrected for infarct size.[52] Patients with right ventricular infarction complicating inferior infarction, as suggested by ST segment elevation in V_4 R, have a greater mortality rate than patients sustaining an inferior infarction without right ventricular involvement.[63] Patients with multiple leads showing ST segment elevation and those with a high sum of ST segment elevation have an increased mortality, especially if their infarct is anterior.[582] Patients whose ECG demonstrates persistent advanced heart block (e.g., Mobitz type II, second-degree, or third-degree AV block) or new intraventricular conduction abnormalities (bifascicular or trifascicular) in the course of an AMI have a worse prognosis than do patients without these abnormalities. The influence of high degrees of heart block is particularly important in patients with right ventricular infarction, for such patients have a markedly increased mortality. Other ECG findings that augur poorly are persistent horizontal or downsloping ST segment depression, Q waves in multiple leads, evidence of right ventricular infarction accompanying inferior infarction,[63] ST segment depressions in anterior leads in patients

with inferior infarction,[583] and atrial arrhythmias (especially atrial fibrillation).

Data from the thrombolytic era have confirmed that important determinants of short- and long-term prognosis appear

to be similar in patients who have received thrombolytic therapy compared with those who have not.[414] A constellation of clinical factors can be detected at the time of presentation to help select patients at particularly high risk of death in the first 4 to 6 weeks after AMI (see Fig. 35-27, p. 1151).

HOSPITAL COURSE.

Soon after CCUs were instituted, it became apparent that left ventricular function is an important early determinant of survival. Hospital mortality from AMI depends directly on the severity of left ventricular dysfunction.[414] Risk stratification by means of clinical findings, estimation of infarct size, and, in appropriate patients, invasive hemodynamic monitoring in the CCU (see p. 1174) provides an assessment of the likelihood of a complicated hospital course[584] and may also identify important abnormalities such as hemodynamically significant mitral regurgitation that convey an adverse long-term prognosis.

Recurrent ischemia and infarction after AMI, either in the same location as the index infarction or "at a distance," influence prognosis adversely. Poor prognosis comes from the loss of viable myocardium, with the resulting larger area of infarction creating a greater compromise in ventricular function. Postinfarction angina generally connotes a less favorable prognosis because it indicates the presence of jeopardized myocardium.[582] In the current era of aggressive revascularization, early postinfarction angina often leads to early interventions that tend to improve outcome, diminishing the long-term impact and significance of angina early after AMI.[585]

Assessment at Hospital Discharge

Both short-term and long-term survival after AMI depend on three factors: (1) resting left ventricular function, (2) residual potentially ischemic myocardium, and (3) susceptibility to serious ventricular arrhythmias. The most important of these factors is the state of left ventricular function[586] (see Fig. 35-41) . The second most important factor is how the severity and extent of the obstructive lesions in the coronary vascular bed perfusing residual viable myocardium impacts the risk of recurrent infarction, additional myocardial damage, and serious ventricular arrhythmias.[582] Thus, survival relates to the quantity of myocardium that has become necrotic and the quantity at risk of becoming necrotic. At one extreme, the prognosis is best for the patient with normal intrinsic coronary vessels whose completed infarction constitutes a small fraction (5 percent) of the left ventricle as a consequence of a coronary embolus and who has no jeopardized myocardium. At the other extreme is the patient with a massive infarct with left ventricular failure whose residual viable myocardium is perfused by markedly obstructed vessels. Obviously, progression of atherosclerosis or lowering of perfusion pressure in these vessels impairs the function and viability of the residual myocardium on which left ventricular function depends. The situation may not be hopeless even in such a patient, however, because revascularization may reduce the threat to the jeopardized myocardium. The third risk factor, the susceptibility to serious arrhythmias, is reflected in ventricular ectopic activity and other indicators of electrical instability such as reduced heart rate variability or baroreflex sensitivity and an abnormal signal-averaged ECG. All of these identify patients at increased risk of death.

In addition, as noted earlier, patients with an occluded infarct-related artery late (e.g., 1 to 2 weeks) after AMI have a higher long-term mortality.[74] Persistent occlusion of the culprit artery is associated with an increased incidence of abnormal late potentials on the ECG[587] and appears to have an adverse prognostic effect independent of the level of ventricular function (Fig. 35-53) .[224]

ASSESSMENT OF LEFT VENTRICULAR FUNCTION.

Left ventricular ejection fraction may be the most easily assessed

Figure 35-53 Impact of patency of the infarct-related artery on long-term mortality. In patients with a patent infarct-related coronary artery at 2 weeks after infarction, the long-term mortality is significantly reduced compared with that of patients with an occluded infarct-related vessel. The beneficial effect of infarct-related artery patency was independent of the number of obstructed coronary arteries or of left ventricular function. *(From Lamas GA, Flaker GC, Mitchell G, et al: Effect of infarct artery patency on prognosis after acute myocardial infarction. Circulation 92:1101, 1995. Copyright 1995, American Heart Association.)*

measurement of left ventricular function, and this measurement is extremely useful for risk stratification (see Fig. 35-41) . However, imaging of the left ventricle at rest may not distinguish adequately between infarcted, irreversibly damaged myocardium and stunned or hibernating myocardium. To circumvent this difficulty, a variety of techniques has been investigated to assess the extent of residual viable myocardium, including exercise and pharmacological stress echocardiography, stress radionuclide ventricular angiography, perfusion imaging in conjunction with pharmacological stress, and positron emission tomography (see Chap. 13) . All of these techniques can be performed safely in postinfarction patients. Because no study has clearly shown one imaging modality to be superior to others, clinicians should be guided in their selection of ventricular imaging technique by the availability and level of expertise with a given modality at their local institution.[414]

In patients with low left ventricular ejection fraction, the measurement of exercise capacity is useful for further identifying those patients at particularly high risk and also for establishing safe exercise limits after discharge.[588] Patients with a good exercise capacity despite a reduced ejection fraction have a better long-term outcome than those who cannot perform more than modest exercise.

ASSESSMENT OF MYOCARDIAL ISCHEMIA.

Because of the potent adverse consequences of recurrent MI after AMI,[562] it is important to assess a patient's risk for future ischemia and infarction. Given the increasing array of pharmacological, interventional catheterization, and surgical options available to modify the likelihood of developing recurrent episodes of myocardial ischemia, most clinicians find it helpful to identify patients at risk for provocable myocardial ischemia before discharge. A predischarge evaluation for ischemia allows clinicians to select patients who might benefit from catheterization and revascularization after

AMI and to assess the adequacy of medical therapy for those patients who are suitable for a more conservative management strategy. Although it may be argued that coronary arteriography for risk stratification after AMI has the advantage of permitting simultaneous identification and treatment (angioplasty) of coronary obstructions, important limitations of this strategy should be noted.[589] As discussed previously (see p. 1116), the coronary artery plaques that are most likely to rupture (and produce future events) are those that are lipid laden and have a thin fibrous cap. These plaques cannot be adequately identified with arteriography because they may be associated with less than a 75 percent stenosis of the coronary artery lumen at the time of angiography after an index AMI. Furthermore, coronary arteriography does not provide information on the functional significance of coronary lesions. Previous studies comparing routine use of coronary angiography versus selected use only in patients with spontaneous or provoked ischemia showed no advantage to the routine catheterization strategy with respect to 6-week mortality and reinfarction.[52] [589]

An exercise test also offers the clinician an opportunity to formulate a more precise exercise prescription and is helpful in boosting patients' confidence in their ability to conduct their daily activities after discharge. Patients who are unable to exercise may be evaluated using a pharmacological stress protocol such as an infusion of dobutamine or dipyridamole with echocardiography or perfusion imaging.

Treadmill exercise testing after AMI has traditionally used a submaximal protocol that requires the patient to exercise until symptoms of angina appear, ECG evidence of ischemia is seen, or a target workload (approximately 5 METS) has been reached (see Chap. 6) . It has been proposed that symptom-limited exercise tests may be safely performed before discharge in patients with an uncomplicated postinfarction course in hospital.[590] Variables derived from exercise tests after AMI that have been evaluated for their ability to predict the occurrence of death or recurrent nonfatal infarction include the development and magnitude of ST segment depression, the development of angina, exercise capacity, and the systolic blood pressure response during exercise.[586]

Myocardial perfusion with ^{99m}Tc sestamibi during exercise or pharmacological (e.g., dipyridamole, adenosine, or dobutamine) stress increases the sensitivity for detection of patients at risk for death or recurrent infarction (see Chap. 9) . Similar results have been reported for dipyridamole stress echocardiography. Although perfusion imaging may be helpful for risk stratification in patients with uninterpretable ECGs or the inability to exercise, the regular use of these more expensive procedures in patients with interpretable ECGs and the ability to exercise has been questioned.[414] [591] An increasing number of patients are treated with thrombolysis,

angioplasty, or surgery and have a more favorable natural history than that reported in patients who have not undergone aggressive reperfusion and revascularization for AMI.[591] Until clinical trials relating the findings of a postinfarction perfusion imaging test to long-term outcome in cohorts of patients receiving contemporary therapy for AMI are available, we do not advocate the *routine* use of perfusion imaging for risk stratification after AMI. At present its use should be restricted to patients who are candidates for further revascularization procedures and have physical limitations preventing them from exercising to an adequate workload or those with conduction abnormalities, significant resting ST segment and T wave abnormalities, or repolarization abnormalities on the ECG due to ventricular hypertrophy or digitalis therapy.[592] We have also used perfusion imaging studies when a conventional exercise ECG is mildly abnormal and there is uncertainty about the significance of the finding or uncertainty about the potential culprit vessel or vessels. In such cases perfusion imaging may help guide decisions after catheterization if multiple coronary vessels have important stenoses.

The Danish Trial in Acute MI (DANAMI) investigators reported that when patients with provokable ischemia after infarction were randomized to catheterization and revascularization versus conservative medical therapy, they experienced a lower requirement for antianginal medications, less unstable angina, and fewer nonfatal infarctions.[585]

ASSESSMENT FOR ELECTRICAL INSTABILITY.

After AMI, patients are at greatest risk for the development of sudden cardiac death due to malignant ventricular arrhythmias over the course of the first 1 to 2 years.[593] [594] Several techniques have been devised to stratify patients into those who are at increased risk of sudden death after AMI: measurement of QT interval dispersion (variability of QT intervals between ECG leads), ambulatory ECG recordings for detection of ventricular arrhythmias (Holter monitoring; see Chap. 22) , invasive electrophysiological testing, recording a signal-averaged ECG (a measure of delayed, fragmented conduction in the infarct zone), and measuring heart rate variability (beat-to-beat variability in RR intervals) or baroreflex sensitivity (slope of a line relating beat-to-beat change in sinus rate in response to alteration of blood pressure).[510]

Given the risks associated with routine use of type I antiarrhythmics prescribed to suppress VPBs that are detected on ambulatory ECG recordings, we do not recommend routine Holter monitoring to determine which patients should receive antiarrhythmic therapy after AMI. The value of empirical administration of the type III antiarrhythmic drug amiodarone after infarction is discussed on p. 1204 .

A variety of noninvasive tests have been used to assess patients for electrical instability after AMI.[510] The presence of a filtered QRS complex duration greater than 120 milliseconds and abnormal late potentials recorded on a signal-averaged ECG after AMI have a positive predictive value between 8 and 27 percent and a negative predictive value of over 95 percent for serious arrhythmic events. When viewed in isolation, the signal-averaged ECG suffers from a high false-positive rate, which may be improved by combining it with other variables, such as left ventricular ejection fraction. Electrophysiological testing also appears to suffer from a high false-positive rate and has the additional disadvantage of being invasive. The ability of electrophysiological testing to identify patients at risk for arrhythmic events after AMI appears to be improved if it is performed in patients who also have an ejection fraction less than 40 percent, an abnormal signal-averaged ECG, and VPBs. Depressed heart rate variability (HRV) is an independent predictor of mortality and arrhythmic complications after AMI, especially if cutoffs of standard deviation of the average interval between normal beats below 50 milliseconds and HRV triangular index (a geometric method for integrating the distribution of intervals between normal beats) less than 15 are used. A depressed baroreflex sensitivity value (3.0 msec/mm Hg) is associated with about a threefold increase in the risk of mortality.[595]

Despite the increased risk of arrhythmic events after AMI in patients who are found to have abnormal results on one or more of the noninvasive tests described earlier, several points should be emphasized. The low positive predictive value (<30 percent) for the noninvasive screening tests limits their usefulness when viewed in isolation. Although the predictive value of screening tests can be improved by combining several of them together, the therapeutic implications of an increased risk profile for arrhythmic events have not been established. The mortality reductions achievable with the general use of beta blockers, ACE inhibitors, aspirin, and revascularization when appropriate after infarction, coupled with concerns about efficacy and safety of antiarrhythmic drugs and cost of implanted defibrillators, leave considerable uncertainty about the therapeutic implications of an abnormal noninvasive test for

electrical instability in an asymptomatic patient. Additional data on patient outcomes when clinicians act on the results of an abnormal finding are required before definitive recommendations can be made for asymptomatic patients.[52] The management of patients with sustained, hemodynamically compromising arrhythmias is discussed in Chapter 23 .

Recommendations for Predischarge Management

An algorithm for predischarge management of patients at varying levels of risk after infarction is outlined in Figure 35-54 . Initially, a judgment is made as to the presence of clinical variables indicative of high risk for future cardiac events. Patients with spontaneous episodes of ischemia or depressed left ventricular function who are considered suitable candidates for revascularization based on their overall medical condition should be referred for cardiac catheterization (Fig. 35-54) . The former group of patients is at increased risk of recurrent infarction (and subsequent increased mortality risk[562]), whereas the latter group may benefit from revascularization surgery if multivessel coronary artery disease is identified at catheterization (see Chap. 37) . [562A] Patients with sustained VT or ventricular fibrillation that occurs more than 48 hours after the acute event (see Fig. 35-54) are at increased risk of sudden cardiac death and should be considered for diagnostic electrophysiology study and treatment as outlined in Chapter 25 .

In the absence of high-risk clinical indicators, two management strategies are possible; the choice between them may be influenced by patient and physician preferences and the availability of resources in the patient's local community for the necessary follow-up procedures (see Fig. 35-54) . Initial exercise testing can use conventional ECG with supplementation by a perfusion imaging study for patients with uninterpretable resting ECGs or an equivocal (i.e., mildly abnormal) initial ECG result. Submaximal exercise testing can be performed before discharge to triage patients to an early catheterization strategy or medical therapy strategy. Plans for a follow-up symptom-limited exercise test in patients without clear indications for catheterization are formulated based on the patient's life style and occupation. Patients who undergo aggressive reperfusion therapy and have an uncomplicated course in the CCU may be suitable candidates for early hospital discharge with plans for a symptom-limited exercise test 2 to 3 weeks later. Subsequent decisions about continued medical therapy or referral for cardiac catheterization can then be made as outlined in Figure 35-54 .

SECONDARY PREVENTION OF RECURRENT ACUTE MYOCARDIAL INFARCTION

The concept of secondary prevention of reinfarction and death after recovery from an AMI has been investigated actively for several decades. Problems in proving the efficacy of various interventions have been related both to the ineffectiveness of certain strategies and to the difficulty in proving a benefit as mortality and morbidity have improved after AMI. Nevertheless, patients who survive the initial course of AMI are at increased risk because of coronary artery disease and its complications; therefore, it is imperative that efforts be made to reduce this risk. Although secondary prevention drug trials generally have tested one form of therapy against placebo in an attempt to demonstrate a benefit of that therapy, the physician must remember that disciplined clinical care of the individual patient is far more important than rote use of an agent found beneficial in the latest drug trial.[17] [596]

LIFE STYLE MODIFICATION.

Efforts to improve survival and the quality of life after MI that relate to life style modification of known risk factors are considered in Chapter 36 . Of these, cessation of smoking and control of hypertension are probably most important. It has been shown that within 2 years of quitting smoking, the risk of a nonfatal MI in these former smokers falls to a level similar to that in patients who never smoked. Being hospitalized for an AMI is a powerful motivation for patients to cease cigarette smoking, and this is an ideal time to encourage that clearly beneficial and highly cost-effective life style change.[597] It is also an ideal time to begin to treat hypertension, to counsel patients to achieve optimal body weight, and to consider various strategies to improve the patient's lipid profile (see later).

Physicians caring for patients after an AMI need to be sensitive to the fact that some patients experience major depression after infarction, and the development of this problem is an independent risk factor for mortality.[598] In addition, lack of an emotionally supportive network in the patient's environment after discharge is associated with an increased risk of mortality and recurrent cardiac events.[599] The precise mechanisms relating depression and lack of social support to worse prognosis after AMI are not clear, but one possibility is lack of adherence to prescribed treatments, a behavior that has been shown to be associated with increased risk of mortality after infarction.[600] Evidence exists that a comprehensive rehabilitation program using primary health care personnel who counsel patients and make home visits favorably impacts the clinical course of patients after infarction and reduces the rate of rehospitalization for recurrent ischemia and infarction. A supportive physician attitude can also have a positive impact on the rate of return to work after AMI.

MODIFICATION OF LIPID PROFILE.

Compelling evidence now exists that an increased cholesterol level, and most importantly an increased low-density lipoprotein (LDL) cholesterol level, is associated with an increased risk of coronary heart disease (see Chap. 33) . Based on this observation and the finding that lowering cholesterol reduces the risk of coronary heart disease,[601] [602] a target LDL cholesterol level of less than 100 mg/dl has been recommended in patients with clinically evident coronary heart disease.[603] This recommendation clearly applies to patients with AMI, and it is therefore important to obtain a lipid profile on admission in all patients admitted with acute infarction. (It should be recalled that cholesterol levels may fall 24 to 48 hours after infarction.) In addition to lowering LDL cholesterol, therapy with statins reduces levels of C-reactive protein, suggesting an antiinflammatory effect.[604]

Surveys of physician practice in the past have revealed a disappointingly low rate of treatment of hypercholesterolemia in patients with proven coronary artery disease, indicating considerable room for improvement in this aspect of secondary prevention after AMI.[603]

Recommendations.

All patients recovering from AMI should be considered potential candidates for modification of their lipid profile. Initial therapy should consist of an AHA Step II diet (<7 percent of total calories as saturated fat and cholesterol <200 mg/d). Patients with an LDL cholesterol level greater than 125 mg/dl despite the AHA Step II diet should be placed on drug therapy to reduce the LDL cholesterol level to less than 100 mg/dl.[52] Our preference at present is to prescribe an HMG-CoA reductase inhibitor before hospital discharge in patients with an LDL cholesterol level greater than 130 mg/dl on admission.[605] For many patients recovering from AMI, a low HDL cholesterol level is their primary lipid abnormality. Gemfibrozil (1200 mg/d) reduces the risk of death, reinfarction, and stroke in such patients.[606]

ANTIPLATELET AGENTS.

On the basis of 11 randomized trials in 20,000 patients with a prior infarction, the Antiplatelet Trialists' Collaboration reported a 25 percent reduction in the risk of recurrent infarction, stroke, or vascular

Figure 35-54 Management algorithm for risk stratification after acute myocardial infarction. Patients with clinical indicators of high risk at hospital discharge such as recurrent ischemia at rest or depressed left ventricular function should be considered candidates for revascularization and referral to cardiac catheterization for ultimate triage to either angioplasty/coronary artery bypass surgery or medical therapy and risk factor reduction (strategy I). Patients with life-threatening arrhythmias such as sustained ventricular tachycardia or ventricular fibrillation should be considered for diagnostic cardiac catheterization, electrophysiology study, and management with implantation of a cardioverter-defibrillator either alone or in conjunction with Amiodarone (strategy I). Patients without indicators of high risk at hospital discharge can be evaluated with either a symptom-limited exercise test at 14 to 21 days (strategy II) or a submaximal exercise test before discharge (strategy III). Patients with either a markedly abnormal exercise test or evidence of reversible ischemia on an exercise imaging study in strategy II or III should be referred for cardiac catheterization. Patients with a negative exercise test or no evidence of reversible ischemia on an exercise imaging study can be managed with medical therapy and risk factor reduction. *(From Ryan TJ, Antman EM, Brooks NH, et al: 1999 update: ACC/AHA Guidelines for the Management of Patients With Acute Myocardial Infarction: Executive Summary and Recommendations: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on Management of Acute Myocardial Infarction]. Circulation 100:1016-1030, 1999.)*

death in patients receiving prolonged antiplatelet therapy (36 fewer events for every 1000 patients treated).[14] No antiplatelet therapy proved superior to aspirin, and daily doses of aspirin between 80 and 325 mg appear to be effective.[607] Data from the Worcester Heart Attack Study suggest that when an AMI occurs in chronic users of aspirin, it is likely to be smaller and non-Q wave in nature.[608] Experimental data on late reperfusion in a rat model of coronary occlusion suggest that aspirin treatment after AMI increases the patency of the microvasculature in the infarcted area, resulting in less infarct expansion and thicker myocardial walls in the infarct zone.[609] The compelling arguments cited earlier serve as the basis for the recommendation that all patients recovering from AMI should, in the absence of contraindications, remain on aspirin for an indefinite period.[596] [610] Patients with true aspirin allergy may be treated with sulfinpyrazone (400 mg twice daily), ticlopidine (250 mg twice daily),[14] or clopidogrel (75 mg once daily),[611] although the data indicating that these agents reduce mortality after AMI are not nearly as robust as those for aspirin.

ACE INHIBITORS.

The rationale for the acute use of ACE inhibitors after AMI has been discussed earlier (see p. 1169). To prevent late remodeling of the left ventricle and also to decrease the likelihood of recurrent ischemic events,[421] [431] we advocate indefinite therapy with an ACE inhibitor to all patients with clinically evident congestive heart failure, a moderate decrease in global ejection fraction, or a large regional wall motion abnormality, even in the face of a normal global ejection fraction.[52] A decision-analytic model that tested strategy of prescription of ACE inhibitors to hypothetical 50- to 80-year-old patients with an ejection fraction of 40 percent or less after AMI reported incremental cost-effectiveness ratios of $4,000 to $10,000 per quality-adjusted life-year (QALY). These calculations compare quite favorably with the costs of other commonly accepted medical procedures such as angioplasty for one- or two-vessel coronary artery disease ($8,000 to $111,000 per QALY).

The optimum duration of therapy with ACE inhibitors after AMI is an intriguing question. Evidence exists that long-term (at least 3 to 5 years) treatment with ACE inhibitors in patients with severely reduced left ventricular function after AMI prolongs survival,[612] [613] especially in diabetic patients.[614] Although the benefit of ACE inhibitors in patients with symptomatic congestive heart failure is greater with higher doses, some protection against death and hospitalization for heart failure is obtained even if lower doses of ACE inhibitors are used.[615] Finally, ACE inhibitors are associated with a reduction in sudden death after AMI,[616] profession of renal failure in insulin-dependent diabetics,[617] and prevention of death, AMI, and stroke when used for primary prevention in patients at high risk for cardiovascular events but without left ventricular dysfunction or heart failure.[618] The observations cited earlier along with data suggesting that ACE inhibitors have direct antiatherosclerotic effects and favorably influence remodeling of vascular walls pose a persuasive argument for a more widespread use of ACE inhibitors for all patients after AMI.

BETA-ADRENOCEPTOR BLOCKERS.

Meta-analyses of trials from the prethrombolytic era involving over 24,000 patients who received beta-adrenoceptor blockers in the convalescent phase of AMI have shown a 23 percent reduction in long-term mortality[417] (see Fig. 35-37) . When beta blockade is initiated early (6 hours) in the acute phase of infarction and continued in the chronic phase of treatment, some of the benefit may result from a reduction in infarct size. However, in the majority of patients who have beta blockade initiated during the convalescent phase of AMI, reduction in long-term mortality is probably due to a combination of an antiarrhythmic effect (prevention of sudden death) and prevention of reinfarction.[417]

Overviews of the results of trials of beta-adrenoceptor blockers with agonist activity have not shown a beneficial effect on mortality compared with more convincing evidence of a beneficial effect and little evidence of harm for trials of beta blockers without agonist activity (odds ratio 0.69 [0.61-0.79]). [186] No differences are seen when cardioselective and noncardioselective agents are compared. The greatest mortality benefit from chronic beta blockade after AMI is seen in patients with the greatest baseline risk--those with compromised ventricular function and ventricular arrhythmias. The results of the Beta-Blocker Pooling Project, in which data were examined from nine separate studies involving more than 10,000 patients, suggest a highly significant reduction in overall mortality among treated patients with pump failure.[619] Treatment with beta blockers after AMI is particularly helpful for reducing mortality in patients who do not undergo revascularization.[620] Mortality is reduced even in patients who receive less than 50 percent of the dosage found to be effective in preventing cardiac death in large randomized trials.[621]

Recommendations.

Given the well-documented benefits of beta-adrenoceptor blockade, it is disturbing that this form of therapy continues to be underused, especially in high-risk groups such as the elderly.[622] We are in agreement with the "Quality Care Alert" issued jointly by several authoritative bodies that beta-adrenoceptor blockers be prescribed to all high-risk patients regardless of whether the event was a Q-wave or non-Q-wave AMI, as long as no contraindications are present.[623] Patients with a relative contraindication to beta blockade (moderate heart failure, bradyarrhythmias) should undergo a monitored trial of therapy in the hospital. The dosage should be sufficient to blunt the heart rate response to stress or exercise. Much of the impact of beta blockers in preventing mortality occurs in the first weeks; treatment should commence as soon as possible. Evidence exists that programs providing physician feedback improve adherence to guidelines such as those noted earlier for prescription of beta-adrenoceptor blockers after AMI.[624]

Some controversy exists as to how long patients should be treated.[625] The collective data from five trials providing information on long-term follow-up of beta-adrenoceptor blockers after infarction suggest that therapy should be continued for at least 2 to 3 years.[626] [627] At that time, if the beta blocker is well tolerated and

if there is no reason to discontinue therapy, such therapy probably should be continued in most patients.[628]

Not all patients derive the same benefit from beta-blocker therapy. The cost-effectiveness of treatment in medium- or high-risk persons compares very favorably with that of many other accepted interventions such as coronary bypass surgery, angioplasty, and lipid-lowering therapy.[625] In patients with an extremely good prognosis (first AMI, good ventricular function, no angina, negative stress test, and no complex ventricular ectopy) in whom a mortality rate of approximately 1 percent per year can be anticipated, beta blockers would have a smaller impact on survival. However, it is our preference to prescribe beta blockers to such patients for whatever postinfarction benefit is achieved and also to have them as part of the patient's usual regimen should AMI recur at an unpredictable time in the future.

NITRATES.

Although these agents are suitable for management of specific conditions after AMI such as recurrent angina or as part of a treatment regimen for congestive heart failure, little evidence indicates that they reduce mortality over the long term when prescribed on a routine basis to all patients with infarction.[425] [426]

ANTICOAGULANTS. (See also Chap. 62.)

At least three theoretical reasons exist for anticipating that anticoagulants might be beneficial in the long-term management of patients after AMI.

1. Because the coronary occlusion responsible for the AMI is often due to a thrombus, anticoagulants might be expected to halt, slow progression, or prevent the development of new thrombi elsewhere in the coronary arterial tree.
2. Anticoagulants might be expected to diminish the formation of mural thrombi and resultant systemic embolization.
3. Anticoagulants might be expected to reduce the incidence of venous thrombosis and pulmonary embolization.

After several decades of evaluation, the weight of evidence now suggests that anticoagulants have a favorable effect on late mortality, stroke, and reinfarction among patients hospitalized with AMI.[13] [629] Long-term anticoagulant therapy has also been shown to be a cost-effective intervention after AMI, with the major cost savings coming from reductions in the rate of recurrent infarction and related interventions.[630]

Previous small trials of aspirin versus oral anticoagulation have led to conflicting results, with no clear consensus regarding superiority of either antithrombotic strategy. The APRICOT investigators reported that after initially successful thrombolysis, aspirin-treated patients had lower rates of reinfarction, need for revascularization, and mortality than did warfarin-treated patients.[273] As expected, cost-effectiveness calculations show that aspirin is associated with a very favorable economic profile, but its true efficacy compared with or combined with oral anticoagulation remains unknown. The Coumadin Aspirin Reinfarction Study (CARS) was discontinued prematurely owing to lack of evidence of benefit of reduced-dose aspirin (80 mg/d) with either 1 or 3 mg of warfarin daily compared with aspirin 160 mg alone daily.[631] The Combination Hemotherapy and Mortality Prevention (CHAMP) study found no benefit of using warfarin (to an international normalized ratio of 1.5-2.5) plus aspirin 81 mg/d versus aspirin 162 mg/d with respect to total mortality, cardiovascular mortality, stroke, and nonfatal MI (mean follow-up 2.7 years) after an index AMI.[632]

Therefore, at present we recommend routine use of aspirin in all AMI patients without contraindications and add warfarin only to patients with clear indications for anticoagulation such as deep vein thrombosis, pulmonary embolism, mural thrombus seen at echocardiography, a large regional wall motion abnormality (especially anterior) seen at echocardiography even in the absence of a visualized thrombus, atrial fibrillation, and a history of embolic cerebrovascular accident.

CALCIUM ANTAGONISTS.

At present we do *not* recommend the routine use of calcium antagonists for secondary prevention of infarction. A possible exception is a patient who cannot tolerate a beta-adrenoceptor blocker because of adverse effects on bronchospastic lung disease but who has well-preserved left ventricular function; such patients may be candidates for a rate-slowing calcium antagonist such as diltiazem or verapamil.

ANTIARRHYTHMICS.

Although it has been recognized for decades that antiarrhythmic therapy can control atrial and ventricular arrhythmias effectively in many patients, careful reviews of clinical trials after AMI have reported an increased risk of mortality with type I drugs[633] [634] (Table 35-22) . The most notable postinfarction trial in this area was the Cardiac Arrhythmia Suppression Trial (CAST), which tested whether encainide, flecainide, or moricizine for suppression of ventricular arrhythmias detected on ambulatory ECG monitoring would reduce the risk of cardiac arrest and death over the long term. Both the first phase of the trial (encainide or flecainide vs. placebo) and the second phase of the trial (moricizine vs. placebo) were stopped prematurely because of increased mortality in the active treatment groups.[634] [635] [636] The mechanism of the increased risk after AMI remains a subject of investigation, but one hypothesis that has been put forth is an adverse interaction between recurrent ischemia and the presence of an antiarrhythmic drug because the risk of death or cardiac arrest was greater in patients with non-Q-wave AMI than with Q-wave AMI.[637] Sodium channel blockade by antiarrhythmics may exacerbate electrophysiological differences between subepicardial and subendocardial zones of myocardium, rendering the latter more susceptible to ischemic injury.[638]

Subsequent to CAST, another postinfarction prophylactic antiarrhythmic drug trial was undertaken with oral d-sotalol (Survival With ORal D-sotalol = SWORD). This trial was designed to test the hypothesis that prophylactic administration of d-sotalol to patients with depressed left ventricular function (ejection fraction = 40 percent) and either a recent (6 to 42 days) or remote (42 days) AMI would reduce total mortality. SWORD also was stopped prematurely after enrollment of only 3121 of a planned 6400 patients because statistical evidence of increased mortality emerged in the active treatment group[639] (Fig. 35-55) .

The Canadian Amiodarone Myocardial Infarction Trial (CAMIAT) showed that amiodarone reduced ventricular premature depolarization frequency in patients with recent MI; this correlated with a reduction in arrhythmic death or resuscitation from ventricular fibrillation[640] (see Fig. 35-55) . However, 42 percent of patients discontinued amiodarone during maintenance therapy in CAMIAT because of intolerable side effects. The European Amiodarone Myocardial Infarction Trial (EMIAT) showed a reduction in arrhythmic death after MI in patients with depressed left ventricular function, but there was no reduction in total mortality or other cardiovascular-related mortality[641] (see Fig. 35-55) .

At the present time, the *routine* use of antiarrhythmic agents (including amiodarone) cannot be recommended.[641A] Given the data cited earlier on the protective effects of beta-adrenoceptor blockers against sudden death (see p. 1203) and the ability of aspirin to reduce the risk of reinfarction (see p. 1201), it is unclear whether additional mortality reductions would be achieved by the empirical addition of amiodarone in the patient who is convalescing from an AMI and is free of symptomatic sustained ventricular arrhythmias. Although several trials that included postinfarction patients in the study population have shown mortality reductions in patients randomized to implantable cardioverter-defibrillator implantation versus antiarrhythmic therapy, the profound financial and societal implications have prevented adoption of widespread implantable cardioverterdefibrillator implantation to asymptomatic patients recovering from AMI but with an abnormal noninvasive test (e.g., ejection fraction < 40 percent, frequent ventricular premature depolarizations).[570] [642] [643] [644] Whether subgroups of patients with indicators of high risk of sudden death, such as abnormal heart rate variability or reduced baroreflex sensitivity, should be treated and, if so, by what strategy remains to be determined.

HORMONE REPLACEMENT THERAPY. (See also Chap. 58.)

Estrogen replacement therapy has been reported to possibly be helpful in the primary prevention of coronary heart disease, improves the coronary artery disease risk factor profile in postmenopausal women,[645] and appears to reduce mortality in women with moderate coronary heart disease. However, the decision to prescribe hormone replacement therapy is often a complex one that involves weighing risks of breast and endometrial cancer versus modification of a coronary artery disease risk factor profile.[646] Of note, despite improvement in lipid profiles, hormone replacement therapy with estrogen plus progestin to postmenopausal women with established coronary heart disease in the Heart and Estrogen/Progestin Replacement Study (HERS) did not prevent recurrent coronary events and was associated with significantly increased risk of venous thromboembolic

TABLE 35-22 -- IMPORTANT ARRHYTHMIA TRIALS IN PATIENTS AFTER ACUTE MYOCARDIAL INFARCTION

TRIAL	OBJECTIVE	NO. OF PATIENTS	ENTRY CRITERIA	TREATMENT ARMS	MAIN RESULTS	CLINICAL IMPORTANCE
CAST	To test whether PVC suppression (asymptomatic or mildly symptomatic) reduced arrhythmia-related mortality.	2309	6 d to 2 yr post-MI 6 PVCs/hr LVEF 40% if MI 90 d to 2 yr	1) Open-label titration during which three drugs (encainide, flecainide, and moricizine) at two doses were tested 2) Titration phase terminated when PVCs suppressed 3) Patients excluded if intolerant or arrhythmia worsened 4) Patients assigned to active drug that suppressed arrhythmia, or placebo	1) 7.7% mortality in encainide/flecainide group vs. 3% in placebo group (p=0.0004). 2) Arrhythmic death was more common in the encainide/flecainide group vs. placebo (4.5% vs. 1.2%, p=0.0004).	Both encainide and flecainide were associated with increased mortality even though PVC suppression was demonstrated.
CAST II	To test whether PVC suppression (asymptomatic or mildly symptomatic) by moricizine reduced mortality.	1325	6-90 days post-MI 6 PVCs/hr LVEF 55% if MI within 90 d LVEF 40% if MI 90 d to 2 yr	Two blinded randomized phases: 1) Early phase to assess risk of starting moricizine post-MI (200 mg tid×14 d vs. placebo) 2) Long-term phase evaluated the effect of moricizine on survival in patients whose PVCs were suppressed	CAST II was stopped early because of increased mortality in the early 14-d phase.	Similar to CAST, moricizine effectively suppressed PVCs, but it was associated with increased mortality.
SWORD	To test whether a pure potassium channel blocker without beta blocking activity reduced mortality	3121	LVEF 40% and either recent (6-42 days) MI or symptomatic heart failure with a remote (242 days) MI	d-sotalol vs. placebo	SWORD was stopped prematurely due to higher mortality in d-sotalol (5% vs. 3.1%; p=0.006).	Subgroup analysis showing higher mortality with d-sotalol in patients with better LVEF (31-40%) compared with patients with lower LVEF (30%) lends support to concept of proarrhythmia.
CAMIAT	To evaluate the efficacy of amiodarone in reducing arrhythmic death.	1202	6-45 days post-MI > 10 PVCs/hr or any run 3 beats VT > 100 beats/min	Amiodarone vs. placebo	1) Amiodarone did not affect total cardiac mortality but reduced SD or recurrent VF ($p < 0.05$) 2) There was concordance between PVC suppression and reduced SD and recurrent VF. 3) Early discontinuation of amiodarone for side effects was common (42.3%).	Amiodarone did not improve overall mortality, but reduced SD or recurrent VF. Improvement was concordant with PVC suppression.
EMIAT	To assess the efficacy of prophylactic antiarrhythmic therapy in patients with asymptomatic complex ventricular ectopy.	1486	5-21 d post-MI LVEF 40% 18-75 yr 24-hr ambulatory monitoring before entry but not used as part of inclusion criteria	Amiodarone vs. placebo	1) No difference in overall mortality. 2) Reduction in arrhythmic death in the amiodarone group (p=0.052). 3) Drug discontinuation due to side effects or intolerance was high in the amiodarone group (45% by 2 yr).	Amiodarone did not decrease overall mortality but reduced SD.

PVC=premature ventricular contraction; LVEF=left ventricular ejection fraction; VT=ventricular tachycardia; VF=ventricular fibrillation; SD=sudden death.

Modified from Tracy CM: Current review of arrhythmia trials. Cardiology Special Edition 5(1):17-23, 1999.

Figure 35-55 Effect of type III antiarrhythmic drugs after acute myocardial infarction. The results of the SWORD, EMIAT, and CAMIAT trials are shown with total mortality plotted in the top panels and arrhythmic deaths plotted in the bottom panels. The SWORD trial was stopped prematurely owing to increased total mortality in patients receiving *d*-sotalol compared with placebo; arrhythmic mortality was also significantly increased. Both the EMIAT and CAMIAT trials showed no significant reduction in total mortality with amiodarone, but there was a reduction in arrhythmic deaths in patients receiving amiodarone. However, the rate of discontinuation due to intolerable side effects was high with amiodarone in both the EMIAT and CAMIAT trials. *(Adapted from Waldo AL, Camm AJ, deRuyter H, et al: Effect of d-sotalol on mortality in patients with left ventricular dysfunction after recent and remote myocardial infarction. GUIDELINES DIAGNOSIS AND MANAGEMENT OF ACUTE MYOCARDIAL INFARCTION

Thomas H. Lee

Key guidelines for the diagnosis and management of acute myocardial infarction (AMI) have been published by the American College of Emergency Physicians (ACEP)[1] and by an ACC/AHA Committee.[2] Additional influential guidelines on management of patients with acute ischemic heart disease syndromes have been published by the National Heart Attack Alert Program (NHAAP),[3] the Agency for Health Care Policy and Research (AHCPR),[4] and an ACC/AHA task force on unstable angina.[5]

Evaluation of Patients with Acute Chest Pain (Table 35-G-1)

In all of these guidelines, the recommended actions in response to the data that are collected during this evaluation are intended to lead to timely care for patients with AMI, unstable angina, aortic dissection, and pulmonary embolus. The ACC/AHA guidelines on unstable angina and non-ST segment elevation MI emphasize that patients with possible acute coronary syndromes should be evaluated at a facility at which a 12-lead electrocardiogram (ECG) can be performed (as opposed to over the telephone).[5] According to these guidelines, patients with suspected acute coronary syndromes of symptom duration of more than 20 minutes, hemodynamic instability, or recent syncope or presyncope are most appropriately seen in an emergency department or specialized chest pain unit. Emergency transport services should be used when available for such patients; private vehicles are acceptable alternatives only if waiting for an emergency vehicle would impose a long delay.

The ACEP statement on the initial evaluation of patients with acute chest pain[1] include "rules" and "guidelines" about the data that should be recorded and the actions that should follow from certain findings. In these guidelines, "rules" are actions that are general principles of good practice; deviation from a "rule" should generally be justified in the record. "Guidelines" are actions that should be considered, but failure to follow a "guideline" does not necessarily imply that care was improper. The ACEP policy statement includes in its appendix forms that can be used to assess compliance with their "rules" and to remind clinicians of their content.

The ACEP statement indicates that the routine evaluation of nontraumatic chest pain should include a history that obtains data on the

TABLE 35--G-1 -- EVALUATION OF ACUTE CHEST PAIN: EXCERPTS FROM THE CLINICAL POLICY OF THE AMERICAN COLLEGE OF EMERGENCY PHYSICIANS (ACEP) (1995)

Variable	Finding	Rule*	Guideline
Pain	Ongoing and severe and crushing and substernal or same as previous pain diagnosed as MI	Intravenous access	Serum cardiac markers
		Supplemental oxygen	CXR
		Cardiac monitor	Anticoagulation
		ECG	
		Aspirin	
		Nitrates	
		Management of ongoing pain	
		Admit	
	Severe or pressure or substernal or exertional or radiating to jaw, neck, shoulder, or arm	ECG	Intravenous access
			Supplemental oxygen
			Cardiac monitor
			Serum cardiac markers
			CXR
			Nitrates
			Management of ongoing pain
			Admit
	Tearing, severe, and radiating to back	Large-bore intravenous access	Differential upper extremity blood pressures
		Supplemental oxygen	
		Cardiac monitor	Aortic imaging
		CXR, ECG	Management of ongoing pain
			Admit
	Similar to that of previous pulmonary embolus	Intravenous access	CXR
		Supplemental O_2	Admit
		Cardiac monitor	
		ABG/oximetry	
		Anticoagulation/pulmonary vascular imaging	
		ECG	
	Indigestion or burning epigastric	None	ECG
	Pleuritic	None	CXR
			ECG

Associated symptoms	Syncope or near-syncope	ECG	Cardiac monitor Hematocrit
	Shortness of breath, dyspnea on exertion, paroxysmal nocturnal dyspnea, or orthopnea	ECG	ABG/oximetry CXR
Past medical history	Previous MI, coronary artery bypass graft, angioplasty, cocaine use within past 96 hours, previous positive cardiac diagnostic studies	ECG	
	Major risk factors for coronary artery disease		ECG

CXR=chest radiograph; ECG=electrocardiogram; ABG=arterial blood gas analysis.

From American College of Emergency Physicians: Clinical policy for the initial approach to adults presenting with a chief complaint of chest pain, with no history of trauma. Ann Emerg Med 25:274-299, 1995.

*Rule: An action reflecting principles of good practice in most situations. There may be circumstances when a rule need not or cannot be followed; in these situations, it is advisable that deviation from the rule be justified in writing. Inability to comply with rules should be incorporated in institutional policies.

Guideline: An action that may be considered, depending on the patient, the circumstances, or other factors. Thus, guidelines are not always followed, and there is no implication that failure to follow a guideline is improper.

character of pain, age, associated symptoms, and past history. The physical examination should include vital signs, a cardiovascular examination, and a pulmonary examination. The performance of an ECG is a "rule" in all but atypical chest pain syndromes. The ACEP statement emphasizes that the decision to admit the patient must be based primarily on clinical judgment.

The NHAAP report also includes guidelines for specific functions related to evaluation and treatment of patients with chest pain aimed at improving the speed with which patients with AMI are identified and treated,[3] including recommendations for which patient subsets should be placed on the AMI protocol. For registration staff, the NHAAP guidelines recommend that patients older than age 30 with the following chief complaints receive immediate assessment by the triage nurse and be referred for further evaluation:

Chest pain, pressure, tightness, or heaviness; radiating pain in neck, jaw, shoulders, back, or one or both arms

Indigestion or "heartburn"/nausea and/or vomiting

Persistent shortness of breath

Weakness/dizziness/lightheadedness/loss of consciousness

The triage nurse should immediately assess patients for initiation of the AMI protocol and obtain an ECG if they have any of the following:

Chest pain

Associated dyspnea

Associated nausea/vomiting

Associated diaphoresis

For physicians, the NHAAP guidelines offer several clinical recommendations

and explicitly note that the use of a so-called GI cocktail (usually including an antacid) as a diagnostic test to differentiate between gastrointestinal and cardiac causes of the patient's symptoms is inappropriate because it frequently leads to erroneous conclusions.

ECG and aspirin are strongly recommended for patients with new-onset angina that is exertional, but admission is not considered mandatory in the ACEP policy statement. The AHCPR guidelines also indicate that not all patients with unstable angina require admission but recommend that patients with unstable angina be monitored electrocardiographically during their initial evaluation and that those with ongoing rest pain should be placed at bed rest during the initial phase of stabilization.[4]

EARLY RISK STRATIFICATION.

The ACC/AHA guidelines for management of unstable angina emphasize the importance of a search for noncoronary causes that might explain the patient's symptoms but recommend that biochemical cardiac markers be performed for all patients with suspected acute coronary syndromes.[5] This recommendation does not mandate the performance of markers in patients with a very low probability of acute coronary syndromes, for whom discharge without such testing is appropriate.[6] The ACC/AHA task force supports the use of cardiac troponins as a preferred marker for acute ischemic injury (Table 36-G-2) .

Specific recommendations for the care of patients with unstable angina are included in the guidelines in Chapter 36 .

Urgent Care of AMI (Table 35-G-2)

The 1999 ACC/AHA update of guidelines on AMI[2] seek to ensure timely revascularization of patients who present early in the course of their infarction by setting a goal for timely evaluations of patients with acute chest pain, including performance of an ECG within 10 minutes and administration of thrombolytic therapy for appropriate patients within 30 minutes. To achieve this goal, the NHAAP guidelines[3] recommend measuring the time at which four specific events occur for patients with AMI:

1. Presentation to the emergency department
2. Performance of the ECG
3. Decision of whether to administer thrombolytic therapy
4. Actual infusion of the thrombolytic agent

Specific time goals can be set for the interval between these events (e.g., 10 minutes). Another critical issue is who gives the order to administer thrombolytic therapy. ACEP guidelines recommend that emergency department physicians be given the authority to administer thrombolytic therapy.[1]

In the ACC/AHA guidelines,[2] thrombolytic therapy is considered appropriate (Class I) for up to 12 hours after the onset of symptoms for patients younger than age 75 years and presenting with ST segment elevation or bundle branch block. The ACC/AHA task force considered the weight of evidence in favor of extending the same approach to patients older than 75. Primary intervention with percutaneous transluminal coronary angioplasty (PTCA) was considered an appropriate (Class I) alternative to thrombolytic therapy within the first 12 hours of infarction and beyond for patients with persisting ischemic symptoms. The ACC/AHA guidelines also define goals for speed and volume for operators and institutions performing primary PTCA. Primary PTCA is also endorsed as a strategy for patients with cardiogenic shock due to MI.

The ACC/AHA guidelines do *not* support routine use of angiography

TABLE 35--G-2 -- ACC/AHA GUIDELINES FOR INITIAL MANAGEMENT OF ACUTE MYOCARDIAL INFARCTION (AMI) AND ISCHEMIC COMPLICATIONS

Indication	Class I	Class IIa	Class IIb	Class III
Telephone triage[5]	Patients with symptoms suggesting possible ACS should be evaluated by a medical practitioner in a facility equipped to record a 12-lead ECG and not over the telephone.			
Emergency department or outpatient facility presentation [5]	Patients with suspected ACS with symptom duration > 20 minutes, hemodynamic instability, or recent syncope or presyncope should be referred to an emergency department or specialized chest pain unit. Other patients with suspected ACS may be seen initially either in an emergency department, chest pain unit, or an outpatient facility.			
Early risk stratification[5]	Patients presenting with chest pain should undergo early risk stratification focusing on anginal symptoms, the presence or absence of traditional risk factors for coronary artery disease, physical findings, and ECG. A 12-lead ECG should be obtained immediately in patients with ongoing chest pain and within 10 minutes of presentation in patients with a history of chest pain consistent with ACS but has resolved by the time of evaluation. Serum cardiac markers should be measured in all patients presenting with chest pain consistent with ACS. A cardiac-specific troponin is the preferred marker and if available should be measured in all patients. For patients presenting within 6 hours of the onset of symptoms, an early marker, myoglobin, should be measured in addition to a cardiac troponin. In patients with negative serum markers within 6 hours of the onset of pain, another determination should be made at 9 hours.	An acceptable but less preferable marker is CK-MB. Mass assays for CK-MB are preferred over activity assays for CK-MB.		Total CK activity, AST, and/or LDH as the serum markers for detecting MI in patients with chest pain suggestive of ACS.
Oxygen	Overt pulmonary congestion Arterial oxygen desaturation (Sa_{O_2} < 90%)	Routine administration to all patients with uncomplicated MI during the first 2 to 3 hours	Routine administration of supplemental O_2 to patients with uncomplicated MI beyond 3 to 6 hours	
Intravenous nitroglycerin	For the first 24 to 48 hours in patients with AMI and CHF, large anterior infarction, persistent ischemia, or hypertension Continued use (beyond 48 hours) in patients with recurrent angina or persistent pulmonary congestion		For the first 24 to 48 hours in all patients with AMI who do not have hypotension, bradycardia, or tachycardia. Continued use (beyond 48 hours) in patients with a large or complicated infarction. (Oral or topical preparations may be substituted.)	Patients with systolic blood pressure < 90 mm Hg or severe bradycardia (< 50/min)
Aspirin	160 to 325 mg on day 1 of AMI and continued indefinitely on a daily basis.		Other antiplatelet agents, such as dipyridamole, ticlopidine, or clopidogrel, may be substituted if true aspirin allergy is present or if the patient is unresponsive to aspirin.	
Atropine	Sinus bradycardia with evidence of low cardiac output and peripheral hypoperfusion or frequent PVCs at onset of symptoms of AMI Acute inferior infarction with type I second- or third-degree AV block associated with symptoms of hypotension, ischemic discomfort, or ventricular arrhythmias Sustained bradycardia and hypotension after administration of nitroglycerin For nausea and vomiting associated with administration of morphine Ventricular asystole	Symptomatic patients with inferior infarction and type I second- or third-degree heart block at the level of the AV node	Administration concomitant with administration of morphine in the presence of sinus bradycardia Asymptomatic patients with inferior infarction and type I second-degree heart block or third-degree heart block at the level of the AV node. Second- or third-degree AV block of uncertain mechanism when pacing is not available.	Sinus bradycardia > 40 beats/min without signs or symptoms of hypoperfusion or frequent PVCs. Type II AV block and third-degree AV block and third-degree AV block with new wide QRS complex presumed due to AMI.
Thrombolysis	ST segment elevation (> 0.1 mV, two or more contiguous leads), time to therapy 12 hr, age < 75 yr BBB (obscuring ST segment analysis) and history suggesting AMI	ST segment elevation, age 75 yr	ST segment elevation, time to therapy>12 to 24 hr Blood pressure on presentation>180 mm Hg systolic and/or > 110 mm Hg diastolic associated with high-risk MI.	ST segment elevation, time to therapy greater than 24 hours, ischemic pain resolved ST segment depression only

Primary percutaneous transluminal coronary angioplasty	As an alternative to thrombolytic therapy in patients with AMI and ST segment elevation or new or presumed new left BBB (LBBB) who can undergo angioplasty of the infarct-related artery within 12 hours of onset of symptoms or beyond 12 hours if ischemic symptoms persist, and performed in a timely fashion* by persons skilled in the procedure and supported by experienced personnel in an appropriate laboratory environment. In patients who are within 36 hours of an acute ST segment elevation/Q wave or new LBBB MI who develop cardiogenic shock, are < 75 years old, and in whom revascularization can be performed within 18 hours of onset of shock.	As a reperfusion strategy in candidates for reperfusion who have a contraindication to thrombolytic therapy	In patients with AMI who do not present with ST segment elevation but who have reduced (< TIMI grade 2) flow in the infarct-related artery and when PTCA can be performed within 12 hours of onset of symptoms.	Patients with AMI who: 1. Undergo elective PTCA of a non-infarct-related artery at the time of AMI 2. Are beyond 12 hours after onset of symptoms and have no evidence of myocardial ischemia 3. Have received thrombolytic therapy and have no symptoms of myocardial ischemia 4. Are eligible for thrombolysis and are undergoing primary angioplasty performed by a low-volume operator in a laboratory without surgical backup
Early coronary angiography in the ST segment elevation or BBB cohort not undergoing primary PTCA		Patients with cardiogenic shock or persistent hemodynamic instability	Patients with evolving large or anterior infarcts treated with thrombolytic agents in whom it is believed that the artery is not patent and adjuvant PTCA is planned	Routine use of angiography and subsequent PTCA within 24 hours of administration of thrombolytic agents
Emergency or urgent coronary artery bypass graft surgery	Failed PTCA with persistent pain or hemodynamic instability in patients with coronary anatomy suitable for surgery AMI with persistent or recurrent ischemia refractory to medical therapy in patients with coronary anatomy suitable for surgery who are not candidates for PCI. At the time of surgical repair of postinfarction ventricular septal defect or mitral regurgitation	Cardiogenic shock with coronary anatomy suitable for surgery	Failed PTCA and small area of myocardium at risk; hemodynamically stable	When the expected surgical mortality rate equals or exceeds the mortality rate associated with appropriate medical therapy
Early coronary angiography and/or interventional therapy in non-ST segment elevation MI	Patients with persistent or recurrent (stuttering) episodes of symptomatic ischemia, spontaneous or induced, with or without associated ECG changes Presence of shock, severe pulmonary congestion, or continuing hypotension			
Glycoprotein IIb/IIIa inhibitors		Patients experiencing an MI without ST segment elevation who have some high-risk features and/or refractory ischemia, provided they do not have a major contraindication due to a bleeding risk		

For definition of classes see p. 1353 .

ACS=acute coronary syndrome; ECG=electrocardiogram; CK=creatine kinase; CK-MB=MB isoenzyme of creatine kinase; AST=aspartate transaminase; LDH=lactate dehydrogenase; CHF=congestive heart failure; BBB=bundle branch block; PVCs=premature ventricular contractions; AV=atrioventricular; PTCA = percutaneous transluminal coronary angioplasty; PCI=percutaneous coronary intervention

Unless otherwise specified, data from Ryan TJ, Antman EM, Brooks NH, et al: 1999 Update: ACC/AHA guidelines for the management of patients with acute myocardial infarction: Executive summary and recommendations: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Acute Myocardial Infarction). Circulation 100:1016-1030, 1999. Copyright 1999, American Heart Association.

*Performance standard: balloon inflation within 90 (±30) minutes of admission.

Individuals who perform > 75 PTCA procedures per year.

Centers that perform > 200 PTCA procedures per year and have cardiac surgical capability.

TABLE 35--G-3 -- ACC/AHA GUIDELINES FOR HEMODYNAMIC MONITORING IN ACUTE MYOCARDIAL INFARCTION (AMI)

Indication	Class I	Class IIa	Class IIb	Class III
Balloon flotation right-sided heart catheter monitoring	Severe or progressive CHF or pulmonary edema Cardiogenic shock or progressive hypotension Suspected mechanical complications of AMI (i.e., VSD, papillary muscle rupture, or pericardial tamponade)	Hypotension that does not respond promptly to fluid administration in a patient without pulmonary congestion		Patients with AMI without cardiac or pulmonary complications
Intraarterial pressure monitoring	Patients with severe hypotension (systolic arterial pressure < 80 mm Hg and/or cardiogenic shock Patients receiving vasopressor agents	Patients receiving intravenous sodium nitroprusside or other potent vasodilators	Hemodynamically stable patients receiving intravenous nitroglycerin for myocardial ischemia Patients receiving intravenous inotropic agents	Patients with acute infarction who are hemodynamically stable

Intraaortic balloon counterpulsation	Cardiogenic shock not quickly reversed with pharmacological therapy as a stabilizing measure for angiography and prompt revascularization Acute MR or VSD complicating MI as a stabilizing therapy for angiography and repair/revascularization Recurrent intractable ventricular arrhythmias with hemodynamic instability Refractory post-MI angina as a bridge to angiography and revascularization	Signs of hemodynamic instability, poor left ventricular function, or persistent ischemia in patients with large areas of myocardium at risk.	In patients with successful PTCA after failed thrombolysis or those with three-vessel coronary disease to prevent reocclusion In patients known to have large areas of myocardium at risk with or without active ischemia	

CHF=congestive heart failure; VSD=ventricular septal defect; MR=mitral regurgitation; PTCA=percutaneous transluminal coronary angioplasty.

For definition of classes see p. 1353 .

and subsequent PTCA within 24 hours after administration of a thrombolytic agent. Emergency or urgent coronary artery bypass graft (CABG) is endorsed only when patients have severe, persistent ischemia that cannot be addressed by medical therapy and/or PTCA or as part of an effort to correct mechanical complications of MI. Such surgery along with correction of the latter is considered appropriate when these complications cause severe hemodynamic compromise.

For patients with AMI without ST segment elevation, the ACC/AHA guidelines consider early coronary angiography appropriate if they have recurrent ischemia, spontaneous or induced, with or without associated ECG changes. In these patients, glycoprotein IIb/IIIa inhibitors are usually appropriate (Class IIa), assuming that patients do not have major contraindications to these agents. (See guidelines in Chapter 36 for more detail.)

Oxygen therapy is recommended for patients even in the absence of complications in the first 2 to 3 hours, but the evidence was considered weak for this intervention after 3 to 6 hours. Similarly, routine use of intravenous nitroglycerin in patients with uncomplicated courses is not generally advised (Class IIb).

HEMODYNAMIC MONITORING (Table 35-G-3)

Routine use of right-sided heart catheterization or intraarterial pressure monitoring in the absence of cardiac or pulmonary complications is considered inappropriate by the ACC/AHA guidelines. These interventions are considered clearly appropriate (Class I) in patients who have severe hemodynamic derangements or who require vasopressor agents. Intraaortic balloon counterpulsation is endorsed for patients with cardiogenic shock or other major hemodynamic instability and as a bridge to angiography and revascularization in patients with refractory post-MI angina.

Management of Arrhythmias (Table 35-G-4)

The ACC/AHA guidelines recommend a rapid response to the development of atrial fibrillation, including prompt electrical cardioversion for

TABLE 35--G-4 -- ACC/AHA GUIDELINES FOR MANAGEMENT OF ARRHYTHMIAS IN ACUTE MYOCARDIAL INFARCTION (AMI)

Indication	Class I	Class IIa	Class IIb	Class III
Atrial fibrillation	Electrical cardioversion for patients with severe hemodynamic compromise or intractable ischemia Rapid digitalization to slow a rapid ventricular response and improve LV function Intravenous beta adrenoceptor blockers to slow a rapid ventricular response in patients without clinical LV dysfunction, bronchospastic disease, or AV block	Either diltiazem or verapamil intravenously to slow a rapid ventricular response if beta-adrenoceptor blocking agents are contraindicated or ineffective		
Ventricular tachycardia (VT)/ventricular fibrillation (VF)	VF should be treated with an electric shock with an initial energy of 200 J; if unsuccessful, a second shock of 200 to 300 J should be given, and, if necessary, a third shock of 360 J Sustained (> 30 seconds or causing hemodynamic collapse) polymorphic VT should be treated with an unsynchronized electric shock using an initial energy of 200 J; if unsuccessful, a second shock of 200 to 300 J should be given, and, if necessary, a third shock of 360 J. Episodes of sustained monomorphic VT associated with angina, pulmonary edema, or hypotension (systolic pressure < 90 mm Hg) should be treated with a synchronized electric shock of 100 J initial energy. Increasing energies may be used if not initially successful. Sustained monomorphic VT not associated with angina, pulmonary edema, or hypotension (systolic pressure < 90 mm Hg) should be treated with one of the following regimens:	Infusions of antiarrhythmic drugs may be used after an episode of VT/VF but should be discontinued after 6 to 24 hours and the need for further arrhythmia management assessed Electrolyte and acid-base disturbances should be corrected to prevent recurrent episodes of VF when an initial episode of VF has been treated.	Drug-refractory polymorphic VT should be managed by aggressive attempts to reduce myocardial ischemia, including therapies such as beta-adrenoceptor blockade, intraaortic balloon pumping, and emergency PTCA/CABG surgery. Amiodarone, 150 mg infused over 10 minutes followed by a constant infusion of 1.0 mg/min for up to 6 hours and then a maintenance infusion of 0.5 mg/min.	Treatment of isolated VPBs, couplets, runs of accelerated idioventricular rhythm, and nonsustained VT Prophylactic administration of antiarrhythmic therapy when using thrombolytic agents.

	1. Lidocaine: bolus 1.0 to 1.5 mg/kg. Supplemental boluses of 0.5 to 0.75 mg/kg every 5 to 10 minutes to a maximum of 3 mg/kg total loading dose may be given as needed. Loading is followed by infusion of 2 to 4 mg/min (30 to 50 mug/kg/min). 2. Procainamide: 20 to 30 mg/min loading infusion, up to 12 to 17 mg/kg. This may be followed by an infusion of 1 to 4 mg/min. 3. Amiodarone: 150 mg infused over 10 minutes followed by a constant infusion of 1.0 mg/min for 6 hours and then a maintenance infusion of 0.5 mg/min. 4. Synchronized electrical cardioversion starting at 50 J (brief anesthesia is necessary).			
Atropine	Symptomatic sinus bradycardia (generally, heart rate < 50 beats/min associated with hypotension, ischemia, or escape ventricular arrhythmia). Ventricular asystole Symptomatic AV block occurring at the AV nodal level (second-degree type I or third-degree with a narrow-complex escape rhythm)			AV block occurring at an infranodal level (usually associated with anterior MI with a wide-complex escape rhythm). Asymptomatic sinus bradycardia
Temporary pacing: placement of transcutaneous patches and active (demand) transcutaneous pacing	Sinus bradycardia (rate less than 50 beats/min) with hypotension (systolic pressure < 80 mm Hg) unresponsive to drug therapy. Mobitz type II second-degree AV block Third-degree heart block Bilateral BBB (alternating BBB, or RBBB) and alternating LAFB, LPFB (irrespective of time of onset) Newly acquired or age-indeterminate LBBB, LBBB and LAFB, RBBB, and LPFB RBBB or LBBB and first-degree AV block	Stable bradycardia (systolic pressure > 90 mm Hg, no hemodynamic compromise, or compromise responsive to initial drug therapy) Newly acquired or age-indeterminate RBBB	Newly acquired or age-indeterminate first-degree AV block	Uncomplicated AMI without evidence of conduction system disease
Temporary transvenous pacing	Asystole Symptomatic bradycardia (includes sinus bradycardia with hypotension and type I second-degree AV block with hypotension not responsive to atropine) Bilateral BBB (alternating BBB or RBBB with alternating LAFB/LPFB) (any age) New or indeterminate-age bifascicular block (RBBB with LAFB or LPFB, or LBBB) with first-degree AV block Mobitz type II second-degree AV block	RBBB and LAFB or LPFB (new or indeterminate) RBBB with first-degree AV block LBBB, new or indeterminate Incessant VT, for atrial or ventricular overdrive pacing Recurrent sinus pauses (greater than 3 seconds) not responsive to atropine	Bifascicular block of indeterminate age New or age-indeterminate isolated RBBB	First-degree AV block Type I second-degree AV block with normal hemodynamics Accelerated idioventricular rhythm BBB or fascicular block known to exist before AMI
Permanent pacing after AMI	Persistent second-degree AV block in the His-Purkinje system with bilateral BBB or complete AV block after AMI Transient advanced (second- or third-degree) AV block and associated BBB Symptomatic AV block at any level		Persistent advanced (second- or third-degree) block at the AV node level	Transient AV conduction disturbances in the absence of intraventricular conduction defects Transient AV block in the presence of isolated LAFB Acquired LAFB in the absence of AV block Persistent first-degree AV block in the presence of BBB that is old or age indeterminate

LV = left ventricular; AV = atrioventricular; PTCA = percutaneous transluminal coronary angioplasty; CABG = coronary artery bypass graft; BBB = bundle branch block; RBBB and LBBB = right and left bundle branch block; LAFB and LPFB = left anterior and posterior fascicular block.

For definition of classes see p. 1253 .

patients who develop hemodynamic compromise or intractable ischemia with this arrhythmia. Intravenous beta blockers are considered appropriate agents to slow a rapid ventricular response in the absence of contraindications.

The guidelines do *not* recommend routine administration of antiarrhythmic therapy for nonsustained ventricular tachycardia or less severe ventricular arrhythmias, nor do they support prophylactic antiarrhythmic therapy for patients receiving thrombolytic agents. Intravenous amiodarone is considered an appropriate agent in patients with sustained monomorphic ventricular tachycardia.

The ACC/AHA guidelines consider temporary pacemaker placement appropriate in patients with second-degree Mobitz type II or third-degree atrioventricular block, as well as various configurations of bifascicular and potentially trifascicular block. Permanent pacemaker placement is supported for symptomatic atrioventricular block at any level but not for uncomplicated unifascicular block.

Pharmacotherapy (Table 35-G-5)

Intravenous heparin therapy is considered clearly appropriate (Class I) for patients undergoing revascularization and probably appropriate (Class IIa) for patients receiving intravenous alteplase therapy or with non-ST segment elevation MI (Table 35-G-5) . Intravenous heparin is also recommended for patients at high risk for embolic events, such as those with large or anterior MIs.

The ACC/AHA guidelines support a low threshold for initiation of beta-adrenoceptor blocker therapy within 12 hours of the onset of MI in patients without contraindications. Early administration of angiotensin-converting enzyme inhibitors is recommended for patients with ST segment elevation in anterior leads. Initiation of this therapy is considered clearly (Class I) or probably indicated (Class IIa) in broad classes of patients without contraindications.

In contrast, the use of calcium channel blockers is discouraged. Exceptions include the use of verapamil or diltiazem for patients in whom beta blockers cannot be used or are ineffective for management of arrhythmia or ischemia. The ACC/AHA task force considered diltiazem only marginally appropriate (Class IIb) in the first 24 hours for patients with non-ST segment elevation infarction without left ventricular dysfunction, pulmonary congestion, or congestive heart failure.

The role of intravenous magnesium therapy was considered unestablished, although evidence supported its use in patients with documented magnesium deficits or episodes of *torsades de pointes type* ventricular tachycardia.

Discharge from Hospital (Table 35-G-6)

The ACC/AHA guidelines strongly support performance of noninvasive risk stratification using exercise or pharmacological stress testing. The guidelines indicate that the lowest cost alternative--exercise electrocardiography--is an appropriate first-line test. Imaging and pharmacological stress testing are recommended when clinical or electrocardiographic findings compromise the reliability of exercise electrocardiography. The ACC/AHA task force concluded that there was not strong evidence to support *routine* use of ambulatory (Holter) monitoring or analyses of heart rate variability (Class IIb).

Routine use of coronary angiography and revascularization in patients without evidence of ongoing ischemia was also considered inappropriate (Class III) or weakly supported by evidence (Class IIb). However, invasive evaluation and treatment was recommended (Class I or IIa) when patients had spontaneous or induced evidence

---

TABLE 35--G-5 -- ACC/AHA GUIDELINES FOR PHARMACOTHERAPY IN ACUTE MYOCARDIAL INFARCTION (AMI)

Indication	Class I	Class IIa	Class IIb	Class III
Heparin	Patients undergoing percutaneous or surgical revascularization	Intravenously in patients undergoing reperfusion therapy with alteplase Intravenous UFH or LMWH subcutaneously for patients with non-ST segment elevation MI. Subcutaneous UFH (e.g., 7500 U b.i.d.) or LMWH (e.g., enoxaparin 1 mg/kg b.i.d.) in all patients not treated with thrombolytic therapy who do not have a contraindication to heparin. In patients who are at high risk for systemic emboli (large or anterior MI, AF, previous embolus, or known LV thrombus), intravenous heparin is preferred. Intravenously in patients treated with nonselective thrombolytic agents (streptokinase, anistreplase, urokinase) who are at high risk for systemic emboli (large or anterior MI, AF, previous embolus, or known LV thrombus)	Patients treated with nonselective thrombolytic agents, not at high risk, subcutaneous heparin, 7500 U to 12,500 U twice a day until completely ambulatory	Routine intravenous heparin within 6 hours to patients receiving a nonselective fibrinolytic agent (streptokinase, anistreplase, urokinase) who are not at high risk for systemic embolism
Beta-adrenoceptor blocking agents: early therapy	Patients without a contraindication to beta-adrenoceptor blocker therapy who can be treated < 12 hours of onset of AMI, irrespective of administration of concomitant thrombolytic therapy or performance of primary angioplasty Patients with continuing or recurrent ischemic pain Patients with tachyarrhythmias, such as AF with a rapid ventricular response Non-ST segment elevation MI		Patients with moderate LV failure (the presence of bibasilar rales without evidence of low cardiac output) or other relative contraindications to beta-adrenoceptor blocker therapy, provided patients can be monitored closely	Patients with severe LV failure

Angiotensin-converting enzyme (ACE) inhibitors	Patients within the first 24 hours of a suspected AMI with ST segment elevation in > 2 anterior precordial leads or with clinical heart failure in the absence of hypotension (systolic BP < 100 mm Hg) or known contraindications to use of ACE inhibitors Patients with MI and LV ejection fraction < 40% or patients with clinical heart failure on the basis of systolic pump dysfunction during and after convalescence from AMI	All other patients within the first 24 hours of a suspected or established AMI, provided significant hypotension or other clear-cut contraindications are absent Asymptomatic patients with mildly impaired LV function (ejection fraction 40% to 50%) and a history of old MI	Patients who have recently recovered from MI but have normal or mildly abnormal global LV function	
Calcium channel blockers		Verapamil or diltiazem in patients in whom beta-adrenoceptor blockers are ineffective or contraindicated (i.e., bronchospastic disease) for relief of ongoing ischemia or control of a rapid ventricular response with AF after AMI in the absence of CHF, LV dysfunction, or AV block	In non-ST segment elevation infarction, diltiazem may be given to patients without LV dysfunction, pulmonary congestion, or CHF. It may be added to standard therapy after the first 24 hours and continued for 1 year.	Nifedipine (short acting) is generally contraindicated in routine treatment of AMI because of its negative inotropic effects and the reflex sympathetic activation, tachycardia, and hypotension associated with its use. Diltiazem and verapamil are contraindicated in patients with AMI and associated LV dysfunction or CHF.
Magnesium		Correction of documented magnesium (and/or potassium) deficits, especially in patients receiving diuretics before onset of infarction Episodes of torsades de pointes-type VT associated with a prolonged QT interval should be treated with 1 to 2 gm of magnesium administered as a bolus over 5 minutes.	Magnesium bolus and infusion in high-risk patients such as the elderly and/or those for whom reperfusion therapy is not suitable	

UFH = unfractionated heparin; LMWH = low molecular weight heparin; AF = atrial fibrillation; LV = left ventricular; BP = blood pressure; VT = ventricular tachycardia; AV = atrioventricular; CHF = congestive heart failure.

For definition of classes see p. 1253 .

TABLE 35--G-6 -- ACC/AHA GUIDELINES FOR PREPARATION FOR DISCHARGE FROM HOSPITAL AFTER ACUTE MYOCARDIAL INFARCTION (AMI)

Indication	Class I	Class IIa	Class IIb	Class III
Noninvasive evaluation of low-risk patients	Stress ECG Before discharge for prognostic assessment or functional capacity (submaximal at 4 to 6 days or symptom limited at 10 to 14 days) Early after discharge for prognostic assessment and functional capacity (14 to 21 days) Late after discharge (3 to 6 weeks) for functional capacity and prognosis if early stress was submaximal Exercise, vasodilator stress nuclear scintigraphy, or exercise stress echocardiography when baseline abnormalities of the ECG compromise interpretation	Dipyridamole or adenosine stress perfusion nuclear scintigraphy or dobutamine echocardiography before discharge for prognostic assessment in patients judged to be unable to exercise Exercise two-dimensional echocardiography or nuclear scintigraphy (before or early after discharge for prognostic assessment)	Stress testing within 2 to 3 days of AMI Either exercise or pharmacological stress testing at any time to evaluate patients with unstable postinfarction angina pectoris At any time to evaluate patients with AMI who have uncompensated CHF, cardiac arrhythmia, or noncardiac conditions that severely limit their ability to exercise. Before discharge to evaluate patients who have already been selected for cardiac catheterization	
Assessment of ventricular arrhythmia--routine testing			Ambulatory (Holter) monitoring, signal-averaged ECG, heart rate variability, baroreflex sensitivity monitoring, alone or in combination for risk assessment after MI, especially in patients at higher perceived risk, when findings might influence management issues, or for clinical research purposes	

Coronary angiography and possible PTCA	Patients with spontaneous episodes of myocardial ischemia or episodes of myocardial ischemia provoked by minimal exertion during recovery from AMI Before definitive therapy of a mechanical complication of infarction such as acute MR, VSD, pseudoaneurysm, or LV aneurysm Patients with persistent hemodynamic instability	When MI is suspected to have occurred by a mechanism other than thrombotic occlusion at an atherosclerotic plaque. This would include coronary embolism, certain metabolic or hematological diseases, or coronary artery spasm Survivors of AMI with depressed LV systolic function (LV ejection fraction less than or equal to 40%), CHF, prior revascularization, or malignant ventricular arrhythmias Survivors of AMI who had clinical heart failure during the acute episode but subsequently demonstrated well-preserved LV function	Coronary angiography performed in all patients after infarction to find persistently occluded infarct-related arteries in an attempt to revascularize the artery or to identify patients with three-vessel disease All patients after a non-Q-wave MI Recurrent VT or VF or both, despite antiarrhythmic therapy in patients without evidence of ongoing myocardial ischemia	Routine use of coronary angiography and subsequent PTCA of the infarct-related artery within days after receiving thrombolytic therapy Survivors of MI who are thought not to be candidates for coronary revascularization
Routine coronary angiography and PTCA after successful thrombolytic therapy				Routine PTCA of the stenotic infarct-related artery immediately after thrombolytic therapy PTCA of the stenotic infarct-related artery within 48 hours of receiving a thrombolytic agent in asymptomatic patients without evidence of ischemia

ECG = electrocardiogram; CHF = congestive heart failure; MR = mitral regurgitation; VSD = ventricular septal defect; LV = left ventricular; VT = ventricular tachycardia; VF= ventricular fibrillation; PTCA = percutaneous transluminal coronary angioplasty.

For definition of classes see p. 1253 .

TABLE 35--G-7 -- SECONDARY PREVENTION

Indication	Class I	Class IIa	Class IIb	Class III
Management of lipids	The AHA step II diet, which is low in saturated fat and cholesterol in all patients after recovery from AMI Patients with LDLC > 125 mg/dl despite the AHA step II diet should be placed on drug therapy, with the goal of reducing LDLC to < 100 mg/dl Patients with normal plasma cholesterol levels with HDLC < 35 mg/dl should receive nonpharmacological therapy (e.g., exercise) designed to raise it	Drug therapy added to diet in patients with LDLC levels < 130 mg/dl but > 100 mg/dl after an appropriate trial of the AHA step II diet Patients with normal total cholesterol levels but HDLC < 35 mg/dl despite diet and other nonpharmacological therapy may be started on drugs such as niacin to raise HDL levels.	Drug therapy with either niacin or gemfibrozil added to diet regardless of LDLC and HDLC when triglyceride levels are > 200 mg/dl.	
Long-term beta-adrenoceptor blocker therapy in survivors of myocardial infarction	All but low-risk patients without a clear contraindication to beta-adrenoceptor blocker therapy. Treatment should begin within a few days of the event (if not initiated acutely) and continue indefinitely.	Low-risk patients without a clear contraindication to beta-adrenoceptor blocker therapy. Survivors of non-ST segment elevation MI.	Patients with moderate or severe LV failure or other relative contraindications to beta-adrenoceptor blocker therapy, provided patients can be monitored closely	
Long-term anticoagulation	Post-MI patients unable to take daily aspirin Post-MI patients in persistent AF Patients with LV thrombus	Post-MI patients with extensive wall motion abnormalities Patients with paroxysmal AF.	Post-MI patients with severe LV systolic dysfunction with or without CHF	
Estrogen replacement therapy and myocardial infarction		HRT with estrogen plus progestin for secondary prevention of coronary events should not be given de novo to postmenopausal women after AMI. Postmenopausal women who are already taking HRT with estrogen plus progestin at the time of AMI can continue this therapy.		

LDLC and HDLC = low- and high-density lipoprotein cholesterol; LV = left ventricular; CHF = congestive heart failure; AF = atrial fibrillation.
For definition of classes see p. 1253 .

of myocardial ischemia or other complications of ischemic heart disease.

Secondary Prevention (Table 35-G-7)

The ACC/AHA guidelines strongly endorse pharmacological and aggressive dietary interventions to reduce low-density lipoprotein (LDL) cholesterol after acute myocardial infarction. An AHA Step II diet is considered appropriate for all patients after recovery from AMI, and initiation for drug therapy is considered clearly appropriate (Class I) if LDL cholesterol is greater than 125 mg/dl despite this diet. The use of a lower LDL cholesterol threshold (100-125 mg/dl) for initiation of drug therapy was considered to be less clearly established (Class IIa). Exercise and other efforts to raise high-density lipoprotein cholesterol are also recommended.

The guidelines reflect enthusiasm for the benefits of beta blockers for all but low-risk patients if there are no contraindications to these agents. Anticoagulation with warfarin is considered appropriate for patients unable to take daily aspirin or for patients who have atrial fibrillation or left ventricular thrombus. The guidelines are somewhat supportive (Class IIa) of anticoagulation in patients with extensive wall motion abnormalities or paroxysmal atrial fibrillation but not for all patients with severe left ventricular dysfunction.

The guidelines do not support initiation of hormone replacement therapy in postmenopausal patients with the goal of preventing coronary events after AMI but did not oppose their continuation.

Chapter 36 - Unstable Angina

Christopher P. Cannon
Eugene Braunwald

Unstable angina lies in the center of the spectrum of clinical conditions caused by myocardial ischemia. These range from chronic stable angina pectoris (see Chap. 37) to the acute coronary syndromes. The latter, in turn, consist of acute myocardial infarction (MI) associated with electrocardiographic ST segment elevation (STEMI) (see Chap. 35) and unstable angina/non-ST segment elevation MI (UA/NSTEMI). The former is most commonly caused by acute total coronary occlusion,[1] [2] and urgent reperfusion is the mainstay of therapy, whereas UA/NSTEMI is usually associated with severe coronary obstruction but not total occlusion of the culprit coronary artery.[3] [4] If the myocardial ischemia that results from the coronary obstruction is long in duration and/or great in severity, myocardial necrosis occurs,[5] and the patient is classified as having a non-Q-wave MI or, now more aptly termed, NSTEMI (see Fig. 35-2) .

Although, with the advent of thrombolysis and other emergency reperfusion therapies, a great deal of attention has focused on acute MI with ST segment elevation, UA/NSTEMI (the focus of this chapter) occurs with much greater frequency. Every year in the United States, approximately 1.3 million patients are admitted to the hospital with unstable angina or NSTEMI compared with approximately 350,000 patients with acute STEMI.[6]

DEFINITION AND CLASSIFICATION

DEFINITION.

This is largely based on the clinical presentation[7] (see p. 1235). *Stable* angina pectoris is characterized by a deep, poorly localized chest or arm discomfort (rarely described as pain) that is reproducibly associated with physical exertion or emotional stress and relieved within 5 to 15 minutes by rest and/or sublingual nitroglycerin. *Unstable* angina is defined as angina pectoris (or equivalent type of ischemic discomfort) with at least one of three features: (1) it occurs at rest (or with minimal exertion) usually lasting more than 20 minutes (if not interrupted by nitroglycerin); (2) it is severe and described as frank pain and of new onset (i.e., within 1 month); and (3) it occurs with a crescendo pattern (i.e., more severe, prolonged, or frequent than previously). Some patients with this pattern of ischemic discomfort, especially those with prolonged rest pain,[5] develop evidence of myocardial necrosis on the basis of the release of cardiac markers and thus have a diagnosis of NSTEMI. Traditionally, this diagnosis has been based on elevation of serum creatine kinase (CK)-MB, but recently troponin T and I assays have been used to define ischemic myocardial damage based on their higher sensitivity for myocardial necrosis and powerful prognostic ability (see pp. 1236 , 1237 , and 1240).

CLASSIFICATION.

Because unstable angina comprises such a heterogeneous group of patients, classification schemes based on clinical features have been proposed.[7] [8] [9] [10] A clinical classification of unstable angina, presented by one of the authors (Table 36-1) ,[8] has been found to be a useful means of stratifying risk.[11] [12] [13] [14] [15] Patients are divided into three groups according to the clinical circumstances of the acute ischemic episode: primary unstable angina, secondary unstable angina (i.e., with unstable angina related to obvious precipitating noncoronary factors such as anemia, infection, or cardiac arrhythmias), and post-MI angina. Patients are also classified according to the severity of the ischemia (acute rest pain, subacute rest pain, or new-onset severe angina)[8] (see Table 36-1) . This classification has been shown to be predictive of plaques with thrombus at angiography[11] [16] [17] or in atherectomy specimens[18] and in risk stratification (see p. 1234).[12] [13] [14]

Because unstable angina is a clinical syndrome rather than a specific disease (much like hypertension rather than pneumococcal pneumonia), and because it has many potential causes, an etiological approach has been proposed.[10] Five pathophysiological processes that may contribute to the development of unstable angina have been identified (Fig. 36-1) :

1. Plaque rupture with superimposed nonocclusive thrombus
2. Dynamic obstruction (i.e., coronary spasm of an epicardial artery, as in Prinzmetal angina [see Chap. 37] or constriction of the small muscular coronary arteries)
3. Progressive mechanical obstruction
4. Inflammation and/or infection
5. Secondary unstable angina, precipitated by increased myocardial oxygen demand or decreased supply (e.g., thyrotoxicosis or anemia)

Individual patients may have several of these processes coexisting as the cause of their episode of unstable angina. Use of this etiological approach will refine the diagnostic approach and help target therapeutic strategies to treat the underlying disease that precipitated the episode of unstable angina.

TABLE 36-1 -- BRAUNWALD CLINICAL CLASSIFICATION OF UNSTABLE ANGINA

CLASS	DEFINITION	DEATH OR MYOCARDIAL INFARCTION TO 1 YEAR*
Severity		
Class I	New onset of severe angina or accelerated angina; no rest pain	7.3%
Class II	Angina at rest within past month but not within preceding 48 hr (angina at rest, subacute)	10.3%
Class III	Angina at rest within 48 hr (angina at rest, subacute)	10.8%
Clinical Circumstances		
A (secondary angina)	Develops in the presence of extracardiac condition that intensifies myocardial ischemia	14.1%
B (primary angina)	Develops in the absence of extracardiac condition	8.5%

C (postinfarction angina)	Develops within 2 weeks after acute myocardial infarction	18.5% *p*<0.001
Intensity of treatment	Patients with unstable angina may also be divided into three groups depending on whether unstable angina occurs (1) in the absence of treatment for chronic stable angina, (2) during treatment for chronic stable angina, or (3) despite maximal antiischemic drug therapy. The three groups may be designated subscripts 1, 2, or 3, respectively.	
Electrocardiographic changes	Patients with unstable angina may be further divided into those with or without transient ST-T wave changes during pain.

p=0.057

PATHOPHYSIOLOGY

The majority of patients with unstable angina have significant obstructive coronary atherosclerosis (see Chap. 30) . Episodes of ischemia can be provoked by an increase in myocardial oxygen demand (e.g., precipitated by tachycardia or hypertension) and/or by a reduction in supply (e.g., due to reduction in coronary lumen diameter by platelet-rich thrombi or vasospasm). Rapid progression of the underlying coronary artery disease has been documented.[19] [20] A sequence of events can be documented in unstable angina in which there is first a reduction in coronary sinus oxygen saturation (signifying a reduction in coronary blood flow), then ST segment depression, followed by chest discomfort.[21] Elevations in blood pressure and/or heart rate sometimes ensue.[21] A patient might have both a small increase in myocardial oxygen demand, in conjunction with a reduction in coronary blood flow, leading to the episode of ischemia. The five major causes of these two broad precipitants of unstable angina are reviewed next.

PLAQUE RUPTURE, FISSURE, OR EROSION.

Rupture or erosion of an atherosclerotic plaque with superimposed nonocclusive thrombus is by far the most common cause of UA/NSTEMI. The type of plaque that ruptures, the so-called vulnerable plaques, are usually lesions with less than 50 percent stenosis.[22] [23] [24] [224A] Plaque rupture can be precipitated by multiple factors, including high plaque lipid content,[25] local inflammation causing breakdown of the thin shoulder of the plaque,[26] coronary artery constriction at the site of the plaque, local shear stress forces, platelet activation,[27] [28]

Figure 36-1 Schematic representation of the causes of unstable angina. Each of the five bars represents one of the etiologic mechanisms, and the red portion of the bar represents the extent to which the mechanism is operative. *A,* Most common form of unstable angina in which atherosclerotic plaque causes moderate (60 percent diameter) obstruction and acute thrombus overlying plaque causes very severe (90 percent diameter) narrowing. *B,* Mild coronary obstruction, adjacent to which there is intense (90 percent diameter) vasoconstriction. (From Braunwald E: Unstable angina: An etiologic approach to management [editorial]. Circulation 98:2219-2222, 1998. Copyright 1998, American Heart Association.)

and the status of the coagulation system (i.e., a potentially prothrombotic state),[29] [30] all of which culminate in the formation of platelet-rich thrombi at the site of the plaque rupture or erosion and the resultant acute coronary syndrome (see also Chaps. 30 and 35) . [31] [32] [33] Circadian variation with a morning increase in the onset of UA/NSTEMI has been reported[34] and likely relates to similar factors as in MI, including morning elevations in platelet aggregability[35] [36] and in myocardial oxygen demand with increases in blood pressure, heart rate, emotional stress, and physical exertion.[37]

INFLAMMATION AND/OR INFECTION.

Recent evidence has also pointed to a role for inflammation, which appears to play a key role in the development of atherosclerosis (see Chaps. 30 and 31) , [38] [39] and in the development and recurrence of unstable angina.[40] [41] [42] [43] Infectious agents, notably *Chlamydia pneumoniae,* appear to be one of the underlying causes of diffuse inflammation in the pathogenesis of coronary artery disease.[44] [45] [46] Others for which there is some, albeit less strong, evidence include *Helicobacter pylori* and cytomegalovirus.[44] An etiological relationship between these infectious agents to the development of unstable angina (or MI) has not been definitively established.[46] [47] [48] On the other hand, evidence from several animal models,[49] [50] [51] and pilot treatment trials in patients, [52] [53] [54] suggests that *Chlamydia pneumoniae* may be an important and *potentially treatable* cause of unstable angina or MI, and larger trials are ongoing.

THROMBOSIS

(see also Chap. 62) . The central role of coronary artery thrombosis in the pathogenesis of unstable angina is supported by a substantial body of evidence.[4] [31] [32] [55] [56] [57] Six sets of observations contribute to this concept:

1. At autopsy, thrombi can usually be identified at the site of a ruptured plaque[31] [32] [58] or a coronary erosion.[59]
2. Coronary atherectomy specimens obtained from patients with unstable angina demonstrate a high incidence of thrombotic lesions, as compared with those obtained from stable angina patients.[18] [57] [60] [61]
3. Coronary angioscopic observations in unstable angina indicate that thrombus is frequently present.[55] [56] [62] [63] [64]
4. Coronary angiography has demonstrated ulceration or irregularities suggesting a ruptured plaque[22] [65] and/or thrombus in many patients (Fig. 36-2). In the Thrombosis in Myocardial Infarction (TIMI) IIIA trial of patients with UA/NSTEMI, 35 percent of patients had definite thrombus and an additional 40 percent had possible thrombus at angiography.[4]
5. Evidence of ongoing thrombosis has been noted with elevation of several markers of platelet activity and fibrin formation.[66] [67] [68] [69] [70]
6. The clinical outcome of patients with acute coronary syndromes improves with antithrombotic therapy with aspirin,[71] [72] [73] [74] heparin, [73] [74] [75] [76] [77] low-molecular-weight heparin,[78] [79] [80] and platelet glycoprotein IIb/IIIa inhibitors. [81] [82] [83]

PLATELET AGGREGATION

(see also Chap. 62) . Platelets play a key role in the transformation of a stable atherosclerotic plaque to an unstable lesion (Fig. 36-3) . With rupture or ulceration of an atherosclerotic plaque, the subendothelial matrix (e.g., collagen and tissue factor) is exposed to the circulating blood. The first step is *platelet adhesion* by means of the platelet glycoprotein Ib receptor through its interaction with endothelial von Willebrand factor. This is followed by *platelet activation*, which leads to (1) a shape change in the platelet (from a smooth discoid shape to a spiculated form, which increases the surface area upon which thrombin generation can occur); (2) degranulation of the alpha and dense granules, thereby releasing thromboxane A_2 , serotonin, and other platelet aggregatory and chemoattractant agents; and (3) expression of

Figure 36-2 Coronary artery thrombus in a patient with unstable angina. A 60-year-old man presented with prolonged rest pain and transient anterior ST segment elevations. Coronary angiography shows an irregular hazy filling defect in the left anterior descending artery at the level of the second diagonal branch (arrow). Contrast medium surrounds the globular thrombus, which extends into the diagonal branch.

glycoprotein IIb/IIIa receptors on the platelet surface with activation of the receptor so that it can bind fibrinogen. The final step is *platelet aggregation*, that is, the formation of the platelet plug. Fibrinogen (or von Willebrand factor) binds to the activated glycoprotein IIb/IIIa receptors of two platelets, thereby creating a growing platelet aggregate. Antiplatelet therapy is one of the cornerstones of therapy in unstable angina (see p. 1243) and is directed at decreasing the formation of thromboxane A_2 (aspirin), inhibiting the adenosine diphosphate (ADP) pathway of platelet activation (ticlopidine and clopidogrel), and directly inhibiting platelet aggregation (glycoprotein IIb/IIIa inhibitors) (see Fig. 36-3) .

SECONDARY HEMOSTASIS.

Simultaneously with formation of the platelet plug, the plasma coagulation system is activated. Release of tissue factor appears to be the predominant mechanism of initiating hemostasis during plaque rupture and coronary thrombosis (see Chap. 62) .[84] [85] [86] Ultimately, factor X is activated (to factor Xa), leading to the generation of thrombin, which plays a central role in arterial thrombosis. Thrombin has several actions: (1) it converts fibrinogen to fibrin in the final common pathway for clot formation; (2) it is a powerful stimulus for platelet aggregation; and (3) it activates factor XIII, which leads to cross-linking and stabilization of the fibrin clot. Thrombin molecules are incorporated into coronary thrombi and can form the nidus of rethrombosis (i.e., reocclusion or reinfarction) as the thrombus undergoes spontaneous or pharmacologically induced fibrinolysis. Accordingly, effective inhibition of thrombin and factor Xa plays an important part of the therapy of unstable angina (see later).

CORONARY VASOCONSTRICTION.

There are three settings in which the process of dynamic coronary obstruction is identified:

1. Prinzmetal variant angina, with intense *focal* spasm of a segment of an epicardial coronary artery, is the prototypical example (see also Chap. 37) .[87] This can occur in patients without coronary atherosclerosis or in patients with a nonobstructive atheromatous plaque. The vasospastic angina appears to be due to hypercontractility of vascular smooth muscle and endothelial dysfunction occurring in the region of spasm.[88] Such patients typically present with rest pain accompanied by transient ST segment elevation.

2. Coronary vasoconstriction causing "microcirculatory angina" results from constriction of the small intramural coronary resistance vessels.[89] Although there are no epicardial coronary artery stenoses, coronary flow is usually slowed (see Chap. 37) .
3. Probably the most common setting in which vasoconstriction occurs is in the presence of coronary atherosclerotic plaques.

Vasoconstriction can occur as the result of local vasoconstrictors released from platelets, such as serotonin and thromboxane A_2 ,[66] [69] as well as those present within the thrombus, such as thrombin.[90] A dysfunctional coronary endothelium, with reduced production of nitric oxide and increased release of endothelin (see Chap. 34) , can also lead to vasoconstriction. Adrenergic stimuli, cold immersion,[91] cocaine,[92] [93] or mental stress[94] can also cause coronary vasoconstriction.

Figure 36-3 Primary hemostasis: process of platelet adhesion (a), activation (b), and aggregation (c). Platelets initiate thrombosis at the site of a ruptured plaque: the first step is *platelet adhesion* (1) via the glycoprotein Ib receptor in conjunction with von Willebrand factor. This is followed by *platelet activation* (2), which leads to a shape change in the platelet, degranulation of the alpha and dense granules, and expression of glycoprotein IIb/IIIa receptors on the platelet surface with activation of the receptor, such that it can bind fibrinogen. The final step is *platelet aggregation* (3), in which fibrinogen (or von Willebrand factor) binds to the activated glycoprotein IIb/IIIa receptors of two platelets. Aspirin (ASA) and clopidogrel act to decrease platelet activation (see text for details), whereas the glycoprotein IIb/IIIa inhibitors inhibit the final step of platelet aggregation.

PROGRESSIVE MECHANICAL OBSTRUCTION.

The fourth etiology of unstable angina results from progressive luminal narrowing. This is most commonly seen in the setting of restenosis after percutaneous coronary intervention (PCI) (see Chap. 38) . However, angiographic[20] and atherectomy studies[60] [95] have demonstrated that many patients without previous intracoronary procedures have shown progressive luminal narrowing of the culprit vessel that is related to rapid cellular proliferation in the period preceding the onset of unstable angina.

SECONDARY UNSTABLE ANGINA.

This form of unstable angina is precipitated by an imbalance in myocardial oxygen supply and demand caused by conditions extrinsic to the coronary arteries in patients with prior coronary stenosis and chronic stable angina.[8] This could occur by either an increased myocardial oxygen demand, a reduction in coronary blood flow, or both. Conditions that increase oxygen demand include tachycardia (e.g., supraventricular tachycardia or new-onset atrial fibrillation with rapid ventricular response), fever, thyrotoxicosis, hyperadrenergic states, and elevations of left ventricular afterload such as hypertension or aortic stenosis. Secondary unstable angina can also occur due to impaired oxygen delivery, as occurs in anemia, hypoxemia (e.g., due to pneumonia or congestive heart failure), and hyperviscosity states or hypotension. Secondary angina appears to have a worse prognosis than primary unstable angina (see Table 36-1) .[14]

CLINICAL PRESENTATION

The clinical profile of patients presenting with unstable angina differs from that of acute ST elevation MI. Unstable angina occurs more frequently in women, who comprise 30 to 45 percent of patients in studies of unstable angina,[96] [97] [98] compared with 25 to 30 percent of patients with NSTEMI and 20 percent of patients with STEMI.[96] [97] [99] In comparison to the latter, patients with unstable angina also have higher rates of prior MI, angina, previous coronary revascularization, and extracardiac vascular disease.[97] [99] Indeed, approximately 80 percent of patients with unstable angina have a prior history of coronary artery disease.

HISTORY AND PHYSICAL EXAMINATION.

A description of "ischemic pain" is the hallmark of unstable angina (see Chap. 3) . Chronic stable angina is usually described as a discomfort or pressure but rarely as a pain; it is usually located in the substernal region, but sometimes is near the epigastrium, and it frequently radiates to the anterior neck, left shoulder and left arm (see Chap. 37) . In unstable angina, the discomfort, occurring either on exertion or at rest, is usually severe enough to be considered painful. The physical examination may be unremarkable or may support the diagnosis of cardiac ischemia (see Chap. 4) Signs that suggest unstable angina (or MI) with ischemia involving a larger fraction of the left ventricle are transient diaphoresis, pale cool skin, sinus tachycardia, a third or fourth heart sound, and basilar rales on lung examination. Rarely, the severity of left ventricular dysfunction causes hypotension.

ELECTROCARDIOGRAM (ECG).

In unstable angina, ST segment depression (or transient ST segment elevation) and T wave changes occur in up to 50 percent of patients.[83] [100] [101] Three analyses have shown that in patients with the clinical presentation of unstable angina, *new* ST segment deviation, even of only 0.05 mV, is a specific and important measure of ischemia and prognosis.[100] [102] [103] T wave changes are sensitive but nonspecific of acute ischemia,

Figure 36-4 Electrocardiogram showing deep symmetrical anterolateral T wave inversion without ST segment deviation. Such findings are frequently associated with critical stenosis of the left anterior descending coronary artery and are a useful marker of a patient at high risk of subsequent death or myocardial infarction. (From Haines DE, Raabe DS, Gundel WD, Wackers FJ: Anatomic and prognostic significance of new T-wave inversion in unstable angina. Am J Cardiol 52:14-18, 1983.)

unless they are marked. Thus, transient, deep T wave inversions (
 0.3 mV) are considered to be relatively specific for acute ischemia, like ST segment deviations, and to signify high risk[7] [83] (Fig. 36-4). On the other hand, the presence of T wave inversions of 0.1 mV in patients with unstable angina may add little to the clinical history.[100] [103]

CONTINUOUS ECG MONITORING.

Continuous ECG monitoring can be used for two purposes in unstable angina: (1) to detect arrhythmias in association with the acute episode and (2) to monitor the ST segments for evidence of recurrent ischemia.[7] Although life-threatening arrhythmias are rare in unstable angina, they may be more common among NSTEMI patients. Guidelines generally recommend continuous monitoring for at least 24 hours in patients hospitalized for UA/NSTEMI.[104] [105] When screening for ischemia, ST segment monitoring appears to be more sensitive than patient's symptoms, and it is a strong marker of adverse short- and long-term outcome.[21] [106] [107] [108] [109] [110] Evidence has shown that continuous 12-lead ST segment monitoring provides independent prognostic information even when it is used in conjunction with troponins and clinical

variables.[110] Silent ischemia was more frequent and prolonged in patients with NSTEMI compared with those with unstable angina.[111]

CARDIAC MARKERS.

Among patients presenting with symptoms consistent with unstable angina, the diagnosis of NSTEMI is made if there is biochemical evidence of myocardial necrosis, that is, positive CK-MB, troponin T or I, or potentially other markers of injury[7] [112] (see also Chap. 35) .

The issue of what "cut point" to use for a positive troponin assay is currently being debated. One group has proposed two cut points: one "diagnostic" cut point to define myocardial infarction (derived from a comparison with CK-MB-defined MI) and a second, lower, "prognostic" cut point, generally the upper detectable limit of the assay or more specifically the 97.5th percentile of a normal population of subjects.[113] Each assay may have different cut points. As an example, at Brigham and Women's Hospital for the Dimension R×L assay for troponin I (Dade-Behring), the cut points are more than 1.5 ng/dl for the diagnosis of MI and 0.1 ng/dl or more for prognosis. Cut points are different for troponin T, and, to date, a cut point of 0.1 ng/dl or more has been used for both diagnosis and prognosis[114] [115] ; however, a cut point for prognosis of as low as 0.01 ng/dl or more is being explored as the prognostic cut point with the third-generation assay.[116]

In patients with UA/NSTEMI, values greater than the upper (diagnostic) cut point indicate evidence of NSTEMI. Smaller elevations in troponin are believed also to signify evidence of myocardial damage, although the extent of myocardial damage has not been documented in patients with the small elevations. The damage is believed to result from obstruction of small, distal coronary vessels, caused by microemboli of thrombus or of plaque debris from a more proximal lesion.[117] Smaller elevations in troponin values (e.g., troponin I between 0.1 and 1.5 ng/dl) have been shown to be of important prognostic value (see Diagnosis, p. 1237, and Risk Stratification, p. 1239) and may assist in the diagnosis of unstable angina when used in conjunction with the clinical history and ECG. Bedside tests can have either a positive versus negative result or provide a quantitative result. However, because each assay is different, each hospital needs to review the specific cut points defined by that assay.

CORONARY ARTERIOGRAPHIC FINDINGS.

The extent of coronary artery disease among patients with UA/NSTEMI enrolled in TIMI IIIB was 15 percent with critical obstruction (> 60 percent luminal diameter stenosis) of three vessels, 30 percent with two-vessel disease, 40 percent with single-vessel disease, and 20 percent with no significant coronary stenosis.[101] Five to 10 percent of patients had left main stem stenosis greater than 50 percent.[100] [101] [118] Similar findings have been reported from registries of unselected UA/NSTEMI patients.[100] [118] Women and nonwhites with UA/NSTEMI have less extensive coronary disease than their counterparts,[96] [97] [98] [118] [119] whereas patients with NSTEMI have more extensive disease than those who present with unstable angina.[97]

Fifteen to 30 percent of patients who present with symptoms of unstable angina will have no significant coronary stenosis on coronary angiography.[96] [97] [100] [101] [118] [119] [120] Women and nonwhites comprise a larger proportion of such patients without epicardial coronary disease,[96] [97] [118] [119] [120] suggesting a difficulty in making a firm diagnosis of unstable angina in these groups and/or a different pathophysiological mechanism for their clinical presentation. Approximately one third of patients with unstable angina without a critical epicardial obstruction will have impaired coronary flow, suggesting a pathophysiological role for coronary microvascular dysfunction.[120] The short-term prognosis is excellent in this group of patients.

The culprit lesion in unstable angina typically exhibits an eccentric stenosis with scalloped or overhanging edges and a narrow neck.[4] [22] [65] These angiographic findings may represent disrupted atherosclerotic plaque, thrombus, or a combination.[121] Features suggesting thrombus include globular intraluminal masses with a rounded or polypoid shape[4] (see Fig. 36-2) . "Haziness" of a lesion has been used as an angiographic marker of possible thrombus, but this finding is less specific. Patients with angiographically visualized thrombus have impaired coronary flow and worse clinical outcomes, compared with those without thrombus.[122] [123] Of interest, however, is that angiographically documented thrombus is present in only 20 to 40 percent of patients using a rigorous definition.[4] [123] [124] It is likely that the frequency is much greater and that angiography simply is not sensitive enough to detect all but the largest thrombi.

ANGIOSCOPY AND INTRAVASCULAR ULTRASOUND.

Greater definition of the culprit lesion has been possible using angioscopy, where "white" (platelet-rich) thrombi are frequently observed as opposed to "red" thrombi, which are more often seen in patients with acute STEMI.[55] [56] [62] [64] Intravascular ultrasound examination identified more soft "echolucent" plaques and fewer calcified lesions among patients with unstable versus stable angina.[17]

OTHER LABORATORY TESTS.

A chest roentgenogram may be useful in identifying pulmonary congestion or edema, which would be more likely in patients with NSTEMI involving a significant proportion of the left ventricle or in those with prior known left ventricular dysfunction.[7]

The presence of congestion has been shown to confer an adverse prognosis.[125] [126]

Obtaining a serum cholesterol level is useful in identifying an important, treatable cause of coronary atherosclerosis. Because serum cholesterol levels begin to fall 24 hours after acute MI or unstable angina, it should be measured at the time of hospital admission. If only a later sample is obtained, but the value falls into a range that warrants long-term treatment (see Chap. 39) appropriate therapy can be initiated,[127] [128] [129] although the optimal timing of initiation of cholesterol-lowering therapy is being studied. Other circulating markers of increased risk are discussed later (see p. 1240). Evaluation for other secondary causes of unstable angina[8] may also be appropriate in selected patients (e.g., checking thyroid function in a patient who presents with unstable angina and a persistent tachycardia).

DIAGNOSIS OF UA/NSTEMI

The diagnosis of unstable angina is a clinical one, based on the patient's description of symptoms, as described earlier. A diagnosis of NSTEMI is made on the basis of a clinical history consistent with UA/NSTEMI and positive circulating cardiac markers[7] (see p. 1240 and Chap. 35) . However, in the United States 6 to 7 million persons per year present to an emergency department (ED) with a complaint of chest pain or other symptoms suggestive of possible acute coronary syndrome, of whom only 20 to 25 percent have a final diagnosis of unstable angina or MI.[130] [131]

ASSESSING LIKELIHOOD OF CORONARY ARTERY DISEASE.

Thus, the key first step in evaluation of patients with possible UA/NSTEMI is to determine the *likelihood* that coronary artery disease is the cause of the presenting symptoms.[7] From several large studies of patients presenting with chest pain to an ED,[100] [112] [130] [132] [133] [134] [135] [136] [137] [138] [139] [140] [141] [142] [143] [144] [145] certain features portend a higher likelihood that the patient actually has unstable angina (Table 36-2) . High likelihood exists among patients with prior coronary disease and/or with symptoms

TABLE 36-2 -- FEATURES ASSOCIATED WITH HIGHER LIKELIHOOD OF CORONARY ARTERY DISEASE AMONG PATIENTS PRESENTING WITH SYMPTOMS SUGGESTIVE OF UNSTABLE ANGINA

History
Chest pain as chief complaint similar to prior ACS symptoms
Known history of coronary artery disease, myocardial infarction, percutaneous coronary intervention, coronary artery bypass graft
History of angina
Age>60
Male gender
More than two major cardiac risk factors
Diabetes
Extracardiac vascular disease (carotid or peripheral)
Physical Examination

Pulmonary rales, hypotension
Transient mitral regurgitation
Diaphoresis

Electrocardiogram

New/presumably new ST deviation >0.05 mV
T wave inversion
0.1 mV
Q waves, left bundle branch block

Cardiac Markers

Elevated CK-MB, troponin I or T

Data supporting these factors come from references [100] [130] [132] [133] [134] [135] [136] [137] [138] [139] [140] [141] [142] [143] [144] [145] and [412] .

---

that are similar to a prior episode of MI or unstable angina.[130] [132] [133] [134] [136] [137] Elevation of cardiac markers or evidence of congestive heart failure or hemodynamic compromise also increase the likelihood of UA/NSTEMI.

CLINICAL AND ECG PREDICTOR RULES.

Several groups have developed predictor rules to enhance clinical assessment of patients presenting with chest pain to the ED.[132] [133] [134] [135] [136] [137] [138] [139] These "predictor rules" use clinical variables as well as ECG findings to define either MI,[132] [133] [135] any acute coronary syndrome (UA, NSTEMI, or STEMI),[134] [137] [138] [139] or subsequent cardiac complications regardless of initial diagnosis.[136] In general, all of these prediction rules can assist the clinician in assessing the likelihood of unstable angina or MI, but because of the numerous questions that are part of the assessment they are not often used in clinical practice. One algorithm, the Acute Cardiac Ischemia--Time Insensitive Prediction Instrument (ACI-TIPI) has been integrated into ECG devices and provides a likelihood of the patient having unstable angina or MI.[137] [139] This device evaluates the ECG for the presence of ST segment deviation, Q waves, and T wave inversion; and the operator enters into the computer the patient's age and gender and whether the patient's primary symptom was chest/left arm pain. The ACI-TIPI algorithm then computes a probability that the patient has an acute coronary syndrome, which is printed with the computer's standard interpretation of the ECG. This device was shown in a randomized trial to reduce unnecessary hospital and coronary care unit admissions and thus provide more cost-effective triage of patients.[139]

CARDIAC-SPECIFIC TROPONINS.

The troponins can be used in two ways in the ED to evaluate patients with possible UA/NSTEMI: (1) to diagnose NSTEMI and (2) to define prognosis (i.e., the risk of developing recurrent cardiac ischemic events, including death, recurrent infarction, and recurrent severe ischemia requiring rehospitalization or urgent revascularization). In numerous studies, in patients admitted to the hospital with unstable angina[115] [141] [142] [143] [144] [145] [146] [147] [148] [149] [150] [151] [152] [153] [154] [155] (see p. 1240) as well as in the broad group of patients presenting to the ED with chest pain,[141] [143] [144] elevations of either troponin T or I have been shown to be very strong predictors of subsequent cardiac events.

However, "false-positive" troponin tests have been noted among series of patients presenting to the ED with chest pain.[156] [157] [158] In patients presenting to the ED with a complaint of chest pain, the clinical suspicion (and prevalence) of coronary artery disease is lower than it is in patients who are admitted to the hospital with unstable angina.[141] [143] Thus, the use of cardiac markers in the ED setting should be integrated with the clinical history and the ECG to arrive at an overall assessment of the likelihood of the patient having unstable angina.[141] [143] [159]

The timing of when blood samples should be obtained during initial evaluation of UA/NSTEMI has been examined in several studies. Most have included a "baseline" sample,[115] [146] [148] [149] which in studies conducted within clinical trials of unstable angina was at the time of randomization (i.e., at least several hours after the patient had presented to the ED). Recent large studies, in which the first blood sample is taken at the time of the patient's initial evaluation in the ED, have shown elevations of troponin T or I to be strongly predictive of subsequent cardiac complications.[141] [144] However, several recent studies have found incremental benefit by adding an additional one or two samples (generally 4, 8, or 16 hours later), with the second or third sample identifying a progressively greater number of patients who are positive and who are found to be high risk.[141] [143] [146] [151] [153]

Serial measurements are definitely needed among patients who present to the hospital within 6 hours from the onset of pain (which comprise the majority of patients[133] [141]) because of the release kinetics of troponins and CK-MB (see Chap. 35) . In this early time window, myoglobin or CK-MB isoforms may be useful markers.[112] [160] [161] However,

---

owing to low specificity of myoglobin for myocardial tissue, it should not be used in isolation but rather confirmed with a later sample analyzed for a more cardiac-specific marker (e.g., troponin or CK-MB).[7]

Emergency Department Chest Pain Pathways

The current approach to evaluating patients with chest pain (or related symptoms suggestive of UA/NSTEMI) incorporates four major diagnostic tools--clinical history, ECG, cardiac markers and provocative stress testing. They have three major objectives: (1) to diagnose infarction (using cardiac markers), (2) to evaluate for evidence of ischemia at rest (using symptoms, ECG, and/or continuous ECG monitoring), and (3) to evaluate for significant coronary artery disease (provocative stress testing).

Most pathways, including that shown in Figure 36-5 , begin with a clinical assessment of the likelihood of the presenting symptoms being angina.[7] Patients with intermediate or high likelihood of ischemia (i.e., those with any feature shown in Table 36-2) are admitted to the hospital and treated with appropriate therapy for UA/NSTEMI (see p. 1241). On the other hand, patients, with atypical pain, not suggestive of ischemia, are discharged home with follow-up to their primary physicians. The remaining patients with a low likelihood of ischemia (i.e., without any of the factors shown in Table 36-2) are observed in the ED (or chest pain unit or related facility)[162] [163] with a standardized protocol.[164] [165]

These patients are monitored for recurrent rest pain and have a panel of markers (currently CK-MB, troponin I, and myoglobin) at arrival and 6 hours later. If the onset of pain was more than 6 hours before arrival, the baseline sample is frequently considered sufficient to "rule out" MI. If cardiac markers are positive or if the patient develops recurrent pain with ECG changes, the patient is admitted to the hospital and treated for UA/NSTEMI. If the patient remains pain free and the markers are negative, the patient goes on to exercise stress testing. For most patients, ECG stress testing is used, but for patients with fixed ECG abnormalities (e.g., left bundle branch block [LBBB]) perfusion imaging is employed and for those who cannot walk, pharmacological stress testing is used. If the clinical history suggests a very low likelihood of acute ischemia, patients are discharged home with subsequent outpatient stress testing. The goal is to carry out the testing and discharge (or admit) patients within 6 to 9 hours from ED arrival with follow-up to their primary physicians.

The safety of early exercise stress testing in patients presenting to the ED with chest pain was initially questioned, but several recent studies have demonstrated no adverse outcomes when applied to appropriately selected patients (as described earlier).[166] [167] [168]

CARDIAC IMAGING: SESTAMIBI PERFUSION IMAGING AND ECHOCARDIOGRAPHY.

The use of additional imaging techniques is taking on increasing importance in the early diagnosis of patients presenting with suspected unstable angina and MI, especially when the ECG findings are obscured by LBBB or a paced rhythm. Sestamibi (see Chap. 9) has been useful for patients presenting with chest pain in the ED without diagnostic ECG, to discriminate patients with coronary artery disease (in whom perfusion defects are observed) from those with noncardiac chest pain (with normal perfusion scans).[169] [170] Sestamibi scanning (and echocardiography) also can provide information about left ventricular ejection fraction and wall motion that may be useful in triage decisions of the patients.

Some centers have utilized stress echocardiography in evaluating chest pain patients.[171] [172] [173] However, in two studies, little additional information was obtained in the *routine* use of echocardiography in all chest pain patients.[162] [174] Echocardiography performed while the patient is at rest in the ED has been used to evaluate whether a wall motion

Figure 36-5 Brigham and Women's Hospital Emergency Department "Rule Out Myocardial Infarction (MI)" critical pathway. The approach to patients presenting with acute chest pain or other symptoms suggestive of possible UA/NSTEMI is first to assess the likelihood of coronary artery disease (CAD). Patients with high or intermediate likelihood are admitted to the hospital and treated according to the UA/NSTEMI pathway. Those with clearly atypical chest pain are discharged home. Patients with a low likelihood enter the pathway and are observed in a monitored bed in the emergency department (ED) observation unit over a period of 6 hours, and 12-lead electrocardiograms (ECGs) are performed if the patient has recurrent chest discomfort. A panel of cardiac markers (e.g., troponin I, CK-MB, and myoglobin) are drawn at baseline and 6 hours later. If the patient develops recurrent pain, has ST segment or T wave changes, or has positive cardiac markers, he or she is admitted to the hospital and treated for UA/NSTEMI. If the patient has negative markers and no recurrence of pain, he or she is sent for exercise treadmill testing (ETT), with imaging reserved for patients with abnormal baseline ECGs (e.g., left bundle branch block or left ventricular hypertrophy with ST-T wave abnormalities). If the test is positive in a patient presenting with acute chest pain, the patient is admitted; if the test is negative, the patient is discharged home with follow-up to his or her primary physician.

abnormality is present, to help in establishing (or excluding) the diagnosis of ischemic heart disease,[175] and in determining prognosis.[176] However, cost issues have precluded widespread *routine* use of echocardiography, but most centers use echocardiography selectively (i.e., in patients with LBBB or paced rhythms or in patients with suspected valvular disease and/or aortic dissection, especially transesophageal echocardiography for the latter).[177] [178] [179]

One study found improved sensitivity of perfusion imaging compared with stress echocardiography or ECG stress testing,[180] whereas another study found similar overall diagnostic capabilities of the two imaging modalities[181] (see also Chap. 13) . Both of these modalities can assess global left ventricular function, a powerful determinant of subsequent prognosis after MI[182] [183] (and presumably after unstable angina as well), and this may be important in triaging medical therapy among patients with confirmed MI or unstable angina (e.g., angiotensin-converting enzyme [ACE] inhibitors).[184] However, because most patients presenting to EDs do not have coronary artery disease,[130] [131] such widespread assessment of left ventricular function would likely not be cost effective.

CHEST PAIN CENTERS.

Many hospitals have developed "chest pain centers" within or closely related to the ED in which patients with suspected acute coronary syndromes can be triaged. Standardized protocols for acute STEMI can be implemented, thereby reducing door-to-needle time[185] (see Chap. 35) , and rapid "rule out MI" protocols for low-risk patients with chest pain can be carried out.[165] [186] Use of such chest pain centers or specialized ED units can reduce by 20 to 30 percent the number of patients who require admission to the hospitals[162] [163] [170] [174] [187] and randomized trials.[163] [174] One multicenter study found that the implementation of a chest pain unit significantly decreased the rate of hospital admission and overall costs, despite an overall increase in the number of patients who underwent "rule-out MI" evaluation instead of being discharged home directly.[187] Thus, there is emerging evidence that chest pain centers or specific protocols/critical pathways in the ED can improve the efficiency of health care for this large population of patients.

Natural History

The outcome of patients with UA/NSTEMI is generally favorable when compared with acute STEMI,[96] [97] [99] although there are several subgroups of patients who can have *higher* mortality (see later). In the TIMI III Registry of patients with UA/NSTEMI, 21 percent "ruled in" for an NSTEMI at the time of admission; 62 percent underwent cardiac catheterization, 22 percent angioplasty, and 13 percent coronary bypass surgery. By 42 days, mortality was 2.4 percent and a new or recurrent MI occurred in 2.9 percent of patients. Within clinical trials, in which inclusion criteria select higher risk patients (see later), rates of death by 30 days ranged from 3.5 to 4.5 percent and rates of new or recurrent MI ranged from 6 to 12 percent.[80] [81] [83]

RISK STRATIFICATION

As already noted, unstable angina is a heterogeneous condition that ranges from one with an excellent outcome with modest adjustments in therapeutic regimen to one in which the risk of death or MI is high and intensive (and expensive) treatment is needed. Evidence is available from recent large clinical trials for important subgroups of patients who are at higher risk of adverse outcomes (Table 36-3) . [7] Furthermore, these groups appear to derive greater benefit from more aggressive antithrombotic therapy (see p. 1246). Clinical predictors can be also used to assist in triage of unstable angina patients to the coronary care unit versus a monitored bed.[5] [7] [104] Patients determined to be at high risk should be admitted to the coronary care unit, whereas those with intermediate or lower risk could be admitted to a monitored bed on a cardiac step-down unit.

TABLE 36-3 -- INDICATORS OF INCREASED RISK IN UNSTABLE ANGINA

History
Advanced age (>65 years)
Diabetes mellitus
Post-myocardial infarction angina
Prior peripheral vascular disease
Prior cerebrovascular disease
Clinical Presentation
Braunwald Class II or III (acute or subacute rest pain)
Braunwald Class B (secondary unstable angina)
Heart failure/hypotension
Electrocardiogram
New/ST segment deviation
0.05 mV
New T wave inversion
0.3 mV
Left bundle branch block
Cardiac Markers
Increased troponin T or I or CK-MB
Increased C-reactive protein (CRP)
Angiogram
Thrombus

CLINICAL VARIABLES.

The Braunwald classification of unstable angina [8] (see Table 36-1) has been shown in several studies to be useful in identifying high-risk patients.[12] [13] [14] In the multicenter TIMI III Registry, which included 3318 consecutive patients with UA/NSTEMI, this classification was an important predictor of rate of death or MI to 1 year--both by the severity of the unstable angina and by the clinical circumstances in which it occurred (see Table 36-1) . High-risk groups of patients with unstable angina are those with acute rest pain, those with post-MI unstable angina, and those with secondary unstable angina.[14]

HIGH-RISK SUBGROUPS.

Increasing age has been shown to be associated with a significant increase in adverse outcomes in patients with UA/NSTEMI.[100] [188] Diabetic patients with UA/NSTEMI are at approximately 50 percent higher risk than nondiabetics (see Chap. 63) .[189] [190] Patients with extracardiac vascular disease (i.e., those with either cerebrovascular disease or peripheral arterial vascular disease) also appear to have approximately 50 percent higher rates of death or recurrent ischemic events compared with patients without previous peripheral or cerebrovascular disease, even after controlling for other differences in baseline characteristics.[191] Patients who present with evidence of congestive heart failure (Killip Class > II) have increased risk of death in the setting of unstable angina.[126] [192] In addition, patients who develop recurrent ischemia after initial presentation have also been found to be at increased risk.[83] [193]

PRIOR ASPIRIN THERAPY.

Another group of patients with UA/NSTEMI that has been identified as high risk are those who present with acute ischemia despite chronic aspirin therapy. These patients are sometimes termed "aspirin failures," and a subset of these patients may actually represent "aspirin resistance"[194] ; however, the pathophysiology of this observation is not fully defined and is actively being studied.[195] This group represents an increasing proportion of patients (from 60 to 80 percent of patients in recent trials) and, among patients not randomized to a glycoprotein IIb/IIIa inhibitor, their subsequent rate of death or MI was 50 percent higher than those not previously taking aspirin.[196] [197] Treatment with a glycoprotein IIb/IIIa inhibitor

appeared to decrease this risk (see p. 1246). In the OPUS-TIMI 16 trial, higher event rates were again observed in prior aspirin users, but this was not an independent predictor of mortality or recurrent cardiac events.[198] Thus, the development of UA/NSTEMI despite aspirin therapy is a useful clinical marker of high risk.

RISK ASSESSMENT BY ECG.

The admission ECG is very useful in predicting long-term adverse outcomes. In the TIMI III Registry of patients with UA/NSTEMI, independent predictors of 1-year death or MI included LBBB (risk ratio 2.8) and ST segment deviation of 0.05 mV or greater (risk ratio 2.45) (both $p<0.001$).[100] The presence of 0.05 mV or more ST segment depression on the admission ECG has also been reported to be an independent determinant of 4-year mortality, with a gradient of increasing risk with increasing ST segment depression.[103] In contrast, the presence of T wave changes of 0.1 mV or more was associated with a modest[103] or no increase in subsequent death or MI compared with patients without ST or T wave changes.[100] Similar findings were observed in predicting 30-day and 6-month outcomes in the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) IIb study, in which the presence of ST segment deviation greater than 0.5 mm confers a worse prognosis than T wave changes.[102]

CK-MB AND THE TROPONINS.

Patients with NSTEMI have a worse long-term prognosis than those with unstable angina.[73] [101] [199] [200] [201] [202] [203] [204] However, the high-risk population extends beyond those who have positive CK-MB fractions, the traditional definition of MI. Studies have found that patients with "microinfarction"[205] or "minor myocardial damage"[206] [207] (i.e., those not meeting usual criteria for MI of elevated CK and CK-MB but with elevated troponin T,[115] [144] [146] [147] [149] [151] [154] [155] [208] troponin I,[148] [150] [152] [155] [209] myosin light chains,[147] or mildly elevated CK-MB[210] [211]) are a high-risk population.

Patients with elevated troponin values are at much higher risk of subsequent cardiac complications, including mortality[115] [144] [146] [147] [148] [149] [150] [151] [152] [153] [154] [155] [208] (Fig. 36-6) . This has been observed even in patients without CK-MB elevation.[146] [148] [153] [212] Beyond just a positive versus negative test result, there is a linear relationship between the level of troponin T or I in the blood and subsequent risk of death--the higher the troponin, the higher the mortality risk (see Fig. 36-6 *B*). Similar results have been obtained using a bedside rapid assay for troponin T, in which time to positivity is a semi-quantitative measure of serum troponin T and related to increased mortality.[144] [212] Thus, troponin T and I are very useful not only in diagnosing infarction[205] (see p. 1237 and Chap. 35) but also in risk assessment in patients presenting with acute UA/NSTEMI and in "targeting" therapies to high-risk patients (see p. 1241).

C-REACTIVE PROTEIN.

Additional markers also appear to be useful in assessing patients with UA/NSTEMI, among which C-reactive protein (CRP) is very promising. Elevated CRP has been related to increased risk of death, MI, and/or need for urgent revascularization.[40] [41] [42] [43] [213] [214] [215] [216] In TIMI 11A, 14-day mortality for patients with an elevated CRP (
1.55 mg/dl, the 99th percentile of normal subjects) was 5.6 percent compared with 0.3 percent for patients without an elevated CRP (Fig. 36-7 *A*).[43] Even among patients with negative troponin T at baseline, who had a 14-day mortality of 1.5 percent overall, CRP was able to discriminate a high- and low-risk group: mortality for patients with an elevated CRP was 5.8 percent versus 0.4 percent for patients without elevated CRP (see Fig. 36-7 *A*). [43] When using both CRP and troponin T, mortality could be stratified from 0.4 percent for patients with both markers negative, to 4.7 percent if either CRP or troponin were positive, to 9.1 percent if both were positive (see Fig. 36-7 *B*). [43] Thus, the combination of a necrosis marker (troponin T or I) and an inflammatory marker (CRP) provides independent and powerful prognostic information in patients with acute coronary syndromes.[43] [214] [216]

Figure 36-6 TIMI IIIB. *A,* The relationship of a positive versus negative troponin I versus 42-day mortality in the total group (left) and those with negative creatine kinase (CK)-MB (right). *B,* A direct relationship was observed between increasing levels of troponin I and a higher 42-day mortality. cTnI=cardiac specific troponin I; Neg=negative. (Adapted from Antman EM, Tanasijevic MJ, Thompson B, et al: Cardiac-specific troponin I levels to predict the risk of mortality in patients with acute coronary syndromes. N Engl J Med 335:1342-1349, 1996, with permission of the New England Journal of Medicine.)

In another recent study, CRP was not predictive of in-hospital events but was a powerful predictor of 30-day and 6-month events.[215]

CRP measured at the time of hospital discharge has been found to be a very strong predictor of outcome to 3 to 12 months.[217] [218] Other inflammatory markers have offered consistent evidence of an association between systemic inflammation and recurrent adverse events, including serum amyloid A,[219] interleukin-6,[220] CD40 ligand,[221] $CD4^{+}$ $CD28^{null}$. [222] These studies indicate that inflammation is related to the instability of patients and an increased risk of recurrent cardiac events.

COMBINED RISK ASSESSMENT SCORES.

An emerging approach to unstable angina is to use a comprehensive approach to risk assessment. As illustrated in Figure 36-8 , patients with symptoms of unstable angina fall on a spectrum. ST segment deviation or deep T wave inversion defines high-risk patients. CK-MB can be used to define NSTEMI. Troponins are more sensitive markers of necrosis and extend the population that is identified as high risk. Finally, even among patients who are troponin negative, CRP can further identify high-risk patients.

By integrating this approach, comprehensive risk scores

Figure 36-7 TIMI 11A. *A,* Relationship of C-reactive protein (CRP) vs. 14-day mortality in all patients with UA/NSTEMI (left) and those with negative baseline troponin T (right). *B,* Use of both troponin T and CRP to predict mortality. (An "early positive" rapid bedside troponin T assay [RTnT] was defined as positive
10 minutes.) These data demonstrate that an elevated CRP (the high-sensitivity assay was used in this study) is a potent predictor of increased mortality and extends beyond the prognostic information that troponin provides. CRP is a marker of inflammation, whereas the troponins are markers of myocardial necrosis, and these data demonstrate the complementary information provided by these two markers in patients with UA/NSTEMI. Early+= early positive; neg=negative. (From Morrow DA, Rifai N, Antman EM, et al: C-reactive protein is a potent predictor of mortality independently and in combination with troponin T in acute coronary syndromes: A TIMI 11A substudy. J Am Coll Cardiol 31:1460-1465, 1998.)

can be developed using both clinical variables, as well as variables from the ECG and initial serum cardiac markers. One such analysis used three simple markers: age 65 years or older, ST segment deviation of 0.5 mm or more, and positive serum cardiac markers (either CK-MB or troponin). When these three parameters were used, the risk of death, MI, or urgent revascularization at 43 days rose from 14.5 percent for none or one of these risks to 19.3 percent and 27.3 percent for patients with one, two or all three factors ($p<0.0001$). [223] The more detailed TIMI risk score was developed using multivariate analysis, which identified

Figure 36-8 Risk stratification across the spectrum of acute coronary syndromes (ACS). Positive tests identify higher risk patients. This summary of the risk stratification tools currently available shows that among the broad spectrum of patients with ischemic heart disease, the electrocardiogram (ECG), cardiac markers creatine kinase (CK-MB) and troponin, and C-reactive protein (CRP) can identify increasing proportions of the overall group as being at high risk of recurrent cardiac events or death. For the ECG, markers of high risk include ST depression of 0.05 mV or more. The newer markers

troponins and CRP identify a higher percentage of patients than did CK-MB, the only marker used in the mid 1990s.

seven independent risk factors: age 65 years or older; more than three risk factors for coronary artery disease; documented coronary artery disease at catheterization; ST segment deviation of 0.5 mm or more, more than two episodes of angina in the last 24 hours, aspirin within prior week, and elevated cardiac markers. Use of this scoring system was able to risk-stratify patients across a 10-fold gradient of risk, from 4.7 to 40.9 percent ($p<0.001$). [224]

MEDICAL THERAPY

TREATMENT GOALS.

The treatment objectives for patients with UA/NSTEMI are focused on stabilizing and "passivating" the acute coronary lesion, treatment of residual ischemia, and long-term secondary prevention. Antithrombotic therapy (e.g., aspirin, low or unfractionated molecular weight heparin, glycoprotein IIb/IIIa inhibitors, and clopidogrel) is used to prevent further thrombosis and allow endogenous fibrinolysis to dissolve the thrombus and reduce the degree of coronary stenosis. Antithrombotic therapy is continued long term to reduce the risk of developing future events and/or to prevent progression to complete occlusion of the coronary artery. Antiischemic therapies (e.g., beta blockers, nitrates, and/or calcium antagonists) are used primarily to reduce myocardial oxygen demand. Coronary revascularization is frequently needed to treat recurrent or residual ischemia that occurs despite the medical therapy. After the acute event is stabilized, the many factors that led up to the event need to be reversed (i.e., treatment of atherosclerotic risk factors such as hypercholesterolemia, hypertension, and cessation of smoking, each of which contributes to stabilization of the cholesterol-laden plaque and healing of the endothelium).

General Measures

The approach to the patient with UA/NSTEMI generally includes admission to a monitored bed. In these settings, continuous ECG monitoring (i.e., telemetry) is used to evaluate

for cardiac arrhythmias and potentially for new asymptomatic ST deviations as markers of ischemia.[7]

Bed rest is usually prescribed initially for patients with UA/NSTEMI.[7] Ambulation as tolerated is permitted if the patient has been stable hemodynamically without recurrent chest discomfort for at least 12 to 24 hours. Means of improving the physical and emotional surroundings for the patient, such as placing the patient in a quiet atmosphere, away from any emotionally taxing arguments, and offering physician's reassurance and/or mild sedation may act to reduce sympathetic drive and thereby reduce ischemia.[7] Supplemental oxygen is frequently administered to patients with UA/NSTEMI, but there are no studies to demonstrate its usefulness. It is advisable to provide supplemental oxygen only to patients with cyanosis, extensive rales, and documented hypoxemia. Oxygen saturation determined by oximetry is useful with supplemental oxygen administered if the arterial oxygen saturation declines below 92 percent.[7]

Relief of chest pain is an initial goal of treatment. In patients with persistent pain despite therapy with nitrates and beta blockers (see later), morphine sulfate, 1 to 5 mg intravenously, is recommended. Contraindications include hypotension or prior allergy (meperidine can be substituted for the patients who are allergic to morphine). With careful blood pressure monitoring, repeat doses can be administered every 5 to 30 minutes. Morphine may act both as an analgesic and anxiolytic, but its venodilatory effects may produce beneficial hemodynamic effects by reducing preload. The latter is especially useful in the setting of acute pulmonary edema. If hypotension develops after administration of morphine, supine positioning or intravenous saline should restore blood pressure and pressors are rarely needed. If respiratory depression develops, naloxone (0.4 to 2.0 mg) may be given.

Nitrates (see also Chap. 37)

Nitrates are endothelium-independent vasodilators that both increase myocardial blood flow by coronary vasodilatation and reduce myocardial oxygen demand. The latter effect is produced by venodilation leading to reduced myocardial preload and reduction in ventricular wall stress, thereby reducing myocardial oxygen demand. Nitrates should initially be given sublingually or by buccal spray (0.3 to 0.6 mg) if the patient is experiencing ischemic pain. If pain persists after three sublingual tablets (or buccal sprays) each 5 minutes apart and initiation of beta blockade, intravenous nitroglycerin (5 to 10 mug/min using nonabsorbing tubing) is recommended.[7] The rate of the infusion may be increased by 10 mug/min every 3 to 5 minutes until symptoms are relieved or systolic blood pressure falls by more than 30 mm Hg or to below 100 mm Hg. Although there is no absolute maximum dose, a dose of 200 mug/min is generally used as a ceiling. Contraindications to use of nitrates are hypotension or the use of sildenafil (Viagra) within the previous 24 hours.[225]

Topical or oral nitrates can be used if the episode of pain has resolved, or they may replace intravenous nitroglycerin if the patient has been pain free for 12 to 24 hours.[7] Dosing of nitrates depends on the formulation (see Table 37-4) , but dosing should attempt to have an 8- to 10-hour nitrate-free interval to avoid the development of tolerance.

The effect of nitrates on mortality was evaluated in the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI)-3 and International Study of Infarct Survival (ISIS)-4 trials for patients with suspected MI (both STEMI and NSTEMI).[226] [227] No benefit on mortality was observed in the overall population or in the subgroup of patients with NSTEMI. Consequently, the goal of nitrate therapy is relief of pain; chronic nitrate therapy can frequently be tapered off in the long-term management of patients, with primary therapy being aspirin and beta blockers and sublingual or buccal nitroglycerin given as needed for new episodes of pain.

Beta Blockers (see also Chap. 37)

Several placebo-controlled trials in UA/NSTEMI have shown benefit of beta blockers in reducing subsequent MI and/or recurrent ischemia.[228] [229] [230] [231] [232] [233] In patients with acute MI (in studies which included patients with both STEMI and NSTEMI in the prethrombolytic era), beta blockers were shown to reduce infarct size, reinfarction, and mortality (see Chap. 35) .[234] [235] [236] [237] In addition, in subgroup analyses of patients with NSTEMI in three trials, the benefits of beta blockers (intravenous followed by oral) have been observed.[237] [238] [239] [240]

Thus, beta blockers are recommended for patients with UA/NSTEMI who do not have contraindications to these agents (e.g., bradycardia, advanced atrioventricular block, persistent hypotension, pulmonary edema, history of bronchospasm).[104] [105] A reduced ejection fraction is no longer a contradiction to beta blockade, and, indeed, such patients may derive added benefit given the benefits on mortality seen with long-term beta blockade in patients with congestive heart failure (see also Chaps. 18 and 21) .[241] [242] [243] If ischemia and chest pain is ongoing, early intravenous beta blockade should be used, followed by oral beta blockade. The choice of which beta blocker to use can be individualized based on the drug's pharmacokinetics, cost, and physician familiarity (Table 37-6) . However, those with intrinsic sympathomimetic activity (ISA), such as pindolol, should not be selected. Examples of doses tested in large trials include atenolol (5-10 mg intravenous bolus followed by 100 mg orally daily)[237] and metoprolol (5 mg intravenous boluses, three given 2 to 5 minutes apart, followed by 50 mg orally twice daily titrated up to 100 mg twice daily).[244] Commencing therapy with intravenous esmolol could be considered in patients with possible contraindications (e.g., a history of possible asthma) with an initial loading dose of 0.5 mg/kg/min over 1 minute, followed by a 0.05 mg/kg/min infusion, with repeat loading doses and increases in the infusion of 0.05 mg/kg/min to achieve the desired heart rate.[245]

Calcium Channel Blockers (see also Chap. 37)

These drugs have vasodilatory effects and lower blood pressure, and some also slow heart rate (Table 37-8) . They may be used in patients who have persistent or recurrent symptoms but are currently recommended only in patients who have persistent ischemia after treatment with full-dose nitrates and beta blockers have been used or in patients with contraindications to beta blockade.[7] Such patients should be treated with heart rate-slowing calcium channel blockers (e.g., diltiazem or verapamil).[104] [105] Oral doses of diltiazem and verapamil range from 30 to 90 mg four times daily to 360 mg once daily of the long-acting preparations.

In the Diltiazem Reinfarction Study, involving 576 patients with non-Q-wave MI, diltiazem reduced recurrent MI from 9.3 percent on placebo to 5.2 percent on diltiazem.[201] A more recent pilot study using intravenous diltiazem[246] and a larger clinical trial using long-acting diltiazam[247] [248] in patients after thrombolytic therapy found trends toward benefit of diltiazem versus placebo. In the Danish Study Group on Verapamil in Myocardial Infarction (DAVIT) II trial of patients with suspected MI or unstable angina, of whom nearly half did not have confirmed MI, verapamil tended to reduce recurrent MI or death.[249] However, meta-analyses have found no beneficial effect of the calcium antagonist drugs as a class in reducing mortality or subsequent infarction.[229] [250] [251] One overview did suggest benefit of verapamil alone.[252]

Importantly, in patients with acute MI with left ventricular dysfunction or congestive heart failure, a harmful effect of diltiazem has been observed.[253] Nifedipine, which

does not lower heart rate, has been shown to increase the incidence

of adverse events in patients with acute MI when not coadministered with a beta blocker.[254] [255] In contrast, no harm was observed in one study with verapamil in patients with congestive heart failure, all of whom were treated with ACE inhibitors.[256] Similarly, no harm with long-term treatment with amlodipine[257] or felodipine [258] was observed in patients with documented left ventricular dysfunction and coronary artery disease, indicating that these vasoselective calcium antagonists may be safely used in patients with unstable angina with left ventricular dysfunction.

In summary, calcium antagonists should be used in patients with UA/NSTEMI if needed for recurrent ischemia despite beta blockade or in patients in whom beta blockade is contraindicated (e.g., bronchospasm);[7] diltiazem should be avoided in patients with left ventricular dysfunction and/or congestive heart failure.

Angiotensin-Converting Enzyme Inhibitors (see also Chap. 29)

ACE inhibitors have been shown to be beneficial in many settings, including patients *post* MI who have demonstrated either impaired left ventricular function (ejection fraction<40 percent)[184] or congestive heart failure.[259] The GISSI-3, ISIS-4, and Chinese Captopril trials showed a 0.5 percent absolute mortality benefit of early (initiated within 24 hours) ACE inhibition in patients with acute MI.[226] [227] [260] However, in the ISIS-4 study, no benefit was observed in patients without ST segment elevation. Thus, *short-term* ACE inhibition does not appear to confer any benefit for patients with unstable angina or NSTEMI without impaired left ventricular function.

On the other hand, *long-term* use of ACE inhibition is applicable to several groups of patients: those with (1) left ventricular dysfunction,[184] (2) congestive heart failure,[259] and (3) based on recent evidence from the Heart Outcomes Prevention Evaluation (HOPE) trial, it may apply to most patients with all forms of ischemic heart disease, including UA/NSTEMI.[261] Recurrent MI and the need for revascularization were reduced with ACE inhibitors in the Survival and Ventricular Enlargement (SAVE) and Studies of Left Ventricular Dysfunction (SOLVD) trials, suggesting an antiischemic effect of this class of agents,[262] [263] which was confirmed in the HOPE trial (see also Chap. 39) .

Lipid-Lowering Therapy (see also Chap. 33)

Long-term treatment with lipid-lowering therapy, especially with statins, has been shown to be beneficial in patients after acute MI and unstable angina[127] [128] [129] (see also Chap. 39) . In the Scandinavian Simvastatin Survival Study (4S), carried out in hypercholesterolemic patients with a history of MI *or* unstable angina, mortality was reduced by 30 percent (p=0.0003) and coronary deaths were significantly reduced by 42 percent.[128] In addition, recurrent MI was significantly reduced by 37 percent (p<0.001), coronary revascularization by 37 percent (p<0.0001), and rehospitalization for acute cardiovascular disease by 26 percent (p<0.001).[128] [264] The cost savings of these reductions offset nearly all the cost of the simvastatin therapy. Thus, the cost-effectiveness is very favorable: cost per year of life saved ranged from $3,800 for 70-year-old men with a cholesterol level of 309 mg/dl to $27,400 for 35-year-old women with a cholesterol level of 213 mg/dl.[265]

The Cholesterol and Recurrent Events (CARE) and Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID) studies extended these benefits to patients with average cholesterol levels (i.e., <240 mg/dl), which constitute the majority of patients with acute coronary syndromes. In CARE, treatment with pravastatin for an average of 5 years led to a 24 percent reduction in cardiovascular death or MI (p=0.003), with similar reductions in need for revascularization and stroke.[127] Interestingly, no benefit was observed in the subgroup of patients with a baseline low-density lipoprotein (LDL) of less than 125 mg/dl. The LIPID trial enrolled more than 9000 patients with a history (at least 3 months prior) of MI or unstable angina. In the prespecified subgroup of more than 3200 patients with unstable angina, pravastatin therapy led to a significant 26 percent reduction in total mortality (p=0.004).[129]

Thus, long-term cholesterol lowering has been shown to have dramatic benefits in secondary prevention after infarction[266] [267] [268] and is very cost effective. For patients with UA/NSTEMI, testing the cholesterol level is critical. To ensure that all patients would benefit from cholesterol lowering, as demonstrated in these three trials, the total cholesterol and LDL cholesterol levels (calculated or direct measurement) should be obtained and treatment initiated with a statin drug if the LDL is more than 125 mg/dl (as suggested by the CARE and LIPID results). The National Cholesterol Education Panel recommends diet therapy if the LDL is higher than 100 mg/dl and drug therapy if the LDL is 130 mg/dl or more, with a target of reducing LDL to 100 mg/dl or less.[267] The timing of the blood sample is ideally in the first 24 hours after admission, because cholesterol levels fall with acute illness. However, cholesterol should be measured at some time during admission, because if it is high, therapy is warranted. Because treatment with statin drugs was associated with the previously mentioned benefits on mortality and cardiovascular morbidity, these are the current first-line lipid-lowering drugs. Additional or alternate therapy is also warranted according to the National Cholesterol Education Program (see also Chap. 39) .[267]

Antithrombotic Therapy in UA/NSTEMI

Aspirin (see also Chap. 62)

Several trials have demonstrated clear beneficial effects of aspirin in patients with UA/NSTEMI, with a more than 50 percent reduction in the risk of death or MI[71] [72] [73] [74] (Fig. 36-9). Thus, aspirin has a dramatic effect in reducing adverse clinical events both early and late in the course of treatment of UA/NSTEMI and is primary therapy for these patients (see Chap. 64) .

The dose of aspirin in the four randomized trials (Fig. 36-9) ranged from 75 mg to 1300 mg/d, and each trial showed a roughly 50 percent reduction in death or MI.[71] [72] [73] [74] Thus, there does not appear to be a dose response in efficacy of aspirin. In the International Study of Infarct Survival (ISIS)-2, a dose of 160 mg/d was shown to be associated with a mortality benefit, so this dose is the minimum initial dose recommended.[269] For safety (e.g., gastrointestinal bleeding), the rate of bleeding appears to be slightly higher with higher doses, and thus a dose of 75 to 81 mg/d could be an appropriate dose for long-term therapy, although major bleeding is relatively rare (<1 percent) even at a dose of 325 mg/d.[270]

Absolute contraindications for aspirin therapy are few but include documented aspirin allergy (e.g., asthma), active bleeding, or a known platelet disorder. In patients who had reported dyspepsia or other gastrointestinal symptoms with long-term aspirin therapy (i.e., intolerance), this would not be expected to be an acute problem of in-hospital treatment, and aspirin therapy is recommended, at least for the short term.

Clopidogrel and Ticlopidine (see also Chap. 62)

Clopidogrel, like its sister drug ticlopidine, is a thienopyridine derivative that inhibits platelet aggregation, increases bleeding time, and reduces blood viscosity by inhibiting ADP action on platelet receptors. *Ticlopidine* was studied in a randomized trial of patients with unstable angina involving 652 patients. The control group did not receive aspirin because at the time of protocol design it was not routinely used to treat unstable angina. At 6-month follow-up,

Figure 36-9 Four randomized trials showing the benefit of aspirin (ASA) in UA/NSTEMI. In UA/NSTEMI, the incidence of death or myocardial infarction was reduced by over 50 percent in each of the four trials. The doses of aspirin in the four trials were 325 mg, 1300 mg, 650 mg, and 75 daily, respectively, indicating no difference in efficacy for aspirin across these doses. (Data from Lewis HD, Davis JW, Archibald DG, et al: Protective effects of aspirin against acute myocardial infarction and death in men with unstable angina. N Engl J Med 309:396-403, 1983; Cairns JA, Gent M, Singer J, et al: Aspirin, sulfinpyrazone, or both in unstable angina. N Engl J Med 313:1369-1375, 1985; Theroux P, Ouimet H, McCans J, et al: Aspirin, heparin or both to treat unstable angina. N Engl J Med 319:1105-1111, 1988; and The RISC Group: Risk of myocardial infarction and death during treatment with low dose aspirin and intravenous heparin in men with unstable coronary artery disease. Lancet 336:827-830, 1990.)

ticlopidine led to a significant 46 percent reduction in vascular death or nonfatal MI.[271] Of note, there was no difference in the number of events over the first 10 days, consistent with the delayed onset of the antiplatelet effect of ticlopidine. Thus, ticlopidine appears to be comparable to aspirin for secondary prevention of events post UA/NSTEMI. Ticlopidine has also been demonstrated to be effective in combination with aspirin for prevention of thrombosis and recurrent ischemic events in patients undergoing coronary stent implantation, a portion of whom have recently suffered UA/NSTEMI (see also Chap. 38) . [272] [273] [274] However, ticlopidine is associated with neutropenia and thrombocytopenia in approximately 1 percent of patients, and quite rarely with thrombotic thrombocytopenic purpura, which can be fatal in 25 to 40 percent of cases.[275] [276] Thus, if ticlopidine is used, short courses (2-3 weeks) and biweekly monitoring of complete blood cell count are generally recommended.

Clopidogrel has been tested for secondary prevention in a broad population of patients with atherosclerosis in the Clopidogrel versus Aspirin in Patients at Risk for Ischemic Events (CAPRIE) trial. An 8.7 percent reduction relative to aspirin in the combined endpoint of ischemic stroke, MI, or vascular death during long-term follow-up was reported (see also Chap. 37) .[270] When added to aspirin, clopidogrel also appears to be as effective as ticlopidine in preventing stent thrombosis,[277] [278] [279] [280] especially when using a loading dose of 300 mg, which achieves effective platelet inhibition within 2 to 5 hours.[281] Clopidogrel is not associated with neutropenia and an extremely low rate of (approximately four cases per million) thrombotic thrombocytopenic purpura. It was associated with a lower rate of gastrointestinal bleeding compared with aspirin.[270] These data support the use of clopidogrel in patients with unstable angina who cannot take aspirin (e.g., a true aspirin allergy). Trials are in progress for patients with UA/NSTEMI testing the combination of clopidogrel plus aspirin versus aspirin alone.

Heparin (see also Chap. 62)

Heparin also appears to be beneficial in UA/NSTEMI: Several randomized trials suggest that unfractionated heparin (UFH) can improve clinical outcome compared with aspirin alone (see Chap. 62) .[73] [74] [75] [76] The greatest benefit was observed during the period of intravenous therapy, with "rebound" in recurrent events after stopping UFH observed in one study.[282] A meta-analysis showed a 33 percent reduction in death or MI at 2 to 12 weeks follow-up when comparing UFH plus aspirin versus aspirin alone, although this reduction was of borderline statistical significance (Fig. 36-10) .[77]

HEPARIN RESISTANCE.

Variability in the anticoagulant effects of UFH, so-called heparin resistance,[283] [284] is thought to be due to the heterogeneity of heparin and to the neutralization of heparin by circulating plasma factors and by proteins released by activated platelets.[285] [286] Clinically, frequent monitoring of the anticoagulant response using activated partial thromboplastin time (APTT) is recommended, with titrations made according to a standardized nomogram (Table 36-4) .[104] The latter minimizes the variability in the dosing adjustments given by various physicians and has been shown to improve the achievement of a target APTT.[287] [288]

THERAPEUTIC RANGE.

The exact level of anticoagulation that constitutes the "therapeutic range" is not yet firmly established. Small studies in unstable angina[289] and acute MI[290] [291] [292] [293] have suggested that lower APTT values may be related to recurrent ischemic events, suggesting that the lower limit of the target range of APTT is at least 1.5 times control. On the upper boundary of the target range, higher APTT values are associated with an increased risk of hemorrhage.[294] The lowest rate of bleeding (and mortality) in

Figure 36-10 Meta-analysis of six randomized trials comparing unfractionated heparin plus aspirin (ASA) vs. ASA alone, showing benefit of the combination therapy. The rate of death or myocardial infarction during follow-up (2-12 weeks in these trials) tended to be reduced in patients randomized to aspirin plus heparin. (Adapted from Oler A, Whooley MA, Oler J, Grady D: Adding heparin to aspirin reduces the incidence of myocardial infarction and death in patients with unstable angina: A meta-analysis. JAMA 276:811-815, 1996. Copyright 1996, American Medical Association.)

TABLE 36-4 -- STANDARDIZED NOMOGRAM FOR TITRATION OF HEPARIN

Initial Dose: 60 U/kg bolus and 12 U/kg/hr infusion
Activated partial thromboplastin time (APTT) should be checked and infusion adjusted at 6, 12, and 24 hours after initiation of heparin, daily thereafter, and 4 to 6 hours after any adjustment in dose.

APTT (secs)	CHANGE	IV INFUSION (U/kg/hr)
<35	70 U/kg bolus	+3
35-49	35 U/kg bolus	+2
50-70	0	+0
71-90	0	-2
>100	Hold infusion for 30 min	-3

From Becker RC, Ball SP, Eisenberg P, et al: A randomized, multicenter trial of weight-adjusted intravenous heparin dose titration and point-of-care coagulation monitoring in hospitalized patients with active thromboembolic disease. Am Heart J 137:59-71, 1999.

patients with STEMI treated with thrombolytic therapy was when the 12-hour APTT was between 50 and 70 seconds.[293] Furthermore, in TIMI IIIB, there appeared to be no advantage of higher levels of anticoagulation in reducing ischemic events.[295]

DOSING.

Dosing of UFH has traditionally used a 5000-U bolus followed by a 1000-U/hr infusion, which is then titrated according to the APTT.[285] The use of weight-adjusted UFH has been suggested as a means of improving APTT control and safety.[296] Three randomized trials of weight-adjusted UFH in unstable angina have been conducted. In one trial, there was a high percentage of patients who "overshot" in the initial APTT at 6 hours (median 150 seconds).[297] A more recent study examined a 60-U/kg bolus and 12-U/kg/hr infusion and found a higher percentage of patients within range without a large number of APTTs above range at 6 hours.[297a] The third trial tested standard dosing versus weight-adjusted dosing (70-U/kg bolus and 15-U/kg/hr initial infusion), and found no significant difference in control of APTT with weight-adjusted dosing.[298] Another approach uses "on-line" feedback of APTT data to a computer algorithm using a pharmacodynamic model of heparin response in the individual patient, with promising results in an initial pilot trial.[299]

CURRENT RECOMMENDATIONS.

Based on available data, the current optimal regimen appears to be a weight-adjusted dose of UFH (60 U/kg bolus and 12 U/kg/hr infusion), frequent monitoring of APTT (every 6 hours until in the target range and every 12 to 24 hours thereafter), and titration of UFH using a standardized nomogram (see Table 36-4) with a target range of APTT between one and one-half to two times control or approximately 50 and 70 seconds.[7]

Low-Molecular-Weight Heparins (see also Chap. 62)

A major advance in the use of heparin has been in the development of low-molecular-weight heparins (LMWH), which *combine* factor IIa and factor Xa inhibition. Thus, they inhibit both the action (anti-IIa action) and generation (anti-Xa action) of thrombin. LMWH are obtained by depolymerization of standard UFH and selecting those with lower molecular weight.[285] [300] As compared with UFH that has nearly equal anti-IIa (thrombin) and anti-Xa activity, LMWH have increased ratios of anti-Xa to anti-IIa activity of either 2:1 (e.g., dalteparin) or 3.8:1 (e.g., enoxaparin) (see Chap. 62) .

LMWH have several potential advantages over UFH. First, their greater anti-factor Xa activity inhibits thrombin generation more effectively.[300] LMWH also induce a greater release of tissue factor pathway inhibitor than does UFH, and they are not neutralized by platelet factor 4.[285] LMWH have been found to have a lower rate of thrombocytopenia compared with UFH.[301] Their high bioavailability allows for subcutaneous administration, which provides a long duration of systemic anticoagulation, so that dosing can be administered twice daily. Finally, LMWH have less binding to plasma proteins (e.g., acute phase reactant proteins) and thus have a more consistent anticoagulant effect in relation to the dose administered. Accordingly, monitoring of the level of anticoagulation (as is necessary using APTT for UFH) is not necessary. These final two differences make LMWH a much simpler anticoagulant to administer than UFH. However, LMWH are more affected by renal dysfunction than UFH, and a reduced dose should be considered in patients with creatinine clearance less than 30 mL/min.

CLINICAL TRIALS.

Five trials have compared LMWH with aspirin,[78] or with UFH plus aspirin.[79] [80] [302] [303] In the Fragmin during Instablity in Coronary Artery Disease (FRISC) study, dalteparin plus aspirin was found to reduce death or MI over the first 6 days compared with aspirin alone (1.8 percent vs. 4.8 percent, p=0.001).[78] However, in the

Fragmin in Unstable Coronary Artery Disease (FRIC) trial, no difference was observed between intravenous UFH and dalteparin.[302] Similarly, no benefit was seen when nadroparin was compared with UFH in the Fraxiparine in Ischaemic Syndrome (FRAXIS) trial.[303]

On the other hand, in two trials, Evaluation of the Safety and Efficacy of Enoxaparin in Non-ST Elevation Coronary Events (ESSENCE) and TIMI 11B, enoxaparin was found to confer a significant benefit in reducing death, MI, or recurrent ischemia compared with UFH. In ESSENCE, death, MI, or recurrent ischemia at 14 days was significantly lower (16.6 percent vs. 19.8 percent for UFH, *p*=0.019). [79] The rates of this endpoint at 30 days were 19.8 percent vs. 23.3 percent *(p*=0.016). Death or MI at 30 days also favored enoxaparin (6.2 percent vs. 7.7 percent).[79] The rates of catheterization (43 percent vs. 46 percent for enoxaparin vs. UFH) and PCI (13 percent vs. 17 percent, respectively) were lower in patients treated with enoxaparin than UFH.[79] A subsequent cost-effectiveness analysis found that there was a minimal increase in the cost for the drug (enoxaparin vs. UFH with APTT measurements) ($75); but with lower rates of catheterization and revascularization, treatment with enoxaparin led to a savings of $1172 per patient treated.[304] Thus, both improved outcomes and lower costs were observed with enoxaparin versus UFH.

The TIMI 11B trial studied high-risk patients with UA/NSTEMI. Death, MI, or severe recurrent ischemia requiring urgent revascularization through day 8 occurred in 12.4 percent of patients treated with enoxaparin versus 14.5 percent of patients treated with UFH (*p*=0.048), a 15 percent relative risk reduction.[80] Parallel reductions in death and MI were also observed. No additional benefit of continuing enoxaparin beyond hospital discharge was observed.

A meta-analysis of the TIMI 11B and ESSENCE trials showed a consistent 20 percent reduction in both the composite endpoint of death, MI, or urgent revascularization and of death or MI that occurred at 8, 14, and 43 days (Fig. 36-11) .[305] Enoxaparin reduced the rate of death, MI, or urgent revascularization from 18.7 to 15.6 percent (*p*=0.0006). [305] Death or MI at 43 days was reduced from 8.6 to 7.1 percent (*p*=0.02) (see Fig. 36-11) . Thus, in two large randomized trials enoxaparin has been shown to be superior to UFH for the treatment of UA/NSTEMI, a benefit that has not been demonstrated yet for the other LMWH. It is not clear whether these differences in clinical results are related to the patients enrolled in the trials, the trial design, or the specific characteristics of the LMWH.

The effects of prolonged administration of LMWH after hospital discharge have been examined in several of the trials with mixed results. No benefit of 6 weeks of therapy was observed with dalteparin therapy in the FRIC trial,[302] of enoxaparin in the TIMI 11B trial,[80] or of 14 days of

Figure 36-11 TIMI 11B/ESSENCE meta-analysis: Data from over 7000 patients randomized in these two trials show a consistent and significant 20 percent reduction in the rate of death or myocardial infarction at each of the four time points in patients treated with enoxaparin (ENOX) vs. unfractionated heparin (UFH). (Adapted from Antman EM, Cohen M, Radley D, et al: Assessment of the treatment effect of enoxaparin for unstable angina/non-Q-wave myocardial infarction: TIMI 11B-ESSENCE meta-analysis. Circulation 100:1602-1608, 1999. Copyright 1999, American Heart Association.)

therapy with nadroparin in the FRAXIS trial.[303] On the other hand, in FRISC II, there was a lower rate of death or MI at 1 month but not at 3 or 6 months in patients treated with a 90-day course of dalteparin.[306] This early benefit was present only in patients randomized to the conservative strategy arm.[307] Thus, the FRISC II Investigators proposed a potential role for continued LMWH therapy after hospital discharge in selected higher-risk patients who are managed conservatively or in patients awaiting angiography and revascularization.[306] All four trials found higher rates of bleeding in patients receiving LMWH after hospital discharge. Thus, the *routine* use of prolonged LWMH therapy is not indicated, but it may be applicable to selected, conservatively managed patients.

Direct Thrombin Inhibitors

Direct thrombin inhibitors have also undergone extensive evaluation. The prototypic agent is hirudin, a naturally occurring anticoagulant from the medicinal leech. Hirudin, which is made by recombinant DNA technology, is a 65 amino acid polypeptide that binds directly to thrombin, independent of antithrombin. The hirudin desirudin was tested in the GUSTO IIb trial involving 12,142 patients with UA/NSTEMI and STEMI. In the entire cohort, the 30-day rate of death or MI tended to be lower, 8.9 percent versus 9.8 percent (*p*=0.06),[99] with no difference in mortality and a modest reduction in reinfarction (5.4 percent vs. 6.3 percent for heparin, *p*=0.04). In the 8011 patients with UA/NSTEMI, 30-day death or MI was not significantly reduced (8.3 percent vs. 9.1 percent, *p*=0.22). [99]

The Organisation to Assess Strategies for Ischemic Syndromes (OASIS-2) trial[308] compared lepirudin to UFH: cardiovascular death or MI at 7 days tended to be lower (3.6 percent vs. 4.2 percent, respectively, *p*=0.08). Major bleeding requiring transfusion was rare but more frequent with lepirudin (1.2 percent vs. 0.7 percent for heparin, *p*=0.01). A meta-analysis of all hirudin trials showed a modest 10 percent benefit favoring hirudin, which was not statistically significant for patients with UA/NSTEMI. Other synthetic direct thrombin inhibitors have also been tested (e.g., argatroban and bivalirudin [Hirulog]), and, again, only modest or no improvements were observed compared with heparin,[309] [310] [311] although lower rates of bleeding have been observed with bivalirudin.[311] The direct thrombin inhibitors have been shown to provide a very stable level of anticoagulation, as measured by APTT,[99] [312] [313] and no episodes of thrombocytopenia were reported for the hirudin class. Of note, lepirudin is approved by the U.S. Food and Drug Administration for use as an anticoagulant in patients with heparin-induced thrombocytopenia and associated thromboembolic disease. Additional trials with this class of drugs are ongoing.

Oral Anticoagulation (see also Chap. 62)

Oral anticoagulation with warfarin has been examined in several recent trials, with the rationale that prolonged treatment might extend the benefit of early anticoagulation with an antithrombin agent (e.g., UFH, LMWH). Although pilot trials suggested benefit of a strategy of initial UFH followed by warfarin,[76] [314] [315] [316] two larger trials have failed to show a significant benefit of long-term warfarin plus aspirin versus aspirin alone. In the OASIS-2 trial of patients with UA/NSTEMI, the rate of cardiovascular death, MI, or stroke at 5 months was 7.4 percent for those receiving warfarin plus aspirin versus 8.2 percent for those receiving aspirin alone (*p*=NS). Similarly, in the Combination Hemotherapy and Mortality Prevention (CHAMP) trial of survivors of MI, there was no difference in the rate of all-cause mortality over an average 2.7-year follow-up between the combination of warfarin plus aspirin versus aspirin alone but there was a higher rate of major bleeding.[317] In addition, fixed-dose warfarin plus aspirin was not better than aspirin alone in the Coumadin Aspirin Reinfarction Study (CARS) trial.[318] Of note, however, a post-hoc analysis of OASIS-2 suggested that if compliance is excellent, a benefit might be observed with the combination of aspirin plus warfarin.[319]

One primary prevention trial in high-risk patients was a 2×2 factorial design of aspirin versus placebo and warfarin adjusted to an international normalized ratio of 1.5 and placebo found a significant reduction in coronary death or MI of the combination of warfarin plus aspirin (8.7 percent vs. 13.3 percent for placebo) but not significantly better than aspirin alone (10.2 percent) or warfarin alone (10.3 percent).[320] In this trial, however, there was an increase in hemorrhagic strokes among patients treated with the combination: 0.9 percent vs. 0.1 percent for warfarin alone, 0.2 percent for aspirin alone, and 0 percent for placebo (*p*=0.009).[320] Thus, the *routine* use of the combination of warfarin plus aspirin cannot be recommended.

Warfarin therapy (without aspirin) has been shown to be superior to placebo after MI (both STEMI and NSTEMI)[321] [322] [323] and could be considered a suitable *alternative* to aspirin. Furthermore, warfarin is indicated in patients with atrial fibrillation[324] [325] or severe left ventricular dysfunction who are at high risk of systemic embolization (see Chap. 62) .[326]

Glycoprotein IIb/IIIa Inhibitors (See also Chap. 62)

Because plaque rupture in a coronary artery is followed by platelet aggregation and thrombosis and given the dramatic clinical benefits of the relatively weak antiplatelet agent aspirin,[327] attention has focused on the new class of drugs that inhibit platelet aggregation by binding to the platelet glycoprotein IIb/IIIa receptor. By preventing the final common pathway of platelet aggregation (i.e., fibrinogen mediated cross-linkage of platelets by means of the glycoprotein IIb/IIIa receptor) (see Fig. 36-3) , these agents are potent inhibitors of platelet aggregation from all types of stimuli (e.g., thrombin, ADP, collagen, serotonin). Three agents are now available for use in UA/NSTEMI--abciximab, tirofiban, and eptifibatide--with the former currently approved only in patients undergoing PCI. Abciximab is a Fab fragment of a monoclonal antibody directed at the glycoprotein IIb/IIIa receptor. Eptifibatide, a synthetic heptapeptide, and tirofiban, a nonpeptide molecule, are antagonists of the glycoprotein IIb/IIIa receptor whose structure mimics the arginine-glycine-aspartic

acid (abbreviated RGD) amino acid sequence by which fibrinogen binds to the glycoprotein IIb/IIIa receptor (see Chap. 62) .

Several trials have shown benefit of glycoprotein IIb/IIIa inhibition in UA/NSTEMI either in patients managed predominantly with medical management,[82] with early interventional management,[328] or with both.[81] [83] [329] [330] [331] In the Platelet Receptor Inhibition for Ischemic Syndrome Management in Patients Limited by Unstable

Signs and Symptoms (PRISM-PLUS) study, tirofiban plus heparin and aspirin significantly reduced the rate of death, MI, or refractory ischemia at 7 days compared with heparin plus aspirin.[83] Death or MI at 30 days was also significantly reduced by 30 percent, from 11.9 percent to 8.7 percent, with improvements generally consistent across all subgroups and management strategies (i.e., medical therapy [25 percent reduction], percutaneous transluminal coronary angioplasty [PTCA, 35 percent reduction], and coronary artery bypass grafting [CABG, 30 percent reduction].[332] In the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integfrilin Therapy (PURSUIT) trial, involving 10,948 patients, eptifibatide also significantly reduced the rate of death or MI at 30 days.[81] In this trial, a greater benefit of eptifibatide was observed in patients undergoing early angioplasty compared with other treatment strategies.[81] Meta-analyses involving over 30,000 patients found that treatment with a glycoprotein IIb/IIIa inhibitor led to a 21 percent reduction in death or MI at 30 days.[330] [331]

The relative benefits of IIb/IIIa inhibition relative to medical versus interventional treatment have been examined more closely. The PRISM trial, involving patients managed medically for the first 48 hours, found a significant 32 percent reduction in death, MI, or refractory ischemia at 48 hours, suggesting a significant clinical benefit during medical treatment alone.[82] In a recent pooling of data from PRISM-PLUS, PURSUIT, and the Chimeric 7E3 Antiplatelet in Unstable Angina Refractory to Standard Treatment (CAPTURE) trials involving 12,296 patients, there was a 34 percent relative reduction in death or MI during a period of 24 to 72 hours of medical management only (3.8 percent vs. 2.5 percent, *p*=0.001) (Fig. 36-12) .[333] These findings support the use of glycoprotein IIb/IIIa inhibition in the medical management of patients with UA/NSTEMI.[7] However, in the recently reported GUSTO-IV ACS trial, conducted in a relatively low-risk unstable angina population in whom the use of early PCI was discouraged,

Figure 36-12 Pooled data from CAPTURE, PRISM-PLUS, and PURSUIT trials of unstable angina, showing benefit of glycoprotein IIb/IIIa inhibition during medical therapy only (left panel), during, and immediately after percutaneous coronary intervention (PCI, right panel). (From Boersma E, Akkerhuis KM, Theroux P, et al: Platelet glycoprotein IIb/IIIa receptor inhibition in non-ST-elevation acute coronary syndromes: Early benefit during medical treatment only, with additional protection during percutaneous coronary intervention. Circulation 100:2045-2048, 1999. Copyright 1999, American Heart Association.)

no clinical benefit was demonstrated when abciximab was added to aspirin and heparin.[333A]

On the other hand, among patients with unstable angina who undergo PCI (i.e., those managed with an early invasive strategy), glycoprotein IIb/IIIa inhibition appears to be beneficial both *before* intervention and especially *during* the intervention. This was first demonstrated in CAPTURE, in which abciximab was shown to reduce death, MI, or the need for urgent revascularization significantly.[328] In the meta-analysis, a significant benefit was seen when the agents are continued during angioplasty (death or MI was reduced from 8.0 to 4.9 percent (see Fig. 36-12) . A broader overview of patients with UA/NSTEMI who underwent PCI can be obtained by including patients enrolled in PCI trials (Fig. 36-13) .[7] In this overview, the benefit of IIb/IIIa inhibition is quite dramatic, with reductions of death or MI seen ranging from 30 to 70 percent. Thus, glycoprotein IIb/IIIa inhibition appears to have an additional benefit in patients in whom the drug is continued through PCI.[7]

NEED FOR INTRAVENOUS HEPARIN.

The long-term effects of glycoprotein IIb/IIIa inhibition appear to be greater when used in conjunction with heparin, as was done in the majority of patients in the PRISM-PLUS and PURSUIT trials.[82] [83] [334] It is not clear whether even greater benefits can be safely achieved when combining glycoprotein IIb/IIIa inhibitors with LMWH. This question is being addressed in several ongoing clinical trials.

SAFETY.

The rate of major hemorrhage was slightly higher for patients treated with glycoprotein IIb/IIIa inhibitors than for those receiving aspirin and heparin alone. For example, in the PRISM-PLUS trial, major bleeding occurred in 4.0 percent of patients treated with tirofiban plus heparin plus aspirin versus 3.0 percent for heparin plus aspirin *(p*=NS). [83] For eptifibatide, the rates of severe or moderate bleeding for eptifibatide versus placebo were 12.8 percent versus 9.9 percent (*p*<0.001).[81]

Thrombocytopenia is an uncommon but important complication of glycoprotein IIb/IIIa inhibitors: For tirofiban in PRISM-PLUS, the rate of severe thrombocytopenia (<50,000 cells/mm[3]) was 0.5 percent versus 0.3 percent for heparin (*p*=NS)[83] ; in the PURSUIT trial, thrombocytopenia (<20,000 cells/mm[3]) occurred in 0.2 percent versus less than 0.1 percent for heparin.[81] Thrombocytopenia is associated with increased bleeding and, in a smaller proportion of patients, with recurrent thrombotic events.[335] [336] This syndrome bears resemblance to heparin-induced thrombocytopenia and indicates a need to monitor platelet count daily during the glycoprotein IIb/IIIa infusion.

ORAL GLYCOPROTEIN IIb/IIIa INHIBITION.

Because the benefit of the small molecule intravenous glycoprotein IIb/IIIa inhibitors (tirofiban and eptifibatide) occurs only during the infusion, whereas abciximab's action dissipates 12 to 48 hours after cessation of the infusion, it has been hoped that prolonged glycoprotein IIb/IIIa inhibition using oral agents might lead to further, and continued, reduction in recurrent events. Unfortunately, four large trials, one in patients with acute coronary syndromes, OPUS-TIMI 16,[337] two in stabilized patients after an acute coronary syndrome, SYMPHONY,[338] [338A] and one in patients undergoing PCI, EXCITE,[339] all failed to show any benefit of the oral glycoprotein IIb/IIIa inhibitors orbofiban, sibrafiban, and xemilofiban, respectively. A higher degree of variability in the drug level and of the degree of platelet inhibition achieved with oral as compared with intravenous drugs is one potential explanation of the difference in outcomes between the two types of IIb/IIIa inhibitors.[340] It also appears that some of the agents may have intrinsic proaggregatory effects.[341] Trials are continuing to evaluate "second generation" oral glycoprotein IIb/IIIa inhibitors, which have longer half-lives and tighter binding to the glycoprotein IIb/IIIa receptor similar to that of abciximab.[342]

MECHANISM OF BENEFIT.

Three new concepts are emerging on the benefit of glycoprotein IIb/IIIa inhibitors in

Figure 36-13 Benefit of glycoprotein IIb/IIIa inhibition among patients with UA/NSTEMI treated with percutaneous coronary intervention across all large trials. As shown, both the relative benefit and the absolute benefit are quite substantial, ranging from 50 to 100 deaths or myocardial infarctions prevented for every 1000 patients treated. (Adapted from Braunwald E, Antman EM, et al: ACC/AHA guidelines for the management of patients with unstable angina/non-ST segment elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on the Management of Unstable Angina and Non-ST Segment Elevation Myocardial Infarction]. J Am Coll Cardiol 36:970-1062, 2000, with data for ESPRIT provided by Tcheng JE.)

UA/NSTEMI. First, angiographic data from two trials have shown that the IIb/IIIa inhibitors lead to greater resolution of thrombus and improved coronary flow compared with aspirin and heparin alone.[123] [343] In PRISM-PLUS, for example, tirofiban led to a 35 percent overall improvement in TIMI flow grade (*p*=0.002).[123] Together these data establish the pathophysiological link between the potent platelet inhibition achieved by glycoprotein IIb/IIIa inhibition, a reduction in thrombus, improvement in coronary blood flow, and consequent improvement in clinical outcome.[344]

A second new concept based on evidence from two trials is that glycoprotein IIb/IIIa inhibitors can reduce the size of an evolving NSTEMI (Fig. 36-14) .[345] [346] It was observed in the PURSUIT trial that the size of the MI, either index or recurrent, measured by peak CK-MB was significantly smaller in patients treated with eptifibatide. Similarly, in the PRISM-PLUS troponin substudy, those randomized to tirofiban plus heparin had a significantly lower peak troponin (see Fig. 36-14) .[346]

The third new concept is that there appears to be a greater benefit of treatment when administered earlier relative to the onset of pain. In an analysis from PURSUIT, the absolute reduction in death or MI with eptifibatide was 2.8 percent for patients treated within 6 hours from the onset of pain and was less for those treated between 6 and 12 and 12 and 24 hours after onset of pain. No benefit was observed in patients treated 24 hours after the onset of pain (Fig. 36-15) . Similar data have been observed in PRISM-PLUS (unpublished data).

COST BENEFIT OF GLYCOPROTEIN IIb/IIIa INHIBITION.

Thus, intravenous glycoprotein IIb/IIIa inhibition has been shown to be beneficial in patients at intermediate to high risk, on the basis of rest pain and either ECG changes or positive cardiac markers.[81] [82] [83] Although these agents add to the expense of therapy, this cost is balanced by a reduction in recurrent cardiac events. A cost-effectiveness analysis from PURSUIT found that the cost per year of life saved was approximately $16,000, well within the generally acceptable range for medical interventions.[346A] As noted later (see p. 1253), benefit of glycoprotein IIb/IIIa inhibition appears to be greatest in patients at higher risk, as evidence by those who have

a positive troponin at baseline,[154] [155] those with diabetes,[189] those with recurrent angina,[83] [193] or those with prior aspirin use.[196] In these high-risk subgroups of patients, the absolute benefit is greater and the therapy is even more cost effective.

In conclusion, it appears reasonable to use an intravenous glycoprotein IIb/IIIa inhibitor with aspirin and UFH as antithrombotic therapy in patients who have UA/NSTEMI with high-risk features (see Table 36-3) , especially those with a positive troponin value.

Thrombolytic Therapy

Because thrombolytic therapy is beneficial in the treatment of patients with acute STEMI, it was thought that it might also be effective in the other acute coronary syndromes in which thrombosis plays a role. In TIMI IIIB, 1473 patients

Figure 36-14 PRISM-PLUS troponin substudy: Peak levels of troponin I (TnI) were reduced in patients treated with the glycoprotein IIb/IIIa inhibitor tirofiban compared with aspirin and heparin in the trial. These data demonstrate that early treatment (within 12 hours from the onset of chest pain in this study) led to a reduced infarct size among patients with UA/NSTEMI. (Data from Januzzi JL, Hahn SS, et al: Reduction of troponin I levels in patients with acute coronary syndromes by glycoprotein IIb/IIIa inhibition with tirofiban. Am J Cardiol [in press].)

Figure 36-15 PURSUIT: Evidence showing greater benefit of glycoprotein IIb/IIIa inhibition with more rapid time to treatment. The absolute reduction in death or myocardial infarction to 30 days in patients treated with eptifibatide versus placebo was greatest for patients treated within 6 hours from the onset of chest pain, with lower benefit as time from onset of pain increased. These data underscore the importance of treating patients with UA/NSTEMI rapidly, preferably in the emergency department, with IIb/IIIa inhibitors. (Data from Bhatt, et al: Circulation 98[Suppl. I]:I-561, 1998. Copyright 1998, American Heart Association.)

with UA/NSTEMI were treated with aspirin, UFH, and antiischemic therapy and were randomized to receive either tissue plasminogen activator (t-PA) or placebo. No differences were observed in the incidence of death, postrandomization MI, or recurrent, objectively documented ischemia through 6 weeks.[101] Fatal and nonfatal MI after randomization actually occurred *more frequently* in t-PA-treated patients (7.4 percent) than in placebo-treated patients (4.9 percent) (p=0.04). In addition, t-PA was associated with a 0.6 percent rate of intracranial hemorrhage compared with 0 percent for UFH alone (p=0.06).

The TIMI IIIB results are corroborated by a meta-analysis of all previous smaller trials of thrombolytic therapy in UA/NSTEMI, in which no benefit of thrombolytic therapy was observed.[104] In both ISIS-2 and the Fibrinolytic Therapy Trialists' overview, patients with suspected MI and ST segment depression had a *higher* mortality with thrombolytic therapy compared with placebo.[269] [347] Accordingly,routine thrombolytic therapy *is not indicated* in UA/NSTEMI.[7]

The proposed mechanism for adverse effect of thrombolysis in UA/NSTEMI is a prothrombotic effect of thrombolysis. Thrombolysis is known to activate platelets[348] and increase fibrinopeptide A,[349] and the dissolution of the fibrin clot exposes clot-bound thrombin, which is enzymatically active and can lead to clot formation.[350] Because most patients with UA/NSTEMI have a patent culprit artery, these prothrombotic forces can lead to progression of the thrombus to total occlusion, thereby causing an MI (as was observed in TIMI IIIB).[101] In STEMI, in contrast, the culprit vessel is occluded at baseline and can only improve with successful thrombolysis.

Registry Experience with Compliance

A major problem recently identified in current practice is that a large proportion of patients do not receive guideline-recommended therapies.[98] [100] [118] [351] [352] For example, in the first National Registry of Myocardial Infarction (NRMI) conducted in 1990 to 1993, only 63 percent of patients with NSTEMI received aspirin.[353] In the TIMI III Registry of UA/NSTEMI conducted in 1992 to 1993, 80 percent of patients received aspirin,[98] [100] and in the Global Unstable Angina Registry and Treatment Evaluation (GUARANTEE) registry conducted in 1996, 83 percent of patients received aspirin.[118] [354] [355] This slight improvement suggests a possible benefit of the widespread dissemination and education after the publication of the Unstable Angina Guideline in 1994.[104] However, despite the overwhelming benefits of aspirin (arguably the best studied and most beneficial medication in cardiovascular medicine),[327] significant proportions of patients do not receive this drug. The American Heart Association published a scientific statement strongly urging physicians to use aspirin in appropriate patients,[356] which includes all UA/NSTEMI patients without contraindications. Similar findings have been observed for beta blockers and UFH,[98] [100] [118] [352] [355] with the latter used in only 57 percent of patients in the TIMI III Registry and in 67 percent of patients in the GUARANTEE Registry.[100] [118] [355] Importantly, recent evidence has suggested that if patients are treated according to the Unstable Angina Guideline recommendations, their adjusted 1-year mortality is lower compared with patients who do not receive all guideline-recommended therapies.[357] Thus, a major focus for physicians, hospitals, and health care systems is to improve the use of aspirin, and other important medications, using critical pathways and other methods (see p. 1254).

TREATMENT STRATEGIES AND INTERVENTIONS

Two general approaches to the use of cardiac catheterization and revascularization in UA/NSTEMI exist: (1) an "early invasive" strategy, involving routine early cardiac catheterization and revascularization with PCI or bypass surgery depending on the coronary anatomy, and (2) a more "conservative" approach with initial medical management, with catheterization and revascularization only for recurrent ischemia either at rest or on a noninvasive stress test. The latter has also been termed an "ischemia-guided" strategy.

Four randomized trials have assessed these two general strategies (Fig. 36-16). In the TIMI IIIB trial, 1473 patients were randomized in a 2×2 factorial design to receive either t-PA or its placebo and follow either an early invasive strategy with routine angiography 18 to 48 hours after randomization with revascularization as appropriate or an early conservative strategy with angiography and revascularization performed only for recurrent ischemia. All patients received intravenous heparin, aspirin, beta blockers, nitrates, and calcium antagonists as clinically indicated.

There was no difference between the early invasive and conservative strategies in the rate of death, postrandomization MI, or a strongly positive exercise test at 6 weeks (16.2 percent vs. 18.1 percent, p=NS). [101] Similarly, there was no difference in the incidence of death or MI at 6 weeks or 1 year (10.8 percent vs. 12.2 percent, p=NS)[199] (see Fig. 36-16). It is worth noting that the conservative strategy was truly an "ischemia-guided" strategy, with the indications for catheterization based on very careful assessment for recurrent ischemia (i.e., ischemia at rest with ECG changes, ST segment depression on a Holter monitor, a "high risk" exercise thallium stress test). However, despite this requirement for objective evidence of recurrent ischemia, 49 percent of patients in the conservative arm subsequently required revascularization, evenly split between PTCA and CABG.[101] The results of TIMI IIIB were nearly duplicated in the smaller Medicine versus Angiography in Thrombolytic Exclusion (MATE) trial[358] (see Fig. 36-16) .

The Veterans Administration Non-Q-Wave Infarction Strategies in-Hospital (VANQWISH) trial compared invasive

Figure 36-16 Results from the four randomized trials of invasive (Inv) vs. conservative (Cons) strategies in UA/NSTEMI. The duration of follow-up is shown for each trial at the top, and the number of patients is shown at the bottom. In addition, the rate of cardiac catheterization (Cath) during the initial hospitalization, as well as the rates of revascularization (revasc) with PCI or CABG are shown. *p=0.05, p=0.025, +p=0.031. (Data from Anderson, et al. [199] ; Boden, et al.[359] ; McCollough, et al.[358] ; and the Fragmin and Fast Revascularisation during InStability in Coronary artery disease Investigators.[307])

and conservative strategies in 920 patients with non-Q-wave MI (not unstable angina, and including 15 percent STEMI). There was no significant difference in the primary endpoint of death or nonfatal MI during follow-up (approximately 2 years): 26.9 percent in the invasive arm versus 29.9 percent in the conservative arm.[359] However, there were significantly more deaths in patients assigned to the invasive compared with the conservative strategy at hospital discharge (4.5 percent vs. 1.3 percent), a difference that remained significant at 1 year. Of the 21 in-hospital deaths in the invasive group, 11 followed within 30 days of coronary bypass surgery, indicating a 11.6 percent perioperative mortality in the invasive group, which explains some of the early hazard of the early invasive group. Of note, the peri-CABG mortality in patients in the conservative arm was only 3.4 percent, with a more delayed CABG (median 24 days, versus 8 days in the invasive group).

Most recently, the FRISC II trial of 2457 patients with UA/NSTEMI found a significant *benefit* of a delayed invasive strategy.[307] Patients with chest pain within 48 hours

with either ST-T wave changes or positive serum markers were enrolled and received subcutaneous dalteparin in hospital. They were then randomized to an invasive versus conservative strategy. In the invasive arm, cardiac catheterization and revascularization were carried out within 3 and 7 days of randomization, respectively, and thus this invasive strategy could be considered a "delayed" invasive strategy. Criteria for catheterization in the conservative strategy were strict and required refractory angina despite maximal medical treatment or a positive ECG exercise test with 0.3 mV or more ST segment depression. Thallium imaging was not performed with the stress testing. With this conservative strategy, only 9 percent of patients underwent revascularization during the first 7 days.[307]

The primary endpoint, death or MI at 6 months, was significantly lower in the invasive versus conservative

group (9.4 percent vs. 12.1 percent, *p*=0.031).[307] Preliminary 1-year results show a significant reduction in *mortality* in the invasive versus conservative groups (2.2 percent vs. 4.0 percent, respectively, *p*=0.018) and of death or MI (10.5 percent vs. 14.2 percent, respectively, *p*=0.007).[360] Additional analyses showed greater benefit of the invasive strategy in higher risk groups identified by age >65 years, ST segment depression on the admission ECG or troponin T of 0.01 ng/dl or more.[116] [361] Of note, the 30-day mortality following CABG was less than 2 percent in this study.[307]

A recent meta-analysis of these four studies has shown that there is an early hazard with an invasive strategy, but that this is balanced by later benefit in the invasive group making overall odds ratio of death or MI 0.94 (95% CI 0.78-1.13).[362] This early hazard was also observed in the Kaplan-Meier event rate curves from the TIMI IIIB and FRISC II trials.[199] [307] One randomized trial of CABG versus medical therapy in patients with unstable angina conducted in the 1980s found no overall difference in mortality at 2 years but a survival benefit in patients with left ventricular dysfunction.[204] [363]

Indications for Invasive Versus Conservative Management Strategies

Thus, balancing the current evidence, either an early conservative or early invasive strategy appears to be appropriate for patients with UA/NSTEMI.[7] However, it may be possible to individualize the approach based on the patient population and the success rates of the coronary interventions. For patients managed in a conservative fashion, indications for coronary angiography are (1) recurrent ischemia at rest or with low-level activity accompanied by ECG changes, (2) congestive heart failure, (3) evidence of ischemia on stress testing,[364] (4) when hemodynamic instability is present,[365] and (5) evidence of sustained ventricular arrhythmias.[7] With regard to the exact criteria for "significant" ischemia on stress testing, the relatively worse outcome of the conservative strategy (with strict criteria) in FRISC II as compared with the invasive group, in contrast to the equal outcomes between invasive versus conservative strategies (with moderately stringent criteria in TIMI IIIB), suggest that criteria for proceeding to angiography in a conservative strategy should not be *too* stringent.

An early invasive strategy can be considered appropriate and more expeditious than an early conservative strategy, and it appears to be *beneficial* in higher risk patients (see Table 36-3) . As noted earlier, a significant benefit of an early invasive strategy was observed in FRISC II in patients with ST segment depression on the admission ECG[307] [361] in patients older than 65 years of age.[199] [307] An early invasive approach appears warranted in those with hemodynamic instability, based on studies in acute MI.[365] [366] In addition, an early invasive strategy in those who present with UA/NSTEMI within 6 months of a prior PCI, in whom restenosis may be frequent, may be a more expeditious strategy.

On the other hand, for the very high-risk patients with NSTEMI and multivessel disease requiring bypass surgery (similar to patients in the VANQWISH trial), and/or at hospitals where intervention complication rates are higher, an *initial* more conservative approach may be most appropriate.[7] For such patients, one might pursue a delayed invasive strategy, based on the lower perioperative mortality in the VANQWISH trial comparing patients who underwent delayed versus early CABG.[359] Results from additional trials such as Treat Angina with Aggrastat and Determine Cost of Therapy with Invasive or Conservative Strategy (TACTICS)-TIMI 18, conducted in the current era of glycoprotein IIb/IIIa inhibition and coronary stenting, should provide additional perspective on the issue of invasive versus conservative strategies in UA/NSTEMI, including a cost-benefit analysis.[367] [368]

Noninvasive Testing

In the management of unstable angina, noninvasive testing is used (1) at presentation, usually in the ED to diagnose the presence or absence of coronary artery disease (in patients with low likelihood of coronary disease) (see p. 1234); (2) after hospitalization and medical therapy has been carried out, to evaluate the extent of residual ischemia to guide further therapy, especially an "ischemia-guided" strategy; (3) to evaluate left ventricular function; and (4) to estimate prognosis (i.e., risk stratification).

The results from noninvasive tests that portend high risk of future cardiac events are shown in Table 36-5 (see also Chaps. 7 , 9 , and 37) . These results are derived from studies involving patients with UA, MI, and stable coronary artery disease. The markers of high risk are either evidence of ischemia on stress testing or left ventricular dysfunction (either at rest or stress induced).[369] [370] [371] [372] [373]

The need for angiography and revascularization for patients who had a positive stress test (i.e., evidence of ischemia) has long been assumed and has been used in the "conservative" arms of most randomized trials.[101] [244] [307] [359] This benefit of revascularization for provokable ischemia has been documented in patients with a positive ECG stress test following thrombolytic therapy of STEMI.[364]

The safety of early stress testing in patients with UA/NSTEMI has been debated, but evidence from several trials has suggested that pharmacological,[374] or symptom-limited stress testing,[375] is safe after at least 24 to 48 hours of stabilization without recurrent ischemia in patients with UA/NSTEMI. Contraindications to stress testing are a recent recurrence of rest pain, especially if associated with ECG changes or other signs of instability (hemodynamic or significant arrhythmias).

The merits of various modalities of stress testing have been compared in relatively small series of patients (see also Chaps. 6 , 7 , and 9) . Stress myocardial perfusion imaging with sestamibi and stress echocardiographic imaging are slightly more sensitive than ECG stress testing alone and have shown greater prognostic value.[180] [376] [377] [378] An overview has suggested that the perfusion imaging tests are

---

more sensitive for ischemia than ECG-only stress testing and that such testing is generally cost effective in higher risk patients.[379] A recommended approach is to individualize the choice based on patient characteristics, local availability, and expertise in interpretation.[7] For most patients, ECG stress testing is recommended if the ECG is without significant ST segment abnormalities.[7] If ST segment abnormalities exist, then perfusion or echocardiographic imaging is recommended. Exercise testing is generally recommended unless the patient cannot walk sufficiently to achieve a significant workload, in which case pharmacological stress testing is recommended.[7]

Intraaortic Balloon Counterpulsation

Intraaortic balloon counterpulsation (IABP) is a very effective means of increasing diastolic coronary blood flow and reducing left ventricular afterload, which act in concert to reduce ischemia (see Chap. 19) . IABP is usually reserved for patients with UA/NSTEMI who are refractory to maximal medical therapy and those with hemodynamic compromise who are awaiting cardiac catheterization or for those identified to have very high risk coronary anatomy (e.g., left main stenosis) as a bridge to coronary angioplasty or bypass surgery.[7] In the TIMI III Registry, only 1 percent of patients required IABP during hospitalization.[98] [100] No randomized

---

trials are available to document its benefit, but this method is very effective in stabilizing patients with refractory ischemia. However, vascular access site complications are relatively common in the elderly, women, and diabetics.[380] [381]

Revascularization (see also Chap. 38)

PERCUTANEOUS CORONARY INTERVENTION.

PCI is an effective means of reducing coronary obstruction, improving acute ischemia, and improving regional and global left ventricular function in patients with UA/NSTEMI.[382] Current angiographic success rates are high, generally more than 95 percent[383] (see also Chap. 38) , although the presence of unstable angina or visualized thrombus has been associated with increased risk of acute complications such as abrupt closure or MI (as compared with patients with stable angina or those without visualized thrombus).[123] [384] Thus, use of glycoprotein IIb/IIIa inhibitors in such patients is associated with improved PCI outcomes (Fig. 36-13 , p. 1248).

The TIMI III investigators reported a favorable experience with balloon angioplasty in patients with a UA/NSTEMI with a periprocedural MI rate of 2.7 percent, an emergency bypass surgery rate of 1.4 percent, and a mortality of 0.5 percent. Since that time, the advent of coronary stenting has reduced the rate of emergency bypass surgery and the increasing use of glycoprotein IIb/IIIa inhibitors has reduced the rates of death and MI.[81] [328] [385] [386] [387] [388] [389] [390] [390A] [391] When CK-MB is measured serially during the 24 hours after a procedure, the rates of MI are higher: 5 to 8 percent among patients treated with aspirin and heparin. These rates are markedly reduced when IIb/IIIa inhibitors are used during the PCI.[81] [328] [387] [388] [389] [390] [390A] [391] (see Fig. 36-13) (see also Chap. 38) .

PCI VERSUS CABG.

When revascularization is required in patients with UA/NSTEMI, the choice is between PCI and CABG. Five trials have compared PTCA and CABG in patients with ischemic heart disease, many of whom had unstable angina.[392] [393] [394] [395] [396] The results of these trials are reviewed in Chapters 37 and 38 . Based on the results of these trials, and those of previous trials of CABG versus medical therapy,[397] [398] [399] [400] and more recent observational data,[401] CABG is recommended for patients with disease of the left main coronary artery, multivessel disease involving the proximal left anterior descending artery, or multivessel disease and impaired left ventricular function or diabetes.[402] For other patients, either PCI or CABG may be suitable: PCI is associated with a slightly lower initial morbidity and mortality than CABG but a higher rate of repeat procedures, whereas CABG is associated with more effective relief from angina.

TARGETING OF NEW THERAPIES TO SPECIFIC SUBGROUPS

With the large array of new therapies and interventions now available for the treatment of patients with UA/NSTEMI, and in light of the limited resources available for health care, there has been a desire to apply the newer (and generally more expensive) therapies to those who will benefit most. Although it had long been assumed that patients at highest risk would benefit most from more aggressive therapy,[7] [104] there is now a growing body of evidence from large randomized trials to support this hypothesis. Early risk assessment (especially using troponins, but also clinical variables) has been useful in predicting which patients will derive the greatest benefit from newer and more potent antithrombotic therapies such as LMWH and glycoprotein IIb/IIIa inhibitors[153] [154] [155] [224] [403] [404] and from an early invasive strategy.[116] [199] [307] [361] Because the high-risk subgroups have a higher event rate, even a similar *relative* benefit translates into a *greater absolute* number of cardiac events prevented. In addition, there appears to be an *increasing relative* benefit of some of the therapies[80] [405] that would extend further the incremental value of these drugs.

ELDERLY PATIENTS.

Outcomes in elderly patients are worse than in younger patients; and, disappointingly, some therapies, notably thrombolysis for STEMI, appear to have *less* relative benefit than in younger patients.[347] In contrast, in UA/NSTEMI, the elderly appear to derive *greater* relative and absolute benefit from the newer more potent antithrombotic therapies. In both the ESSENCE and TIMI 11B trials, the LMWH enoxaparin, compared with UFH, appeared to exert a greater relative and absolute benefit in patients older than 65 years as compared with younger patients.[80] [405] For the glycoprotein IIb/IIIa inhibitors, an equivalent relative benefit has been observed that translated into a greater *absolute* benefit in older versus younger patients.[81] [82] [83]

With regard to an invasive versus conservative management strategy, in the FRISC II trial, the benefit of an early invasive strategy was confined to patients older than age 65 years with no difference in outcome by strategy in younger patients.[307] A similar trend was observed in the TIMI IIIB trial.[199] Thus, in unstable angina, elderly patients are at higher risk and appear to derive particular *benefit* from more aggressive antithrombotic or interventional therapy.

CLINICAL SUBGROUPS.

Diabetics are known to be at high risk, and there is now evidence of a greater *relative* benefit of intravenous glycoprotein IIb/IIIa inhibition in diabetic patients with UA/NSTEMI, with a dramatic 72 percent risk reduction in 30-day death or MI (15.5 percent for heparin alone vs. 4.7 percent for tirofiban plus heparin), as compared with 13 percent reduction in nondiabetics.[189] Similarly, for patients presenting with unstable angina while already taking aspirin, there was a trend for greater benefit from eptifibatide or enoxaparin in the PURSUIT and TIMI 11B trials, respectively, compared with non-prior-aspirin users.[196] [197] In addition, patients who develop recurrent angina after initial presentation to the hospital are at high risk and derive greater benefit from glycoprotein IIb/IIIa inhibitors.[83] [193]

ELECTROCARDIOGRAPHY.

In both the ESSENCE and TIMI 11B trials, patients with ST segment deviation exhibited a significant reduction in cardiac events from enoxaparin compared with UFH, whereas those without ST segment deviation did not.[80] [405] For glycoprotein IIb/IIIa inhibitors, the greatest benefit has been observed in patients with transient ST segment elevation, followed by ST segment depression, with an absolute benefit two to three times greater than for patients without ST segment changes.[83] Evidence from the FRISC II trial of invasive versus conservative strategies found particular benefit of an invasive strategy in patients with ST segment depression at presentation.[361] Thus, ST segment deviation is a marker of increased risk but also of greater benefit from aggressive antithrombotic and interventional therapy.

CARDIAC MARKERS.

Elevated circulating cardiac markers have been shown to correlate with a higher rate of thrombus at angiography. This has been demonstrated with both CK-MB[4] [123] and troponin T and I.[124] [154] It has been proposed that minor myocardial damaged as assessed by troponin is a marker of microemboli from coronary thrombi.[117] A greater antithrombotic effect has been observed in patients with positive markers: for example, the degree of resolution of thrombus after 24 hours of therapy with abciximab in the CAPTURE trial was greater in patients who were troponin T positive versus troponin T negative.[154]

Clinical benefits have followed the same pattern: When treating with the IIb/IIIa inhibitor abciximab there was a 68

Figure 36-17 *Left,* Benefit of abciximab in the CAPTURE trial of patients with refractory unstable angina treated with angioplasty in those with positive versus negative troponin T values at study entry. *Right,* Greater benefit of tirofiban versus heparin in patients with UA/NSTEMI was also seen in those with positive troponin I values in the PRISM trial, with a nearly 70 percent reduction in death or myocardial infarction at 30 days with the IIb/IIIa inhibitor. (Data from Hamm CW, Heeschen C, Goldmann B, et al: Benefit of abciximab in patients with refractory unstable angina in relation to serum troponin T levels. c7E3 Fab Antiplatelet Therapy in Unstable Refractory Angina (CAPTURE) Study Investigators. N Engl J Med 340:1623-1629, 1999; and Heeschen C, Hamm CW, Goldmann B, et al: Troponin concentrations for stratification of patients with acute coronary syndromes in relation to therapeutic efficacy of tirofiban. PRISM Study Investigators. Platelet Receptor Inhibition in Ischemic Syndrome Management. Lancet 354:1757-1762, 1999.)

percent reduction in death or MI at 6 months in the CAPTURE trial in those who were troponin T positive versus no significant benefit for those who were troponin T negative ($p<0.001$) [154] (Fig. 36-17) . These findings have recently been essentially duplicated with tirofiban versus heparin in the PRISM trial (see Fig. 36-17) .[155] However, a benefit of abciximab was not observed in GUSTO IV ACS in troponin-positive patients.[333A] In the TIMI 11B trial, even among patients who were CK-MB negative, those with elevations of troponin I derived a significantly greater benefit from the LMWH enoxaparin versus UFH compared with those with negative troponins.[153] Similar findings may also be emerging for selecting patients for an invasive versus conservative strategy: In the FRISC II study, the majority of the benefit of invasive therapy at 1 year was obtained in patients with an elevated troponin T level, using an ultra low threshold of 0.01 ng/dl or more, whereas no benefit was observed in patients with troponin T of less than 0.01 ng/dl.[116]

Thus, there is now evidence from several trials that use of troponins can assist in both risk stratification and in determining which patients should be treated with the newer antithrombotic agents, such as LMWH or glycoprotein IIb/IIIa inhibitors, and potentially with an invasive management strategy.[7]

C-REACTIVE PROTEIN.

One small study of patients with unstable angina found that a glycoprotein IIb/IIIa inhibitor attenuated the increase in CRP levels as compared with placebo.[406] During long-term treatment of patients after MI, pravastatin has been shown to reduce CRP,[407] and a greater

Figure 36-18 TIMI 11B: Use of a simple, but comprehensive clinical risk stratification score to identify (1) increasing risk of death, myocardial infarction, or urgent revascularization to day 14, and (2) increasing benefit of enoxaparin versus unfractionated heparin (UFH). The risk factors are age 65 years or older, more than three risk factors for coronary artery disease, documented coronary artery disease at catheterization, ST segment deviation of 0.5 mm or more, more than two episodes of angina in last 24 hours, aspirin within prior week, and elevated cardiac markers. (Adapted from Antman EM, Cohen M, Bernink PJLM, et al: The TIMI Risk Score for unstable angina/non-ST elevation MI: A method for prognostication and therapeutic decision making. JAMA 284:835-842, 2000.)

TABLE 36-6 -- FACTORS ASSOCIATED WITH FAILURE OF INITIAL MEDICAL THERAPY IN PATIENTS WITH UNSTABLE ANGINA AND NON-Q-WAVE MYOCARDIAL INFARCTION FROM THE TIMI IIIB TRIAL

FACTOR	DEATH, MYOCARDIAL INFARCTION, RECURRENT ISCHEMIA (ODDS RATIO)	DEATH, MYOCARDIAL INFARCTION, RECURRENT ISCHEMIA, MARKEDLY POSITIVE TEST (ODDS RATIO)
ST segment depression	2.6*$p<0.01$	3.2 $p<0.0001$
History of angina	1.8	1.9$p<0.01$
Heparin use	1.7$p<0.01$	1.3
Aspirin use	1.4$p<0.01$.	1.3
Age (per 10 years)	1.3$p<0.01$.	1.2
Family history of coronary artery disease	1.2	1.2

Markedly positive test was defined as: 20 minutes of ST depression
0.1 mV on a Holter monitor, a "high risk" exercise test (ischemic discomfort before end of stage II, ST depression
0.2 mV, or fall in systolic blood pressure >10 mm Hg on two determinations), a "high risk" thallium perfusion imaging with
2 regions of reversible hypoperfusion or increased lung uptake and one region of reversible hypoperfusion. From Stone PH, et al. Factors associated with failure of medical therapy in patients with unstable angina and non-Q wave myocardial infarction: A TIMI-IIIB database study. Eur Heart J 20:1084-1093, 1999.

relative benefit of this therapy was observed in patients with elevated baseline levels of CRP compared with patients with normal baseline levels of CRP.[38] [408] Additional studies are ongoing to examine the usefulness of CRP in targeting acute therapies for unstable angina.

COMBINED RISK ASSESSMENT SCORES.

Risk scores combining clinical factors have been used to identify patients who derived the greatest benefit from enoxaparin versus UFH (Fig. 36-18) [223] [224] or GP IIb/IIIa inhibitors (Reference Sabative 2000).[224A] Another use of clinical risk stratification score is to predict not just mortality or recurrent MI, but also failure of medical therapy (i.e., recurrent ischemia--either spontaneous or on a provocative test despite therapy). Such an analysis was carried out in the patients randomized to the conservative treatment strategy of the TIMI IIIB trial to identify patients with a high likelihood of failing medical therapy in whom an early invasive strategy might be advisable. Several predictors emerged, including ST segment deviation, history of prior angina, family history of coronary disease, prior use of heparin or aspirin, and advanced age (Table 36-6) . By combining these baseline risk characteristics, the likelihood of developing death, MI, recurrent rest ischemia, or a strongly positive test for ischemia ranged from 8 percent if none was present to 63 percent if all six were present.[409] It seems reasonable that if three or more of these risk factors are present, patients could be referred for early coronary angiography, because it will ultimately be required in the majority, whereas if fewer than three were present, a conservative approach is more likely to be successful, without recurrent ischemia. Such a "risk-based" triage approach could be useful in selecting an appropriate management strategy (see Table 36-6) .

A proposed treatment algorithm integrating the risk assessment and the targeting of therapy is illustrated in Figure 36-19 . Risk assessment based on the clinical

history, ECG, and serum markers identifies patients with medium to high risk who are appropriate candidates for aggressive antithrombotic therapy. For patients with uncertain history and negative ECG and markers, a rapid "rule-out MI" pathway is appropriate.

CRITICAL PATHWAYS.

With rising restraints on health care costs, there has been increasing focus on the creation and implementation of "critical pathways," with an initial goal to reduce length of stay. However, several other goals are appropriate: (1) improving the use of appropriate medications (e.g., aspirin, beta blockers), (2) improving triage of the patient to the appropriate level of care,[164] [410] and (3) reducing the number of unnecessary tests that are performed (e.g., laboratory blood tests, echocardiography). With regard to triage, coronary care unit admission was standard practice for patients with all forms of acute coronary syndromes in the past. However, at present, coronary care unit admission is generally reserved for STEMI patients and those with hemodynamic compromise or other complications.

The pathway for management of UA/NSTEMI at Brigham and Women's Hospital[411] emphasizes (1) early relief of ischemic pain, which has been found to be a determinant of development of NSTEMI among patients presenting with symptoms of acute ischemia[5] ; (2) administration of antithrombotic and antiischemic therapy as outlined earlier; (3) reminders of eligibility criteria of ongoing clinical trials; (4) detailed list of suggested blood and laboratory tests in an effort to reduce unnecessary tests; and (5) choice of either an early conservative strategy or an early invasive strategy, as used in TIMI IIIB.[164] Initial experience with this pathway has shown a reduction in hospital length of stay from a median of 5 days before the pathway to 2 days, as well as an improvement in the use of appropriate medications. As institutions gain experience with implementation of critical pathways, their impact on coronary care will be able to be assessed more clearly.

"CARDIAC CHECKLIST".

One simple method of ensuring better compliance with recommended therapies is to use a checklist of the medications when first treating patients with UA/NSTEMI.[411] Indeed, checklists currently are used for preadmission testing and procedures, and thus this notion can be extended to treatments. Table 36-7 (Table Not Available) shows a proposed "cardiac checklist" for patients with UA/NSTEMI, which includes aspirin, heparin or LMWH, glycoprotein IIb/IIIa inhibition, beta blockers, heart-rate-lowering calcium antagonists (in the absence of congestive heart failure

TABLE 36-7 -- CARDIAC CHECKLIST FOR UNSTABLE ANGINA/NON-ST ELEVATION MYOCARDIAL INFARCTION

(Not Available)

Adapted from Cannon CP: Optimizing the medical management of acute coronary syndromes. J Thromb Thrombolysis 7:171-189, 1999.

Figure 36-19 Algorithm for risk stratification and treatment of patients with UA/NSTEMI. Using the clinical history of the type of pain and prior medical history, the electrocardiogram (ECG), and cardiac markers, one can identify patients who have a low likelihood of UA/NSTEMI, for whom a diagnostic "rule-out" myocardial infarction (MI) or acute coronary syndrome (ACS) is warranted. If this is negative the patient is discharged home; and if it is positive, the patient is admitted and treated for UA/NSTEMI. On the other end of the spectrum patients with acute ongoing pain and ST segment elevation are treated with thrombolysis or percutaneous coronary intervention (PCI) (see Chap. 35) . For those with UA/NSTEMI, all patients are given standard treatment with aspirin (ASA), unfractionated or low-molecular-weight heparin [LMWH], and antiischemic therapy with beta blockers and nitrates. Risk stratification is used to identify patients at medium to high risk, for whom aggressive treatment with glycoprotein IIb/IIIa inhibition and an early invasive strategy is warranted. (Data on the safety and efficacy of the combination of LMWH and glycoprotein IIb/IIIa inhibition are still emerging at the time of this writing.) For patients at low risk, standard treatment is likely sufficient, and a more conservative approach could be expected to be equivalent in outcomes to a more invasive one. DM=diabetes mellitus; Rx=treatment; STEMI=ST elevation myocardial infarction.

or left ventricular dysfunction), cholesterol lowering, and other risk factor modifications. This "cardiac checklist" could be used in two ways: (1) physicians who encounter these patients frequently could keep a copy on a small index card in their pocket and run down the list when writing admission orders for patients or (2) it could be used in developing standard orders for unstable angina (either printed order sheets or computerized orders).

Therapy at Hospital Discharge

After the acute treatment of patients with acute coronary syndromes, the focus turns to preventing recurrent ischemic events (i.e., secondary prevention). The drugs that have been proven to be of benefit in long-term treatment are aspirin or clopidogrel as antiplatelet therapy, beta blockers, ACE inhibitors, and statin therapy. Efforts should be undertaken to ensure that patients receive such therapies to ensure optimal outcomes during long-term treatment (see Chap. 39) . In patients who have managed on a conservative strategy, a maximal exercise stress test 2 to 6 weeks after discharge is indicated to identify high-risk patients who may benefit from coronary revascularization and who should therefore undergo coronary angiography.

GUIDELINES
MANAGEMENT OF UNSTABLE ANGINA/NON-ST SEGMENT ELEVATION MYOCARDIAL INFARCTION

Thomas H. Lee

Key guidelines for management of unstable angina and non-ST segment elevation myocardial infarction (UA/NSTEMI) were issued by an American College of Cardiology/American Heart Association (ACC/AHA) task force in 2000.[1] These guidelines updated and extended recommendations published in 1994 by the Agency for Health Care Policy and Research (AHCPR) and the National Heart, Lung and Blood Institute.[2] Other guidelines relevant to the diagnosis and management of this population have been issued by the American College of Emergency Physicians and other ACC/AHA task forces and are described in the Guidelines to Chapter 35 .

The ACC/AHA guidelines on UA/NSTEMI used the customary ACC/AHA classification system to provide recommendations for the appropriateness of indications, described in Chapter 37 .

In addition, these ACC/AHA guidelines adapted the AHCPR approach of grading the strength of evidence used to develop these recommendations. The weight of evidence was ranked highest (A) if the data were derived from multiple randomized trials involving large numbers of patients. An intermediate rank (B) was assigned if the data were derived from a limited number of randomized trials with small numbers of patients or from careful analysis of nonrandomized studies or observational data bases. A lower rank of "C" was assigned when the basis of the recommendation was expert consensus.

These guidelines focus on the care of patients with *acute coronary syndrome* (ACS), which includes acute myocardial infarction and UA. UA and NSTEMI are considered closely related conditions that differ primarily in severity. Excluded is the care of patients with acute myocardial infarction and ST segment elevation, who would be eligible for acute reperfusion (see Chap. 35) .

Initial Evaluation and Management (Fig. 36-G-1)

The guidelines emphasize the importance of prompt evaluation of patients with acute chest pain in settings in which a 12-lead electrocardiogram (ECG) can be performed, as opposed to over the telephone. Patients with prolonged (>20 minutes) chest pain or symptoms suggesting hemodynamic instability or arrhythmia should be triaged to an emergency department or chest pain unit; transport should ideally occur by emergency medical vehicles. Patients with*possible ACS* should have a 12-lead ECG and undergo observation with serial measurement of cardiac markers. Cardiac-specific troponins are identified as preferred markers, while creatine kinase MB isoenzyme (CK-MB) is considered a less preferable but acceptable marker.

Immediate Management (Table 36-G-1)

After identifying and appropriately treating patients with reperfusion-eligible acute myocardial infarction (see Chap. 35) , as well as others with cardiac conditions that are not due to ACS, the clinical findings should be used to assign the remaining patients with chest pain to one of four categories (see Table 36-G-1) :

1. A noncardiac diagnosis
2. Chronic stable angina
3. Possible ACS
4. Definite ACS

Management of patients with chronic stable angina is expected to be according to ACC/AHA guidelines on this topic, as summarized in the Guidelines to Chapter 37 .

For patients with possible ACS who have no recurrent chest discomfort over a 4- to 8-hour period and have normal results of follow-up 12-lead ECGs and biochemical cardiac markers, stress testing is considered appropriate (Table 36-G-1) . Patients with negative stress tests can be discharged for further management as outpatients. Patients with strongly positive stress tests are considered to be at high risk (Table 36-G-2) and should be admitted to the hospital. Management of patients with intermediate test results must be determined by clinical judgment. The ACC/AHA guidelines indicate that exercise ECG is an appropriate first-line test for risk stratification.

Hospital Care (Table 36-G-2 , Fig. 36-G-2)

The guidelines recommend that patients with recurrent symptoms, ECG ST segment deviations, positive cardiac markers (CK-MB or troponin), or hemodynamic instability be admitted to an inpatient unit with continuous rhythm monitoring. For this population, observation in such facilities for at least 24 hours without any recurrence of ischemia or major complications is recommended before considering transfer to a lower level of care. Factors that suggest triage to a coronary care unit (as opposed to a unit with a lower nurse/patient ratio) are elevated serum markers or hemodynamic instability.

TABLE 36--G-1 -- INITIAL EVALUATION AND MANAGEMENT

Issue	Class	Recommendation	Level of Evidence
Immediate management	I	The history, physical examination, 12-lead ECG, and initial serum marker tests should be integrated to assign patients with chest pain to 1 of 4 categories: a noncardiac diagnosis, chronic stable angina, possible ACS, and definite ACS	C
		Patients whose symptoms are suggestive of ACS or are believed to be consistent with definite ACS but whose initial 12-lead ECG and serum cardiac marker levels are normal should be observed in a facility with cardiac monitoring (e.g., chest pain unit),and a repeat ECG and serum marker measurement should be obtained 4-8 hr later	C C
		If the follow-up 12-lead ECG and cardiac marker measurements are normal, a stress test to provoke ischemia may be performed. Patients with a negative stress test can be managed as outpatients. Patients with a strongly positive stress test are considered to have myocardial ischemia and, in the presence of a clinical picture of acute ischemia, should be admitted to the hospital for further management. The stress test can be conducted on an outpatient basis in low-risk patients with unstable angina/non-ST segment elevation myocardial infarction	C C
		Patients who are unable to exercise or who have an abnormal resting ECG should have stress myocardial perfusion imaging	
		Patients believed to have an ACS with an abnormal initial 12-lead ECG should be managed according to the findings of the 12-lead ECG. Patients with ST elevation should be evaluated for immediate reperfusion therapy. Patients with new ST depression and/or T wave abnormalities should be admitted to the hospital for further management	C C

ACS=acute coronary syndrome; ECG=electrocardiogram.

Figure 36-36-G-1 Algorithm for evaluation and management of patients suspected of having acute coronary syndrome (ACS). ACP=American College of Physicians; ECG=electrocardiogram; LV=left ventricular. (From Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA guidelines for the management of patients with unstable angina: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients with Unstable Angina). TABLE 36--G-2 -- HOSPITAL CARE

Issue	Class	Recommendation	Level of Evidence
Antiischemic therapy	I	Bed rest with continuous ECG monitoring for ischemia and arrhythmia detection in patients with ongoing pain at rest	C
		NTG, sublingual tablet or spray or IV, for immediate relief of ischemia and associated symptoms	C
		Supplemental oxygen for patients with cyanosis, respiratory distress, or high-risk features. Finger pulse oximetry or arterial blood gas determination to confirm adequate arterial oxygen saturation (Sa_{O_2} >92%) and continued need for supplemental oxygen in the presence of hypoxemia	C
		Morphine sulfate IV when symptoms are not immediately relieved with NTG or when acute pulmonary congestion and/or severe agitation is present	C
		A beta blocker, oral or IV, in the absence of contraindications	B
		In patients with continuing or frequently recurring ischemia in whom beta blockers are either contraindicated or fully deployed, a nondihydropyridine calcium antagonist (e.g., diltiazem or verapamil), oral and/or IV, as initial therapy in the absence of severe LV dysfunction or other contraindications	B
		Intraaortic balloon pump counterpulsation for patients with either ischemia that is continuing or recurs frequently despite intensive medical therapy or hemodynamic instability	C
		An ACE inhibitor when hypertension persists despite treatment with NTG and a beta blocker and in patients with LV systolic dysfunction	B
	IIa	Nondihydropyridine calcium antagonist (diltiazem or verapamil), oral and/or IV, as initial therapy in the absence of severe LV dysfunction or other contraindications	B
		Oral long-acting dihydropyridine calcium antagonists in the absence of contraindications for recurrent ischemia when beta blockers and nitrates are fully deployed	C
		An ACE inhibitor for diabetic patients	B
	IIb	Long-acting nondihydropyridine calcium antagonists instead of a beta blocker	B
		Immediate-release dihydropyridine calcium antagonists in the presence of a beta blocker	B
	III	NTG or other nitrate within 24 hr of sildenafil (Viagra) use	C
		Immediate-release dihydropyridine calcium antagonists in the absence of a beta blocker	B
Antiplatelet and anticoagulation therapy	I	Antiplatelet therapy should be initiated promptly. ASA is the first choice and is administered as soon as possible after arrival and then continued indefinitely	A
		Patients unable to take ASA because of hypersensitivity or major GI intolerance should receive an ADP receptor antagonist as a substitute	B
		Ticlopidine has been found effective	B
		Clopidogrel may be preferred because of safety	
		Parenteral anticoagulation with IV unfractionated heparin or with subcutaneous low-molecular-weight heparin should be added to antiplatelet therapy	A
		A platelet GP IIb-IIIa receptor antagonist should be administered, in addition to ASA and heparin, to patients with unstable angina with continuing ischemia or with other high-risk features. Eptifibatide and tirofiban are approved for this use. Abciximab can also be used for 12-24 hr in patients with UA/NSTEMI in whom an interventional procedure within the following 24 hr is planned	A
	III	IV thrombolytic therapy in patients without acute ST segment elevation of a presumably new left bundle branch block	A
Risk stratification	I	Noninvasive stress testing in patients who have been free of angina at rest or with low-level activity and CHF for a minimum of 24-28 hr and who are not otherwise considered high risk	C
		Choice of stress test is based on the resting ECG, ability to perform exercise, local expertise, and technologies available. Treadmill exercise is suitable in patients able to exercise in whom the ECG is free of baseline ST segment abnormalities, left bundle branch block, LV hypertrophy, intraventricular conduction defect, preexcitation, or digoxin effect	C
		In patients with resting ST segment depression (1 mm), LV hypertrophy, left bundle branch block, intraventricular conduction defect, preexcitation, or digoxin who are able to exercise, an imaging modality is added	C
		Pharmacological stress testing with imaging when physical limitations (e.g., arthritis, amputation, severe peripheral vascular disease, severe COPD, general debility) preclude exercise	B
		Choice among different imaging modalities used with stress testing should be based primarily on local expertise	C
		A noninvasive test (echocardiogram, radionuclide angiogram) to evaluate LV function in patients with definite ACS	C
		Prompt angiography without noninvasive risk stratification for failure of stabilization with medical treatment	B
	III	Noninvasive stress testing or coronary angiography in patients with extensive comorbidity in whom revascularization is contraindicated	C

Early conservative vs. invasive strategies	I	An early invasive strategy involving prompt coronary angiography to evaluate for revascularization in patients with any of the following high-risk indicators: Patients receiving intensive antiischemic therapy with recurrent angina/ischemia at rest or with low-level activities or accompanied by CHF symptoms, and S_3 gallop, or new or worsening MR High-risk findings on noninvasive stress testing (see Table G-3) Depressed LV systolic function (EF <0.4) by noninvasive study) Hemodynamic instability Sustained ventricular tachycardia Prior revascularization (PCI or CABG)	C
	IIa	In the absence of findings in Class I, either an early conservative or early invasive strategy may be performed in hospitalized patients without contraindications for revascularization	C
		An early invasive strategy in patients who prefer and have no contraindications to revascularization	C
		Repeated attacks of ACS without evidence for ischemia or high risk	
	III	Coronary angiography in patients with extensive comorbidities (e.g., liver or pulmonary failure, cancer) in whom the risks of revascularization are not likely to outweigh the benefits	
Coronary revascularization using PCI and CABG in patients with UA/NSTEMI	I	CABG for patients with significant left main CAD, as well as in patients with severe multivessel CAD or two-vessel disease involving the proximal LAD and depressed LV systolic function	A A A
		PCI or CABG for nondiabetic patients with multivessel CAD. PCI for patients with coronary anatomy suitable for catheter-based therapy and preserved LV function.	A
		Platelet GP IIb-IIIa receptor inhibitor in UA/NSTEMI patients undergoing percutaneous revascularization	
	IIa	CABG for patients with multivessel disease and diabetes mellitus	B
		PCI or CABG for patients with 2-vessel disease not involving the proximal LAD	B
		PCI or CABG for patients with single-vessel, proximal LAD disease	B
	IIb	PCI for patients with multivessel disease and diabetes of LV dysfunction	B
		PCI for patients with significant left main disease in whom CABG cannot be carried out	C

ACE=angiotensin-converting enzyme; ACS=acute coronary syndrome; ADP=adenosine diphosphate; ASA=acetylsalicylic acid; CABG=coronary artery bypass grafting; CAD=coronary artery disease; CHF=congestive heart failure; COPD=chronic obstructive pulmonary disease; ECG=electrocardiogram; EF=ejection fraction; GI=gastrointestinal; GP=glycoprotein; LAD=left anterior descending artery; LV=left ventricular; MR=mitral regurgitation; NTG=nitroglycerin; PCI=percutaneous coronary intervention; UA/NSTEMI=unstable angina/non-ST segment elevation myocardial infarction.

ANTIISCHEMIC THERAPY.

Early initiation of beta blocker therapy in the absence of contraindications is recommended. Calcium antagonists are considered useful primarily for symptom control and appropriate for second or third choices following initiation of nitrates and beta blockers. For agents that slow the heart rate (verapamil and diltiazem), early use is more appropriate because of the lack of controlled trial evidence of harm, and some trends suggest potential benefit. The guidelines consider the use of immediate-release dihydropyridine calcium antagonists in the absence of a beta blocker to be *inappropriate* (Class III).

ANTIPLATELET AND ANTICOAGULATION THERAPY.

The guidelines encourage prompt initiation of an array of agents to impede thrombus formation. Antiplatelet therapy should begin immediately, ideally with acetylsalicylic acid (ASA), but with newer agents (clopidogrel or ticlopidine) if the use of ASA is contraindicated. The guidelines also support a low threshold for anticoagulation with intravenous heparin or with subcutaneous low-molecular-weight heparin for patients with ACS. High-risk patients should also be considered for therapy with a platelet glycoprotein (GP) IIb-IIIa receptor antagonist.

Intravenous thrombolytic therapy in the absence of acute ST segment elevation or a presumably new left bundle branch block is considered inappropriate (Class III).

RISK STRATIFICATION (see Table 36-G-2) .

Early use of noninvasive tests for risk stratification after patients have been free of angina at rest or during low-level activity, heart failure, or other major complications for 24 to 48 hours is recommended. As noted above, an exercise ECG is considered the most appropriate first-line test for patients with adequate functional capacity and appropriate rest ECGs. This recommendation is based on its "simplicity, lower cost, and widespread familiarity with performance and interpretation." For other patients, choices among different imaging modalities should be based on local expertise. Findings on noninvasive testing that predict a high risk for adverse outcomes are shown in Table 36-G-3 .

For patients with definite ACS, left ventricular function should be assessed to help guide long-term management strategies. If medical treatment is not able to control symptoms of ischemia, patients should undergo prompt coronary angiography, as long as other considerations (e.g., extensive comorbidity) would not preclude coronary revascularization.

Early Conservative Versus Invasive Strategies (see Table 36-G-2)

Two strategies for coronary angiography were discussed. In the *early conservative strategy*, patients routinely undergo noninvasive risk stratification, and coronary angiography is reserved for patients identified as being at high risk for adverse outcomes based on their clinical courses or noninvasive test results. In the *early invasive strategy*, patients without obvious contraindications to coronary revascularization are routinely recommended for coronary angiography followed by revascularization, if possible.

A clearly appropriate (Class I) assessment was given to the use of an early invasive strategy for patients with high-risk indicators, including

Figure 36-36-G-2 Acute ischemia pathway. EF=ejection fraction; GP=glycoprotein; LV=left ventricular. *(From Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA guidelines for the management of patients with unstable angina: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on the Management of Patients with Unstable Angina]. J Am Coll Cardiol, 36:970-1062, 2000.)*

recurrent ischemia, markedly abnormal noninvasive test results (see Table 36-G-2) , a history of prior revascularization, depressed left ventricular function, hemodynamic instability, or sustained ventricular tachycardia. In other patients, either strategy is acceptable (Class I). The early invasive approach was considered reasonably appropriate (Class IIa) for patients who prefer revascularization to medical therapy and for patients who have repeated attacks of suspected ACS without

evidence of ischemia or increased risk.

CORONARY REVASCULARIZATION.

The indications for revascularization in patients with UA/NSTEMI are similar to those for patients with chronic stable angina (see Guidelines to Chap. 37). These guidelines reflect the growing experience with percutaneous coronary interventions (PCIs) and the benefit of platelet GP IIb-IIIa receptor inhibitors in high-risk patients. Coronary artery bypass graft (CABG) surgery remains the appropriate intervention for patients with left main disease, for patients with severe multivessel disease and depressed left ventricular function, and for patients with two-vessel disease that includes the proximal left anterior descending coronary artery (LAD) with depressed left ventricular function (see Table 36-G-2) . In addition, the guidelines consider CABG surgery most appropriate for patients with multivessel disease and diabetes (Class IIa). Either CABG or PCI may be used in patients with one- or two-vessel disease without significant proximal LAD obstruction. However, PCI is considered appropriate (Class I) for nondiabetic patients with single or multivessel disease if the coronary anatomy is suitable for such procedures. Use of platelet GP IIb-IIIa receptor inhibitors for patients with UA/NSTEMI who are undergoing PCI is also endorsed by these guidelines.

Hospital Discharge And Post-Hospital Discharge Care (Table 36-G-4)

Long-term medical treatment of patients who have been stabilized with medical therapy or revascularization should include, in the absence of contraindications, ASA and beta blockers. Dietary interventions should be used if low-density lipoprotein (LDL) cholesterol is greater than 100 mg/dl; 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors should be started if LDL cholesterol is 125 mg/dl or higher. Angiotensin-converting enzyme inhibitors should be considered, especially in patients with evidence of left ventricular dysfunction.

The ACC/AHA guidelines emphasize the importance of careful follow-up within a few weeks after discharge. Recurrent unstable angina should lead to consideration of coronary revascularization. Explicit recommendations on appropriate educational messages for patients and families are provided (see Table 36-G-4) . These discussions should include information about resumption of sexual activity. The guidelines also recommend control of other risk factors besides elevated LDL cholesterol, including consideration of referral of patients who are smokers to a smoking cessation program.

Special Patient Populations (Table 36-G-5)

The guidelines conclude that women with ACS should be managed in a manner similar to men--that is, no evidence supports the use of different management strategies or indications for procedures. They also recommend similar management strategies for patients with diabetes

TABLE 36--G-3 -- NONINVASIVE TEST RESULTS PREDICTING HIGH RISK FOR AN ADVERSE OUTCOME

Exercise ECG Testing
Abnormal horizontal or down-sloping ST segment depression with
Onset at heart rate <120/min or 6.5 METS Magnitude 2.0 mm Postexercise duration 6 min Depression in multiple leads
Abnormal systolic blood pressure response--with a sustained decrease of >10 mm Hg or a flat blood pressure response (130 mm Hg), associated with abnormal ECG findings
Other
Exercise-induced ST segment elevation Ventricular tachycardia
Stress Radionuclide Myocardial Perfusion Imaging
Abnormal myocardial tracer distribution in more than one coronary artery region at rest or with stress or a large anterior defect that reperfuses Abnormal myocardial distribution with increased lung uptake Cardiac enlargement

Adapted from Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA guidelines for the management of patients with unstable angina: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients with Unstable Angina). J Am Coll Cardiol, 36:970-1062, 2000. Reprinted with permission from the American College of Cardiology.)

mellitus, while emphasizing the importance of diabetes as a risk factor for cardiovascular complications and the importance of glucose control as an approach to minimizing the effects of this condition. If revascularization is needed for patients with diabetes mellitus and multivessel disease, CABG (with particular attention to the use of internal mammary grafts) is preferred over PCI.

In patients who have previously undergone CABG, decisions about medical treatment or the use of revascularization should be similar to those used in other patients with UA/NSTEMI. The ACC/AHA guidelines considered the use of imaging technologies with stress testing appropriate (Class IIa) in this population. The task force also thought that a lower threshold for angiography may be appropriate in post-CABG patients because of the multiple potential causes of ischemia.

The ACC/AHA guidelines do not suggest qualitatively different strategies for the management of elderly patients with UA/NSTEMI but encourage greater attention to the impact of comorbidities, life expectancy, and the pharmacokinetics and side effects of drugs. Since the survival benefit of interventions may not be similar to those demonstrated in randomized trials involving younger patients, clinicians should give particular emphasis to the impact of interventions on quality of life.

For patients with chest pain after cocaine use, the guidelines support the use of nitroglycerin and calcium channel blockers if they have ST segment deviations. Coronary arteriography or thrombolytic therapy should be used for patients with ST segment elevation that persists despite these interventions.

Coronary arteriography, nitrates, and calcium channel blockers are also considered appropriate for patients with demonstrated coronary spasm (Prinzmetal's angina). The guidelines discourage provocative testing for spasm without coronary arteriography.

For patients with syndrome X (angina or angina-like discomfort with exercise, ST segment depression on treadmill testing, and normal or nonobstructed coronary arteries by arteriography), the guidelines recommend reassurance in view of the excellent long-term prognosis for these patients. To help relieve symptoms, the task

force recommends medical therapy with antianginal agents, as well as risk factor reduction to help prevent the development of atherosclerotic coronary artery disease.

TABLE 36--G-4 -- HOSPITAL DISCHARGE AND POSTDISCHARGE CARE

Issue	Class	Recommendation	Level of Evidence
Hospital discharge and postdischarge care	I	Patients who do not undergo coronary revascularization, patients with unsuccessful revascularization, or patients with recurrent symptoms following revascularization should continue taking the regimen required in the hospital to control ischemia after hospital discharge	C
		Postdischarge antianginal therapy is not required for patients with successful revascularization and recurrent ischemia	C
		All patients should be given sublingual NTG and instructed in its use	C
Long-term medical therapy	I	ASA 75-160 mg/d in the absence of contraindications	A
		Beta blockers in the absence of contraindications in patients with prior MI	A
		Beta blockers in the absence of contraindications in patients without prior MI	B
		Lipid-lowering agents and diet in patients with LDL cholesterol >125 mg/dl, including after revascularization	A
		Diet for LDL >100 mg/dl	C
		Angiotensin-converting enzyme inhibitors, especially if LV dysfunction, <40% EF, or CHF is present	A
		HMG-CoA reductase inhibitors for LDL >125 mg/dl	A
Postdischarge follow-up	I	Discharge instructions should include a follow-up appointment. Low-risk medically treated patients and revascularized patients should return in 2-6 wk and higher-risk patients in 1-2 wk	C
		Patients managed initially with a conservative strategy who experience recurrent UA or severe (Canadian class III) chronic stable angina despite medical management should be considered for coronary arteriography if they are suitable for revascularization	B
		Patients who have tolerable stable angina or no anginal symptoms at follow-up visits should be managed with long-term medical therapy for stable CAD	C
Use of medication	I	Prior to hospital discharge, patients and/or designated responsible caregivers should be provided with instruction with respect to medication type, purpose, dose, frequency, and pertinent side effects that are well understood	All C
		Anginal discomfort lasting more than 2 or 3 min should prompt the patient to discontinue the activity or remove himself/herself from the stressful event. If pain does not subside immediately, the patient should be instructed to take NTG. If the first tablet or spray does not provide relief within 5 min, a second and third dose, at 5-min intervals, should be taken. Pain lasting longer than 15-20 min and persistent pain despite 3 NTG doses should prompt the patient to seek immediate medical attention by going to the nearest hospital ED, preferably by ambulance or the quickest available alternative	
		If the pattern of anginal symptoms changes (e.g., pain more frequent or severe, precipitated by less effort, or now occurring at rest), the patient should contact his/her physician to determine the need for additional treatment or testing	
Risk factor modification	I	Specific instructions should be given on	
		Smoking cessation, achievement or maintenance of optimal weight, daily exercise, and diet	B
		Cholesterol-lowering medications for LDL >125 mg/dl	A
		Diet for LDL >100 mg/dl	C
		Hypertension control	B
		Tight control of hyperglycemia in diabetics	B
		Consider referral of patients who are smokers to a smoking cessation program or clinic and/or an outpatient cardiac rehabilitation program	B
Life style issues	I	Health care providers should discuss the safety and timing of resumption of sexual activity (e.g., 1-2 wk for low-risk patients, 4 wk for post-CABG surgery patients)	C
		Beyond the instructions for daily exercise, patients require specific instructions on activities (e.g., heavy lifting, climbing stairs, yard work, household activities) that are permissible and those that should be avoided. Specific mention should be made about when they can resume driving and return to work	C

ASA=acetylsalicylic acid; CAD=coronary artery disease; CHF=congestive heart failure; ED=emergency department; EF=ejection fraction; HMG-CoA=3-hydroxy-3-methylglutaryl coenzyme A; LDL=low-density lipoprotein; LV=left ventricular; MI=myocardial infarction; NTG=nitroglycerin; UA=unstable angina.

TABLE 36--G-5 -- MANAGEMENT OF SPECIAL POPULATIONS

Issue	Class	Recommendation	Level of Evidence
Patients with chest pain after cocaine use	I	NTG and calcium channel blockers for patients with ST segment elevation or depression	B
		Immediate coronary arteriography, if possible, in patients whose ST segments remain elevated after NTG and calcium channel blockers. Thrombolysis (with or without PCI) if thrombus is detected	C
	IIa	IV calcium channel blockers for patients with ST segment elevation or depression	B
		Beta blockers for hypertensive patients (systolic B: >150 mm Hg) or those with sinus tachycardia (pulse >100/min)	C
		Thrombolytic therapy if ST segments remain elevated despite NTG and calcium blockers and if coronary angiography is not possible	C
		Coronary arteriography, if available, for patients with ST depression or isolated T wave changes not known to be old and who are unresponsive to NTG and calcium channel blockers	C
	III	Coronary arteriography in patients with chest pain without ST-T wave changes	C
Variant (Prinzmetal) angina	I	Coronary arteriography in patients with episodic chest pain and ST segment elevation that resolves with NTG and/or calcium channel blockers	B
		Treatment with nitrates and calcium channel blockers in patients whose coronary arteriogram is normal or shows only nonobstructive lesions	B
	IIa	In the absence of significant CAD on coronary arteriography, provocative testing with methylergonovine, acetylcholine, or methacholine when coronary spasm is suspected but there is no ECG evidence of transient ST segment elevation	B
	IIb	Provocative testing in patients with a nonobstructive lesion on coronary arteriography, a clinical picture of coronary spasm, and evidence of transient ST segment elevation	B
		Provocative testing in patients with nonobstructive lesions on coronary arteriography and a clinical picture of coronary spasm and transient ST segment depression	B
	III	Provocative testing carried out without coronary arteriography	C
		Provocative testing in patients with high-grade obstructive lesions on coronary arteriography	B

Syndrome X	I	Reassurance and medical therapy with nitrates, beta blockers, and calcium channel blockers alone or in combination	B
		Risk factor reduction	C
	IIb	Intracoronary ultrasound to rule out missed obstructive lesions	B
		If no ECGs are available during chest pain and coronary spasm cannot be ruled out, coronary arteriography and provocative testing using methylergonovine, acetylcholine, or methacholine should be carried out	C
		Hormone replacement in postmenopausal women unless contraindicated	C
		Imipramine for continued pain despite Class I measures	C

BP=blood pressure; CAD=coronary artery disease; ECG=electrocardiogram; NTG=nitroglycerin; PCI=percutaneous coronary intervention.

Chapter 37 - Chronic Coronary Artery Disease

BERNARD J. GERSH
EUGENE BRAUNWALD
ROBERT O. BONOW

Chronic coronary artery disease (CAD) is most commonly due to obstruction of the coronary arteries by atheromatous plaque[1] (the pathogenesis of atherosclerosis is described in Chapter 30) . Factors that predispose to this condition are discussed in Chapter 31 , the control of coronary blood flow in Chapter 34 , acute myocardial infarction in Chapter 35 , and unstable angina in Chapter 36 ; sudden cardiac death, another significant consequence of CAD, is presented in Chapter 26 .

No uniform syndrome of signs and symptoms is initially seen in patients with CAD. Chest discomfort is usually the predominant symptom in chronic (stable) angina (see p. 1273), unstable angina (see Chap. 36) , Prinzmetal (variant) angina (p. 1324), microvascular angina (p. 1329), and acute myocardial infarction (Chap. 35) . However, syndromes of CAD also occur in which ischemic chest discomfort is absent or not prominent, such as asymptomatic (silent) myocardial ischemia (see p. 1330), congestive heart failure, cardiac arrhythmias, and sudden death (Chap. 26) . Obstructive CAD also has many nonatherosclerotic causes, including congenital abnormalities of the coronary arteries, myocardial bridging, coronary arteritis in association with the systemic vasculitides, and radiation-induced coronary disease.[2] [3] Whether coronary ectasia is a cause of angina pectoris in the absence of coronary artery obstruction remains to be clarified.[4] Myocardial ischemia and angina pectoris may also occur in the *absence* of obstructive CAD, as in the case of aortic valve disease (see Chap. 46) , hypertrophic cardiomyopathy (Chap. 48) , and idiopathic dilated cardiomyopathy (Chap. 48) . Moreover, CAD may coexist with these other forms of heart disease.

THE MAGNITUDE OF THE PROBLEM

The importance of CAD in contemporary society is attested to by the almost epidemic number of persons afflicted--especially when this number is compared with the anecdotal reports of its occurrence in the medical literature before this century. Moreover, as the challenges posed by infectious, parasitic, and nutritional disorders and perinatal mortality are overcome, particularly in the developing world, a global epidemic of CAD looms large on the horizon (see Chap. 1) . It is estimated that 12,200,000 Americans have CAD, 6,300,000 of whom have angina pectoris and 7,200,000 have had myocardial infarction.[5] [6] The economic cost of CAD and stroke in the United States in 2000 is estimated at $326.6 billion ($118.2 billion for CAD).[5] Given the current magnitude of the problem and the increasing prevalence of CAD that is anticipated because of aging of the population, recognition, management, and prevention of CAD are of major public health importance.[5] [6]

CAD mortality rates vary widely among countries and even within a country. Recent 10-year data from the World Health Organization Monitoring of Trials and Determinants in Cardiovascular Disease (MONICA) Project in 37 different populations demonstrated a reduction in CAD events and mortality rates in most countries, but with contradictory results for a few countries, mostly in central and eastern Europe and Asia.[7] Within the United States, death rates from cardiovascular disease among black males and females are substantially higher than those among whites.[5] Among American Indians, not only do rates of CAD exceed those reported for other U.S. populations, but the disease is more often fatal.[8] However, there is encouraging evidence that in the last three decades the age-adjusted death rate from CAD, which had reached pandemic proportions in industrial countries during the middle years of the 20th century, has decreased.[9] For example, between 1961 and 1991, the age-adjusted death rate for CAD declined by 52 percent, more so in men than women.[5] Similar trends have been observed in many industrialized nations with different health care systems. Multiple causes may have contributed to this favorable trend, including a reduction in risk factors (see Chap. 31) , improvements in socioeconomic circumstances such as enhanced access to care, and new methods of diagnosis and treatment. In the United States, it has been estimated that approximately 50 percent of the decrease in CAD mortality during the last decade has resulted from reductions in primary and secondary risk factors, but the contributions from new methods of treatment are also considered substantial.[10]

Stable Angina Pectoris

CLINICAL MANIFESTATIONS

CHARACTERISTICS OF ANGINA (see also Chap. 3) .

Angina pectoris is a discomfort in the chest or adjacent areas caused by myocardial ischemia. It is usually brought on by exertion and associated with a disturbance in myocardial function, but without myocardial necrosis.[11] Heberden's initial description of the chest discomfort as conveying a sense of "strangling and anxiety" is still remarkably pertinent, although adjectives frequently used to describe this distress include "viselike," "constricting," "suffocating," "crushing," "heavy," and "squeezing." In other patients, the quality of the sensation is more vague and described as a mild pressure-like discomfort**,** an uncomfortable numb sensation, or a burning sensation. The site of the discomfort is usually retrosternal, but radiation is common and usually occurs down the ulnar surface of the left arm; the right arm and the outer surfaces of both arms may also be involved[11] (see Fig. 3-2) . Epigastric discomfort alone or in association with chest pressure is not uncommon. Anginal discomfort above the mandible, below the epigastrium, or confined to the ear is rare. Anginal "equivalents" (i.e., symptoms of myocardial ischemia other than angina), such as dyspnea, faintness, fatigue, and eructations, are common, particularly in the elderly. A history of abnormal exertional dyspnea may be an early indicator of CAD even when angina is absent or no electrocardiographic (ECG) evidence of ischemic heart disease can be found.[12] Dyspnea at rest or with exertion may be a manifestation of severe ischemia and lead to increases in left ventricular filling pressure. Nocturnal angina should raise the suspicion of sleep apnea.[13]

A careful clinical history is key to making the correct diagnosis and is particularly important in this era of cost-conscious practice of medicine because it may obviate more expensive testing. If the quality of the pain and its duration, precipitating factors, and associated symptoms are taken into consideration, it is usually possible to arrive at a correct diagnosis (see Table 3-4) . The typical episode of angina pectoris usually begins gradually and reaches its maximum intensity over a period of minutes before dissipating. It is unusual for angina pectoris to reach its maximum severity within seconds, and it is characteristic that patients with angina usually prefer to rest, sit, or stop walking during episodes.[11] Chest discomfort while walking in the cold, uphill, or after a meal is suggestive of angina. Features suggesting the *absence* of angina pectoris include pleuritic pain, pain localized to the tip of one finger, pain reproduced by movement or palpation of the chest wall or arms, and constant pain lasting many hours or, alternatively, very brief episodes of pain lasting seconds. Pain radiating into the lower extremities is also a highly unusual manifestation of angina pectoris.

Typical angina pectoris is relieved within minutes by rest or by the use of nitroglycerin. The response to the latter is often a useful diagnostic tool, although it should be remembered that esophageal pain and other syndromes may also respond to nitroglycerin. A delay of more than 5 to 10 minutes before relief is obtained by rest and

nitroglycerin suggests that the symptoms are either not due to ischemia or, alternatively, are due to severe ischemia, i.e., acute myocardial infarction or unstable angina. The phenomenon of "first effort" or "warm-up" angina is used to describe the ability of some patients in whom angina develops with exertion to subsequently continue at the same level of exertion without symptoms after an intervening period of rest. This attenuation of myocardial ischemia observed with repeated exertion has been postulated to be due to ischemic preconditioning.[14]

An important component of the history is to assess the degree of cardiovascular disability caused by angina pectoris. Such assessment is a crucial part of the evaluation for coronary revascularization. Although several classifications for assessing cardiovascular disability are available,[15] the Canadian Cardiovascular Society Functional Classification System (see Table 3-11) is most widely used.[16]

MECHANISMS.

The mechanisms of cardiac pain and the neural pathways involved are poorly understood.[1] It is presumed that angina pectoris results from ischemic episodes that excite chemosensitive and mechanoreceptive receptors in the heart. Stimulation of these receptors results in the release of adenosine, bradykinin, and other substances that excite the sensory ends of the sympathetic and vagal afferent fibers. The afferent fibers traverse the nerves that connect to the upper five thoracic sympathetic ganglia and upper five distal thoracic roots of the spinal cord. Impulses are transmitted by the spinal cord to the thalamus and hence to the neocortex. Within the spinal cord, cardiac sympathetic afferent impulses may converge with impulses from somatic thoracic structures, which may be the basis for referred cardiac pain, for example, to the chest. In comparison, cardiac vagal afferent fibers synapse in the nucleus tractus solitarius of the medulla and then descend to excite the upper cervical spinothalamic tract cells, which may contribute to the anginal pain experienced in the neck and jaw.[17] On the basis of positron-emission tomographic (PET) findings on changes in regional cerebral blood flow associated with angina pectoris, it has been proposed that cortical activation is necessary for pain sensation and the thalamus acts as a gate for afferent pain signals.[18]

Differential Diagnosis of Chest Pain (see Fig. 3-3 (Figure Not Available) and Table 3-4)

Differentiation of various disorders from CAD is challenging because the severity of the chest pain and the seriousness of the underlying disorder are not necessarily related. Compounding the difficulty in differential diagnosis is the common myth that pain in the left arm or left side of the chest is an ominous sign signifying the presence of CAD. However, a host of other disorders can also cause discomfort in these locations.

ESOPHAGEAL DISORDERS.

The common esophageal disorders that may simulate or coexist with angina pectoris are gastroesophageal reflux and disorders of esophageal motility, including diffuse spasm as well as "nutcracker" esophagus, which is characterized by high-amplitude peristaltic contractions and vigorous achalasia.[19] Symptomatic esophageal reflux is common and estimated to occur in 7 to 14 percent of an otherwise "healthy" U.S. population. In a comparative study of patients with chest pain and normal coronary angiograms and controls with confirmed CAD, esophageal function testing (including manometry, provocation tests, and 24-hour ambulatory pH monitoring) commonly implicated the esophagus as a cause of pain in patients with normal coronary angiograms. Nonetheless, a similar high frequency of esophageal abnormalities among patients with angina pectoris suggests that the esophagus may be an unrecognized source of pain in both groups of patients.[19] Further evidence of a relationship between esophageal abnormalities and angina pectoris was provided by a prospective study demonstrating that esophageal acid stimulation can cause anginal attacks in association with a significant reduction in coronary blood flow in patients with CAD.[20] A lack of any significant effect in this study in heart transplant recipients with cardiac denervation suggests a neural origin.

The classic manifestation of esophageal pain is "heartburn," particularly in connection with changes in posture and meals and in association with dysphagia. Esophageal spasm may also cause constant retrosternal discomfort of uniform intensity or severe spasmodic pain during or after

swallowing. To further compound the difficulty in distinguishing between angina and esophageal pain, both may be relieved by nitroglycerin. However, esophageal pain is often relieved by milk, antacids, foods, or, occasionally, warm liquids.

GASTROESOPHAGEAL REFLUX.

The esophageal acid perfusion, or Bernstein, test may be helpful in its use of alternate infusions of dilute acid and normal saline by a nasal gastric catheter with the tip placed at the level of the midesophagus.[19] Infusion of acid produces pain in over 90 percent of patients with subjective and objective evidence of gastroesophageal acid reflux, but it is particularly useful if the patient's symptoms are reproduced. Acid reflux into the esophagus can also be recognized by recording the pH from an electrode at the tip of a catheter inserted into the distal portion of the esophagus.

ESOPHAGEAL MOTILITY DISORDERS.

Esophageal motility disorders are not uncommon in patients with retrosternal chest pain of unclear cause and should be specifically excluded or confirmed, if possible.[21] In addition to chest pain, the majority of such patients have dysphagia. Although barium studies may reveal motility problems, esophageal manometry may show diffuse esophageal spasm, increased pressure at the lower esophageal sphincter, and other motility disorders. Provocative pharmacological agents such as methacholine may provoke esophageal pain and manometric signs of spasm.

A more complex problem is determining whether part or all of the symptoms in patients with *known* CAD are due to esophageal disease. Both CAD and esophageal disease are common clinical entities that may coexist. Diagnostic evaluation for an esophageal disorder may be indicated in patients with CAD who have a poor symptomatic response to antianginal therapy in the absence of documentation of severe ischemia or in patients with persistent symptoms despite adequate coronary revascularization.

BILIARY COLIC.

Although visceral symptoms are a common association of myocardial ischemia (particularly acute inferior myocardial infarction [see Chap. 35]), cholecystitis and related hepatobiliary disorders may also mimic ischemia and should always be considered in patients with atypical chest discomfort, particularly those with diabetes.[22] The pain is steady, usually lasts 2 to 4 hours, and subsides spontaneously without any symptoms between attacks. It is generally most intense in the right upper abdominal area but may also be felt in the epigastrium or precordium. This discomfort is often referred to the scapula, may radiate around the costal margin to the back, or may in rare cases be felt in the shoulder and suggest diaphragmatic irritation. Ultrasonography is accurate in diagnosing gallstones and allows determination of gallbladder size and thickness and whether the bile ducts are dilated.

COSTOSTERNAL SYNDROME.

In 1921, Tietze first described a syndrome of local pain and tenderness, usually limited to the anterior chest wall and associated with swelling of costal cartilage. This condition causes pain that can resemble angina pectoris. The full-blown Tietze syndrome, i.e., pain associated with tender *swelling* of the costochondral junctions, is uncommon, whereas costochondritis causing tenderness of the costochondral junctions (without swelling) is relatively common.[23] Pain on palpation of these joints is a useful clinical sign. Local pressure should be applied routinely to the anterior chest wall during examination of a patient with suspected angina pectoris. In addition, costochondritis is usually well localized. Although palpation of the chest wall often reproduces pain in patients with various musculoskeletal conditions, it should be appreciated that chest wall tenderness may also be associated with and does not exclude symptomatic CAD.[24]

OTHER MUSCULOSKELETAL DISORDERS.

Cervical radiculitis may be confused with angina. This condition may occur as a constant ache, sometimes resulting in a sensory deficit. The pain may be related to motion of the neck, just as motion of the shoulder triggers attacks of pain from bursitis. A hyperalgesic area noted by running the finger down the back and exerting pressure may lead to a suspicion of thoracic root pain. Occasionally, pain mimicking angina can be due to compression of the brachial plexus by the cervical ribs**,** and tendinitis or bursitis involving the left shoulder may also cause angina-like pain. Physical examination may also detect pain brought about by movement of an arthritic shoulder or a calcified shoulder tendon.

OTHER CAUSES OF ANGINA-LIKE PAIN.

Acute myocardial infarction is usually associated with prolonged (>30 minutes), severe pain occurring at rest that apart from duration and intensity, may be similar to angina pectoris. It is associated with characteristic ECG changes and the release of cardiac markers (see Chap. 35) . Unstable angina is a severe form of angina that may also occur at rest and may not be relieved by nitroglycerin (see Chap. 36) .

The classic symptom of *dissecting aortic aneurysm* is a severe, often sharp pain that radiates to the back (see Chap. 40) . Although aortic dissection is generally part of the differential diagnosis of acute myocardial infarction, the syndrome may be chronic in some patients. The pain is often described as sharp, but its pleuropericarditic quality is usually helpful in the differential diagnosis.

Severe pulmonary hypertension may be associated with exertional chest pain with the characteristics of angina pectoris, and indeed, this pain is thought to be due to right ventricular ischemia that develops during exertion (see Chap. 53) . Other associated symptoms include exertional dyspnea, dizziness, and syncope. Associated findings on physical examination, such as parasternal lift, a palpable and loud pulmonary component of the second sound, and right ventricular hypertrophy on the ECG, are usually readily recognized.

Pulmonary embolism is initially characterized by dyspnea as the cardinal symptom, but chest pain may also be present (see Chap. 52) . Pleuritic pain suggests pulmonary infarction, and a history of exacerbation of the pain with inspiration, along with a pleural friction rub, usually helps distinguish it from angina pectoris.

The pain of *acute pericarditis* (see Chap. 50) may at times be difficult to distinguish from angina pectoris. However, pericarditis tends to occur in younger patients than does angina, and the diagnosis depends on the combination of chest pain not relieved by rest or nitroglycerin, a pericardial friction rub, and ECG changes.

Chronic CAD can and frequently does coexist with any of the other disorders mentioned above, and noncardiac disease can trigger a true angina attack in a patient with CAD. An additional component of the history is an evaluation of risk factors for CAD because such risk factors in turn have an effect on both the probability of significant obstructive CAD and the overall prognosis.[25]

Physical Examination

GENERAL EXAMINATION.

Inspection of the eyes may reveal a *corneal arcus*, and examination of the skin may show xanthomas (see Fig. 4-2) . Among patients with heterozygous familial hypercholesterolemia (in whom CAD is common), the presence of a corneal arcus increases with age and, in some studies, correlates positively with levels of cholesterol and low-density lipoprotein (LDL) and also with the prognosis.[26] [27] *Xanthelasma*, in which lipid deposits are intracellular, appears to be promoted by increased levels of triglycerides and a relative deficiency of high-density lipoprotein (HDL). The presence of xanthelasma is a strong marker of dyslipidemia and, often, a family history of cardiovascular disease, and should provide a strong impetus for performing a comprehensive lipid profile.[28] Retinal arteriolar changes are common in patients with CAD and diabetes mellitus or hypertension. Moreover, diabetes-associated visual impairments, including retinopathy, are independent predictors of increased mortality from all causes, including CAD.[29]

Some correlation has been noted between CAD and a *diagonal earlobe crease* (except in American Indians and Asians). A unilateral diagonal earlobe crease is often present in younger persons with CAD and becomes bilateral with advancing age.[30] A hospital-based, case-control study of men admitted with a first nonfatal myocardial infarction demonstrated that the presence of a diagonal earlobe crease was associated with a relative risk of 1.37 for myocardial infarction; the risk is similarly increased in the presence of baldness and thoracic hairiness.[31]

Blood pressure may be chronically elevated or may rise acutely (along with the heart rate) during an angina attack. Changes in blood pressure may precede (and precipitate) or follow (and be caused by) angina.

Other important features of the general physical examination are abnormalities in arterial pulses and the venous system. A rapid pulse may be a clue to cardiac decompensation

or to a systemic condition such as thyrotoxicosis or anemia, which can exacerbate angina pectoris. The association between peripheral vascular disease and CAD is strong and well documented.[32] [33] This association is not confined to patients with symptomatic or clinically overt peripheral vascular disease or CAD but is also seen in asymptomatic subjects with a reduced ankle-brachial blood pressure index or evidence of early carotid disease on ultrasonography.[34] The presence of carotid and peripheral arterial disease on palpation and auscultation increases the likelihood that chest discomfort of unclear origin is caused by CAD. Evaluation of the patient's venous system, particularly in the legs, may have an important bearing on the type of grafting procedure used in subsequent coronary bypass surgery.

CARDIAC EXAMINATION.

The physical findings of hypertrophic cardiomyopathy (see Chap. 48) or aortic valve disease (Chap. 46) suggest that angina may be due to conditions other than (or in addition to) CAD. It is often helpful to examine the heart *during* an episode of pain because ischemia may produce transient left ventricular dysfunction with a third heart sound and pulmonary rales detectable on physical examination.[35] If massage of the carotid sinus produces pain relief in a patient without a carotid bruit, the pain is probably anginal. Softening of the mitral component of the first heart sound as a result of ischemic left ventricular dysfunction may also be demonstrated during angina. Paradoxical splitting of the second heart sound (see Chap. 4) may occur transiently during angina and appears to be related to asynergy and prolongation of left ventricular contraction, which results in delayed closure of the aortic valve. If other obvious cardiac diseases are absent, a third or loud fourth heart sound suggests ischemia as the basis for the chest pain. These sounds are common in patients with angina at rest, and their frequency is increased during handgrip exercise,[36] even if the latter does not precipitate angina pectoris. A sustained apical cardiac impulse is common in patients with moderate or severe left ventricular dysfunction. A displaced ventricular impulse, particularly if dyskinetic, is a sign of significant left ventricular systolic dysfunction, especially in a patient who previously had a myocardial infarction.

Transient apical systolic murmurs are quite common in CAD and have been attributed to reversible papillary muscle dysfunction secondary to transient myocardial ischemia. When persistent, such murmurs may be due to papillary muscle fibrosis, which is often a manifestation of subendocardial infarction or a regional wall motion abnormality altering the alignment of the papillary muscles in relation to other components of the mitral valve apparatus. These murmurs are more prevalent in patients with extensive CAD, especially those with prior myocardial infarction and left ventricular dysfunction, and may indicate an adverse prognosis.[37] Systolic murmurs may assume a variety of configurations (early, late, or holosystolic) and may be accentuated by exertion or during angina. A midsystolic click, often followed by a late systolic murmur produced by mitral valve prolapse (see Chap. 46) , also occurs in patients with CAD. A diastolic murmur or a continuous murmur is a rare finding in CAD and has been attributed to turbulent flow across a proximal coronary artery stenosis.[38]

PATHOPHYSIOLOGY

Angina pectoris results from myocardial ischemia, which is caused by an imbalance between myocardial O_2 requirements and myocardial O_2 supply.[1] The former may be elevated by increases in heart rate, left ventricular wall stress, and contractility (see Chap. 34) ; the latter is determined by coronary blood flow and coronary arterial O_2 content (Fig. 37-1) .

ANGINA CAUSED BY INCREASED MYOCARDIAL C_2 REQUIREMENTS.

In this condition, sometimes termed "demand angina," the myocardial O_2 requirement increases in the face of a constant and usually restricted O_2 supply. The increased requirement commonly stems from norepinephrine release by adrenergic nerve endings in the heart and vascular bed, a physiological response to exertion, emotion, or mental stress. Of great importance to the myocardial O_2 requirement is the *rate* at which any task is carried out. Hurrying is particularly likely to precipitate angina, as are efforts involving motion of the hands over the head. Mental stress may also precipitate angina, presumably by increased hemodynamic and catecholamine responses to stress, increased adrenergic tone, and reduced vagal activity.[39] [40]

Figure 37-1 Factors influencing the balance between myocardial O_2 requirements *(left)* and supply *(right)*. Arrows indicate effects of nitrates. In relieving angina pectoris, nitrates exert favorable effects by reducing O_2 requirements and increasing supply. Although a reflex increase in heart rate would tend to reduce the time for coronary flow, dilation of collaterals and enhancement of the pressure gradient for flow to occur as the left ventricular end-diastolic pressure (LVEDP) falls tend to increase coronary flow. A_o P=aortic pressure; NC=no change. *(From Frishman WH: Pharmacology of the nitrates in angina pectoris. Am J Cardiol 56:8I, 1985. By permission of Excerpta Medica.)*

The combination of physical exertion and emotion in association with sexual activity commonly precipitates angina pectoris, but sexual activity seldom triggers myocardial infarction.[41] Anger may produce constriction of coronary arteries with preexisting narrowing without necessarily affecting O_2 demand. Other factors causing angina secondary to an increase in myocardial O_2 requirement in patients with obstructive CAD include physical exertion after a heavy meal and the excessive metabolic demands imposed by chills, fever, thyrotoxicosis, tachycardia from any cause, and hypoglycemia. Among patients with stable, fixed obstructive CAD, several studies using ambulatory ECG monitoring have documented the importance of increases in myocardial O_2 requirement and, in particular, tachycardia as a precipitant of ischemia. [42]

In all these conditions, underlying coronary artery obstruction is usually present, and the other factors (e.g., exertion, emotion, or fever) precipitate ischemia and chest discomfort by stimulating myocardial O_2 need in the presence of a relatively fixed and limited myocardial O_2 supply.

ANGINA CAUSED BY TRANSIENTLY DECREASED C_2 SUPPLY.

Increasing evidence suggests that not only unstable angina but also chronic stable angina may be caused by transient reductions in O_2 supply as a consequence of coronary vasoconstriction, [1] [43] a condition that is sometimes termed "supply angina" and due to the entity of "dynamic stenosis." [44] The coronary arterial bed is well innervated, and a variety of stimuli alter coronary tone (see Chap. 34) . Two main explanations have been offered for the association between coronary vasoconstriction and spasm in the presence of organic stenoses. First, platelet thrombi and leukocytes may elaborate vasoconstrictor substances such as serotonin and thromboxane A_2 . Second, endothelial damage in atherosclerotic coronary arteries may result in decreased production of vasodilator substances and an abnormal vasoconstrictor response to exercise and other stimuli. A variable threshold of myocardial ischemia in patients with chronic stable angina may be due to dynamic changes in peristenotic smooth muscle tone and also to constriction of arteries distal to the stenosis.[45] In this setting, calcium antagonists and nitrates are less effective than in patients with variant angina, perhaps because of the nature of the constricting stimuli and the site of constriction.[45]

Patients with angina precipitated by a transient reduction in myocardial O_2 supply may have a spectrum of signs and symptoms that depend on the severity of the underlying fixed defect and the degree of the dynamic change in coronary arterial tone. In a typical patient with chronic stable angina, the degree of fixed obstruction is sufficient to result in an inadequate coronary flow rate to cope with the increased O_2 demands of exercise. However, episodes of transient coronary vasoconstriction may be superimposed on this inadequate flow rate and cause additional limitations to coronary flow reserve in many patients.

In rare patients without organic obstructing lesions, severe dynamic obstruction occurring at rest alone can cause myocardial ischemia and result in angina (see Prinzmetal [Variant] Angina, p. 1324). On the other hand, in patients with severe fixed obstruction to coronary blood flow, only a minor increase in dynamic obstruction is necessary for blood flow to fall below a critical level and cause myocardial ischemia.

FIXED COMPARED WITH VARIABLE-THRESHOLD ANGINA.

The threshold for angina differs widely among patients with chronic angina. In patients with fixed-threshold angina precipitated by increased O_2 demands with few if any dynamic (vasoconstrictor) components, the level of physical activity required to precipitate angina is relatively constant. Characteristically, these patients can predict the amount of physical activity that will precipitate angina, e.g., walking up exactly two flights of stairs at a customary pace. When these patients are tested on a treadmill or bicycle, the pressure-rate product (the so-called double product, a correlate of the myocardial O_2 requirement) that elicits angina and/or ECG evidence of ischemia is relatively constant.

In patients with fixed-threshold, demand angina, the specific threshold at which ischemia develops (as reflected in angina and/or ST segment depression) is a function of the myocardial O_2 requirement. As the activity of the left ventricle (and therefore its O_2 requirement) increases, a point is reached at which perfusion distal to a critical coronary arterial obstruction cannot supply sufficient O_2 to myocardium perfused by the obstructed artery; ischemia and angina ensue. This relationship is, however, modified by the effects of coronary vasomotor tone on myocardial O_2 supply.[46] Coronary vascular reserve (or coronary vasodilator or flow reserve) is impaired in patients with significant obstructive CAD and also in those with microvascular disease or endothelial damage from conditions such as hypertension.[47]

The majority of patients with variable-threshold angina have atherosclerotic coronary arterial narrowing, but dynamic obstruction caused by vasoconstriction plays an important role in causing myocardial ischemia. These patients typically have "good days," when they are capable of substantial physical activity, as well as "bad days," when even minimal activity can cause clinical and/or ECG evidence of myocardial ischemia or angina at rest. Often, even in the course of a single day, they may be capable of substantial physical activity at one time while minimal activity results in angina at another. Patients with variable-threshold angina often complain of a circadian variation in angina that is more common in the morning. Angina on exertion and sometimes even at rest may be precipitated by cold temperature,[48] emotion, and mental stress.[49] A cold environment has been shown to increase peripheral resistance, both at rest and during exercise.[50] The rise in arterial pressure, by augmenting myocardial O_2 requirements, lowers the threshold for the development of angina. An alternative or additional explanation is the development of cold-induced coronary vasoconstriction via activation of peripheral and reflex mechanisms.[50]

The entity of postprandial angina has been recognized for about two centuries and may be a marker of severe multivessel CAD.[51] The mechanism has not been explained, but it may be due to redistribution of coronary blood flow away from the territory supplied by severely stenosed vessels.[52] Some evidence indicates that this phenomenon is more prominent after high-carbohydrate than high-fat meals.[51]

MIXED ANGINA.

The term *mixed angina* has been proposed by Maseri and colleagues to describe the many patients who fall between the two extremes of fixed-threshold and variable-threshold angina.[53] The pathophysiological and clinical correlations of ischemia in patients with stable CAD may have important implications for the selection of antiischemic agents, as well as for their timing. The greater the contribution from increased myocardial O_2 requirements to the imbalance between supply and demand, the greater the likelihood that beta-blocking agents will be effective, whereas nitrates and calcium channel blocking agents, at least on theoretical grounds, are likely to be especially effective in episodes caused primarily by coronary vasoconstriction. The finding that in most patients with chronic stable angina an increase in myocardial O_2 requirement precedes episodes of ischemia, i.e., that they have demand angina, argues in favor of beta blockers as essential therapeutic agents.[54]

GRADING OF ANGINA PECTORIS.

A system of grading the severity of angina pectoris proposed by the Canadian Cardiovascular Society has gained widespread acceptance[16] (see Table 3-11) . The system is a modification of the New York Heart Association functional classification but allows patients to be categorized in more specific terms. Other grading systems include a specific activity scale developed by Goldman and associates[15] and an anginal "score" developed by Califf and colleagues.[55] The Goldman scale is based on the metabolic cost of specific activities and appears to be valid when used by both physicians and nonphysicians. The anginal score of Califf and coworkers integrates the clinical features and "tempo" of angina together with ECG ST and T wave changes and offers independent prognostic information above that provided by age, gender, left ventricular function, and coronary angiographic anatomy. A limitation of all these grading systems is their dependence on accurate patient observation and patients' widely varying tolerance for symptoms. Prospective evaluation of the reproducibility of the New York Heart Association estimates of functional class made by two physicians demonstrated a reproducibility of only 56 percent, and only 51 percent of the estimates agreed with treadmill exercise performance. Functional estimates based on the Canadian Cardiovascular Society criteria were more reproducible (73 percent) but still did not correlate well with objective measures of exercise performance.[15]

TABLE 37-1 -- PRETEST LIKELIHOOD OF CORONARY ARTERY DISEASE IN SYMPTOMATIC PATIENTS ACCORDING TO AGE AND SEX*

AGE (yr)	NONANGINAL CHEST PAIN		ATYPICAL ANGINA		TYPICAL ANGINA	
	Men	Women	Men	Women	Men	Women
30-39	4	2	34	12	76	26
40-49	13	3	51	22	87	55
50-59	20	7	65	31	93	73

*Each value represents the percentage with significant coronary artery disease on catheterization (combined data from Diamond and Forrester[56] and Chaitman et al. [59]).

CORRELATION BETWEEN HISTORICAL FEATURES AND CORONARY ANGIOGRAPHY.

An important objective of the history and physical examination is to acquire information that can be used to estimate the probability of the presence of obstructive CAD. The importance of this point is emphasized by the impact of the pretest likelihood of CAD on the performance of a standard exercise test.[35] The ability to predict the probability of CAD with reasonable accuracy from the history and physical examination was demonstrated originally by Diamond and Forrester and expanded on by other studies in both men and women referred for cardiac catheterization or stress testing.[56] [57] [58] The inclusion of such risk factors as cigarette smoking, hyperlipidemia, and diabetes mellitus strengthens the predictability of these models, as do certain changes on the ECG.[57] Subsequently, the Diamond and Forrester model was shown to be in strong agreement with the findings of the Coronary Artery Surgery Study (CASS).[59] The joint American College of Cardiology and American Heart Association (ACC/AHA) Guidelines Committee[35] combined data from both studies to illustrate the pretest likelihood of CAD in men and women stratified by age and nature of the chest pain (Table 37-1) .

Although the clinical manifestations of CAD, including rest angina and nocturnal and postprandial angina, tend to be more severe in patients with multivessel than single-vessel disease, neither the severity, duration, or nature of the pain nor its precipitating factors correlate with the extent of disease at angiography. Perhaps the most striking example of the lack of historical-arteriographic correlation is in two subgroups of patients--those with advanced obstructive CAD who are asymptomatic with "silent ischemia" (see p. 1330 and those with Prinzmetal, or variant, angina, who may have episodes of very severe anginal discomfort, yet have minimal or no underlying coronary atherosclerosis (see p. 1324).

NONINVASIVE TESTING

Biochemical Tests

In patients with chronic stable angina, metabolic abnormalities that are risk factors for the development of CAD are frequently detected. These abnormalities include hypercholesterolemia and other dyslipidemias (see Chap. 31) , carbohydrate intolerance, and insulin resistance.[60] [61] All patients with established or suspected CAD warrant biochemical evaluation of total cholesterol, LDL cholesterol, HDL cholesterol, triglycerides, and fasting blood glucose.[62] New biochemical markers, such as C-reactive protein, lipoprotein Lp(a), and homocysteine, have been shown to increase the likelihood of future cardiovascular events,[63] [64] [65] especially in patients with hypercholesterolemia, but no consensus has been reached regarding routine measurement of these markers, and measuring them is not generally recommended.[66]

Serum levels of cardiac markers are normal in patients with chronic stable angina, which serves to differentiate them from patients with acute myocardial infarction.

Resting Electrocardiogram (see also Chap. 5)

The resting ECG is normal in approximately half of patients with chronic stable angina pectoris, and even patients with severe CAD may have a normal tracing at rest. A normal resting ECG suggests the presence of normal resting left ventricular function[67] and is an unusual finding in a patient with an extensive previous infarction. The most common ECG abnormalities in patients with chronic CAD are nonspecific ST-T wave changes with or without abnormal Q waves. Numerous pitfalls must be avoided when using the *resting* ECG for the diagnosis of myocardial ischemia. In addition to myocardial ischemia, other conditions that can produce ST-T wave abnormalities include left ventricular hypertrophy and dilatation, electrolyte abnormalities, neurogenic effects, and antiarrhythmic drugs.[68] In patients with known CAD, however, the occurrence of ST-T wave abnormalities on the resting ECG may correlate with the severity of the underlying heart disease, including the number of vessels involved and the presence of left ventricular dysfunction.[69] This association may explain the adverse impact of ST-T wave changes on prognosis in these patients. In contrast, a normal resting ECG is a more favorable long-term prognostic sign in patients with suspected or definite CAD.[35] [70]

Interval ECGs may reveal the development of Q wave infarctions that have gone unrecognized clinically. Various conduction disturbances, most frequently left bundle branch block and left anterior fascicular block, may occur in patients with chronic stable angina, and they are often associated with impairment of left ventricular function[71] and reflect multivessel disease and previous myocardial damage. Hence, such conduction disturbances are an indicator of a relatively poor prognosis.[35] In patients with chronic stable angina, abnormal Q waves are relatively specific, but insensitive indicators of previous myocardial infarction. Various arrhythmias, especially ventricular premature beats, may be present on the ECG, but they too have low sensitivity and specificity for CAD.

Ambulatory ECG monitoring has shown that many patients with symptomatic myocardial ischemia also have episodes of silent ischemia that would otherwise go unrecognized during normal daily activities (see p. 1330). Although this form of ECG testing provides a quantitative estimate of the frequency and duration of ischemic episodes during routine activities, its sensitivity for detecting CAD is less than that of exercise ECG.

Left ventricular hypertrophy on the ECG is a poor prognostic factor in patients with chronic stable angina. This finding should suggest the presence of underlying hypertension, aortic stenosis, or hypertrophic cardiomyopathy and warrants further evaluation, such as echocardiography to assess left ventricular size, wall thickness, and function.

During an episode of angina pectoris, the ECG becomes abnormal in 50 percent or more of patients with normal resting ECGs. The most common finding is ST segment depression, although ST segment elevation and normalization of previous resting ST-T wave depression or inversion ("pseudonormalization") may develop.

Noninvasive Stress Testing (see also Chap. 13)

Noninvasive stress testing can provide useful and often indispensable information to establish the diagnosis and estimate the prognosis in patients with chronic stable angina.[35] [72] However, several studies have emphasized that the indiscriminate use of such tests may provide limited *incremental* information over and above that provided by the physician's detailed and thoughtful clinical assessment.[35] [57] [73] [74] [75] [76] Appropriate application of noninvasive tests requires consideration of Bayesian principles (see Chap. 6) . These principles state that the reliability and predictive accuracy of any test is defined not only by its sensitivity and specificity but also by the prevalence of disease (or pretest probability) in the population under study.

In an era of emphasis on cost-effectiveness, optimal utilization of testing requires an assessment of the *incremental* amount of information provided by a test, over and above what can be obtained from standard clinical variables alone. Noninvasive testing should be performed only if the test result will alter the planned management strategy. The value of noninvasive stress testing is greatest when the pretest likelihood is intermediate because the test result will have the greatest effect on the

posttest probability of CAD and, hence, on clinical decision-making in this group of patients.

Exercise Electrocardiography (see also Chap. 6)

DIAGNOSIS OF CORONARY ARTERY DISEASE.

As a screening test for CAD, the exercise ECG is useful in that it is relatively simple and inexpensive. It is particularly helpful in patients with chest pain syndromes who are considered to have a moderate probability of CAD and in whom the resting ECG is normal, provided that they are capable of achieving an adequate workload.[77] Although the incremental diagnostic value of exercise testing is limited in patients in whom the estimated prevalence of CAD is either high or low, the test provides useful, additional information about the degree of functional limitation in both groups of patients and about the severity of ischemia and prognosis in patients with a high pretest probability of CAD.[35] [78] [79]

The exercise ECG variable most useful for the detection of CAD and, in particular, multivessel disease is the ST segment shift during exercise and recovery.[78] [80] The sensitivity of the ST segment response increases with age, with the severity of CAD, and with the magnitude of the ST segment change itself (see Fig. 6-7) .[35] The predictive value for the detection of CAD is 90 percent if typical chest discomfort occurs during exercise along with horizontal or downward-sloping ST segment depression of 1 mm or more. ST segment depression of 2 mm or more accompanied by typical chest discomfort is virtually diagnostic of significant CAD.[80] In the absence of typical angina pectoris, downsloping or horizontal ST segment depression of 1 mm or more has a predictive value of 70 percent for the detection of significant coronary stenosis, but the predictive value increases to 90 percent with ST segment depression of 2 mm or more. The early onset of ST segment depression during exercise, its long persistence following discontinuation of exercise, a downsloping or horizontal depression, and a low work capacity or exercise duration are all strongly associated with multivessel disease. Exercise-induced QRS prolongation also appears to be a function of exercise-induced ischemia[81] and is related to the extent of exercise-induced segmental contraction abnormalities.

A meta-analysis of 147 published studies involving more than 24,000 patients was performed in the process of establishing the ACC/AHA Guidelines on Exercise Testing.[78] Wide variability in sensitivity and specificity was reported, with a mean sensitivity of 68 percent and mean specificity of 77. The results of stress testing often influence the subsequent decision for angiography and create a posttest referral bias that tends to inflate sensitivity and decrease specificity.[82] When meta-analyses are restricted to studies designed to avoid such work-up bias, the sensitivity is only 45 to 50 percent but the specificity is 85 to 90 percent.[78]

A major factor contributing to the low sensitivity of exercise ECG is that many patients are incapable of reaching the level of exercise required for near-maximal effort (85 percent or more of the maximal predicted heart rate), particularly those receiving beta-adrenergic blockers, those in whom fatigue, leg cramps, or dyspnea develops, and those with musculoskeletal symptoms. ST segment changes have low specificity in patients taking digitalis and those with left ventricular hypertrophy and repolarization abnormalities. ST segment changes cannot be interpreted when patients have left bundle branch block, Wolff-Parkinson-White syndrome, or an artificial pacemaker. In these subsets of patients, noninvasive *imaging* with exercise or pharmacological stress testing or diagnostic coronary angiography may be indicated.

INFLUENCE OF ANTIANGINAL THERAPY.

Antianginal pharmacological therapy reduces the sensitivity of exercise testing as a screening tool. Beta blockade increases the exercise duration and suppresses, diminishes, or delays the appearance of ST segment depression and thus obscures the diagnostic interpretation of exercise testing.[78] [83] Because beta blockade reduces the sensitivity of the test, a negative exercise test in patients receiving antianginal drugs does not exclude significant and possibly life-threatening myocardial ischemia.

Therefore, if the purpose of the exercise test is to diagnose ischemia, it should be performed, if possible, in the absence of antianginal medications. However, the advisability of withholding medications in an individual patient before exercise testing is a matter of judgment. Two or 3 days are required for patients receiving long-acting beta blockers. Unless the patient has severe angina, sublingual nitroglycerin for 1 or 2 days is likely to be sufficient to control symptoms if other therapy is withdrawn. For long-acting nitrates, calcium antagonists, and short-acting beta blockers, discontinuing use of the medications the day before testing usually suffices. If the purpose of the exercise test is to identify safe levels of daily activity or the extent of functional disability, the test should be performed while the patient is taking the usual medications.

Nuclear Cardiology Techniques (see Chap. 9)

STRESS MYOCARDIAL PERFUSION IMAGING.

Exercise perfusion imaging incorporates all the components of the exercise ECG with images of myocardial blood flow by using either thallium-201 or a technetium-99m (^{99m}Tc)-based perfusion tracer. [84] The radionuclide is injected intravenously at peak exercise or at a symptom-limited endpoint, such as angina pectoris or dyspnea; the patient is encouraged to exercise for another 30 to 45 seconds to ensure that initial myocardial uptake of the tracer reflects the perfusion pattern at peak stress. Acquisition of the stress images is performed several minutes later when the patient is at rest. A separate image acquisition is obtained at rest to compare the stress images with images of resting perfusion. Reversible perfusion defects between stress and rest indicate exercise-induced ischemia, whereas irreversible defects usually represent regions of myocardial fibrosis (see Fig. 9-12) . In the case of thallium-201, a stress-redistribution protocol is usually followed, in which rest images are obtained 3 to 4 hours after the stress test without a second injection of tracer. More rapid washout rates of thallium from normal versus ischemic myocardium produce apparent filling in of perfusion defects caused by reversible ischemia, a process termed "redistribution." With ^{99m}Tc perfusion tracers, which do not redistribute appreciably, two separate injections are required, one during stress and the other at rest. This technique can be accomplished by using either 1-day or 2-day imaging protocols.[84] [85]

A hybrid dual-isotope protocol has evolved in which both thallium and a ^{99m}Tc tracer are used. [86] [87] The lower-energy thallium is injected at rest and imaged, followed immediately by stress imaging with the higher-energy, ^{99m}Tc-labeled compound. This latter procedure can be accomplished within 90 minutes and has the advantage of requiring a much shorter time for completing the study than with standard thallium stress-redistribution or ^{99m}Tc stress-rest imaging protocols.

Exercise perfusion imaging with simultaneous ECG is

superior to exercise ECG alone in detecting CAD, in identifying multivessel disease, in localizing diseased vessels, and in determining the magnitude of ischemic and infarcted myocardium (see also Chap. 13) . The published results of exercise single-proton emission computed tomographic (SPECT) imaging involving more than 5200 patients with angiographic documentation of the presence or absence of CAD yield an average sensitivity and specificity of 89 and 76 percent, respectively (range, 71 to 98 percent and 43 to 92 percent, respectively).[35] Referral bias may account, in part, for the low specificity of many studies, and the few studies that adjusted for referral bias report a specificity higher than 90 percent.[35] The results with thallium-201 are comparable to those obtained with ^{99m}Tc-sestamibi or ^{99m}Tc-tetrofosmin, so these agents can in general be used interchangeably for the diagnosis of CAD.

Perfusion imaging is valuable for detecting myocardial viability in patients with regional or global left ventricular dysfunction, with or without Q waves[88] [89] (see Chap. 13) . Stress perfusion imaging also provides important information in regard to prognosis.[74] [75] [90] [91]

Stress myocardial scintigraphy is particularly helpful in the diagnosis of CAD in patients with abnormal resting ECGs and those in whom ST segment responses cannot be interpreted accurately, such as patients with left ventricular hypertrophy and repolarization abnormalities, those with left bundle branch block, and those receiving digitalis. Because stress myocardial perfusion imaging is a relatively expensive test (three to four times the cost of an exercise ECG), certain issues should be considered: (1) a regular exercise ECG should always be considered first in patients with chest pain and a normal resting ECG for screening and detection of CAD[35] [78] ; (2) stress myocardial perfusion scintigraphy should *not* be used as a screening test in patients in whom the prevalence of CAD is low because the majority of abnormal tests will be false-positive results; (3) stress perfusion imaging is more sensitive in detecting CAD, especially in patients with single-vessel CAD, than exercise ECG[35] [84] ; (4) perfusion imaging is more accurate in patients with resting ECG abnormalities and those receiving digitalis; and (5) perfusion imaging is more accurate in localizing and quantifying regions of myocardial ischemia, which is of particular importance in patients who previously had revascularization, and in determining the extent of viable myocardium in patients with left ventricular dysfunction.

PHARMACOLOGICAL NUCLEAR STRESS TESTING.

For patients unable to exercise adequately, especially the elderly and patients with peripheral vascular disease, pulmonary disease, arthritis, or a previous stroke,

pharmacological vasodilator stress with dipyridamole or adenosine may be used.[84] [92] [93] In most nuclear cardiology laboratories, such patients account for approximately 40 percent of those referred for perfusion imaging. A comparison of 2000 patients undergoing adenosine and dipyridamole pharmacological stress testing demonstrated that adverse effects occurred less often with dipyridamole than with adenosine.[94] However, the effects of adenosine are very brief, whereas those associated with dipyridamole are more difficult to manage and necessitate longer monitoring time, as well as fairly frequent intravenous administration of aminophylline for reversal. In patients with asthma, dobutamine stress perfusion imaging is a useful and safe alternative to vasodilator stress imaging,[95] but adenosine and dipyridamole are more sensitive for detecting CAD because they produce a greater increase in coronary blood flow.[96] Although the diagnostic accuracy of pharmacological vasodilator stress perfusion imaging is comparable to that achieved with exercise perfusion imaging,[97] treadmill testing is preferred for patients who are capable of exercising because the exercise component of the test provides additional diagnostic information about ST segment changes, effort tolerance and symptomatic response, and heart rate and blood pressure response.

EXERCISE RADIONUCLIDE ANGIOGRAPHY.

The use of radionuclide angiography for detecting and estimating prognosis in CAD has been supplanted largely by exercise echocardiography. Although radionuclide angiography is more accurate than echocardiography in measuring the ejection fraction, failure to augment the ejection fraction with exercise is a nonspecific finding that is influenced by age, gender, and the presence of hypertension. The addition of radionuclide ventriculography in patients with a normal ECG at rest adds little to the diagnostic information provided by clinical and other exercise variables.[84] Echocardiography provides a more accurate assessment of exercise-induced changes in regional wall motion and systolic wall thickening, which are more specific markers of reversible ischemia than are changes in ejection fraction.

Stress Echocardiography (see also Chap. 7)

EXERCISE ECHOCARDIOGRAPHY.

Two-dimensional echocardiography is useful in the evaluation of patients with chronic CAD because it can assess global and regional left ventricular function in the absence and presence of ischemia, as well as detect left ventricular hypertrophy and associated valve disease. Echocardiography is relatively inexpensive and safe. Stress echocardiography, in which imaging is performed at rest and immediately after exercise, allows the detection of regional ischemia by identifying new areas of wall motion disorders. Adequate images can be obtained in more than 85 percent of patients, and the test is highly reproducible. The inability to image at peak exercise is only a minor disadvantage because most wall motion abnormalities do not normalize immediately upon cessation of exercise.

Detection of ischemic myocardium has been enhanced with the development of systems that allow simultaneous side-by-side display of rest and postexercise images. Numerous studies have shown that exercise echocardiography can detect the presence of CAD with an accuracy that is similar to that of stress myocardial perfusion imaging and superior to exercise ECG alone.[35] [98] [99] Stress echocardiography is also valuable in localizing and quantifying ischemic myocardium. Published results in more than 3200 patients with angiographic confirmation of the presence or absence of CAD yield an average sensitivity of 85 percent and specificity of 86 percent.[35] As with perfusion imaging, stress echocardiography also provides important prognostic information in patients with known or suspected CAD.[35]

Indications for stress echocardiography are similar to those discussed above for stress myocardial perfusion imaging. Stress echocardiography is an excellent alternative to nuclear cardiology procedures. Although less expensive than nuclear perfusion imaging, stress echocardiography is more expensive and less available than exercise ECG, and a regular exercise ECG should always be considered first for screening and detection of CAD in patients with a normal resting ECG who are capable of performing treadmill exercise.[35] [78]

PHARMACOLOGICAL STRESS ECHOCARDIOGRAPHY.

In patients unable to exercise, those unable to achieve adequate heart rates with exercise, and those in whom the quality of the echocardiographic images during or immediately after exercise is poor, alternative approaches are available. The most well studied and clinically available method is dobutamine stress echocardiography,[35] [100] [101] in which constant echocardiographic imaging is performed during the infusion of dobutamine beginning at 5 to 10 mug/kg/min with graded increases to a maximum of 40 to 45 mug/kg/min. Dobutamine increases both the heart rate and contractility and produces diagnostic changes in regional wall motion and systolic wall thickening as ischemia develops. Low-dose dobutamine infusion (5 to 10 mug/kg/min) is also valuable for assessing contractile reserve in regions with hypokinetic or akinetic wall motion at rest, as a means of identifying viable myocardium that may improve in function after revascularization[89] [102] [103] (see Chap. 13) . Atropine increases the accuracy of dobutamine stress echocardiography in patients with inadequate heart rate responses,[104] especially

those taking beta blockers and those in whom second-degree heart block develops at higher atrial rates. Dobutamine stress imaging achieves diagnostic accuracy comparable to that of exercise echocardiography,[35] [100] [101] but as with myocardial perfusion imaging, exercise stress imaging is preferable in patients capable of performing adequate exercise. An exception to this general policy is a patient with left ventricular dysfunction who is undergoing dobutamine echocardiography to assess myocardial viability. Dobutamine stimulation is safe, especially if the test is terminated at the onset of the first ischemic regional wall motion abnormalities.

An alternative form of pharmacological stress echocardiography is the use of high-dose dipyridamole infusion[105] or adenosine infusion, but exercise and dobutamine stress appear to have greater sensitivity than vasodilator stress in detecting CAD[100] [101] and are superior in assessing the extent of CAD.[100] All forms of stress echocardiography have similar high specificity because a new wall motion abnormality in a patient with normal resting left ventricular function is a highly specific finding for reversible ischemia.

Transesophageal dobutamine stress echocardiography has been shown to be feasible, safe, and accurate for the detection of myocardial ischemia. Although not a readily available technique for large numbers of patients, it may allow extension of dobutamine stress testing to patients with inadequate transthoracic echocardiographic imaging.[106]

STRESS ECHOCARDIOGRAPHY VERSUS STRESS NUCLEAR PERFUSION IMAGING (see also Chap. 13) .

The two stress imaging methods in general provide similar accuracy in detecting CAD. In studies in which the same patients were studied with both techniques and with coronary angiography, nuclear myocardial perfusion imaging had slightly greater sensitivity and stress echocardiography had greater specificity.[107] The potential advantage of stress echocardiography in terms of enhanced specificity has also been demonstrated in meta-analyses (which did not account for possible posttest referral bias).[99] Stress echocardiography is also associated with lower cost and easier implementation in the physician's office. The choice of diagnostic test to perform, however, depends on several additional factors, including local expertise and available facilities.

CONTRAST ECHOCARDIOGRAPHY (see also Chap. 7) .

Contrast echocardiography is a rapidly evolving field in noninvasive testing for the diagnosis and assessment of CAD.[108] A major objective is the development of intravenous ultrasonic contrast agents for noninvasive myocardial perfusion imaging. With greater spatial resolution than nuclear perfusion imaging, echocardiography has the potential for evaluating transmural distribution of flow heterogeneity and detecting changes in subendocardial perfusion. Although this goal has not been fully realized with the intravenous administration of ultrasonic contrast agents, early work is promising.[109] An outgrowth of this research is two developments that have improved wall motion assessment during standard stress echocardiography. The first is blood pool opacification with intravenous injection of a contrast agent, which has improved delineation of the left ventricular endocardial surface.[110] The second is the use of harmonic imaging, which can be used even without administration of a contrast agent and, in addition, enhances definition of the endocardial border.[111] Poor visualization of endocardial borders in a sizable subset of patients has been a limitation of stress echocardiography for many years, and these two new developments have significantly improved endocardial border definition, with the potential for enhanced detection of ischemic myocardium.

Clinical Application of Noninvasive Testing

GENDER DIFFERENCES IN THE DIAGNOSIS OF CAD (see also Chap. 58) .

On the basis of earlier studies that indicated a much higher frequency of false-positive stress test results in women than in men, it is generally accepted that ECG stress testing is not as reliable in women. However, the prevalence of CAD among women in the patient populations under study was low, and the lower positive predictive value of exercise ECG in women can be accounted for, in large part, on the basis of Bayesian principles (Table 37-1) .[112] Once men and women are stratified appropriately according to the pretest prevalence of disease, the results of stress testing are similar.[78] [113]

Exercise imaging modalities have greater diagnostic accuracy than exercise ECG in both men and women.[35] [78] Although soft tissue attenuation artifacts, especially those caused by breast tissue, may reduce the specificity of myocardial perfusion imaging in women, these artifacts can usually be identified by experienced observers without a substantial reduction in diagnostic accuracy, and risk assessment by nuclear perfusion imaging is not diminished in women compared with men.[114] In addition, the use of gated SPECT imaging has greatly improved identification of these artifacts by demonstrating that regions with apparently irreversible perfusion defects have normal wall motion, thereby enhancing diagnostic accuracy.[115] Among women without a history of myocardial infarction, exercise echocardiography was superior to exercise ECG in the detection of CAD.[116] [117]

IDENTIFICATION OF PATIENTS AT HIGH RISK.

When applying noninvasive tests to the diagnosis and management of CAD, it is useful to grade the results as "negative"; "indeterminate"; "positive, not high risk"; and "positive, high risk." The criteria for high-risk findings on stress ECG, myocardial perfusion imaging, and stress echocardiography are listed in Table 37-2 .

Regardless of the severity of symptoms, patients with high-risk noninvasive test results have a very high likelihood of CAD and, if they have no obvious contraindications to revascularization, should undergo coronary arteriography. Such patients, even if asymptomatic, are at risk for left main or three-vessel CAD, and many will have impaired left ventricular function. Hence, they are at high risk for experiencing coronary events. The prognosis in these patients may often be improved by coronary bypass surgery. In contrast, patients with clearly negative exercise tests, regardless of symptoms, have an excellent prognosis that cannot usually be improved by revascularization. If they do not have serious symptoms, they generally do not require coronary arteriography.

ASYMPTOMATIC PERSONS.

In asymptomatic persons or in those with chest pain not likely to be angina, the pretest likelihood of CAD is low (<15 percent). In such patients, a negative exercise ECG, for practical purposes, excludes ischemic heart disease. However, if such a patient has an abnormal exercise ST segment response, several alternatives exist. If the ST segment is abnormal but not high risk (<2-mm depression) and the patient demonstrates excellent exercise capacity (i.e., to stage IV of a Bruce protocol or the

TABLE 37-2 -- HIGH-RISK FINDINGS ON NONINVASIVE STRESS TESTING

EXERCISE ELECTROCARDIOGRAPHY
2.0-mm or greater ST segment depression
1.0-mm or greater ST segment depression in stage I
ST segment depression for longer than 5 min during the recovery period
Achievement of a workload of less than 4 METs or a low exercise maximal heart rate
Abnormal blood pressure response
Ventricular tachyarrhythmias
MYOCARDIAL PERFUSION IMAGING
Multiple perfusion defects (total plus reversible defects) in more than one vascular supply region (e.g., defects in coronary supply regions of the left anterior descending and left circumflex vessels)
Large and severe perfusion defects (high semiquantitative defect score)
Increased lung thallium-201 uptake reflecting execise-induced left ventricular dysfunction
Postexercise transient left ventricular cavity dilatation
Left ventricular dysfunction on gated single-photon emission computed tomography
STRESS ECHOCARDIOGRAPHY
Multiple reversible wall motion abnormalities
Severity and extent of these abnormalities (high global wall motion score) Severe reversible cavity dilation
Left ventricular systolic dysfunction at rest

equivalent), the likelihood of left main CAD or multivessel CAD is low, the prognosis is favorable, and the patient may usually be observed without further testing. If, however, such a patient has a high-risk positive exercise ECG, coronary angiography is usually indicated to determine whether left main CAD or severe multivessel disease with left ventricular dysfunction is present. If the patient falls into an intermediate category (a positive but not high-risk exercise test result), a stress imaging study (echocardiography or perfusion scintigraphy) may provide further information. If both studies are abnormal but not high risk, the likelihood of CAD approaches 90 percent.

PATIENTS WITH ATYPICAL ANGINA.

In these patients, the pretest probability of CAD is approximately 50 percent. If two noninvasive tests are abnormal, the likelihood of CAD exceeds 95 percent; if both tests are normal, it falls below 5 percent. When test results are discordant, they should be evaluated in light of the exercise level achieved, the presence of accompanying symptoms, and whether one of the tests is positive with high risk. Thus, for example, a patient who has atypical angina and a normal exercise ECG with multiple large perfusion defects on a stress thallium-201 scintigram at a heart rate of 130 beats/min has a much greater likelihood of having CAD than one who has a normal exercise ECG and a single small perfusion defect without chest pain at a heart rate of 185 beats/min. Although the indications for performing a stress imaging test directly in such a patient without an initial exercise ECG are controversial, such an approach is reasonable if the patient with atypical angina also has multiple cardiovascular risk factors, such as smoking, hypercholesterolemia, or a positive family history of premature CAD.

PATIENTS WITH TYPICAL ANGINA.

In patients with a high pretest likelihood of disease of approximately 90 percent, noninvasive testing is most valuable for estimating the extent and severity of CAD and thereby the prognosis. The development of a high-risk positive stress test points to multivessel disease and a high risk of subsequent coronary events, and unless the patient has contraindications to revascularization, coronary angiography is indicated.

Chest Roentgenogram

The chest roentgenogram is usually within normal limits in patients with chronic stable angina, particularly if they have a normal resting ECG and have not experienced a myocardial infarction. If cardiomegaly is present, it is indicative of severe CAD with previous myocardial infarction, preexisting hypertension, concomitant valvular heart disease, or an associated nonischemic condition such as cardiomyopathy.

ELECTRON BEAM COMPUTED TOMOGRAPHY (see also Figs. 10-40 , 10-41 , and 10-42)

Noninvasive detection of coronary artery calcification has long been possible with fluoroscopy. Such calcific deposits are diagnostic of coronary atherosclerosis.[118] Electron beam cardiac computed tomography (CT) has emerged as a highly sensitive method for detecting coronary calcification and is being used at several centers as a screening technique for CAD. The calcium score is a quantitative index of total coronary artery calcium detected by CT, and this score has been shown to be a good marker of the total coronary atherosclerotic burden.[119] However, the relationship of the coronary calcium score to subsequent cardiac events in asymptomatic persons has not been fully established.[97] [120] Several other uncertainties persist as well, including (1) the value of coronary calcium screening in comparison to multiple risk factor assessment, (2) whether coronary calcium scores add incremental value beyond the standard risk factors, and (3) whether coronary calcium screening is more accurate and cost-effective in asymptomatic persons than are other new methods that assess atherosclerotic burden, such as the ankle-brachial index and ultrasonic carotid intimal-medial thickening.[121] [122]

The *absence* of calcium on CT imaging is predictive of the absence of significant atherosclerotic disease in older persons,[119] but it is possible for young people (men younger than 45 years, women younger than 55) to have obstructive CAD and, hence, a risk for future cardiac events in the absence of detectable calcification or with a low calcium score.[123] Although coronary calcification is a highly sensitive finding in patients who have CAD and the presence of coronary calcification is an accurate marker of coronary atherosclerosis, the specificity of this finding for identifying patients with obstructive CAD is very low.[124] Thus, in patients with known or suspected CAD, exercise testing is preferable to electron beam CT imaging for determining the extent of CAD and the indications for coronary angiography.[124] An analysis by a committee of the AHA on the potential value of electron beam CT and more recent consensus statements of the ACC and AHA[66] [124] concluded that whereas the technique is highly predictive for the presence of atherosclerosis, the degree of atherosclerosis cannot be predicted and the prognostic importance has not been established. Although this modality was considered to have great potential, it was not recommended for routine screening of patients.[66] [124] The results of several ongoing studies will probably provide important information in regard to defining the role of this promising technique in the future.

MAGNETIC RESONANCE IMAGING (see Chap. 10)

Magnetic resonance imaging is emerging as a versatile noninvasive imaging modality with high spatial resolution that will have many applications for patients with CAD. The potential of this technique for detecting regional myocardial ischemia with dobutamine stress[125] and for identifying viable myocardium in patients with left ventricular dysfunction has been demonstrated.[126] Exciting new developments on the horizon include contrast agents for myocardial perfusion imaging and, ultimately, noninvasive magnetic resonance coronary angiography.[127]

CATHETERIZATION, ANGIOGRAPHY, AND CORONARY ARTERIOGRAPHY

The clinical examination and noninvasive techniques described above are extremely valuable in establishing the diagnosis of CAD and are indispensable to an overall assessment of patients with this condition. However, definitive diagnosis of CAD and precise assessment of its anatomical severity and its effects on cardiac performance still require cardiac catheterization, coronary arteriography, and left ventricular angiography[128] (see Chaps. 11 and 12) . Among patients with chronic stable angina pectoris referred for coronary arteriography, approximately 25 percent each have one-, two-, or three-vessel disease (i.e., >70 percent luminal diameter narrowing). Five to 10 percent have obstruction of the left main coronary artery, and in approximately 15 percent no critical obstruction is detectable. Coronary angiographic findings differ between patients with an initial attack of acute myocardial infarction and those with chronic stable angina. Patients with unheralded myocardial infarction have fewer diseased vessels, fewer stenoses and chronic occlusions, and less diffuse disease than do chronic stable angina patients, thus suggesting that the pathophysiological substrate and the propensity for thrombosis differ between these two groups of patients.[129] In patients with chronic angina who have a history of prior infarction, total occlusion of at least one major coronary artery is more common than in those without such a history.

CORONARY ARTERY ECTASIA AND ANEURYSMS.

Patulous, aneurysmal dilatation involving most of the length of a major epicardial coronary artery is present in approximately 1 to 3 percent of patients with obstructive CAD at autopsy or angiography. This angiographic lesion does not appear to affect symptoms, survival, or the incidence of myocardial infarction.[130] [131] Most coronary artery ectasia and/or aneurysms are due to coronary atherosclerosis (50 percent), and the rest are due to congenital anomalies and inflammatory diseases such as Kawasaki disease. Despite the absence of overt obstruction, 70 percent of patients with multivessel fusiform coronary artery ectasia/aneurysms demonstrated evidence of cardiac ischemia based on cardiac lactate levels during ergometry and atrial pacing. Moreover, nitroglycerin was of no benefit.[132]

Coronary ectasia should be distinguished from discrete *coronary artery aneurysms*, which are almost never found in arteries without severe stenosis, are most common in the left anterior descending coronary artery, and are usually associated with extensive CAD.[133] These discrete atherosclerotic coronary artery aneurysms do not appear to rupture, and resection of them is not warranted.

CORONARY COLLATERAL VESSELS (see Fig. 12-29) (Figure Not Available) .

Provided that they are of adequate size, collaterals may protect against myocardial infarction when total occlusion occurs.[134] In patients with abundant collateral vessels, myocardial infarct size is smaller than in patients

without collaterals, and total occlusion of a major epicardial artery may not lead to left ventricular dysfunction.[135] In patients with chronic occlusion of a major coronary artery but without infarction, collateral-dependent myocardial segments show nearly normal baseline blood flow and O_2 consumption but severely limited flow reserve. This finding provides an explanation for the ability of collaterals to protect against resting ischemia but not exercise-induced angina.[136]

MYOCARDIAL BRIDGING.

Bridging of coronary arteries (see Chap. 12) is observed in angiographically normal coronary arteries and ordinarily does not constitute a hazard. Occasionally, compression of a portion of a coronary artery by a myocardial bridge can be associated with clinical manifestations of myocardial ischemia during strenuous physical activity and may even initiate malignant ventricular arrhythmias.[137]

LEFT VENTRICULAR FUNCTION.

Ventricular relaxation, as reflected in the early diastolic ventricular filling rate, may be impaired at rest in patients with chronic CAD. Diastolic filling becomes even more abnormal (slowed) during exercise, when ischemia intensifies. In patients with chronic stable angina, the frequency of elevated left ventricular end-diastolic pressure and reduced cardiac output at rest, generally attributed to abnormal left ventricular dynamics, increases with the number of vessels exhibiting critical narrowing and with the number of prior infarctions.[138] However, a great deal of overlap is seen in individual patients, so the severity of coronary arterial disease cannot be predicted from these measurements. Left ventricular end-diastolic pressure may be elevated secondary to reduced ventricular compliance, left ventricular systolic failure, or a combination of these two processes.[139] Both impaired systolic and impaired diastolic function may occur as a consequence of acute, reversible ischemia and/or chronic scar formation. In many patients with normal hemodynamics in the resting state, abnormalities of left ventricular function can be elicited by dynamic or isometric exercise. Elevations of left ventricular end-diastolic pressure usually occur *before* angina develops and before ECG ST segment depression occurs.

Left ventricular function can be assessed by means of biplane contrast ventriculography (see Chap. 15) . Global abnormalities of left ventricular function are reflected by elevations in left ventricular end-diastolic and end-systolic volume and depression of the ejection fraction. These changes are, however, quite nonspecific and can occur in many forms of heart disease. Abnormalities of *regional* wall motion (hypokinesis, akinesia, or dyskinesia) are more characteristic of CAD because the latter is usually regional in distribution. Also, hyperkinetic contraction of nonischemic myocardium, detected by left ventriculography, may compensate for hypokinetic or akinetic ischemic or necrotic myocardium, thereby maintaining normal or nearly normal global left ventricular function despite marked depression of function in one region of the ventricle.

Left ventricular function (global or regional) may be normal at rest in patients with chronic CAD without previous myocardial infarction but may become abnormal during or after stress. Abnormalities of left ventricular function detected angiographically may signify irreversible damage, i.e., prior infarction, or they may indicate acute ischemia or chronic hypoperfusion sufficient to maintain viability, but not contractility of the myocardium, i.e., "myocardial hibernation" [140] [141] [142] (see Chaps. 13 , 14 , and 34 and also Chap. 37 , p. 1316). Reversibility of this form of left ventricular dysfunction in patients with CAD and chronic stable angina is reflected by improved contraction assessed angiographically after an inotropic stimulus (postextrasystolic potentiation or the infusion of a sympathomimetic amine[102] [103] [143]) or by long-term improvement after myocardial revascularization.

In addition to demonstrating areas of asynergy, left ventriculography may also show mitral valve prolapse, which occurs in approximately 20 percent of patients with obstructive CAD[144] and probably results from impaired contractility of the ventricular myocardium and papillary muscles. Mitral regurgitation secondary to left ventricular dilatation may be observed in patients with chronic stable angina and ischemic cardiomyopathy.

CORONARY BLOOD FLOW AND MYOCARDIAL METABOLISM.

Cardiac catheterization can also document abnormal myocardial metabolism in patients with chronic stable angina. With a catheter in the coronary sinus, arterial and coronary venous lactate measurements are obtained at rest and after suitable stress, such as the infusion of isoproterenol[145] or pacing-induced tachycardia. [146] Because lactate is a byproduct of anaerobic glycolysis, its production by the heart and subsequent appearance in coronary sinus blood is a reliable sign of myocardial

ischemia. When combined with coronary arteriography, this technique may be helpful in localizing significant coronary obstructive lesions and myocardial ischemia.[147]

Studies of coronary flow reserve (maximum flow divided by resting flow) and endothelial function are frequently abnormal in patients with CAD and chronic stable angina. They are discussed in Chapter 34 .

MEDICAL MANAGEMENT

Comprehensive management of chronic stable angina has five aspects: (1) identification and treatment of associated diseases that can precipitate or worsen angina; (2) reduction of coronary risk factors; (3) application of general and nonpharmacological methods, with particular attention toward adjustments in life style; (4) pharmacological management; and (5) revascularization by percutaneous catheter-based techniques or by coronary bypass surgery. Although discussed individually, all five of these approaches must be considered, often simultaneously, in each patient. Among the medical therapies, only two (aspirin and effective lipid lowering) have been convincingly shown to reduce mortality and morbidity in patients with chronic stable angina and preserved left ventricular function. A single large multicenter randomized trial has provided strong evidence that angiotensin-converting enzyme (ACE) inhibitors may also reduce mortality and ischemic events in such patients. Other therapies such as nitrates, beta blockers, and calcium antagonists have been shown to improve symptomatology and exercise performance, but their effect, if any, on survival has not been demonstrated.

In stable patients with left ventricular dysfunction following myocardial infarction, data consistently indicate that ACE inhibitors and beta blockers reduce both mortality and the risk of repeat infarction, and these agents are recommended in such patients, along with aspirin and lipid-lowering drugs.

TREATMENT OF ASSOCIATED DISEASES.

Several common medical conditions that can increase myocardial O_2 demand or reduce O_2 delivery may contribute to the onset of new angina pectoris or the exacerbation of previously stable angina. These conditions include anemia, marked weight gain, occult thyrotoxicosis, fever, infections, and tachycardia. Drugs such as amphetamines and isoproterenol all increase myocardial O_2 demand, as do other agents that stimulate the sympathetic nervous system. Cocaine, which can cause acute coronary spasm and myocardial infarction, is discussed in Chapter 48 . Congestive heart failure, by causing cardiac dilatation, mitral regurgitation, or tachyarrhythmias, including sinus tachycardia, can increase myocardial O_2 need, along with an increase in the frequency and severity of angina. Identification and treatment of these conditions are critical to the management of chronic stable angina.

Reduction of Coronary Risk Factors

HYPERTENSION (see also Chaps. 28 and 29) .

Epidemiological links between increased blood pressure and CAD severity and mortality are well established.[62] [148] [149] Hypertension predisposes to vascular injury, accelerates the development of atherosclerosis, increases myocardial O_2 demand, and intensifies ischemia in patients with preexisting obstructive coronary vascular disease. Although the relationship between hypertension and CAD is linear,[150] left ventricular hypertrophy is a stronger predictor of myocardial infarction and CAD death than is the actual degree of

increase in blood pressure.[151] A meta-analysis of clinical trials of treatment of mild to moderate hypertension showed a statistically significant 16 percent reduction in CAD events and mortality in patients receiving antihypertensive therapy.[152] This treatment effect is nearly twice as great in older than younger persons.[153] It is logical to extend these observations on the benefits of antihypertensive therapy on mortality and ischemic events to patients with established CAD. Therefore, blood pressure control is an essential aspect of the management of patients with chronic stable angina.

Dietary and Life Style Modification.

Alterations in life style and dietary treatment should be initiated in conjunction with antihypertensive therapy. Attainment of ideal body weight is particularly important in obese patients, in whom weight reduction, in addition to assisting in blood pressure control, greatly aids in control of lipid abnormalities, diabetes, and hyperinsulinemia, which otherwise increase the risk of ischemic events.[62] [154] More directly, weight loss increases the threshold for and may even abolish angina pectoris.

CIGARETTE SMOKING.

Smoking remains one of the most powerful risk factors for the development of CAD in all age groups (see Chap. 31) , and cardiac events occur at a younger age in smokers, especially among women.[61] [150] [155] Postmortem data suggest that smoking predisposes to atherosclerotic plaque erosion and acute thrombosis,[156] which is consistent with the known effects of smoking on fibrinogen and platelet adhesion.[157] Smoking also aggravates other CAD risk factors. Among patients with angiographically documented CAD, cigarette smokers have a higher 5-year mortality and relative risk of infarction or sudden death than do those who have stopped smoking,[158] and smoking cessation lessens the risk of adverse coronary events in patients with established CAD.[159] In patients who have undergone coronary bypass surgery, cessation of cigarette smoking has been shown to decrease both morbidity and mortality substantially.[160] [161]

Cigarette smoking may be responsible for aggravating angina pectoris other than through the progression of atherosclerosis. It may increase myocardial O_2 demand and reduce coronary blood flow by means of an alpha-adrenergically mediated increase in coronary artery tone and thereby cause acute ischemia.[162] Cigarette smoking also appears to reduce the efficacy of antianginal drugs.[163] Smoking cessation is one of the most effective and certainly the least expensive approach to the prevention of disease progression in native vessels and bypass grafts. Techniques for smoking cessation are discussed in Chapter 39 .

Passive cigarette smoking, air pollution, and ascent to high altitude all lower the threshold for angina, and their avoidance represents an important aspect of therapy.

MANAGEMENT OF DYSLIPIDEMIA (see also Chap. 33) .

The beneficial effect of reducing serum cholesterol in patients with hypercholesterolemia is incontrovertible. Cholesterol lowering by diet and drugs has been shown to reduce the incidence of clinical CAD events in primary prevention trials. Among men with moderate hypercholesterolemia in the West of Scotland trial, treatment with pravastatin significantly reduced the incidence of myocardial infarction and death without adversely affecting the risk of death from noncardiovascular causes.[164] Similarly, lovastatin reduced fatal and nonfatal coronary events in the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS), which enrolled both men and women with average levels of total cholesterol and LDL cholesterol for age and gender and low levels of HDL cholesterol.[165] In view of the low-risk characteristics of the population, no significant effect of therapy on mortality alone was observed.

In patients with established CAD, clinical trials have demonstrated a significant reduction in disease progression and subsequent cardiovascular events in patients with a wide range of serum cholesterol and LDL cholesterol levels who are treated with 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins).[166] [167] [168] [169] [170] [171] Angiographic trials of cholesterol lowering in patients with chronic CAD, many of whom had chronic stable angina, have shown that the effects on coronary obstruction are modest whereas the reduction in cardiovascular events is quite impressive. Several studies have shown that statins significantly improve endothelium-mediated responses in the coronary and systemic arteries of patients with hypercholesterolemia or known atherosclerosis.[172] [173] [174] In addition, pravastatin has been shown to reduce circulating levels of C-reactive protein[175] and decrease thrombogenicity [176] ; these effects do not appear to correlate well with the change in serum LDL cholesterol and suggest antiatherothrombotic properties of this and possibly other statin agents.[175] [176] [177] These findings may explain the improvement in blood flow,[47] [178] the reduction in inducible myocardial ischemia, [179] and the disproportionate reduction in coronary events in patients treated with statins despite very small degrees of anatomical regression of atherosclerotic stenoses.

Results from the three secondary prevention trials of patients with a history of angina, unstable angina, or previous myocardial infarction provide convincing evidence that effective lipid-lowering therapy significantly improves overall survival and reduces cardiovascular mortality in patients with coronary heart disease[168] [170] [171] (see Chap. 33) . These effects have been demonstrated in both men and women and in the elderly[180] [181] [182] and provide a cost-effective approach to the management of large numbers of patients with chronic CAD.[183] [184]

The National Cholesterol Education Program Guidelines advocate cholesterol-lowering therapy for all patients with coronary heart disease or extracardiac

atherosclerosis to LDL levels below 100 mg/dl, and these guidelines have been adopted by the AHA and ACC.[35]

Low HDL Cholesterol.

Patients with low levels of HDL cholesterol represent a subgroup with considerable risk for future coronary events.[61] [185] Low HDL levels are often associated with obesity, hypertriglyceridemia, and insulin resistance[61] [186] [187] and often signify the presence of small lipoprotein remnants and small dense LDL particles that are thought to be particularly atherogenic.[188] Therapy has focused on diet and exercise, as well as LDL cholesterol reduction in patients with a concomitant increase in LDL cholesterol.[61] [189] The Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) Study Group has demonstrated the efficacy of gemfibrozil treatment in patients with low HDL cholesterol (
40 mg/dl) without elevations in LDL cholesterol (
140 mg/dl) or triglycerides (mean, 160 mg/dl).[190] Gemfibrozil resulted in a 6 percent increase in HDL cholesterol and a 31 percent decrease in triglycerides, and these changes were associated with a 24 percent reduction in death, nonfatal myocardial infarction, and stroke (p=0.006). The 22 percent reduction in cardiac death achieved only borderline statistical significance (p=0.07).

DYSLIPIDEMIA AFTER MYOCARDIAL REVASCULARIZATION.

In patients who have undergone coronary artery bypass surgery (CABG), elevation of LDL cholesterol is a risk factor for the development of saphenous vein graft occlusive disease, as well as progression of atherosclerosis in the native coronary arteries.[191] [192] In the Post Coronary Artery Bypass Graft Clinical Trial, patients randomly assigned to receive treatment with lovastatin and the addition of cholestyramine as necessary to achieve an LDL cholesterol level less than 100 mg/dl had a 31% reduction in saphenous vein occlusive disease at a mean of 4.3 years in comparison to patients randomly assigned to receive placebo.[191] This effect was observed in both men and women and in both young and old patients.[193] In patients with low HDL cholesterol after bypass surgery, similar benefits have been obtained with gemfibrozil.[194] Lipid-lowering therapy reduces mortality and acute coronary

events in patients who have undergone either surgical or percutaneous revascularization,[195] and therapy for dyslipidemia should be given to these patients, as to all patients with chronic CAD. However, lipid-lowering strategies do not have an effect on restenosis at the site of angioplasty.[196]

ESTROGEN REPLACEMENT (see also Chaps. 32 and 58) .

Male gender and, in women, the postmenopausal state are risk factors for the development and progression of CAD. Epidemiological studies have shown that the favorable cardiovascular risk profile in premenopausal women changes after menopause--the levels of total cholesterol, LDL cholesterol, apolipoprotein B, and triglycerides all increase and HDL cholesterol levels decrease slightly or are unchanged.[197] Several long-term studies have identified reduced HDL cholesterol and increased triglyceride levels as powerful predictors of CAD risk among postmenopausal women,[198] and several large cross-sectional studies[199] and a randomized trial[200] have indicated that hormone replacement therapy with estrogens, alone or in combination with medroxyprogesterone acetate, has a favorable effect on the cardiovascular risk factor lipid profile. These changes are similar to, but less pronounced than, those achieved with therapy with statin agents.[201]

The potential beneficial effect of estrogen replacement therapy is probably not limited to altering the lipid profile favorably. Estrogens have multiple complex and interrelated beneficial effects on vascular structure and function,[202] [203] including immediate, short-term, and long-term effects. The principal short-term pharmacological effect is vasodilatation mediated directly via stimulation of estrogen receptors and indirectly through elaboration of nitric oxide (NO). The long-term effects, mediated via genetic signaling, include a reduction in vascular inflammation and injury, delay in lipid accumulation and LDL oxidation, enhanced function of the vascular endothelium to promote vasodilatation and reduce thrombosis, and reduction in vascular smooth muscle proliferation.

A large data base derived from observational studies suggests an important protective effect of hormone replacement therapy for postmenopausal women, with a 30 to 50 percent reduction in overall mortality from cardiovascular disease.[204] [205] Most of these studies evaluated the effects of estrogen alone, primarily in healthy women. Several randomized primary and secondary prevention trials investigating hormone replacement therapy are under way. The only completed randomized trial to date is the Heart and Estrogen/Progestin Replacement Study (HERS),[206] which randomly assigned postmenopausal women (mean age, 68 years) with established CAD to receive conjugated estrogen plus medroxyprogesterone or placebo, with a follow-up period of 4 years. No difference was seen in cumulative cardiac mortality or total cardiovascular events between the two groups despite a greater decrease in LDL cholesterol and increase in HDL cholesterol in the treatment group. This result has generated considerable discussion and controversy about the efficacy or lack of efficacy as well as the safety of hormone replacement therapy. Most endpoints took place in the first year, when more events occurred in the group randomly assigned to receive hormone therapy. This finding raises the possibility that the potential long-term beneficial antiatherogenic efficacy of therapy is offset by a short-term risk, perhaps related to increased thrombogenicity. This limitation is supported by the finding of greater venous thrombosis in the first year in the treatment group in HERS[206] and other patients who have received hormone replacement therapy.[207] Because of the specific progestin used in HERS, the question has also been raised about a less favorable reduction in lipids than might have occurred with estrogen alone.

In light of the HERS results, the case for estrogen replacement therapy as secondary prevention of CAD is now less strong. The other ongoing secondary prevention trials will help clarify this issue. The HERS findings may not be representative of the effects of estrogen or estrogen-progestin replacement when used as primary prevention in younger women, and this point will also be clarified by current and future trials. While awaiting these results and in view of the increased risk of estrogen alone and estrogen-progesterone combinations on the development of breast cancer and the increased risk of "unopposed estrogen" on uterine cancer, it is *not* advised that hormone replacement therapy be *commenced* in women with CAD. However, such therapy may be continued in women who are already receiving it, once CAD is discovered.

ANTIOXIDANTS (see also Chap. 32)

Oxidized LDL particles are strongly linked to the pathophysiology of atherogenesis, and descriptive, prospective cohort, and case-control studies suggest that a high dietary intake of antioxidant vitamins (A, C, and beta-carotene) and flavonoids (polyphenolic antioxidants), naturally present in vegetables, fruits, tea, and wine, is associated with a decrease in coronary heart disease events.[208]

RANDOMIZED TRIALS.

All three primary prevention trials, each involving between 18,000 and 29,000 subjects monitored from 4 to 12 years, failed to demonstrate a positive effect of beta-carotene on major cardiac events.[209] [210] [211] The single trial that also studied vitamin E showed no cardiovascular benefit but rather an increased risk of death from hemorrhagic stroke in subjects receiving vitamin E.[209] The Cambridge Heart Antioxidant Study (CHAOS) investigators studied 2002 patients with angiographic evidence of CAD who were randomly assigned to receive alpha-tocopherol, 400 and 800 mg daily, versus placebo.[212] During the brief follow-up period (mean, 510 days), patients receiving alpha-tocopherol had a 77 percent reduction in myocardial infarction and a 47 percent reduction in all cardiovascular events. No effect on cardiac mortality was demonstrated. Similar, but less impressive results were obtained in a secondary analysis of 1862 patients with previous myocardial infarction in the Alpha-Tocopherol and Beta-Carotene (ATBC) study, in which vitamin E treatment was associated with a 38 percent reduction in recurrent myocardial infarction.[213] In a third nonrandomized study, analysis of patients who had undergone previous coronary bypass surgery indicated less angiographic progression of CAD in subjects with a supplementary vitamin E intake of 100 IU/d or more than in those with lower intake.[213A] However, the largest trial to date with the longest duration of study has shown no benefit of vitamin E supplementation. The Heart Outcomes Prevention Evaluation (HOPE) investigators randomly assigned more than 9200 patients with known atherosclerotic vascular disease or diabetes and another CAD risk factor to receive vitamin E or placebo and demonstrated no effect of vitamin E supplementation on cardiovascular death, myocardial infarction, or stroke over the course of 5 years.[214]

Taken together, current data bases indicate that beta-carotene, vitamin C, and vitamin E have little cardiovascular benefit and do not support the case for antioxidant vitamin supplementation to reduce cardiovascular events. The use of vitamin E supplementation must be balanced against the potential for increased risk of bleeding, especially in patients who are taking aspirin. Unless new clinical trials in this area provide more positive information, *there is no basis for recommending antioxidant vitamins to patients with chronic CAD*.[215] [216]

However, another possible role for antioxidant therapy is in prevention of restenosis after percutaneous coronary intervention. Two studies have demonstrated that probucol (a lipid-lowering agent with potent additional antioxidant properties) significantly reduces restenosis when administered 1 month before and continued for 6 months after the procedure.[217] [218]

EXERCISE (see also Chap. 39)

The conditioning effect of exercise on skeletal muscles allows a greater workload at any level of total-body O_2 consumption. By decreasing the heart rate at any level of exertion, a higher cardiac output can be achieved at any level of myocardial O_2 consumption. The combination of these two effects of exercise conditioning permits patients with chronic stable angina to increase physical performance substantially following institution of a continuing exercise program.[219]

Most of the information about the physiological effects of exercise and their effect on prognosis in patients with CAD comes from studies on patients entered into cardiac rehabilitation programs,[219] [220] many of whom previously sustained a myocardial infarction. Less information is available on the benefits of exercise in patients with chronic stable CAD, but nine small randomized studies with a total of 980 patients have consistently demonstrated improved effort tolerance, O_2 consumption, and quality of life in patients undergoing exercise training.[35] Six studies have shown a consistent reduction in indexes of myocardial ischemia during the course of conditioning,[35] [221] [222] and a seventh study has demonstrated a striking and direct relationship between the intensity of exercise and favorable changes in the morphology of obstructive lesions on angiography.[223] The question of

whether exercise accelerates the development of collateral vessels in patients with chronic CAD remains unsettled.

Exercise is safe if begun under supervision,[219] and if survivors of myocardial infarction can be used as a yardstick, it is probably cost-effective.[224] The psychological benefits of exercise are difficult to evaluate. However, a single nonrandomized study demonstrated significant improvement in well-being scores and positive effect scores, as well as a reduction in disability scores, in patients in a structured exercise program.[225] In addition, exercise conditioning programs may be quite helpful in increasing the self-confidence of patients with chronic CAD (as they are in patients recovering from acute myocardial infarction). Patients who are involved in exercise programs are also more likely to be health conscious, to pay attention to diet and weight, and to discontinue cigarette smoking. Thus, in addition to a conditioning effect on skeletal and cardiac muscle, regular dynamic exercise provides the patient with a feeling of well-being, an important consideration in the management of any chronic disease.

For all the aforementioned reasons, patients should be urged to participate in regular exercise programs--usually walking (see below)--in conjunction with their drug therapy.[35]

ASPIRIN (see also Chaps. 32 and 62) .

A meta-analysis of 140,000 patients in 300 studies confirmed the prophylactic benefit of aspirin in both men and women with angina pectoris, previous myocardial infarction or stroke, and after bypass surgery.[226] In a Swedish trial of both men and women with chronic stable angina, 75 mg daily of aspirin in conjunction with the beta blocker sotalol caused a 34 percent reduction in acute myocardial infarction and sudden death.[227] In a smaller study confined to men with chronic stable angina but without a history of myocardial infarction, 325 mg of aspirin on alternate days reduced the risk of myocardial infarction during 5 years of follow-up by 87 percent.[228] Therefore, 75 to 325 mg of aspirin daily is advisable in patients with chronic stable angina but without contraindications to this drug.[229]

Two other orally acting drugs that block platelet aggregation are the thienopyridine derivatives ticlopidine and clopidogrel,[230] and they may be substituted for aspirin in patients with aspirin hypersensitivity or those who cannot tolerate this drug (see Chap. 36) .

In addition to its antithrombotic effects, aspirin may be beneficial in reducing cardiovascular events in patients with chronic CAD via its antiinflammatory effects, properties not shared by ticlopidine or clopidogrel. Aspirin reduces the risk of subsequent myocardial infarction in healthy men with increased levels of C-reactive protein,[63] and in patients with established CAD and inducible myocardial ischemia, aspirin reduces circulating levels of C-reactive protein, macrophage colony-stimulating factor, and interleukin-6.[231] Aspirin also improves endothelial function in patients with atherosclerosis through a mechanism that may involve blockade of cyclooxygenase-dependent release of endothelium-derived constricting factors.[232]

Although warfarin has proved beneficial in postinfarct patients, no data support the use of chronic anticoagulation in patients with stable angina. However, a single large randomized trial in patients with risk factors for atherosclerosis but without symptoms of angina has shown that low doses of warfarin (achieving a mean international normalized ratio [INR] of 1.47) combined with aspirin decrease the risk of coronary death and myocardial infarction when used for primary prevention in high-risk groups.[233] Any benefit of this combination must be balanced against the potential for increased bleeding, which was also noted in this study.

INTERACTION WITH ACE INHIBITORS.

With the increasing use of ACE inhibitors in patients with cardiovascular disease, concern has arisen about a possible adverse interaction between aspirin and these drugs. Aspirin has the potential to inhibit prostaglandin-mediated pathways of ACE inhibition, and evidence of such antagonism has been demonstrated in patients with hypertension and heart failure.[234] [235] In the Second Cooperative New Scandinavian Enalapril Survival Study (CONSENSUS II) of survival after myocardial infarction, evidence for such an interaction was observed.[234] Patients taking aspirin had less benefit of enalapril on survival than did those not taking aspirin, and the enalapril-aspirin interaction term was a significant predictor of mortality (p=0.047). Such an effect has not been reported in patients with chronic stable CAD, and evidence demonstrating no such effect was reported by the Bezafibrate Infarction Prevention Trial investigators.[236] Among 1247 patients with established CAD treated with ACE inhibitors, 618 (50 percent) were also treated with aspirin. Five-year mortality was significantly lower among patients taking ACE inhibitors and aspirin than those taking ACE inhibitors alone (19 vs. 27 percent, p0.001). The beneficial effect of aspirin was even more marked in patients with symptomatic heart failure. These data are supported by findings of the HOPE Study investigators, who reported no difference in the cardiovascular benefits of ramipril in patients with or without concomitant aspirin therapy (Fig. 37-2) .[214] Thus, current evidence supports aspirin therapy for all patients with CAD, including those taking ACE inhibitors. Ongoing clinical trials in this area will provide additional information.

BETA BLOCKERS.

The value of beta blockers in reducing death and recurrent myocardial infarction in patients who have experienced a myocardial infarction is well established[237] [238] (see Chap. 35) , as is their usefulness in the treatment of angina (see p. 1290). Whether these drugs are also of value in preventing infarction and sudden death in patients with chronic stable angina is uncertain. However, there is no reason to assume that the favorable effects of beta blockers on ischemia and perhaps on arrhythmias should not apply to patients with chronic stable angina pectoris. Therefore, it is sensible to use these drugs when angina, hypertension, or both are present in patients with chronic CAD and when these drugs are well tolerated.

ANGIOTENSIN CONVERTING-ENZYME (ACE) INHIBITORS.

Studies of the effect of ACE inhibitors on the severity of angina pectoris and ischemia are limited by small sample size and brief duration of therapy. ACE inhibitors are not indicated for the treatment of angina. However, ACE inhibitors appear to have important benefits in reducing the risk of future ischemic events.

An unexpected and far-reaching finding from recent randomized trials of ACE inhibitors in postinfarct and other patients with ischemic and nonischemic causes of left ventricular dysfunction is the striking reduction in incidence of subsequent ischemic events such as myocardial infarction, unstable angina, and the need for coronary revascularization procedures.[239] [240] [241] [242] [243] Data from four trials including approximately 11,000 patients demonstrated a statistically significant risk reduction in myocardial infarction of 21 percent and in subsequent unstable angina of 15 percent.[243] The potentially beneficial effects of ACE inhibitors include a reduction in left ventricular hypertrophy, vascular hypertrophy, progression of atherosclerosis, plaque rupture, and thrombosis, in addition to a potentially favorable influence on myocardial O_2 supply/demand relationships and cardiac hemodynamics and a reduction in sympathetic activity.[243] Recent evidence also indicates that ACE inhibitors enhance coronary endothelial vasomotor function in patients with CAD,[244] which may contribute to enhanced myocardial blood flow during increases in myocardial demand.[245]

These beneficial effects of ACE inhibitors on vascular structure and function should in theory extend beyond patients with left ventricular dysfunction to a much wider range of patients with CAD, including those with normal left ventricular function. This is the subject of several ongoing randomized multicenter trials. The first of these trials to be completed has provided strong evidence supporting the therapeutic benefit of ACE inhibitors. The HOPE Study enrolled 9297 patients with atherosclerotic vascular disease or diabetes and at least one other CAD risk factor and randomly assigned them to receive ramipril (10 mg daily) or placebo; the mean follow-up was 5 years (Fig. 37-2) .[214] Eighty percent of patients had CAD, only 12 percent of whom had a myocardial infarction within 1 year after enrollment. No patient had heart failure symptoms on study entry, and echocardiograms (available for 5183 patients) demonstrated preserved left ventricular function (ejection fraction

40%) in 92 percent of patients. Ramipril significantly decreased the risk of the primary composite endpoint of cardiovascular death, myocardial infarction, and stroke from 17.7 to 14.1 percent (relative risk reduction of

Figure 37-2 Kaplan-Meier estimates of the composite outcome of myocardial infarction, stroke, or death from cardiovascular causes in the ramipril group and the placebo group (Heart Outcomes Prevention Evaluation [HOPE] Study). The relative risk of the composite outcome in the ramipril group versus the placebo group was 0.78 (95 percent confidence interval, 0.70 to 0.86). *(From Yusuf S, Dagenais G, Pogue J, et al: Vitamin E supplementation and cardiovascular events in high-risk patients. The Heart Outcomes Prevention Evaluation Study Investigators. N Engl J Med 342:154, 2000. By permission of the Massachusetts Medical Society.)*

22 percent, *p*0.001). The relative decreases in cardiovascular death, myocardial infarction, and stroke were 25, 20, and 31 percent, respectively. Ramipril also reduced secondary endpoints such as myocardial revascularization and all-cause mortality. The results were similar when examined in patient subsets defined by age, sex, known CAD, hypertension, diabetes, left ventricular function, or previous myocardial infarction. Beneficial effects were also similar in patients who were or were not taking aspirin.

The results of the HOPE Study have wide-reaching implications and suggest that all patients with stable CAD should be receiving ACE inhibitor therapy. Although these results were obtained from a large and well-designed and well-executed clinical trial, they represent the results of only a single trial. Definite recommendations should await the findings of two other ongoing randomized trials: Prevention of Events with Angiotensin-Converting Enzyme Inhibition (PEACE) and the European trial on reduction of cardiac events with perindopril in stable coronary artery disease (EUROPA) in patients with stable CAD, which will also clarify whether the benefits in patients with preserved left ventricular function are unique to ramipril (Fig. 37-2) .

Counseling and Changes in Life Style

The psychosocial issues faced by a patient with chronic stable angina for the first time are similar to, although usually less intense than, those experienced by a patient with an acute myocardial infarction. Many patients have an unrealistically gloomy perception of their prognosis; they should be offered a realistic appraisal, together with an understandable explanation of the pertinent clinical features of the disease.

An important aspect of the physician's role is to counsel patients in the kinds of work they can do and in their leisure activities, eating habits, vacation plans, and the like.[246] Certain changes in life style may be helpful, such as modifying strenuous activities if they constantly and repeatedly produce angina. These changes may be minor in many instances. For example, golfing could be modified to include the use of a golf cart instead of walking. A history of CAD and stable angina is not inconsistent with the ability to continue to perform vigorous exertion, which is important not only in regard to recreational activities and life style but also for patients in whom some physical exertion is required in their employment. However, isometric activities such as weight lifting[247] and other activities such as snow shoveling, which involves an energy expenditure between 60 and 65 percent of peak oxygen consumption,[248] and cross-country or downhill skiing[249] are undesirable. In addition, some activities expose the individual to the detrimental effects of cold on the O_2 demand/supply relationship,[50] [250] and these activities should also be avoided if possible.

Thoughtful counseling, which may include supervised exercise sessions simulating the particular activity in question, can play a vital role in maintaining a productive and enjoyable life style in patients with chronic stable angina. Many activities, such as shopping or climbing stairs, need not be discontinued by patients with chronic angina; often, it is necessary merely to perform them more slowly or pause intermittently for brief periods of rest. Patients with chronic stable angina should avoid excessive fatigue and exhaustion. Although it is desirable to minimize the number of bouts of angina, an occasional episode is not to be feared. Indeed, unless patients occasionally reach their angina threshold, they may not appreciate the extent of their exercise capacity. Most patients with chronic stable angina should not be treated as invalids. Often, the propensity for angina actually declines with time, perhaps as a result of the development of collaterals and/or because of training effects.

Eliminating or reducing the factors that precipitate anginal episodes is of obvious importance. Patients learn their usual threshold by trial and error. Because many anginal episodes are precipitated by increases in mechanical activity of the heart (because of increases in myocardial O_2 requirements), patients should avoid *sudden* bursts of activity, particularly after long periods of rest or after meals and in cold weather. Both chronic angina and unstable angina exhibit a circadian rhythm characterized by a lower angina threshold shortly after arising.[251] Therefore, morning activities such as showering, shaving, and dressing should be done at a slower pace and, if necessary, with the use of prophylactic nitroglycerin. The stress of sexual intercourse is approximately equal to that of climbing one flight of stairs at a normal pace or any activity that induces a heart rate of approximately 120 beats/min. With proper precautions, i.e., commencing more than 2 hours postprandially and taking an additional dose of a short-acting beta blocker 1 hour before and nitroglycerin 15 minutes before, the majority of patients with chronic stable angina are able to continue satisfactory sexual activity.

Just as exercise has a role in the management of CAD, so too rest has a role, especially when angina has become frequent or severe. Marked restriction in activity or even complete bed rest, in addition to drug therapy, may occasionally

be necessary to control symptoms. In less critical situations, merely reducing the amount of time spent working or increasing the rest periods has a beneficial effect. For example, a long lunch break that includes a short nap may be beneficial. It may be helpful for the patient to use a face mask or scarf to cover the mouth or nose in cold weather. A hot, humid environment may also precipitate angina, and air conditioning may be a necessity rather than a luxury for patients with chronic angina. Large meals can have a similar effect if they are followed by exertion. An effort should be made to minimize emotional outbursts because they too increase myocardial O_2 requirements and sometimes induce coronary vasoconstriction. Occasionally, antianxiety drugs and sedatives or relaxation techniques using biofeedback mechanisms may be helpful. Hostility is an adverse risk factor in CAD.

PHARMACOLOGICAL MANAGEMENT

Nitrates

MECHANISM OF ACTION.

Even though the clinical effectiveness of amyl nitrite in angina pectoris was first described in 1867 by Brunton, organic nitrates are still the drugs most commonly used in the treatment of patients with this condition. The action of these agents is to relax vascular smooth muscle.[252] The vasodilator effects of nitrates are evident in both systemic (including coronary) arteries and veins in normal subjects and in patients with ischemic heart disease, but they appear to be predominant in the venous circulation. The venodilator effect reduces ventricular preload,[253] which in turn reduces myocardial wall tension and O_2 requirements. The action of nitrates in reducing both preload and afterload makes them useful in the treatment of heart failure (see Fig. 37-1) , as well as angina pectoris.

Posture is important in evaluating the hemodynamic effects of nitrates. In a supine patient, venous return is normally greater and exercise tolerance and the angina threshold are lower than in the upright position. The hemodynamic and angina-relieving effects of nitrates are most marked when patients are sitting or standing, i.e., when the preload-reducing effects of these drugs are most prominent. By reducing the heart's mechanical activity, volume, and O_2 consumption, nitrates increase exercise capacity in patients with ischemic heart disease, thereby allowing a greater total-body workload to be achieved before the angina threshold is reached.

EFFECTS ON THE CORONARY CIRCULATION

Conductance Vessels (see Table 37-3) .

Quantitative, computer-assisted measurements of coronary arterial diameter have been used to show that nitroglycerin causes dilatation of epicardial stenoses. These stenoses are often eccentric lesions, and nitroglycerin causes relaxation of the smooth muscle in the wall of the coronary artery that is not encompassed by plaque. Even a small increase in a narrowed arterial lumen can produce a significant reduction in resistance to blood flow across obstructed regions[254] (see Fig. 34-21) . Nitrates may also exert a beneficial effect in patients with impaired coronary flow reserve by alleviating the vasoconstriction caused by endothelial dysfunction.[255]

REDISTRIBUTION OF MYOCARDIAL BLOOD FLOW.

Studies in experimental animals with coronary obstruction have shown that nitroglycerin causes redistribution of blood flow from normally perfused to ischemic areas, particularly in the subendocardium.[256] This redistribution may be mediated in part by an increase in collateral blood flow and in part by lowering of ventricular diastolic pressure, thereby reducing subendocardial compression. In patients with chronic stable angina responsive to nitroglycerin, topical nitroglycerin under resting conditions alters myocardial perfusion by preferentially increasing flow to areas of reduced perfusion with little or no change in global myocardial perfusion.[257]

The results of studies of nitroglycerin on coronary blood flow in patients have been conflicting. Some studies have reported increased blood flow after sublingual or intravenous nitroglycerin,[257] but most report no change or reduced flow.[258] However, because myocardial O_2 demand fell, the net effect on O_2 balance became favorable in the latter studies. Intracoronary injection of xenon-133 (as well as retrograde perfusion during coronary bypass surgery) has been used to demonstrate that blood flow in regions of myocardium perfused by stenotic coronary arteries rises after the administration of nitroglycerin when well-developed collaterals supplying those regions are present. In patients with chronic stable angina, topical nitroglycerin alters myocardial perfusion by preferentially increasing flow to areas of reduced perfusion with little or no change in global myocardial perfusion.[257]

The presence of well-developed collaterals may be an important determinant of a good therapeutic response to nitrates.[259] After systemic nitroglycerin, the heart can be paced to higher rates before

TABLE 37-3 -- EFFECTS OF ANTIANGINAL AGENTS ON INDICES OF MYOCARDIAL OXYGEN SUPPLY AND DEMAND*

INDEX	NITRATES	BETA-ADRENOCEPTOR BLOCKERS				CALCIUM ANTAGONISTS

=decrease; 0=little or no definite effect. The number of arrows represents the relative intensity of effect. Symbols in parentheses indicate reflex-mediated effects.

Effect of calcium entry on left ventricular *contractility,* as assessed in the intact animal model. The net effect on *left ventricular performance* is variable since it is influenced by alterations in afterload, reflex cardiac stimulation, and the underlying state of the myocardium.

Figure 37-3 Mechanisms of the effects of nitrates in the generation of nitric oxide (NO) and stimulation of guanylate cyclase cyclic guanosine monophosphate (GMP), which mediates vasodilation. Sulfhydryl (SH) groups are required for the formation of NO and stimulation of guanylate cyclase. Isosorbide dinitrate is metabolized by the liver, whereas the liver is bypassed by mononitrates. GTP=guanosine triphosphate. *(Redrawn from Opie LH: Drugs for the Heart. 4th ed. Philadelphia, WB Saunders, 1995, p 33. By permission.)*

angina occurs. However, such is not the case after intracoronary administration, which implies that the systemic effects of nitrates may predominate in patients with pure effort angina.[258] Nitrates have also been shown to improve ventricular wall motion in patients with CAD, as demonstrated by contrast ventriculography, echocardiography, and radionuclide ventriculography, both at rest and during exercise. They also reduce the extent of myocardial ischemia, as reflected in exercise-thallium tomographic perfusion defect severity.[260]

ANTITHROMBOTIC EFFECTS.

Stimulation of guanylate cyclase by NO results in inhibitory action on platelets in addition to vasodilation. Although the antithrombotic effects of intravenous nitroglycerin have been demonstrated both in patients with unstable angina and in those with chronic stable angina,[261] the clinical significance of these actions is not clear.

CELLULAR MECHANISM OF ACTION.

Nitrates have the ability to cause vasodilation regardless of whether the endothelium is intact. After entering the vascular smooth muscle cell, nitrates are converted to reactive oxygen species, such as nitric oxide (NO) or *S*-nitrosothiols, which activate intracellular guanylate cyclase to produce cyclic guanosine monophosphate,[262] which in turn triggers smooth muscle relaxation and antiplatelet aggregatory effects (Fig. 37-3) . Sulfhydryl (SH) groups are required for both formation of NO and stimulation of guanylate cyclase, and nitroglycerin-induced vasodilation can be enhanced by prior administration of *N*-acetylcysteine, an agent that increases the availability of SH groups.[263] This action of *N*-acetylcysteine potentiates peripheral hemodynamic responses[263] and the coronary vasodilator effect of nitroglycerin[264] and reverses the partial tolerance to the coronary vasodilator effect of nitroglycerin.

Types of Preparations and Routes of Administration (see Table 37-4)

Nitroglycerin administered sublingually remains the drug of choice for the treatment of acute angina episodes and for the prevention of angina. Because sublingual administration avoids first-pass hepatic metabolism, a transient but effective concentration of the drug rapidly appears in the circulation. The half-life of nitroglycerin itself is brief, and it is rapidly converted to two inactive metabolites, both of which are found in the urine. The liver possesses large amounts of hepatic glutathione organic nitrate reductase, the enzyme that breaks down nitroglycerin, but there is also evidence that blood vessels (veins and arteries) may metabolize nitrates directly. Within 30 to 60 minutes, hepatic breakdown has abolished the hemodynamic and clinical effects.

The usual sublingual dose is 0.3 to 0.6 mg, and most patients respond within 5 minutes to one or two 0.3-mg tablets. If symptoms are not relieved by a single dose, additional doses of 0.3 mg may be taken at 5-minute intervals, but no more than 1.2 mg should be used within a 15-minute period. The development of tolerance (see below) is rarely a problem with intermittent use. Sublingual nitroglycerin

TABLE 37-4 -- RECOMMENDED DOSING REGIMENS FOR LONG-TERM NITRATE THERAPY

PREPARATION OF AGENT	DOSE	SCHEDULE
NITROGLYCERIN*		
Ointment	0.5-2 inches	2-3 times daily
Buccal or transmucosal	1-3 mg	3 times daily
Transdermal patch	0.2-0.8 mg/hr	q24hr; remove at bedtime for 12-14 hr
Sublingual tablet	0.3-0.6 mg	As needed up to 3 doses 5 min apart
Spray	1-2 sprays	As needed up to 3 doses 5 min apart
Oral sustained release	2.5-6.5 mg	2-3 times daily
ISOSORBIDE DINITRATE*		
Oral	10-40 mg	2-3 times daily
Oral sustained release	80-120 mg	1-2 times daily (eccentric schedule)
ISOSORBIDE 5-MONONITRATE		
Oral	20 mg	2 times daily (given 7-8 hr apart)
Oral sustained release	30-240 mg	Once daily

*A 10- to 12-hour nitrate-free interval is recommended.

Very limited data available on efficacy.

is especially useful when it is taken prophylactically shortly before undertaking physical activities that are likely to cause angina. When used for this purpose, it may prevent angina for up to 40 minutes.

ADVERSE REACTIONS.

Adverse reactions are common and include headache, flushing, and hypotension. The latter is rarely severe, but in some patients with volume depletion and in an upright posture, nitrate-induced hypotension is accompanied by a paradoxical bradycardia, consistent with a vasovagal or vasodepressor response. This reaction is more common in the elderly, who are less able to tolerate hypovolemia. Administration of nitrates before a meal, particularly in patients with a tendency toward postprandial hypotension, may enhance venous pooling, preload reduction, and the extent of the fall in blood pressure after the meal.[265] In addition, the partial pressure of O_2 in arterial blood may fall after large doses of nitroglycerin because of a ventilation-perfusion imbalance caused by inability of the pulmonary vascular bed to constrict in areas of alveolar hypoxia, thereby leading to perfusion of less hypoxic tissues.[266] Methemoglobinemia is a rare complication of very large doses of nitrates; commonly used doses of nitrates cause small elevations of methemoglobin that are probably not of clinical significance.

PREPARATIONS (see Table 37-4)

Nitroglycerin Tablets.

Nitroglycerin tablets tend to lose their potency, especially if exposed to light, and should thus be kept in dark containers. Other nitrate preparations are available in sublingual, buccal, oral, spray, and ointment forms. An oral nitroglycerin spray that dispenses metered, aerosolized doses of 0.4 mg may be better absorbed than the sublingual form in patients with dry mucosal membranes.[267] It can also be quickly sprayed onto or under the tongue. For prophylaxis, the spray should be used 5 to 10 minutes before angina-provoking activities.

Isosorbide Dinitrate.

This drug is an effective antianginal agent but has low bioavailability after oral administration. It undergoes hepatic metabolism rapidly, and marked variation in plasma concentrations may be seen after oral administration. It has two metabolites (one has potent vasodilator action) that are cleared less rapidly than the parent drug and excreted unchanged in the urine. It is available in tablets for sublingual use, in chewable form, in tablets for oral use, and in sustained-release capsules.

Partial or complete nitrate tolerance (see below) develops with regimens of isosorbide dinitrate when it is administered as 30 mg three or four times daily.[268] A dosage schedule should be adopted that allows a 10- to 12-hour nitrate-free interval. If the drug is administered on a three-times-daily schedule (e.g., at 8 A.M., 1 P.M., and 6 P.M.), the antianginal benefit lasts for approximately 6 hours, and the magnitude of the antianginal benefit decreases with each successive dose.[268]

Isosorbide 5-Mononitrate.

This active metabolite of the dinitrate is completely bioavailable with oral administration because it does not undergo first-pass hepatic metabolism,[269] and it is efficacious in the treatment of chronic stable angina.[270] Plasma levels of isosorbide 5-mononitrate reach their peak between 30 minutes and 2 hours after ingestion, and the drug has a plasma half-life of 4 to 6 hours. A single 20-mg tablet still exhibits activity 8 hours after administration. Tolerance has not been demonstrated with once-a-day or eccentric dosing intervals but does occur with a twice-daily dosing regimen at 12-hour intervals. The only sustained-release preparation of isosorbide 5-mononitrate is Imdur, which is given once daily in a dose of 30 to 240 mg. Presumably, this preparation avoids tolerance by either providing a sufficiently low nitrate level or a duration of activity of 12 hours or less.

Topical Nitroglycerin

Ointment.

Nitroglycerin ointment (15 mg/inch) is efficacious when applied (most commonly to the chest) in strips of 0.5 to 2.0 inches. The delay in onset of action is approximately 30 minutes. Because this form of the drug is effective for 4 to 6 hours, it is particularly useful in patients with severe angina or unstable angina who are confined to bed and chair. Nitroglycerin ointment may also be used prophylactically after retiring by patients with nocturnal angina. Skin permeability increases with increased hydration, and absorption is also enhanced if the paste is covered with plastic whose edges are taped to the skin.

Transdermal Patches.

Application of silicone gel or polymer matrix impregnated with nitroglycerin results in absorption for 24 to 48 hours at a rate determined by various methods of preparation of the patch, including a semipermeable membrane placed between the drug reservoir and the skin (usually 7.5 to 10 mg/12 hr patch, to remove after 12 hrs, and 15 mg for the phasic nitroglycerin patch). The release rate of the patches varies from 2.5 to 15 mg per 24 hours. Relatively low doses (2.5 to 5 mg per 24 hours) may not produce sufficient plasma and tissue concentrations to sustain consistent, effective antianginal effects. Transdermal nitroglycerin therapy has been shown to increase exercise duration and maintain antiischemic effects for 12 hours after patch application throughout 30 days of therapy without significant evidence of nitrate tolerance or rebound phenomena,[271] provided that the patch is not applied for more than 12 out of 24 hours.

NITRATE TOLERANCE

A major problem with the use of nitrates is the development of nitrate tolerance, which has been demonstrated with all forms of nitrate administration delivering continuous, relatively stable blood levels of the drug.[253] [268] [271] [272] Although nitrate tolerance is rapid in onset, renewed responsiveness is easily established after a short nitrate-free interval. The problem of tolerance applies to all nitrate preparations and is particularly important in patients with chronic stable angina pectoris, as opposed to those receiving short-acting courses of nitrates (e.g., unstable angina and myocardial infarction). Nitrate tolerance appears to be limited to the capacitance and resistance vessels and has not been noted in the large conductance vessels, including the epicardial coronary arteries and radial arteries, despite continuous administration of nitroglycerin for 48 hours.[273]

A meta-analysis of randomized clinical trials of nitroglycerin patches suggested that in doses of 5 to 10 mg, exercise duration was improved early after administration but, by 24 hours, the effect of nitroglycerin on exercise performance was attenuated by the development of nitrate tolerance. However, a regimen in which transdermal nitroglycerin was applied for 12 hours and removed for 12 hours improved exercise performance for 8 to 12 hours after application of the patch. After 1 month of such therapy, responsiveness to transdermal nitroglycerin remained virtually unchanged. Therefore, after application of a transdermal nitroglycerin patch, one can expect therapeutic efficacy (improved exercise performance) for 8 to 12 hours. Provided that patients have a substantial nitrate-free interval (10 to 12 hours) every 24-hour period, sustained improvement in exercise performance may be maintained. If a state of tolerance is induced, a nitrate-free interval restores responsiveness. If large intermittent doses of transdermal or oral nitrates are used (equivalent to 20 mg per 24 hours of a transdermal patch), rebound angina may occur during the nitrate-free period.

MECHANISMS (Fig. 37-3) .

Several mechanisms of nitrate tolerance have been proposed,[253] but their relative importance has not been defined.

Depletion of Sulfhydryl Groups.

The most widely accepted and most extensively studied explanation of nitrate tolerance is that intracellular SH co-factors are depleted and that they are a crucial component of the metabolic conversion of nitroglycerin to NO or *S*-nitrosothiols, a conversion necessary for activation of guanylate cyclase.[274]

Neurohormonal Activation.

Nonspecific activation of neurohormonal mechanisms may occur in response to the hypotensive effects of nitrates, with a resultant increase in plasma catecholamines, plasma renin activity, and arginine vasopressin causing sodium retention and weight gain.[275] [276] It has been suggested that ACE inhibitors modify nitrate tolerance by blunting the neurohormonal response to nitrate therapy.[277]

Plasma Volume Expansion.

Plasma volume expansion occurs during continuous nitrate administration,[275] even in the absence of neurohormonally mediated sodium retention. It may be the result of a fluid shift from the extravascular to the intravascular space in response to the vasodilating or hemodynamic actions of nitrates. However, diuretic therapy appears to have no effect on nitrate tolerance in patients with chronic CAD.[278]

Downregulation of Nitrate Receptors.

It has been proposed that high-affinity receptors, which respond to low concentrations of nitrates,

are downregulated during the development of tolerance. The activity of low-affinity receptors is maintained, and these continue to respond but require increasing concentrations of nitrate.[279]

Free Radical Generation.

A novel mechanism that may contribute to nitrate tolerance is the production of superoxide anions and other free radicals by the endothelium.[280] This mechanism is supported by two small clinical studies reporting positive results of antioxidant vitamin supplements in reducing tolerance in patients with chronic CAD.[281] [282] The mechanism of nitrate-induced free radical generation is uncertain but may involve endothelin and angiotensin II.[283]

MANAGEMENT.

The only practical strategy to manage nitrate tolerance is to prevent it by providing a "nitrate-free" interval. The optimal interval is unknown, but with patches or ointment of nitroglycerin or preparations of isosorbide dinitrate or isosorbide 5-mononitrate, a 12-hour off period is recommended.[269] The timing of administration should be adapted to the pattern of symptoms, e.g., whether angina is predominantly exercise related during the day or nocturnal. Moreover, nitroglycerin administered by the sublingual route does not result in tolerance, and even after 2 weeks of therapy, efficacy is not reduced when sublingual nitroglycerin is administered two or three times daily.[284] The use of supplemental antioxidant vitamins to attenuate nitrate tolerance is attractive, but larger-scale studies are needed to confirm the current preliminary findings.

NITRATE WITHDRAWAL.

A common form of nitrate withdrawal (rebound) is observed in patients whose angina is intensified after discontinuation of large doses of long-acting nitrates.[285] In this situation, patients may also have heightened sensitivity to constrictor stimuli.[276] [277] The potential for rebound can be modified by adjusting the dose and timing of administration in addition to the use of other antianginal drugs.

Because of the possibility of nitrate dependence, nitrate therapy should be withdrawn carefully. In persons exposed to industrial doses of nitroglycerin, nitrate tolerance,

nitrate dependence, and withdrawal symptoms may cause serious problems. During the manufacture of dynamite, substantial levels of nitrates are often present in the atmosphere and can be absorbed through the skin and lungs. After an acute response of headache, hypotension, palpitations, and gastrointestinal disturbances, adaptation occurs.[286] Withdrawal from this environment may result in angina unrelated to exertion or emotion. In fact, spontaneous coronary vasospasm and acute myocardial infarction have been documented during a period of withdrawal.

INTERACTION WITH SILDENAFIL.

The combination of nitrates and sildenafil may cause serious, prolonged, and potentially life-threatening hypotension.[287] Nitrate therapy is an absolute contraindication to the use of sildenafil and vice versa. Patients who wish to take sildenafil should be aware of the serious nature of this adverse drug interaction and be warned about taking sildenafil within 24 hours of any nitrate preparation, including short-acting sublingual nitroglycerin tablets.

Beta-Adrenoceptor Blocking Agents

Beta-adrenoceptor blocking drugs (beta blockers) constitute a cornerstone of therapy for angina pectoris. In addition to their antiischemic properties, beta blockers are effective antihypertensives (see Chap. 29) and antiarrhythmics (Chap. 23) . They have also been shown to reduce mortality and reinfarction in patients after myocardial infarction (see Chap. 35) and reduce mortality in patients with heart failure (Chap. 18) . This combination of actions makes them extremely useful in the management of chronic stable angina. A number of studies have shown that beta blockers, in doses that are generally well tolerated, reduce the frequency of anginal episodes and raise the anginal threshold, both when given alone and when added to other antianginal agents.

The salutary action of these drugs (which have a chemical structure resembling that of beta-adrenoceptor agonists) depends on their ability to cause competitive inhibition of the effects of neuronally released and circulating catecholamines on beta adrenoceptors[288] (Table 37-5) . Beta blockade reduces myocardial O_2 requirements, primarily by slowing the heart rate; the slower heart rate in turn increases the fraction of the cardiac cycle occupied by diastole, with a corresponding increase in the time available for coronary perfusion (Fig. 37-4 and Table 37-6 ; see also Table 37-3) . These drugs also reduce exercise-induced increases in blood pressure and limit exercise-induced increases in contractility. Thus, beta blockers reduce myocardial O_2 demand primarily during activity or excitement, when surges of increased sympathetic activity occur.[54] Thus, in the face of impaired myocardial perfusion, the effects of beta blockers on myocardial O_2 demand may critically and favorably alter the imbalance between supply and demand, thereby resulting in the elimination of ischemia.

Beta blockers may reduce blood flow to most organs by means of the combination of unopposed alpha-adrenergic vasoconstriction and $beta_2$ receptor blockade. Complications are relatively minor, but in patients with peripheral vascular disease, the reduction in blood flow to skeletal muscles with the use of nonselective beta blockers may reduce maximal exercise capacity. In patients with preexisting left ventricular dysfunction, beta blockade may increase ventricular volume and thereby enhance O_2 demand.

Characteristics of Different Beta Blockers (see Table 37-6)

SELECTIVITY.

Two major subtypes of beta receptors, designated $beta_1$ and $beta_2$, are present in different proportions in different tissues. $Beta_1$ receptors predominate in the heart, and stimulation of these receptors leads to an increase in heart rate, atrioventricular (AV) conduction, and contractility; release of renin from juxtaglomerular cells in the kidneys; and lipolysis in adipocytes. $Beta_2$ stimulation causes bronchodilation, vasodilation, and glycogenolysis. Nonselective beta-blocking drugs (propranolol, nadolol,

TABLE 37-5 -- PHYSIOLOGICAL ACTIONS OF BETA-ADRENERGIC RECEPTORS

ORGAN	RECEPTOR TYPE	RESPONSE TO STIMULUS
HEART		
SA node	$Beta_1$	Increased heart rate
Atria	$Beta_1$	Increased contractility and conduction velocity
AV node	$Beta_1$	Increased automaticity and conduction velocity
His-Purkinje system	$Beta_1$	Increased automaticity and conduction velocity
Ventricles	$Beta_1$	Decreased automaticity, contractility, and conduction velocity
ARTERIES		
Peripheral	$Beta_2$	Dilatation
Coronary	$Beta_2$	Dilatation
Carotid	$Beta_2$	Dilatation
OTHER	$Beta_1$	Increased insulin release
		Increased liver and muscle glycogenolysis
LUNGS	$Beta_2$	Dilatation of bronchi
UTERUS	$Beta_2$	Smooth muscle relaxation

AV=atrioventricular; SA=sinoatrial.

Figure 37-4 Effects of beta blockade on the ischemic heart. Beta blockade has a beneficial effect on ischemic myocardium unless (1) the preload rises substantially as in left-sided heart failure or (2) vasospastic angina is present, in which case spasm may be promoted in some patients. Note the recent proposal that beta blockade diminishes exercise-induced vasoconstriction. *(Redrawn from Opie LH: Drugs for the Heart. 4th ed. Philadelphia, WB Saunders, 1995. Figure copyright L.H. Opie.)*

penbutolol, pindolol, sotalol, timolol, carteolol) block both $beta_1$ and $beta_2$ receptors, whereas cardioselective beta blockers (acebutolol, atenolol, betaxolol, bisoprolol, esmolol, and metoprolol) block $beta_1$ receptors while having less effect on $beta_2$ receptors. Thus, cardioselective beta blockers reduce myocardial O_2 requirements while tending to not block bronchodilation, vasodilation, or glycogenolysis. However, as the doses of these drugs are increased, this cardioselectivity diminishes. Because cardioselectivity is only relative, the use of cardioselective beta blockers in doses sufficient to control angina may still cause bronchoconstriction in some susceptible patients.

Some beta blockers also cause vasodilatation. Such drugs include labetalol (an alpha-adrenergic blocking agent and $beta_2$ agonist, see Chap. 29) , carvedilol (with alpha- and $beta_1$ -blocking activity), and bucindolol (a nonselective beta blocker that causes direct [non-alpha-adrenergic-mediated] vasodilation).[289]

ANTIARRHYTHMIC ACTIONS (see also Chap. 23) .

Beta blockers have antiarrhythmic properties as a direct effect of their ability to block sympathoadrenal myocardial stimulation, which in certain situations may be arrhythmogenic.[290] Sotalol has combined class II (beta blocking) and class III antiarrhythmic activities; it is an attractive drug when it is desired to treat angina and

suppress ventricular tachyarrhythmias.[291]

MEMBRANE-STABILIZING ACTIVITY.

This property refers to the "quinidine-like" effect of certain beta blockers in reducing the rate of rise in cardiac action potential. The clinical relevance of this effect is negligible (except perhaps in cases of overdose) because it is observed only at concentrations far exceeding therapeutic levels.[292]

INTRINSIC SYMPATHOMIMETIC ACTIVITY.

Beta blockers with intrinsic sympathomimetic activity (ISA), such as acebutolol, carteolol, celiprolol, penbutolol, and pindolol, are partial beta agonists that also produce blockade by shielding beta receptors from more potent beta agonists. Pindolol and acebutolol produce low-grade beta stimulation when sympathetic activity is low (at rest), whereas these partial agonists behave more like conventional beta blockers when sympathetic activity is high. Agents with ISA may not be as effective as those without this property in reducing the heart rate or the frequency, duration, and magnitude of ambulatory ST segment changes or in increasing the duration of exercise in patients with severe angina.[293]

POTENCY.

Potency can be measured by the ability of beta blockers to inhibit the tachycardia produced by isoproterenol. All drugs are considered in reference to propranolol, which is given a value of 1.0 (see Table 37-6) . Timolol and pindolol are the most potent agents, and acebutolol and labetalol are the least potent.

LIPID SOLUBILITY.

The hydrophilicity or lipid solubility of beta blockers is a major determinant of their absorption and metabolism. The lipid-soluble (lipophilic) beta blockers propranolol, metoprolol, and pindolol are readily absorbed from the gastrointestinal tract, are metabolized predominantly by the liver, have a relatively short half-life, and usually require administration twice or more daily to achieve continuing pharmacological effects. The water-soluble (hydrophilic) beta blockers (atenolol, sotalol, and nadolol) are not as readily absorbed from the gastrointestinal tract, are not as extensively metabolized, have relatively long plasma half-lives, and can be administered once daily. If either metoprolol or propranolol is administered intravenously, a much higher concentration reaches the bloodstream, and therefore intravenous dosing has much greater potency than oral dosing.

ALPHA ADRENOCEPTOR BLOCKING ACTIVITY.

The alpha-blocking potency of labetalol is approximately 20 percent of its beta-blocking potency, and it is also one of the weaker beta blockers in comparison with propranolol,[294] although it possesses significant ISA (see Table 37-6) . Labetalol's combined alpha- and beta-blocking effects make it a particularly useful antihypertensive agent (see Chap. 29) , and it is especially so in patients with hypertension and angina. The major side effects of labetalol are postural hypotension and retrograde ejaculation.

OXIDATION PHENOTYPE.

Metoprolol and propranolol are lipid-soluble beta blockers noted for the variability of their pharmacokinetics, drug metabolism, and pharmacodynamics. The oxidative metabolism of metoprolol exhibits the debrisoquin type of genetic polymorphism; poor hydroxylators or metabolizers (up to 10 percent of whites) have significant prolongation of the elimination half-life of the drug in comparison to extensive hydroxylators or metabolizers. Thus, angina might be controlled by a single daily dose of metoprolol in poor metabolizers, whereas extensive metabolizers require the same dose two or three times a day.[295] If a patient exhibits an exaggerated clinical response (e.g., extreme bradycardia) following the administration of metoprolol, propranolol, or other lipid-soluble beta blockers, it may be the result of prolongation of the elimination half-life because of slow oxidative metabolism.

EFFECTS ON SERUM LIPIDS.

Beta blocker therapy (with agents lacking ISA) usually causes no significant changes in total or LDL cholesterol but increases triglycerides and reduces HDL cholesterol.[296] The most commonly studied drug has been propranolol, which can increase plasma triglyceride concentrations by up to 50 percent and reduce HDL cholesterol by approximately 15 percent. Adverse effects on the lipid profile may be more frequent with nonselective than with $beta_1$ -selective blockers. Two drugs possessing ISA--acebutolol and pindolol--do not significantly change total cholesterol, triglycerides, or LDL cholesterol, and pindolol increases serum HDL cholesterol. The effects of these changes in serum lipids by long-term administration of beta blockers must be considered when this therapy is begun or maintained for either hypertension or angina.[296]

DOSAGE.

For optimal results, the dosage of a beta blocker should be carefully adjusted. In the case of propranolol, it is usual to start with a dose of 80 mg daily (20 mg four times a day); other beta blockers should be started

*Determined by the distribution ratio between octanol and water.

Half-life of the active metabolite, diacetolol, is 12 to 15 hours.

Acebutolol is mainly eliminated by the liver, but its major metabolite, diacetolol, is excreted by the kidney.
§Rapid metabolism by esterases in the cytosol of red blood cells.
¶Beta$_1$ selectivity is maintained at lower doses, but beta$_2$ receptors are inhibited at higher doses.

at comparable doses. Twenty-four to 48 hours is required for the drug to achieve an antianginal effect. Efficacy is determined by its effect on the heart rate and symptoms, and when these are unclear, its effect on exercise performance can be evaluated by treadmill exercise testing. The resting heart rate should be reduced to between 50 and 60 beats/min, and an increase of less than 20 beats/min should occur with modest exercise[297] (e.g., climbing one flight of stairs). The usual dosage of propranolol ranges from 80 to 320 mg/day, but some patients require (and tolerate) much higher doses. Therapy needs to be individualized and requires repeated clinical evaluation during the initial period of drug administration.

ADVERSE EFFECTS AND CONTRAINDICATIONS.
