The threshold for activation of $I_{Ca.L}$ i.e., the voltage that the cell must reach to "turn on" the slow inward current, is about -30 to -40 mV. In fast-response-type fibers, $I_{Ca.L}$ is normally activated during phase 0 by the regenerative depolarization caused by the fast sodium current. Current flows through both fast and slow channels during the latter part of the action potential upstroke. However, $I_{Ca.L}$ is much smaller than the peak Na+ current and therefore contributes little to the action potential until the fast Na+ current is inactivated, after completion of phase 0. Thus, $I_{Ca.L}$ affects mainly the plateau of action potentials recorded in atrial and ventricular muscle and His-Purkinje fibers. When the fast Na+ current is inactivated rapidly, such as in frog ventricle, $I_{Ca.L}$ may contribute noticeably to the peak of phase 0. In addition, $I_{Ca.L}$ can be activated and may play a prominent role in partially depolarized cells in which the fast Na+ channels have been inactivated, if conditions are appropriate for slow-channel activation.

At least two types of calcium current exist in cardiac myocytes: a slowly inactivating dihydropyridine-sensitive current $I_{Ca.L}$ and a fast inactivating dihydropyridine-insensitive current ($I_{Ca.T}$). $I_{Ca.L}$ produces repolarization and propagation in sinus and AV nodal cells and contributes to the plateau by triggering calcium release from the sarcoplasmic reticulum in atrial, ventricular, and His-Purkinje cells. Calcium channel blockers block this channel, which is strongly modulated by neurotransmitters. $I_{Ca.T}$ is activated at membrane potentials intermediate between I_{Na} and $I_{Ca.L}$ and probably contributes inward current to the later stages of phase 4 depolarizations in the sinus node and His-Purkinje cells.[51] [52] [53] [54] [55] [56] [57] [58] [59] A functional role of $I_{Ca.T}$ in atrial and ventricular myocytes is less certain. Whether Ca^{2+} influx through open T-type channels provides a sufficient trigger for Ca^{2+} release from the sarcoplasmic reticulum is controversial. The density of T-type Ca^{2+} channels has been found to be increased in myocytes from hearts with experimentally induced hypertrophy,[60] but the role of enhanced T-type channel density under these conditions remains to be determined.

Other significant differences exist between the fast and slow channels (see Table 22-4) . Drugs that elevate cAMP levels such as beta-adrenoceptor agonists, phosphodiesterase inhibitors such as theophylline, and the lipid-soluble derivative of cAMP dibutyryl cAMP, increase $I_{Ca.L}$. Binding of the beta-adrenoceptor agonist to specific sarcolemmal receptors facilitates the dissociation of two subunits of a regulatory protein (G protein, see Chap. 14) , one of which (C_s) activates adenylate cyclase and thus increases intracellular levels of cAMP. The latter binds to a regulatory subunit of a cAMP-dependent protein kinase that promotes phosphorylation of specific phosphorylation sites on the channel protein (see Fig. 22-8 *A*), ultimately resulting

TABLE 22-4 -- CHARACTERISTICS OF FAST AND SLOW INWARD CURRENTS IN CARDIAC TISSUE

CHARACTERISTIC	FAST	SLOW
Primary charge carrier	Na	Ca (Na)
Activation threshold* (mV)	-70 to -55	-55 to -30
Magnitude (muA)	1-30	0.1-3.0
Time constant of		
Activation (msec)	<1	<5
Inactivation (msec)	<1	3-80
Inhibitors	Tetrodotoxin, local anesthetics, sustained depolarization at less than -40 mV	Verapamil, D-600, nifedipine, diltiazem, Mn, Co, Ni, La, Ca^{2+}
Resting membrane potential (mV)	-80 to -95	-40 to -70
Conduction velocity (M/sec)	0.3-3.0	0.01-0.10
Rate of rise (V_{max}) of action potential upstroke (V/sec)	200-1000	1-10
Action potential amplitude (mV)	100-130	35-75
Response to stimulus	All or none	Affected by characteristics of stimulus
Recovery of excitability	Prompt, ends with repolarization	Delayed, outlasts full repolarization
Safety factor for conduction	High	Low
Major current of action potential upstroke in the following:		
SA node	-	+
Atrial myocardium	+	-
AV node (N region)	-	+
His-Purkinje system	+	-
Ventricular myocardium	+	-
Neurotransmitter influence		

Beta-adrenergic	-	
Alpha-adrenergic	-	
Muscarinic, cholinergic	-	In atrium
		In ventricle

AV=atrioventricular; SA=sinoatrial.

*Note that the term "threshold" does not stand for a sharp voltage threshold for channel opening but a threshold for reversal of the net membrane current. This situation occurs when the membrane potential reaches a range where just enough Na^{1} (or Ca^{2+}) channels open to make an inward current that opposes the sum of outward currents carried by K^{+} and other ions.

in enhanced open-state probability of the channel (see Fig. 22-13 *A* and *B*).

Acetylcholine reduces $I_{Ca.L}$ by decreasing adenylate cyclase activity. However, acetylcholine stimulates cyclic guanosine monophosphate (cGMP) accumulation. cGMP has negligible effects on basal $I_{Ca.L}$ but decreases $I_{Ca.L}$ levels that have been elevated by beta-adrenoceptor agonists. This effect is mediated by cAMP hydrolysis via a cGMP-stimulated cyclic nucleotide phosphodiesterase.[23]

DIFFERENCES BETWEEN CHANNELS.

Fast and slow channels can be differentiated on the basis of their pharmacological sensitivity. Drugs that block the slow channel with a *fair* degree of specificity include verapamil, nifedipine, diltiazem, and D-600 (a methoxy derivative of verapamil). Antiarrhythmic agents such as lidocaine, quinidine, procainamide, and disopyramide (see Chap. 23) affect the fast channel and not the slow channel. The puffer fish poison TTX, which is too toxic to be used clinically, blocks the fast channel with considerable specificity (see Table 22-4).

While fast-response action potentials are characteristic of atrial and ventricular muscle and His-Purkinje tissue, slow-response-type action potentials are found in the normal sinus and AV nodes and many kinds of diseased tissue (see Table 22-4) . Normal action potentials recorded from the sinus node and the N region of the AV node have a reduced resting membrane potential, action potential amplitude, overshoot, upstroke, and conduction velocity when compared with action potentials in muscle or Purkinje fibers (see Fig. 22-17) .

Slow-channel blockers, but not TTX, suppress sinus and AV nodal action potentials. The prolonged time for reactivation of $I_{Ca.L}$ probably accounts for the fact that sinus and AV nodal cells remain refractory longer than the time that it takes for full voltage repolarization to occur. Thus, premature stimulation immediately after the membrane potential reaches full repolarization leads to action potentials with reduced amplitudes and upstroke velocities. Therefore, slow conduction and prolonged refractoriness are characteristic features of nodal cells. These cells also have a reduced "safety factor for conduction," which means that the stimulating efficacy of the propagating impulse is low and conduction block occurs easily. Membranes of nodal cells probably do have Na channels that are inactivated by the relatively depolarized range of potentials over which activity takes place. Hyperpolarization exposes a fast TTX-sensitive sodium current in nodal cells.

INWARD CURRENTS.

Thus, I_{Na} and I_{Ca} represent two important inward currents. Another important inward current is I_{f} , also called the *pacemaker current.* [18] [19] [20] [21] [22] This current is activated by hyperpolarization and is carried by Na+ and K+. It generates phase 4 diastolic depolarization in the sinus node. I_{f} activation is the major mechanism by which beta-adrenergic and cholinergic neurotransmitters regulate cardiac rhythm under physiological conditions. Catecholamines increase the probability of channel opening, with no change in single-channel amplitude, and increase the discharge rate, with cholinergic action, in general, having an opposite effect.

A variety of manipulations, including those that block or inactivate I_{Na} (such as administration of TTX or sustained depolarization of the cell membrane with submillimolar concentrations of external Ba^{2+} to block K+ efflux through I_{kl} channels), combined with those that increase $I_{Ca.L}$ (such as administration of catecholamines), can transform a fast-channel-dependent fiber (e.g., a Purkinje fiber) to a slow-channel-dependent fiber. Whether these artificial in vitro alterations have clinical relevance is not known, but it is possible that myocardial ischemia or infarction, for example, can produce this transformation (see Fig. 22-17 *F*).

The electrophysiological changes accompanying *acute* myocardial ischemia may represent a depressed form of a fast response in the center of the ischemic zone and a slow response in the border area. Probable slow-response activity has been shown in myocardium resected from patients undergoing surgery for recurrent ventricular tachyarrhythmias. Whether and how slow responses play a role in the genesis of ventricular arrhythmias in these patients have not been established.

Phase 1--Early Rapid Repolarization

Following phase 0, the membrane repolarizes rapidly and transiently to nearly 0 mV, partly because of inactivation of I_{Na} and concomitant activation of several outward currents:

1. The 4-aminopyridine-sensitive transient outward K+ current, commonly termed I_{to} , turns on rapidly by depolarization and is then rapidly inactivated. Both the density and recovery of I_{to} from inactivation exhibit transmural gradients in the left ventricular free wall, with the density decreasing (Fig. 22-20) and reactivation becoming progressively prolonged from epicardium to endocardium.[61] It is currently unknown whether these nonuniformities in I_{to} recovery reflect transmural differences in channel subunit composition or in posttranslational modification of channel proteins that are thought to underlie I_{to} (Kv4.2 and Kv4.3). Gradients in I_{to} channel density and reactivation kinetics give rise to regional differences in action potential shape, with increasingly slower phase 1 restitution kinetics along the transmural axis. These regional differences might create transmural voltage gradients, specifically at higher rates, thereby increasing dispersion of repolarization, a putative arrhythmogenic factor. Since I_{to} overlaps I_{Na} , changes in I_{to} density or properties may also affect cellular excitability.
2. The 4-aminopyridine-resistant, Ca^{2+} -activated chloride current $I_{Cl.Ca}$ also contributes a significant outward current during phase 1 repolarization. This current is activated by the action potential-evoked intracellular Ca^{2+} transient. Therefore, interventions that augment the amplitude of the Ca^{2+} transient associated with the twitch (such as beta-adrenergic receptor stimulation) also enhance outward $IC_{l.Ca}$. It is not currently known whether human cardiac myocytes express Ca^{2+} -activated chloride channels. Other, time-*in*dependent chloride currents may also play a role in determining the time course of early repolarization, such as the cAMP- or swelling-activated chloride conductances $I_{Cl.cAMP}$ and $I_{Cl.swell}$.
3. A third current contributing to early repolarization is Na+ outward movement through the Na/Ca exchanger operating in reverse mode (see Fig. 22-16) . Overexpression of the exchanger in transgenic mice causes accentuation of the early "notch" in left ventricular myocytes.[61A]

Sometimes, a transient depolarization follows phase 1 repolarization. This "notch" is well defined and separated from phase 2 in Purkinje fibers and left ventricular epicardial and midmyocardial myocytes (see Fig. 22-20) .

Phase 2--Plateau

During the plateau phase, which may last several hundred milliseconds, membrane conductance to all ions falls to rather low values. Thus, less change in current is required near plateau levels than near resting potential levels to produce the same changes in transmembrane potential. The plateau is maintained by the competition between outward current carried by K+ and Cl-- ions and inward current carried by Ca^{2+} moving through open L-type Ca^{2+} channels and Na+ being exchanged for internal Ca^{2+} by the Na/Ca exchanger operating in forward mode. After depolarization, potassium conductance falls to plateau levels as a result of inward rectification,

in spite of the large electrochemical driving force on K+ ions,

Rectification simply means that membrane conductance changes with voltage. Specifically, inward rectification means that K+ channels are open at negative potentials but shut at less negative or positive voltages. Membrane depolarization-induced internal block by intracellular ionized magnesium is thought to underlie inward rectification of cardiac I_{Kl} channels. The mechanism underlying rectification of the rapid component of the delayed rectifier K+ current (I_{Kr}) in cardiac cells is the inactivation that channels rapidly undergo during depolarizing pulses. More I_{Kr} channels enter the inactivated state with stronger depolarizations, thereby causing inward rectification. This fast inactivation mechanism is sensitive to changes in extracellular K+ in the physiological range, with inactivation more accentuated at low extracellular K+ concentrations.[62] Thus, hypokalemia would decrease outward I_{Kr} , thereby prolonging action potential duration.

Outward K+ movement carried by the slow component of the delayed rectifier K+ current (I_{Ks}) also contributes to plateau duration since (1) I_{Ks} density has been shown to be correlated with action potential duration[63] and (2) isolated defects in the KvLQT1 subunit, which in combination with the IsK subunit (minK) reconstitutes the cardiac I_{Ks} current, is associated with abnormally prolonged ventricular repolarization (long QT syndrome type 1; see Chap. 25) . Although I_{Ks} activates slowly in comparison to action potential duration, it also does not or is only very slowly inactivated. Therefore, increases in heart rate can cause this activation to accumulate during successive depolarizations. Thus, cumulative activation can determine the contribution to repolarization of K+ currents that are active during the plateau of the action potential. In conditions of reduced intracellular ATP concentration (hypoxia, ischemia), K+ efflux through activated K_{ATP} channels is enhanced, thereby shortening the plateau phase of the action potential. Other ionic mechanisms that control plateau potential and duration include the kinetics of inactivation of the L-type Ca^{2+} current. Reduced efficiency of intracellular free Ca^{2+} to induce

Figure 22-20 Action potential plots demonstrating differences in the action potential shape of human ventricular myocytes of subepicardial *(A)* and subendocardial *(B)* origin. Subepicardial myocytes present a prominent notch during phase 1 repolarization of the action potential, most likely caused by a larger I_{to} in these cells. The notch is absent in subendocardial cells. The peak plateau potential is higher in subendocardial than in subepicardial myocytes, and the action potential duration tends to be shorter in subepicardial cells. Recording temperature = 35°C; V_m = membrane potential. *C* and *D,* Voltage dependence of the current density of I_{to} . Panels denote voltage-clamp protocol *(top)*, original current recordings *(middle)*, and mean peak current densities (pA/pF) in subepicardial and subendocardial myocytes. Upon depolarization, myocytes from both nonpaced and paced hearts displayed a rapidly activating outward current, which then decayed to nonzero steady-state current levels. As cells were depolarized to more and more positive potentials, the transient outward current became larger and peaked sooner. At each voltage, the peak I_{to} amplitude was quantified as the difference between the maximum and steady-state current at the end of the test pulse and normalized to cell capacitance to obtain the peak I_{to} density. Endocardial cells exhibit a significantly smaller peak I_{to} amplitude than epicardial cells do. (From Nabauer M, Beuckelmann DJ, Uberfuhr P, Steinbeck G: Regional differences in current density and rate-dependent properties of the transient outward current in subepicardial and subendocardial myocytes of human left ventricle. Circulation 93:168-177, 1996. By permission of the American Heart Association, Inc.)

Ca^{2+} -dependent inactivation, such as in myocytes from hypertrophic hearts, may result in delayed repolarization. Steady-state components of both I_{Na} and $I_{Ca.L}$ may shape the plateau phase (see Fig. 22-12) .

One type of the long QT syndrome, LQT3, is caused by a defective sodium channel gene, *SCN5A.* One mutation in patients with LQT3 involves a deletion of three amino acids in the S3-S4 cytoplasmic linker loop (see Fig. 22-19), which is thought to mediate inactivation. The mutant sodium channel is inactivated only incompletely, which results in prolonged depolarizations. Na, K-ATPase generates a net outward current by pumping out three Na+ ions in exchange for 2 K+. Noninactivating chloride currents, such as $I_{Cl.swell}$ and $I_{Cl.cAMP}$, may produce significant outward currents during the plateau phase under certain conditions, thereby significantly shortening action potential duration. A recently discovered, nonselective, swelling-induced cation current has been shown to cause action potential prolongation in myocytes from failing ventricles.[64]

Phase 3--Final Rapid Repolarization

In this portion of the action potential, repolarization proceeds rapidly owing at least in part to two currents: time-dependent inactivation of $I_{Ca.L}$, with a decrease in the intracellular movement of positive charges, and activation of repolarizing K+ currents, including the slow and rapid components of the delayed rectifier K+ current I_{Ks} and I_{Kr} and the inwardly rectifying K+ currents I_{Kl} and $I_{K.Ach}$, with an increase in the movement of positive charges out of the cell. The net membrane current becomes more outward, and the membrane potential shifts to the resting potential. Mutations in the human ether-a-go-go-related gene (*HERG*), which is responsible for I_{Kr} , prolong phase 3 repolarization, thereby predisposing to the development of torsades de pointes. Macrolide antibiotics such as erythromycin, antihistamines such as terfenadine, and antifungal drugs such as ketoconazole all inhibit I_{Kr} and have been implicated in the acquired form of long QT syndrome. A decrease in I_{Kl} activity, as is the case in left ventricular myocytes from

Figure 22-21 Differences in action potential characteristics and whole-cell I_{Kl} activity in left ventricular myocytes isolated from patients with ischemic cardiomyopathy (ICM) and dilated cardiomyopathy (DCM). *A,* Transmembrane action potential recordings. Late phase 3 repolarization was slowed and resting membrane potential was depolarized for DCM when compared with ICM. *B,* Whole-cell I_{Kl} recordings in ventricular myocytes from patients with ICM and DCM. A test pulse (TP) was applied for 300 milliseconds to the potential indicated. The current magnitude for DCM was smaller than that for ICM. *C,* Average I_{Kl} -voltage relationship in ventricular myocytes from patients with ICM and DCM. The whole cell current slope conductance at E_K for DCM was smaller (41 pS) than that for ICM (81 pS). (From Koumi S, Backer CL, Arentzen CE: Molecular and cellular cardiology: Characterization of inwardly rectifying K+ channel in human cardiac myocytes: Alterations in channel behavior in myocytes isolated from patients with idiopathic dilated cardiomyopathy. Circulation 92:164-174, 1995. By permission of the American Heart Association, Inc.)

patients with dilated cardiomyopathy,[65] causes action potential prolongation via slowing of phase 3 repolarization and resting membrane depolarization (Fig. 22-21) .

Phase 4--Diastolic Depolarization (see also p. 680)

Under normal conditions, the membrane potential of atrial and ventricular muscle cells remains steady throughout diastole. I_{Kl} is the current responsible for maintaining the resting potential near the K+ equilibrium potential in atrial, AV nodal, His-Purkinje, and ventricular cells. I_{Kl} is the inward rectifier and shuts off during depolarization. It is absent in sinus nodal and AV nodal cells. In other fibers found in certain parts of the atria, in the muscle of the mitral and tricuspid valves, in His-Purkinje fibers, and in the sinus node and distal portion of the AV node, the resting membrane potential does not remain constant in diastole but gradually depolarizes (see Fig. 22-17 *A*). If a propagating impulse does not depolarize the cell or group of cells, it may reach threshold by itself and produce a spontaneous action potential. The property possessed by spontaneously discharging cells is called *phase 4 diastolic depolarization;* when it leads to initiation of action potentials, automaticity results. The discharge rate of the sinus node normally exceeds the discharge rate of other potentially automatic pacemaker sites and thus maintains dominance of the cardiac rhythm. The discharge rate of the sinus node is more sensitive to the effects of norepinephrine and acetylcholine than is the discharge rate of ventricular muscle cells (Fig. 22-22) . Normal or abnormal automaticity at other sites can cause discharge at rates faster than the sinus nodal discharge rate and can usurp control of the cardiac rhythm for one cycle or many.

Normal Automaticity

The ionic basis of automaticity is explained by a net gain in intracellular positive charges during diastole. Contributing to this change is a voltage-dependent channel activated by potentials negative to -50 to -60 mV, i.e., a hyperpolarization-activated inward pacemaker current. At this potential an inward current called I_f becomes activated and is carried by a channel relatively nonselective for monovalent cations. Hyperpolarization increases its rate of activation, and at -70 mV, the time constant of activation ranges from 2 to 4 seconds. I_f probably underlies the slow diastolic depolarization that occurs between -90 and -60 mV in Purkinje fibers. Although either K+ or Na+ can serve as ion transporters, I_f carries largely Na+ at the more negative intracellular voltages. Extracellular K+ ions activate I_f , but $[Na+]_o$ does not influence its conductance.[18] [19] [20] [21] [22]

AUTOMATICITY IN SINUS NODAL CELLS.

At the reduced membrane potentials of sinus nodal cells, I_f contributes only about 20 percent of the pacemaker current, and automaticity is primarily dependent on I_K and $I_{Ca.L}$. However,

Figure 22-22 Effects of different doses of acetylcholine (ACh) on spontaneous activity in a single sinoatrial node cell. *A-D,* Activity in the control Tyrode solution *(C)* is compared with that in the presence of 0.01, 0.1, 1.0, and 10 muM ACh, respectively. Each concentration of ACh was perfused for about 20 seconds. Note that slowing occurred with 0.01 and 0.1 muM ACh and that the cell ceased to beat at higher concentrations, at which point hyperpolarization of the maximum diastolic depolarization also clearly appeared. (From DiFrancisco D: Current i_f and the neuronal modulation of heart rate. *In* Zipes DP, Jalife J (eds): Cardiac Electrophysiology. From Cell to Bedside. Philadelphia, WB Saunders, 1990.)

sinus nodal cells exhibit significant I_f current if they are hyperpolarized in the range of -50 to -100 mV. Conversely, I_K in normally polarized Purkinje fibers adds little to the pacemaker current. Deactivation of I_K , the presence of an unidentified background inward current, deactivation of $I_{Ca.T}$, and activation of $I_{Ca.L}$ are the essential processes governing the rate of pacemaker depolarization in sinus and AV nodal cells and in Purkinje fibers whose membrane potential has been depolarized to voltages largely positive to the activation range of I_f .[66]

The sinus nodal discharge rate maintains dominance over latent pacemaker sites because it depolarizes more rapidly and because of the mechanism called *overdrive suppression,* a phenomenon characterized by prolonged suppression of normal pacemakers in proportion to the duration and rate of stimulation by a more rapidly discharging pacemaker. The mechanism may relate to active Na extrusion during the more rapid rate that maintains diastolic depolarization of latent pacemakers at a level more negative than the threshold potential for automatic discharge.

The rate of sinus nodal discharge can be varied by several mechanisms in response to autonomic or other influences. The pacemaker locus can shift within or outside the sinus node to cells discharging faster or more slowly. If the pacemaker site remains the same, alterations in the slope of the diastolic depolarization, maximum diastolic potential, or threshold potential can speed or slow the discharge rate (see Fig. 22-22) . For example, if the slope of diastolic depolarization steepens and if the resting membrane potential becomes less negative or the threshold potential more negative (within limits), discharge rate increases. Opposite changes slow the discharge rate.

Acetylcholine activates K+ efflux through acetylcholine-sensitive inward rectifier K+ channels, which are expressed in both sinus nodal and AV nodal cells, thereby shifting the maximum diastolic potential to more negative values. The same mechanism reduces input resistance at diastolic potentials, which means that a greater depolarizing current would be required to achieve "threshold" for firing an action potential.

Passive Membrane Electrical Properties

We have just discussed many of the features of active membrane properties. In addition, it is important to be aware of some features of the passive membrane properties of cardiac myocytes, such as membrane resistance, capacitance, and cable properties.[44] [49]

Although the cardiac cell membrane is resistant to current flow, it also has capacitative properties, which means that it behaves like a battery and can store charges of opposite sign on its two sides: an excess of negative charges inside the membrane balanced by equivalent positive charges outside the membrane. These resistive and capacitative properties cause the membrane to take a certain amount of time to respond to an applied stimulus, rather than responding instantly, because the charges across the capacitative membrane must be altered first. A subthreshold rectangular-shaped current pulse applied to the membrane produces a slowly rising and decaying membrane voltage change rather than a rectangular voltage change. A value called the *time constant of the membrane* reflects this property. The time constant tau is equal to the product of membrane resistance R_m and cell capacitance C_m ,

and is the time taken by the membrane voltage to reach 63 percent of its final value after application of a steady current.

When aligned end to end, cardiac cells, particularly the His-Purkinje system, behave like a long cable in which current flows more easily inside the cell and to the adjacent cell across the gap junction than it does across the cell membrane to the outside. When current is injected at a point, most of it flows along the cell, but some leaks out. Because of this loss of current, the voltage change of a cell at a site distant from the point of applied current is less than the change in membrane voltage where the stimulus was given. A measure of this property of a cable is called the space or length constant lambda, which is the distance along the cable from the point of stimulation that the voltage at steady state is 1/e (37 percent) of its value at the point of introduction.

Restated, lambda describes how far current flows before leaking passively across the surface membrane to a value about one-third its initial value. This distance is normally about 2 mm for Purkinje fibers, 0.5 mm for the sinus node, and 0.8 mm for ventricular muscle fibers. Lambda is about 10 times the length of an individual cell. As an example, if e is about 2.7 and a hyperpolarizing current pulse in a Purkinje fiber produces a membrane voltage change of 15 mV at the site of current injection, the membrane potential change one space constant (2 mm) away would be 15/2.7=5.5 mV.

Since the current loop in any circuit must be closed, current must flow back to its point of origin. Local circuit currents pass across gap junctions between cells and exit across the sarcolemmal membrane to close the loop and complete the circuit. Inward excitation currents in one area (carried by Na+ in most regions) flow intracellularly along the length of the tissue (carried mostly by K+), escape across the membrane, and flow extracellularly in a longitudinal direction. The outside local circuit current is the current recorded in an electrocardiogram (ECG). Through these local circuit currents the transmembrane potential of each cell influences the transmembrane potential of its neighbor because of the passive flow of current from one segment of the fiber to another across the low-resistance gap junctions.

If two cells having different resting membrane potentials are coupled to one another, the resting potentials of each cell will equalize; i.e., one cell will depolarize and the other will hyperpolarize. This "electrotonic" influence of neighboring cells on each other is determined chiefly by the length constant of the fiber and is due to the passive spread of current.

As discussed earlier, the speed of conduction depends on active membrane properties such as the magnitude of the Na+ current, a measure of which is Vmax. Passive membrane properties also contribute to conduction velocity and include excitability threshold, which influences the capability of cells adjacent to the one that has been discharged to reach threshold; the intracellular resistance of the cell, which is determined by the free ions in the cytoplasm; the resistance of the gap junction; and the cross-sectional area of the cell. Direction of propagation is crucial because of the influence of anisotropy, as mentioned earlier.

Loss of Membrane Potential and Arrhythmia Development

Most acquired abnormalities of cardiac muscle or specialized fibers that result in arrhythmias produce a loss of

membrane potential; i.e., maximum diastolic potential becomes less negative. This change should be viewed as a symptom of an underlying abnormality, analogous to fever or jaundice, rather than as a diagnostic category in and of itself because both the ionic changes resulting in cellular depolarization and the more fundamental biochemical or metabolic abnormalities responsible for the ionic alterations are probably multicausal. Cellular depolarization can result from elevated $[K+]_o$ or decreased $[K+]_o$, an increase in membrane permeability to Na+ (P_{Na} increases), or a decrease in membrane permeability to K+ (P_K decreases). Reference to Equation 4 (see p 670) illustrates that these changes alone or in combination make V_r less negative.

Normal cells perfused by an abnormal milieu (e.g., hyperkalemia), abnormal cells perfused by a normal milieu (e.g., healed myocardial infarction), or abnormal cells perfused by an abnormal milieu (e.g., acute myocardial ischemia and infarction) may exist alone or in combination and reduce resting membrane voltage. Each of these changes can have one or more biochemical or metabolic causes. For example, acute myocardial ischemia results in decreased $[K+]_i$ [67] [68] [69] and increased $[K+]_o$, norepinephrine release, and acidosis that may be related to an increase in intracellular Ca^{2+} and Ca^{2+} induced transient inward currents and accumulation of

amphipathic lipid metabolites and oxygen free radicals. All these changes can contribute to the development of an abnormal electrophysiological environment and arrhythmias during ischemia and reperfusion. Knowledge of these changes may provide insight into therapy that actually reverses basic defects and restores membrane potential or other abnormalities to normal.

Figure 22-23 Rate-dependent conduction from the normal zone into the abnormal zone. When the pacing cycle length in the normal zone was shortened from 1200 to 400 milliseconds (panels *A* to *F*), increasing degrees of entrance block into the abnormal area occurred and progressed from 1:1 conduction at a cycle length of 1200 milliseconds to 4:3 conduction at 1100 milliseconds, 3:2 conduction at 1000 milliseconds, 2:1 conduction at 900 milliseconds, 3:1 conduction at 600 milliseconds, and 4:1 conduction at 400 milliseconds. Pacing the abnormal zone (not shown) resulted in block to the normal zone (unidirectional propagation). Vertical calibration: 50 mV. Horizontal calibration: 4 seconds in *A* and *B* and 2 seconds in *C* to *F*. (From Gilmour RF Jr, Heger JJ, Prystowsky EN, et al: Cellular electrophysiologic abnormalities of diseased human ventricular myocardium. Am J Cardiol 51:137, 1983.)

EFFECTS OF REDUCED RESTING POTENTIAL.

The reduced resting membrane potential alters the depolarization and repolarization phases of the cardiac action potential. For example, partial membrane depolarization causes a decrease in the steady-state availability of fast sodium channels (see Fig. 22-12) , thereby reducing the magnitude of peak I_{Na} during phase 0 of the action potential. The subsequent reduction in V_{max} and action potential amplitude prolongs the conduction time of the propagated impulse, at times to the point of block.

Action potentials with reduced upstroke velocity resulting from partial inactivation of I_{Na} are called depressed fast responses (see Fig. 22-21 *C*). Their contours often resemble and may be difficult to distinguish from slow responses, in which upstrokes are due to $I_{Ca.L}$ (see Fig. 22-19 *F*). Membrane depolarization to levels of -60 to -70 mV may inactivate half the Na+ channels, while depolarization to -50 mV or less may inactivate all the Na+ channels. At membrane potentials positive to -50 mV, $I_{Ca.L}$ can be activated to generate phase 0 if conditions are appropriate. These action potential changes are likely to be heterogeneous, with unequal degrees of Na+ inactivation that create areas with minimally reduced velocity, more severely depressed zones, and areas of complete block. These uneven changes are propitious for the development of arrhythmias (Fig. 22-23) .

In these cells with reduced membrane potential, refractoriness may outlast voltage recovery of the action potential; i.e., the cell may still be refractory or partially refractory after the resting membrane potential returns to its most negative value. Furthermore, if block of the cardiac impulse occurs in a fairly localized area without significant slowing of conduction proximal to the site of block, cells in this proximal zone exhibit short action potentials and refractory periods because unexcited cells distal to the block (still in a polarized state) electrotonically speed recovery in cells proximal to the site of block.

If conduction slows gradually proximal to the site of block, the duration of these action potentials and their refractory periods may be prolonged. Some cells may exhibit abnormal electrophysiological properties even though they have a relatively normal resting membrane potential.

MECHANISMS OF ARRHYTHMOGENESIS (Table 22-5)

The mechanisms responsible for cardiac arrhythmias are generally divided into categories of disorders of impulse formation, disorders of impulse conduction, or combinations of both.[45] [70] [71] [72] [73] It is important to realize, however, that our present diagnostic tools do not permit unequivocal determination of the electrophysiological mechanisms responsible for many clinically occurring arrhythmias or their ionic bases. This is especially true for ventricular arrhythmias. It may be very difficult to separate reentry from automaticity clinically, and often, one is left with a postulate that a particular arrhythmia is "most consistent with" or "best explained by" one or the other electrophysiological mechanism. Some tachyarrhythmias can be started by one mechanism and perpetuated by another. An episode of tachycardia caused by one mechanism can precipitate another episode caused by a different mechanism.[74] For example, an initiating tachycardia or premature complex caused by abnormal automaticity can precipitate an episode of tachycardia sustained by reentry. However, by using the features of entrainment (see below), arrhythmias caused by macro-reentry circuits can be identified.

TABLE 22-5 -- MECHANISMS OF ARRHYTHMOGENESIS

Disorders of Impulse Formation	
Automaticity	
Normal automaticity	
Experimental examples--Normal in vivo or in vitro in sinus node, Purkinje fibers, others	
Clinical examples--Sinus tachycardia or bradycardia inappropriate for the clinical situation, possibly ventricular parasystole	
Abnormal automaticity	
Experimental example--Depolarization-induced automaticity in Purkinje fibers or ventricular muscle	
Clinical example--Possibly accelerated ventricular rhythms after myocardial infarction	
Triggered activity	
Early afterdepolarizations	
Experimental examples--EADs produced by barium, hypoxia, high concentrations of catecholamines, drugs such as sotalol, *N*-acetylprocainamide, cesium	
Clinical examples--Possibly idiopathic and acquired long QT syndromes and associated ventricular arrhythmias	
Delayed afterdepolarizations	
Experimental example--DADs produced in Purkinje fibers by digitalis	
Clinical example--Possibly some digitalis-induced arrhythmias	
Disorders of Impulse Conduction	
Block	
Bidirectional or unidirectional without reentry	
Experimental example--SA, AV, bundle branch, Purkinje-muscle, others	
Clinical example--SA, AV, bundle branch, others	
Unidirectional block with reentry	
Experimental examples--AV node, Purkinje-muscle junction, infarcted myocardium, others	
Clinical examples--Reciprocating tachycardia in WPW syndrome, AV nodal reentry, VT due to bundle branch reentry, others	
Reflection	
Experimental example--Purkinje fiber with area of inexcitability	
Clinical example--Unknown	
Combined Disorders	
Interactions between automatic foci	
Experimental examples--Depolarizing or hyperpolarizing subthreshold stimuli speed or slow automatic discharge rate	
Clinical examples--Modulated parasystole	
Interactions between automaticity and conduction	
Experimental examples--Deceleration-dependent block, overdrive suppression of conduction, entrance and exit block	
Clinical examples--Similar to experimental	

AV=atrioventricular; SA=sinoatrial; WPW=Wolfe-Parkinson-White.

Disorders of Impulse Formation

Disorders in this category are characterized by an inappropriate discharge rate of the normal pacemaker, the sinus node (e.g., sinus rates too fast or too slow for the physiological needs of the patient), or discharge of an ectopic pacemaker that controls atrial or ventricular rhythm. Pacemaker discharge from ectopic sites, often called *latent* or *subsidiary pacemakers,* can occur in fibers located in several parts of the atria, the coronary sinus and pulmonary veins, AV valves, portions of the AV junction, and the His-Purkinje system. Ordinarily kept from reaching the level of threshold potential because of overdrive suppression by the more rapidly firing sinus node or electrotonic depression from contiguous fibers, ectopic pacemaker activity at one of these latent sites can become manifested when the sinus nodal discharge rate slows or block occurs at some level between the sinus node and the ectopic pacemaker site and permits *escape* of the latent pacemaker at the latter's normal discharge rate. A clinical example would be sinus bradycardia to a rate of 45 beats/min that permits an AV junctional escape complex to occur at a rate of 50 beats/min.

Alternatively, the discharge rate of the latent pacemaker can speed up inappropriately and usurp control of cardiac rhythm from the sinus node, which has been discharging at a normal rate. A clinical example would be interruption of normal sinus rhythm by a premature ventricular complex or a burst of ventricular tachycardia. It is important to remember that such disorders of impulse formation can be due to speeding or slowing of a *normal* pacemaker mechanism (e.g., phase 4 diastolic depolarization that is ionically normal for the sinus node or for an ectopic site such as a Purkinje fiber but occurs inappropriately fast or slow) or due to an ionically *abnormal* pacemaker mechanism.

A patient with persistent sinus tachycardia at rest or sinus bradycardia during exertion exhibits inappropriate sinus nodal discharge rates, but the ionic mechanisms responsible for sinus nodal discharge may still be normal, although the kinetics or magnitude of the currents may be altered. Conversely, when a patient experiences ventricular tachycardia during an acute myocardial infarction, ionic mechanisms ordinarily not involved in formation of spontaneous impulses for this fiber type may be operative and generate this tachycardia. For example, although pacemaker activity is not generally found in ordinary working myocardium, the effects of myocardial infarction can perhaps depolarize these cells to membrane potentials at which inactivation of I_K and activation of $I_{Ca.L}$ cause automatic discharge. Because the maximum rate that can be achieved by adrenergic stimulation of normal automaticity is generally less than 200 beats/min, it is likely that episodes of faster tachycardia are not due to enhanced normal automaticity.

ABNORMAL AUTOMATICITY.

Mechanisms responsible for *normal* automaticity were described earlier (see p. 677). *Abnormal* automaticity can arise from cells that have reduced maximum diastolic potentials, often at membrane potentials positive to -50 mV, when I_K and $I_{Ca.L}$ may be operative.

Automaticity at membrane potentials more negative than -70 mV may be due to I_f . When the membrane potential is between -50 and -70 mV, the cell may be quiescent. Electrotonic effects from surrounding normally polarized or more depolarized myocardium will influence the development of automaticity. Abnormal automaticity has been found in Purkinje fibers removed from dogs subjected to myocardial infarction, in rat myocardium damaged by epinephrine, in human atrial samples, and in ventricular myocardial specimens from patients undergoing aneurysmectomy and endocardial resection for recurrent ventricular tachyarrhythmias.

Abnormal automaticity can be produced in normal muscle or Purkinje fibers by appropriate interventions such as current passage that reduces diastolic potential. An automatic discharge rate speeds up with progressive depolarization, while hyperpolarizing pulses slow the spontaneous firing. It is possible that partial depolarization and failure to reach normal maximal diastolic potential can induce automatic discharge in most if not all cardiac fibers. Although this type of spontaneous automatic activity has been found in human atrial and ventricular fibers, its relationship to the genesis of clinical arrhythmias has not been established.

Rhythms resulting from automaticity may be slow atrial, junctional, and ventricular escape rhythms; certain types of atrial tachycardias (such as those produced by digitalis or perhaps those coming from the pulmonary veins); accelerated junctional (nonparoxysmal junctional tachycardia) and idioventricular rhythms; and parasystole (see Chap. 25) .

Triggered Activity

Automaticity is the property of a fiber to initiate an impulse *spontaneously,* without need for prior stimulation, so that electrical quiescence does not occur. *Triggered activity* is initiated by afterdepolarizations, which are depolarizing oscillations in membrane voltage induced by one or more

Figure 22-24 Early afterdepolarizations (EADs). EADs occur spontaneously in an isolated canine cardiac Purkinje fiber when exposed to a reduced extracellular potassium concentration. Note that spontaneous phase 4 diastolic depolarization is present. In the initial two action potentials, a series of spontaneous depolarizations (EADs) result before the membrane returns to its maximum diastolic potential. Following the second series of EADs, pacing is begun (S) and normal action potentials follow. Horizontal calibration bar = 5 seconds; vertical bar =2 mV. (From Kovacs RJ, Bailey JC, Zipes DP: Mechanisms of cardiac arrhythmias. *In* Parmley WW, Chatterjee K, Cheitlin M, et al (eds): Cardiology. Philadelphia, JB Lippincott, 1989.)

preceding action potentials. Thus, triggered activity is pacemaker activity that results *consequent* to a preceding impulse or series of impulses, without which electrical quiescence occurs (Figs. 22-24 and 22-25) . This triggering activity is not caused by an automatic self-generating mechanism, and the term *triggered automaticity* is therefore contradictory. These depolarizations can occur before (Fig. 22-24) or after (Fig. 22-25) full repolarization of the fiber and are best termed *early afterdepolarizations* [75] [76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] when they arise from a reduced level of membrane potential during phases 2 (type 1) and 3 (type 2) of the cardiac action potential and called *late* or *delayed afterdepolarizations* (DADs) when they occur after completion of repolarization (phase 4), generally at a more negative membrane potential than that from which EADs arise[89] (Table 22-6) . All afterdepolarizations may not reach threshold potential, but if they do, they can trigger another afterdepolarization and thus self-perpetuate.

Early Afterdepolarizations

A variety of interventions, each of which results in an increase in intracellular positivity, can cause EADs.[75] [76] [77] [78] [79] EADs may be responsible for the lengthened repolarization time and ventricular tachyarrhythmias in several clinical situations, such as the acquired and congenital forms of the long QT syndrome.[80] [81] [82] [83] [84] [85] [86] [87] [88] Left ansae subclaviae stimulation (Fig. 22-26) increases the amplitude of cesium-induced EADs in dogs and the prevalence of ventricular tachyarrhythmias more than does right ansae subclaviae stimulation, possibly because of a greater quantitative effect of the left than the right stellate ganglion on the left ventricle.

TABLE 22-6 -- DETERMINANTS OF THE AMPLITUDE OF AFTERDEPOLARIZATIONS

INTERVENTION	EFFECT ON AMPLITUDE OF	
	EADs	DADs
Long cycles (basic and premature)		
Long action potential duration		
Reduced membrane potential		
Na channel blockers	No effect	
Ca channel blockers		
Catecholamines		

=increase amplitude;
=decrease amplitude; DADs=delayed afterdepolarizations; EADs=early afterdepolarizations.

Figure 22-25 Triggered sustained rhythmic activity and delayed afterdepolarizations in diseased human ventricle. *A,* Spontaneous activity triggered by a series of driven action potentials *(indicated by the dots)* at recording site X1. Note the gradual increase in size of the delayed afterdepolarizations *(arrows)* until the afterdepolarizations reach threshold and maintain sustained rhythmic activity after cessation of pacing. The sustained rhythmic activity finally terminates when the last afterdepolarization fails to reach threshold *(arrow)*. *B,* Initiation of triggered activity by intracellular current injection *(indicated by dots beneath the respective action potential recordings)* at sites X1 and X2, which lie along the same trabeculum. Although sites X1 and X2 were only about 4 mm apart, triggered sustained rhythmic activity from one site did not propagate to the other site, thus indicating complete dissociation between these two sites. For current pulses, cycle length = 2000 milliseconds; pulse duration = 10 milliseconds; pulse intensity=200 nA. Vertical calibration: 50 mV; horizontal calibration: 10 seconds (From Gilmour RF Jr, Heger JJ, Prystowsky EN, et al: Cellular electrophysiological abnormalities of diseased human ventricular myocardium. Am J Cardiol 51:137, 1983.)

Figure 22-26 Following cesium administration during left ansae subclaviae stimulation (LAS), early afterdepolarizations increase in amplitude *(arrows)* and culminate in a short run of nonsustained ventricular tachycardia. LVEG = left ventricular electrograms; LVMAP = left ventricular monophasic action potential recording; RVMAP = right ventricular monophasic action potential recording; time lines-1 second. (From Ben-David J, Zipes DP: Differential response to right and left stellate stimulation of early afterdepolarizations and ventricular tachycardia in the dog. Circulation 78:1241, 1988. By permission of the American Heart Association, Inc.)

Patients with the heritable long QT syndrome have either potassium channel defects (LQT1 and LQT2) or sodium channel-linked defects (LQT3) and, consequently, an abnormally prolonged cardiac action potential duration. In patients with the long QT syndrome, T wave morphology is often abnormal, and the QT interval corrected for heart rate (QTc) is prolonged. The genesis of long QT syndrome-associated ventricular tachycardia/fibrillation is uncertain. Experimental observations[90] suggest an important role of transmural heterogeneity of repolarization. Multiple studies in isolated ventricular myocytes or in tissue preparations have demonstrated spatial dispersion of repolarization along the transmural axes of the left and right ventricular free wall (Fig. 22-27) . A prominent spike and dome is apparent in myocytes from epicardium and the M region but not in myocytes from endocardium. Action potential duration-rate relationships are considerably more pronounced in cells isolated from the M region. The ionic basis for electrophysiological distinctions among epicardial, midmyocardial, and endocardial myocytes is a large gradient in both the density- and rate-dependent properties of the transient outward K+ current[91] and a smaller density of the slow component of the delayed rectifier K+ current I_{Ks} in midmyocardial cells than in myocytes of endocardial and epicardial origin.[63]

Marked transmural dispersion of repolarization can create a vulnerable window for the development of reentry. EADs arising from M cells may underlie the premature beat that initiates polymorphic ventricular

Figure 22-27 Comparison of the electrophysiological characteristics of myocytes isolated from the epicardial, midmyocardial (M cell), and endocardial regions of the canine left ventricular free wall. Each panel shows superimposed action potentials recorded at basic cycle lengths of 300 to 8000 milliseconds. An increase in basic cycle length leads to progressive accentuation of the spike-and-dome configuration of the action potential in epicardial and midmyocardial cells. In cells from the M region, but not in those from the epicardial and endocardial regions, deceleration causes remarkable prolongation in action potential duration (APD). Thus, a much steeper APD-rate relationship is observed in myocytes from the M region. (From Liu DW, Antzelevitch C: Characteristics of the delayed rectifier current (I_{Kr} and I_{Ks}) in canine ventricular epicardial, midmyocardial, and endocardial myocytes. Circ Res 76:351, 1995. By permission of the American Heart Association, Inc.)

tachycardia (torsades de pointes; see Fig 22-29) in patients with the long QT syndrome.

Sympathetic stimulation, primarily left, could periodically increase the EAD amplitude to provoke ventricular tachyarrhythmias (Fig. 22-26) .

Figure 22-28 Isoproterenol and elevated external calcium activate a transient inward current in canine left ventricular myocytes in the absence of sodium and potassium. *A,* Whole-cell current recordings in the presence of isoproterenol and 5 mM $CaCl_2$. Spontaneous transient inward currents were recorded at a potential of -80 mV following a short depolarizing pulse to 0 mV. *B,* Inward current transients disappeared when holding potential was made equal to E_{Cl} (-50 mV; see Table 22-3) . (From Zygmunt AC: Intracellular calcium activates a chloride current in canine ventricular myocytes. Am J Physiol 267:H1984-H1995, 1994.)

Figure 22-29 Torsades de pointes. Ventricular tachycardia with varying morphology is characteristic of torsades de pointes. A continuous recording of lead II is shown. (From Zipes DP, Ben-David J: Autonomic neural modulation of cardiac rhythm: 2. Mechanisms and examples. Mod Concepts Cardiovasc Dis 57:47, 1988. By permission of the American Heart Association, Inc.)

Alpha-adrenoceptor stimulation also increases the amplitude of cesium-induced EADs and the prevalence of ventricular tachyarrhythmias, both of which are suppressed by magnesium.

The ionic basis of EADs is unclear but may be via the L-type calcium channel.[75] [76] [79] [89] [92] [93] [94] EADs that arise at voltages close to the plateau (phase 2) appear to result from time- and voltage-dependent reactivation of L-type Ca^{2+} channels. Lengthening the action potential by a variety of ways allows the development of this type of EAD. They may occur preferentially in Purkinje cells and M cells of ventricular myocardium.[77] EADs that arise at voltages negative to the action potential plateau appear to have separable time- and voltage-dependent properties, but the mechanism is uncertain. Short coupling intervals and rapid rates suppress EADs.

In patients with the acquired long QT syndrome and torsades de pointes from drugs such as quinidine, *N*-acetylprocainamide, cisapride, erythromycin,[95] and some class III antiarrhythmic agents, EADs may also be responsible. Such drugs easily elicit EADs experimentally and clinically, while magnesium suppresses them. It is possible that multiple drugs can cause summating effects to provoke EADs and torsades de pointes in patients.[96] Activators of ATP-dependent potassium channels, such as pinacidil and cromakalim, can eliminate EADs.

Delayed Afterdepolarizations

DADs and triggered activity have been demonstrated in Purkinje fibers, specialized atrial fibers and ventricular muscle fibers exposed to digitalis preparations, normal Purkinje fibers exposed to Na-free superfusates from the endocardium of the intact heart, ventricular myocardial cells,[97] and endocardial preparations 1 day after a myocardial infarction. When fibers in the rabbit, canine, simian, and human mitral valves and in the canine tricuspid valve and coronary sinus are superfused with norepinephrine, they exhibit the capacity for sustained triggered rhythmic activity.

Triggered activity caused by DADs has also been noted in diseased human atrial and ventricular fibers (see Fig. 22-25) studied in vitro. Left stellate ganglion stimulation can elicit DADs in canine ventricles. In vivo, atrial and ventricular arrhythmias apparently caused by triggered activity have been reported in the dog and possibly in humans. It is tempting to ascribe certain clinical arrhythmias to DADs, such as some arrhythmias precipitated by digitalis. The accelerated idloventricular rhythm 1 day after experimental canine myocardial infarction may be due to DADs, and some evidence suggests that certain ventricular tachycardias, such as those arising in the right ventricular outflow tract, may be due to DADs,[98] while other data suggest that EADs[99] are responsible.

IONIC BASIS OF DELAYED AFTERDEPOLARIZATIONS.

DADs appear to be caused by a transient inward current (I_{ti}) that is small or absent under normal physiological conditions.

When intracellular Ca^{2+} overload occurs, as is the case during adrenergic stimulation, elevated extracellular Ca^{2+} levels, prolonged action potentials, and rapid repetitive stimulation or after large doses of digitalis, spontaneous release of Ca^{2+} from the sarcoplasmic reticulum can activate Cl-- currents[100] (Fig. 22-28) or the Na/Ca exchanger [48] [48A] and result in transient inward currents and brief membrane depolarizations. Compounds that reduce the sarcoplasmic Ca^{2+} load (L-type Ca^{2+} channel antagonists, beta-adrenergic receptor blocker) or inhibit sarcoplasmic Ca^{2+} release (thapsigargin, ryanodine, cyclopiazonic acid) suppress DADs. Inhibitors of calmodulin kinase eliminated I_{ti} carried by inward $I_{Na/Ca}$ in isolated rabbit ventricular myocytes,[48] thus indicating that activation of this enzyme appears to play an important role in cardiac arrhythmogenesis. In addition, drugs that reduce I_{Na} also reduce $[Na+]_{ti}$, relieve Ca^{2+} overload, and can also abolish DADs.

DADs caused by *digitalis toxicity* (see Chap. 18) behave differently from DADs caused by catecholamines. Catecholamine-induced triggering often slows slightly after initiation, then regularizes, but slows still further prior to termination, without a progressive increase in maximum diastolic potential. A subthreshold DAD often follows termination of triggered activity. Spontaneous termination may be due in part to an increase in the rate of electrogenic sodium extrusion.

Figure 22-30 *Left,* Modulation of pacemaker activity by subthreshold current pulses in diseased human ventricle. *A,* Two recording sites along the same trabeculum in a spontaneously active preparation. Current pulses *(indicated by the dots)* 30 milliseconds in duration were injected through the lower microelectrode at various times. The interval between the spontaneous action potentials is given in milliseconds above each cycle. Injection of a subthreshold current pulse through the lower microelectrode relatively early in the spontaneous cycle (about 680 milliseconds after initiation of the rapid portion of the preceding action potential upstroke) produced a subthreshold depolarization in the upper recording and delayed the next spontaneous discharge by 400 to 1900 milliseconds. This response curve would fall in the first half of the curve indicated in *C.* A current pulse of the same intensity and duration delivered later in the spontaneous cycle (950 milliseconds after the preceding upstroke) accelerated the next discharge by 210 to 1390 milliseconds relative to the previous two action potentials. The response to this current injection falls in the second half of the graph depicted in *C. B,* A stimulus at a precise interval in the cardiac cycle (called the singular point, in this example, 930 milliseconds after the preceding action potential upstroke) abolishes pacemaker activity. (From Gilmour RF Jr, Heger JJ, Prystowsky EN, et al: Cellular electrophysiological abnormalities of diseased human ventricular myocardium. Am J Cardiol 51:137, 1983.) *C,* Phase-response curves from experimental data obtained in canine Purkinje fibers in a manner similar to the human experiment shown in *A* and *B.* Two different runs are shown. Ordinate = percent increase or decrease in spontaneous cycle length of the "parasystolic focus" (control cycle length equals 100 percent); abscissa = percentage of the "parasystolic focus" spontaneous cycle length during which stimulation was performed. The spontaneous cycle length was maximally prolonged (by 26 percent) or shortened (by 20 percent) by subthreshold depolarizations that entered the "parasystolic focus" after approximately 50 and 60 percent of the cycle had elapsed, respectively. Very similar curves can be plotted for patients with parasystole (for example, see Figs. 9 and 10 from Zipes DP: Plenary lecture. Cardiac electrophysiology: Promises and contributions. J Am Coll Cardiol 13:1329, 1989). (*From Jalife J, Moe GK: Effect of electronic potentials on pacemaker activity of canine Purkinje fibers and relation to parasystole. Circ Res 39:801, 1976. By permission of the American Heart Association, Inc.*)

Termination of digitalis-induced triggering is often characterized by speeding of the rate, a decrease in action potential amplitude, and a decrease in membrane potential, possibly because of $[Na^{+}]_1$ or $[Ca^{2+}]_1$, accumulation.

Short coupling intervals or pacing at rates more rapid than the triggered activity rate (overdrive pacing) increases the amplitude and shortens the cycle length of the DAD following cessation of pacing (overdrive acceleration) rather than suppressing and delaying the escape rate of the afterdepolarization, as in normal automatic mechanisms. Premature stimulation exerts a similar effect; the shorter the premature interval, the larger the amplitude and shorter the escape interval of the triggered event.

The clinical implication might be that tachyarrhythmias caused by DAD-triggered activity may not be suppressed easily or, indeed, may be precipitated by rapid rates, either spontaneous (such as a sinus tachycardia) or pacing induced. Finally, because a single premature stimulus can both initiate and terminate triggered activity, differentiation from reentry (see below) becomes quite difficult. The response to overdrive pacing may help separate triggered arrhythmias from reentrant ones.

Parasystole (See also Chap. 25)

Classically, parasystole has been likened to the function of a fixed-rate asynchronously discharging pacemaker: Its timing is not altered by the dominant rhythm, it produces depolarization when the myocardium is excitable, and the intervals between discharges are multiples of a basic interval.[101] Complete *entrance block,* constant or intermittent, insulates and protects the parasystolic focus from surrounding electrical events and accounts for such behavior. Occasionally, the focus may exhibit *exit block,* during which it may fail to depolarize excitable myocardium. In fact, the dominant cardiac rhythm may modulate parasystolic discharge to speed up or slow down its rate. Experimental simulations of parasystole demonstrate that the discharge rate of an isolated, "protected" focus can be modulated by electrotonic interactions with the dominant rhythm across an area of depressed excitability. Brief subthreshold depolarizations induced during the first half of the cardiac cycle of a spontaneously discharging pacemaker will delay the subsequent discharge, while similar depolarizations induced in the second half of the cardiac cycle will accelerate it (Fig. 22-30) .

The ionic basis for these rate changes is not totally established, but it is probable that early depolarizing stimuli reactivate outward potassium currents and retard depolarization while late stimuli contribute depolarizing current that enables the cell to reach threshold more quickly. Early hyperpolarizing subthreshold stimuli accelerate while late hyperpolarizing stimuli retard discharge. Similar examples have been noted in human ventricular tissue, and interactions may be predicted according to the general rules of biological oscillators. Numerous clinical examples have been published to support these experimental observations.

DISORDERS OF IMPULSE CONDUCTION

Conduction delay and block[102] can result in bradyarrhythmias or tachyarrhythmias, the former when the propagating impulse is blocked and is followed by asystole or a slow escape rhythm and the latter when the delay and block produce reentrant excitation (see below). Various factors involving both active and passive membrane properties determine the conduction velocity of an impulse and whether conduction is successful. Among these factors are the stimulating efficacy of the propagating impulse, which is related to the amplitude and rate of rise of phase 0, the excitability of the tissue into which the impulse is conducted, and the geometry of the tissue.

DECELERATION-DEPENDENT BLOCK.

Diastolic depolarization has been suggested as a cause of conduction block at slow rates, so-called bradycardia- or deceleration-dependent block (see Chap. 25) . Yet excitability *increases* as the membrane depolarizes until about -70 mV, despite a reduction in action potential amplitude and V_{max} . Evidently, depolarization-induced inactivation of fast Na+ channels is offset by other factors such as reduction in the difference between membrane potential and threshold potential. A more probable explanation of deceleration-dependent block is the reduction in action potential amplitude and excitability at long diastolic intervals. Rapid pacing can also produce overdrive suppression of conduction, with a similar mechanism related to the depression of action potential amplitude and excitability.

PHASE 3 OR TACHYCARDIA-DEPENDENT BLOCK.

More commonly, impulses are blocked at rapid rates or short cycle lengths as a result of incomplete recovery of refractoriness caused by incomplete time- or voltage-dependent recovery of excitability (see Chap. 5) . For example, such incomplete recovery is the usual mechanism responsible for a nonconducted premature P wave or one that conducts with a functional bundle branch block.

DECREMENTAL CONDUCTION.

Decremental conduction is used commonly in the clinical literature but is often misapplied to describe any Wenckebach-like conduction block, i.e., responses similar to block in the AV node during which progressive conduction delay precedes the nonconducted impulse. Correctly used, *decremental conduction* refers to a situation in which the properties of the fiber change along its length so that the action potential loses its efficacy as a stimulus to excite the fiber ahead of it. Thus, the stimulating efficacy of the propagating action potential diminishes progressively, possibly as a result of its decreasing amplitude and V_{max} .

Reentry

Electrical activity during each normal cardiac cycle begins in the sinus node and continues until the entire heart has been activated. Each cell becomes activated in turn, and the cardiac impulse dies out when all fibers have been discharged and are completely refractory. During this absolute refractory period, the cardiac impulse has "no place to go." It must be extinguished and restarted by the next sinus impulse. If, however, a group of fibers not activated during the initial wave of depolarization recover excitability in time to be discharged before the impulse dies out, they may serve as a link to reexcite areas that were just discharged and have now recovered from the initial depolarization. Such a process is given various names, all meaning approximately the same thing: reentry, reentrant excitation, circus

movement, reciprocal or echo beat, or reciprocating tachycardia.

ANATOMICAL REENTRY.

The earliest studies on reentry were with models that had anatomically defined separate pathways in which it could be shown that they had (1) an area of unidirectional block, (2) recirculation of the impulse to its point of origin, and (3) elimination of the arrhythmia by cutting the pathway. In models with anatomically defined pathways, because the two (or more) pathways have different electrophysiological properties, e.g., a refractory period longer in one pathway than the other, the impulse (1) is blocked in one pathway (site A in Fig. 22-31 *A*) and (2) propagates slowly in the adjacent pathway (serpentine arrow, D to C, Fig. 22-31 *A*). If conduction in this alternative route is sufficiently depressed, the slowly propagating impulse excites tissue beyond the blocked pathway (horizontal lined area in Fig. 22-31 *A*) and returns in a reversed direction along the pathway initially blocked (B to A in Fig. 22-31 *A*) to (3) reexcite tissue proximal to the site of block (A to D in Fig. 22-31 *A*). A clinical arrhythmia caused by anatomical reentry is most likely to have a monomorphic contour.

Figure 22-31 *A,* Diagram of reentry published by Schmitt and Erlanger in 1928. A Purkinje fiber (D) divides into two pathways (B and C), both of which join ventricular muscle. It is assumed that the original impulse travels down D, is blocked in its anterograde direction at site A *(arrow followed by a double bar)*, but continues slowly down C *(serpentine arrow)* to excite ventricular muscle. The impulse then reenters the Purkinje twig at B and retrogradely excites A and D. If the impulse continues to propagate through D to the ventricular myocardium and elicits ventricular depolarization, a reentrant ventricular extrasystole results. Continued reentry of this type would produce ventricular tachycardia. *B,* Schematic representation of intranodal dissociation responsible for an atrial echo *(left diagram).* A premature atrial response fails to penetrate the beta pathway, which exhibits a unidirectional block but propagates anterogradely through the alpha pathway. Once the final common pathway (FCP) is engaged, the impulse may return to the atrium via the now-recovered beta pathway to produce an atrial echo. The neighboring *(right)* diagram illustrates the pattern of propagation during generation of a ventricular echo. A premature response in the His bundle traverses the FCP, encounters a refractory beta pathway (unidirectional block), reaches the atrium over the alpha pathway, and returns through a now-recovered beta pathway to produce a ventricular echo. *C,* Actual recordings from the atrium *(top tracing)*, with cells impaled in the beta region *(second tracing)*, alpha region *(third tracing)*, and N portion of the atrioventricular (AV) node *(bottom tracing)* in an isolated rabbit preparation. The basic response to A_1 activated both alpha and beta pathways and the N cell (first tier of action potentials). The premature atrial response A_2 caused only a local response in the beta cell *(heavy arrow)*, was delayed in transmission to the alpha cell, and was further delayed in propagation to the N cell. Following the alpha response, a retrograde spontaneous response occurred in the beta cell and propagated to the atrium (E). This atrial response represents an atrial echo. The echo returned to stimulate the alpha cell but was not propagated to the N cell. It is important that while intranodal reentry has been shown to occur within the rabbit AV node, AV nodal reentry in humans probably occurs over extranodal pathways. (From Mendez C, Moe GK: Demonstrations of a dual AV nodal conduction system in the isolated rabbit heart. Circ Res 19:378, 1966. By permission of the American Heart Association.)

For reentry of this type to occur, the time for conduction within the depressed but unblocked area and for excitation of the distal segments must exceed the refractory period of the initially blocked pathway (A in Fig. 22-31 *A*) and the tissue proximal to the site of block (D in Fig. 22-31 *A*). Stated another way, continuous reentry requires the anatomical length of the circuit traveled to equal or exceed the reentrant wavelength. The latter is equal to the mean conduction velocity of the impulse multiplied by the longest refractory period of the elements in the circuit. Both values can be different at different points along the reentry pathway, and thus, the wavelength value is somewhat contrived.

CONDITIONS FOR REENTRY.

The length of the pathway is fixed and determined by the anatomy. Conditions that depress conduction velocity or abbreviate the refractory period will promote the development of reentry in this model, whereas prolonging refractoriness and speeding conduction velocity can hinder it. For example, if conduction velocity (0.30 m/sec) and refractoriness (350 m/sec) for ventricular muscle were normal, a pathway of 105 mm (0.30 milliseconds × 0.35 seconds) would be necessary for reentry to occur. However, under certain conditions, conduction velocity in ventricular muscle and

Purkinje fibers can be very slow (0.03 m/sec), and if refractoriness is not greatly prolonged (600 milliseconds), a pathway of only 18 mm (0.03 m/sec × 0.60 seconds) may be necessary. Such reentry frequently exhibits an excitable gap, i.e., a time interval between the end of refractoriness from one cycle and the beginning of depolarization in the next, when tissue in the circuit is excitable. This condition results because the wavelength of the reentrant circuit is less than the pathway length. Electrical stimulation during this time period can invade the reentrant circuit and reset its timing or terminate the tachycardia.

Rapid pacing can entrain the tachycardia, i.e., continuously reset it by entering the circuit and propagating around it in the same way as the reentrant impulse, which increases the tachycardia rate to the pacing rate without terminating the tachycardia. In reentrant circuits with an excitable gap, conduction velocity determines the revolution time of the impulse around the circuit and, hence, the rate of the tachycardia. Prolongation of refractoriness, unless it is great enough to eliminate the excitable gap and make the impulse propagate in relatively refractory tissue, will not influence the revolution time around the circuit or the rate of the tachycardia. Anatomical reentry occurs in patients with the Wolff-Parkinson-White syndrome, in AV nodal reentry, in some atrial flutters, and in some ventricular tachycardias.

FUNCTIONAL REENTRY.

Functional reentry lacks confining anatomical boundaries and can occur in contiguous fibers that exhibit functionally different electrophysiological properties caused by local differences in transmembrane action potential. Dispersion of excitability and/or refractoriness, as well as anisotropic distributions of intercellular resistance, permits initiation and maintenance of reentry.[103] [104] [105] A clinical arrhythmia caused by functional reentry is most likely to be polymorphic because of charging circuits.

Leading Circle Reentry.

Leading circle reentry, important in atrial fibrillation (AF), is reentrant excitation during which the reentrant circuit propagates around a functionally refractory core and follows a course along fibers that have a shorter refractory period so that the impulse is blocked in one direction in fibers with a longer refractory period (Fig. 22-32) .

The pathway length of a functional circuit is determined by the smallest circuit in which the leading wavefront is just able to excite tissue ahead that is still relatively refractory. If these parameters change, the size of the circuit may change also and alter the rate of the tachycardia. Shorter wavelengths may predispose to fibrillation. No or a very short excitable gap exists, and the duration of the refractory period of the tissue in the circuit primarily determines the

Figure 22-32 Functional models of reentry. *Leading circle model,* a diagrammatic representation of the leading circle model of reentry in isolated left atrium of the rabbit. The central area is activated by converging centripetal wavelets. (From Allessie MA, Bonke FIM, Schopman FJG: Circus movement in rabbit atrial muscle as a mechanism of tachycardia: III. The "leading circle" concept: A new model of circus movement in cardiac tissue without the involvement of an anatomical obstacle. Circ Res 41:9, 1977. By permission of the American Heart Association, Inc.) *Figure-of-8 model,* activation map (in 20 millisecond isochrones) of a figure-of-8 circuit in the surviving epicardial layer of a dog 4 days after ligation of the left anterior descending coronary artery (LAD). The circuit consists of clockwise and counterclockwise wavefronts around two functional arcs of block that coalesce into a central common front that usually represents the slow zone of the circuit. (From El-Sherif N: The figure 8 model of reentrant excitation in the canine post-infarction heart. *In* Zipes DP, Jalife J (eds): Cardiac Electrophysiology and Arrhythmias. New York, Grune & Stratton, 1985, p 363.) *Anisotropic model* showing stimulation from the center of a multiple-electrode array (at the pulse symbol, *A*) on the epicardial border zone of a 4-day-old canine infarct producing an elliptical pattern of activation characteristic of conduction in an anisotropic medium. Arrows indicate the direction of the fast axes of conduction and the longitudinal orientation of the myocardial fibers. *B,* activation map of a reentrant circuit on the epicardial border obtained with the same electrode array during sustained ventricular tachycardia in the same heart. Arrows indicate the sequence of isochrones and thus the direction of movement of activation. (From Wit AL, Janse MJJ: The Ventricular Arrhythmias of Ischemia and Infarction: Electrophysiological Mechanisms. Mt Kisco, NY, Futura, 1992.) *Spiral wave model,* activation map of spiral wave activity in a thin slice of isolated ventricular muscle from a sheep heart *(right panel).* Isochrone lines were drawn from raw data by overlaying transparent paper on snapshots of video images during spiral wave activity (*left panel,* not from the same experiment). Each line represents consecutive positions of the activation front recorded every 16.6 milliseconds. (From Brugada J, Boersma L, Kirchhof C, et al: Sustained monomorphic ventricular tachycardia: A single electrocardiographic expression of different patterns of reentry. Pacing Clin Electrophysiol 14:1943-1946, 1991.)

cycle length of the tachycardia because the stimulating efficacy of the head of the next impulse is just sufficient to excite the relatively refractory tissue in the wake of the preceding impulse. Propagating impulses originating outside the circuit cannot easily enter the circuit to reset, entrain, or terminate the reentry.[106]

Theoretically, drugs that prolong refractoriness and do not delay conduction would slow tachycardia as a result of the leading circle mechanism and not affect

tachycardia with an excitable gap until the prolongation of refractoriness exceeded the duration of the excitable gap. Drugs that primarily slow conduction would have major effects on tachycardia with an excitable gap and not on tachycardias resulting from the leading circle concept. Mixed circuits with both anatomical and functional pathways obfuscate these differences.

Random Reentry.

Random reentry, also important in AF, occurs when the reentry propagates continuously and randomly and reexcites areas that were excited shortly before by another wavelet.

ANISOTROPIC REENTRY.

Anisotropic reentry is due to the structural features responsible for variations in conduction velocity and the time course of repolarization, such as a concentration of gap junctions at the ends rather than on the side of cells, which can result in block and slowed conduction with subsequent reentry[95] [95A] (Fig. 22-32) . Even in normal cardiac tissue showing normal transmembrane potentials and uniform refractory periods, conduction can be blocked in the direction parallel to the long axis of fiber orientation, propagate slowly in the direction transverse to the long axis of fiber orientation, and reenter the area of block. Spatial differences in refractoriness may not be necessary for reentry to occur. Such anisotropic reentry has been shown in atrial and ventricular muscle and may be responsible for ventricular tachycardia in epicardial muscle surviving myocardial infarction. An excitable gap may be present.[105]

Figure-of-8 Reentry.

Figure-of-8 reentry consists of clockwise and counterclockwise wavefronts around two functional arcs of block that coalesce into a central common from commonly representing the slow zone of the circuit. Such reentry has been shown in both atrial and ventricular muscle[103] (Fig. 22-32) .

Spiral Wave Reentry.

Spiral waves of excitation have been demonstrated in cardiac muscle and represent a two-dimensional form of reentry; in three dimensions, spiral waves may be represented by scroll waves. Spiral waves may be stationary when the shape, size, and location of the arc remain unchanged throughout the episode; drifting when the arc migrates away from its site of origin; or anchoring when the drifting core becomes anchored to some small obstacle, such as a blood vessel. One can speculate that a stationary spiral wave could be responsible for a monomorphic tachycardia, a drifting spiral wave responsible for rhythm with changing contours such as torsades de pointes, and an anchoring spiral wave responsible for the transition from a polymorphic to a monomorphic tachycardia[107] [108] [109] (Fig. 22-32) [32] . The use of voltage-sensitive probes in combination with high-resolution video imaging to record electrical wave propagation on the surface of the heart has recently provided experimental evidence for the role of spiral wave reentry in cardiac fibrillation. Experiments in isolated perfused hearts[110] [111] demonstrate that a single rapidly moving rotor or a small number of coexisting, but short-lived rotors give rise to ECG patterns of activity indistinguishable from ventricular fibrillation (VF). The rotors may drift and interact with each other and with boundaries in the heart and result in annihilation and/or formation of new, but also short-lived rotors.

REFLECTION.

Reflection can be considered a special subclass of reentry. As in reentry, an area of conduction delay is required, and the total time for the impulse to leave and return to its site of origin must exceed the refractory period of the proximal segment. Reflection differs from reentry in that the impulse does not require a circuit but appears to travel along the *same* pathway in both directions.

Tachycardias Caused by Reentry

Reentry is probably the cause of many tachyarrhythmias, including various kinds of supraventricular and ventricular tachycardias, flutter, and fibrillation. However, in complex preparations, such as large pieces of tissue in vitro or the intact heart, it becomes much more difficult to unequivocally prove that reentry exists.

BRUGADA SYNDROME.

A reentry mechanism has been implicated in the genesis of ventricular tachycardia/fibrillation associated with the inheritable Brugada syndrome, which is characterized by ST segment elevation (unrelated to ischemia, electrolyte abnormalities, or structural heart disease) in the right precordial (V_1 to V_3) ECG leads, often but not always accompanied by an apparent right bundle branch block. The Brugada syndrome appears to be a congenital ion channel disorder since mutations in the cardiac sodium channel gene *SCN5A* have been reported.[112] The gene defect caused either acceleration of recovery of the sodium channel from inactivation or a nonfunctional sodium channel. Inhibition of the sodium channel current causes heterogeneous loss of the action potential dome (plateau) in the right ventricular epicardium, which leads to a marked dispersion of repolarization and refractoriness and the potential for reentry. Whether transmural heterogeneity in Na+ channel recovery in the right ventricular free wall causes arrhythmia by a similar mechanism remains to be determined.

In addition, many other factors such as stretch, autonomic stimulation, and a host of modulating influences can act on these electrophysiological mechanisms and obscure the cause of many arrhythmias. Initiation or termination of tachycardia by pacing stimuli, the demonstration of electrical activity bridging diastole, fixed coupling, and a variety of other clinically used techniques such as entrainment and resetting curves, while consistent with reentry, do not constitute absolute proof of its existence. The most compelling evidence is probably provided by entrainment.[113]

ENTRAINMENT.

It has been shown that if one could entrain the tachycardia, that is, increase the rate of the tachycardia to a faster rate by pacing, with resumption of the intrinsic rate of the tachycardia when pacing was stopped, the presence of reentry could be established. (Fig. 22-33 *A*). Entrainment represents capture or continuous resetting of the reentrant circuit of the tachycardia by the pacing-induced activation. Each pacing stimulus creates a wavefront that travels in an anterograde direction (orthodromic) and resets the tachycardia to the pacing rate. A wavefront propagating retrogradely in the opposite direction (antidromic) collides with the orthodromic wavefront of the previous beat (Fig 22-33 *B*). These wavefront interactions create ECG and electrophysiological features that can be explained only by reentry. Therefore, the criteria of entrainment can be used to prove the reentrant mechanism of a clinical tachycardia and form the basis for localizing the pathway traveled by the tachycardia wavefront. Such localization is essential for ablation therapy.[114]

ATRIAL FLUTTER (see also Chap. 25) .

Reentry is the most likely cause of the usual form of atrial flutter, with the reentrant circuit confined to the right atrium, where it usually travels counterclockwise, in a caudocranial direction in the interatrial septum and in a craniocaudal direction in the right atrial free wall.[113] [115] [116] [117] [118] [119] [120] [121] [122] [123] [124] An area of slow conduction is present in the posterolateral to posteromedial inferior area of the right atrium with a central area of block that can include an anatomical (inferior vena cava) and functional component. It is possible that several different reentrant circuits exist in patients with atrial flutter (see Chap. 25) . However, this area of slow conduction is rather constant and represents the site of successful ablation of atrial flutter. Ablation results are consistent with a macro-reentry circuit.[125] [126] [127] [128] [129] [130] [131] [132]

VENTRICULAR FIBRILLATION (see also Chap. 25)

Electrical Restitution and Critical Mass.

Substantial experimental support has accumulated in favor of the concept that the onset of VF involves the disintegration of a single spiral wave into many self-perpetuating waves.[133] It has been proposed that the breakup of spiral waves is precipitated by oscillations of action potential duration that are of sufficiently large amplitude to cause conduction block along the spiral wavefront.

Experimental support for this idea comes from most recent studies demonstrating that if action potential duration restitution (which relates action potential duration to the preceding diastolic interval) contains a region of slope greater than 1, action potential duration alternans is possible and can lead to the formation of reentrant waves.[134] [135] Reduction of the slope of the restitution relationship prevented the induction of VF, thus indicating that the kinetics of electrical restitution appears to be a key determinant of VF. The mass of the tissue appears to be another important factor in the development of fibrillation. In an isolated swine model, it was recently shown that tissue mass reduction resulted in the termination of VF when a critical mass (I9 gm) was reached.[136] In humans, this value appears to be much greater (>111 gm).[135] Similarly, partitioning the atrium into its small segments prevents AF, a concept that has led to a corrective surgical[137] [138] and ablation[139] [140] [141]

procedure (see Chap. 23) .

Figure 22-33 *Top panel,* Illustrated criteria for entrainment exemplified in a case of postinfarct ventricular tachycardia (VT). *A, left,* Two electrocardiographic (ECG) leads of a VT and intracardiac recordings from a mapping catheter (*Map*) at a left ventricular site critical for VT continuation, as well as from the right ventricular apex (*RV*). Note the diastolic potential (*dark arrow*) during VT. Recordings are similarly arranged in all subsequent panels. *A, right,* RV pacing in the setting of sinus rhythm. *B,* RV pacing at a cycle length (CL) slightly shorter than VT produces a QRS complex that is a blend between fully VT and fully paced ("fusion") complexes. All recordings are accelerated to the paced CL, and after pacing ceases, the same VT resumes. Each fused QRS complex is identical and the last beat is entrained, but surface fusion is absent. *C* and *D,* The same phenomena, but at shorter-paced CL. Note that the fused QRS complex appears more similar to pacing than it does to VT as the pacing CL shortens. *B* through *D* thus illustrate a progressive degree of ECG fusion. The Map recording of *B* through *D* also shows a progression of fusion, with both the morphology and timing of a portion of the electrogram changing with faster pacing. *E,* Finally, a still shorter paced CL results in a sudden change in both the Map electrogram (block in the small diastolic potential, *white arrow*) and the surface ECG, which is now fully paced. When pacing ceases, VT has been interrupted. (From Zipes DP: A century of cardiac arrhythmia: In search of Jason's Golden Fleece. J Am Coll Cardiol 34:959-965, 1999). *Bottom panel,* Diagrammatic representation of the reentrant circuit during spontaneous atrial flutter (AFL) and during transient entrainment of the AFL. *Left,* The reentrant circuit during spontaneous type I AFL. *f* = circulating wavefront of the AFL. *Center,* Introduction of the first pacing impulse (X) during rapid pacing from a high atrial site during AFL. The *large arrow* indicates entry of the pacing impulse into the reentrant circuit, whereupon it is conducted orthodromically (*Ortho*) and antidromically (*Anti*). The antidromic wavefront of the pacing impulse (*X*) collides with the previous beat, in this case the circulating wavefront of the spontaneous AFL (*f*), which results in an atrial fusion beat and, in effect, terminates the AFL. However, the orthodromic wavefront from the pacing impulse (*X*) continues the tachycardia and resets it to the pacing rate. *Right,* Introduction of the next pacing impulse (*X* + 1) during rapid pacing from the same high atrial site. The large arrow again indicates the entry of the pacing impulse into the reentrant circuit, whereupon it is conducted orthodromically and antidromically. Once again, the antidromic wavefront from the pacing impulse (*X* + 1) collides with the orthodromic wavefront of the previous beat. In this case, it is the orthodromic wavefront of the previous paced beat (*X*), and an atrial fusion beat results. The orthodromic wavefront from the pacing impulse (*X* + 1) continues the tachycardia and resets it to the pacing rate. In all three parts, arrows indicate the direction of spread of the impulses; the serpentine line indicates slow conduction through a presumed area of slow conduction (stippled region) in the reentrant circuit, and the black dots with tails indicate bipolar electrodes at the high atrial pacing site, the posteroinferior portion of the left atrium (PLA), and another atrial site. (From Waldo AL: Atrial flutter. Entrainment characteristics. J Cardiovasc Electrophysiol 8:337-352, 1997.)

Lower and Upper Limit of Vulnerability.

The cardiac response to electrical stimulation depends on the strength and timing of the stimulus relative to cardiac recovery (coupling interval). A vulnerable zone is present during which a stimulus with appropriate strength may induce VF. When the heart is beating spontaneously (e.g., during sinus rhythm), the timing of the vulnerable period corresponds to the T wave on the surface ECG, more precisely, to the latter part of its upslope and its peak.[142] The strength of a stimulus may not be either too low or too high. There is a lower limit of stimulus strength that can induce VF, as well as an upper limit of vulnerability, defined as a current strength at or above which VF cannot be induced.

Propagated graded responses may underlie the mechanisms of ventricular vulnerability to a single premature stimulus. A stimulus delivered during incomplete recovery evokes a gradual response that propagates slowly to neighboring recovered cells and, if its amplitude is large enough, may induce an all-or-none response. This all-or-none response spreads in all directions except into regions near the site of stimulus because of a graded response-induced increase in ERP at the latter site, which results in unidirectional block and reentry (propagated graded-response hypothesis of ventricular vulnerability). When the extrastimulus strength and thus the magnitude of gradual responses increase beyond a critical level, the increase in refractoriness at the site of the stimulus becomes so long that the unidirectional block becomes bidirectional and prevents the formation of reentry (upper limit of vulnerability).[142]

ATRIAL FIBRILLATION

Spatiotemporal Organization and Focal Discharge (see also Chap. 25) .

According to the multiple-wavelet hypothesis, AF is characterized by fragmentation of the wavefront

into multiple daughter wavelets that wander randomly throughout the atrium and give rise to new wavelets that collide with each other and are mutually annihilated or that give rise to new wavelets in a perpetual activity.

The randomness of the irregular electrical activity during AF has been disputed recently on the basis of both statistical methods and experimental studies. A combination of high-resolution video imaging, ECG recordings, and spectral analysis was used to demonstrate that reentry in anatomically or functionally determined circuits forms the basis of spatiotemporal periodicity during acute AF.[143] The cycle length of the source in the left atrium determines the dominant peak in the frequency spectra. The underlying periodicity may stem from a repetitive focal source of activity propagated from an individual pulmonary vein to the remainder of the atrium as fibrillating waves.[144] If a single repetitive focal source(s) of activity that undergo(es) fractionation underlie(s) maintenance of AF, ablation of this focal source should interrupt AF. Indeed, delivery of radiofrequency energy to discrete sites in the distal pulmonary veins in humans has been shown to eliminate or reduce recurrence of AF.[145] Localization and subsequent ablation of sources of repetitive electrical activity may therefore represent a novel approach for future treatment of AF.

Electrical Remodeling of the Heart.

Electrical remodeling of the atria appears to be a key determinant for maintenance of AF. Prolonged rapid atrial pacing in goats[146] and dogs[147] [148] causes electrophysiological alterations of the atria, including shortening and loss of the physiological rate adaptation of refractoriness and decrease in conduction velocity. Since abbreviation of the atrial refractory period is disproportionally larger than reduction of conduction velocity, the wavelength of the reentrant wavelets shortens and thereby promotes reentrant activity (the wavelength is the distance traveled by the depolarization wavefront during the duration of its refractory period and equals conduction velocity time refractoriness).

The ionic basis of shortening of the refractory period and slowing of conduction may be a significant reduction in the density of both the L-type Ca^{2+} and the fast Na^{+} current. [147] [148] The electrophysiological changes are paralleled by similar decreases in mRNA levels of Ca^{2+} and Na^{+} channel genes, which suggests alterations in gene expression as the underlying molecular mechanisms of atrial electrical remodeling.[149] Changes in the density and/or spatial distribution of various connexin types may also cause alterations in atrial impulse propagation.[150] [151] [152] Autonomic remodeling also appears to play a key role in both triggering and maintaining AF. Long-term selective vagal denervation of the atria and sinus and AV nodes prevents induction of AF.[17] Heterogeneous sympathetic denervation of the atria favors the development of sustained AF.[154] [154A]

Prolonged rapid ventricular pacing reproducibly causes action potential prolongation in a variety of species, similar to what has been observed in cells isolated from human hearts with dilated cardiomyopathy. The ionic basis for these repolarization abnormalities varies among species, but a reduction in the density of L-type Ca^{2+} currents and downregulation and upregulation of I_{to} and $I_{Na/Ca}$, respectively, appear to be involved.[155] [156] [157] [157A] [157B] A change in ventricular rate, even of short duration, can cause lasting changes in cardiac electrophysiology. Transient superimposition of a fast ventricular rate on a slow rate was found to lengthen the QT interval and refractoriness for hours and to facilitate induction of torsades de pointes.[158] Action potential prolongation was still present in cells isolated from hearts subjected to transient tachycardia[159] and resulted from a reduction in I_{to} and enhanced $I_{Ca.L}$.[159A] Besides the rate, other factors have been found to electrically remodel the heart: Left ventricular hypertrophy reduced the expression of voltage-gated K^{+} channels,[160] and Na^{+} channel function was altered in myocytes from the epicardial border zone over an infarct.[161] Together, these results underline that the process of remodeling probably plays a role in the pathogenesis of atrial and ventricular arrhythmias.

SINUS REENTRY (see also Chap. 25) .

The sinus node shares with the AV node electrophysiological features such as the potential for *dissociation of conduction;* i.e., an impulse can conduct in some nodal fibers but not in others, thereby permitting reentry to occur.[162] The reentrant circuit may be located entirely within the sinus node or involve both the sinus node and atrium. Supraventricular tachycardias caused by sinus node reentry may generally be less symptomatic than other supraventricular tachycardias because of slower rates. Ablation of the sinus node may be necessary in an occasional refractory tachycardia.[163]

ATRIAL REENTRY (see also Chap. 25) .

Reentry within the atrium, unrelated to the sinus node, may be a cause of supraventricular tachycardia in humans.[164] [165] [166] [167] [168] [169] Atrial reentry appears to be less

frequently encountered than other types of supraventricular tachycardia.[167] It has been shown to be due to reentry,[164] [169] automaticity,[170] and afterdepolarizations causing triggered activity. Adenosine has been used to probe for the mechanism.[171] Distinguishing atrial tachycardia caused by automaticity from atrial tachycardia sustained by reentry over quite small areas, i.e., micro-reentry of the leading circle type, is difficult. Multiple foci can be present.[172]

AV NODAL REENTRY (see also Chap. 25) .

Longitudinal dissociation of the AV node into two or more pathways has been demonstrated in the isolated rabbit AV node, where cells in the upper portion of the AV node can be dissociated during propagation of premature stimuli so that one group of cells, called *alpha,* can discharge in response to a premature stimulus at a time when another group of cells, called *beta,* fails to discharge. The impulse can then turn around (without needing to activate the His bundle) to reexcite the beta group of cells and produce an atrial echo (see Fig. 22-31 *B*) or sustained tachycardia.

The presence of dual AV nodal pathways has also been supported by the finding that an impulse traveling from the ventricle to the atrium, if timed properly, can reach the atrium at the same time that another impulse is traveling from the atrium to the ventricle (Fig. 22-34) . For this event to occur, the impulses traveling in opposite directions without colliding must be conducting in different AV nodal pathways. Another convincing fact is the finding of two ventricular responses to a single atrial depolarization or two atrial responses to a single ventricular depolarization as a result of simultaneous transmission over both the slow and fast AV nodal pathways.[173] [174] Finally, the onset of AV of nodal reentry (AVNR) is consistent with dual AV nodal pathways.[175] [176] [177] [178] [179] [180] [181] [182] [183]

Usually, a premature atrial response can block anterogradely in one AV nodal pathway that conducts more rapidly (fast pathway, or beta pathway in Fig. 22-31 *B*), but has a longer refractory period than a second pathway (slow pathway, or alpha pathway in Fig. 22-31 *B*). The premature atrial response travels to the ventricle over the slow (alpha) pathway, thereby prolonging the A-H interval, and returns back to the atrium over the fast (beta) pathway with a short H-A interval, so-called slow-fast AVNR. Less commonly, the slow pathway has a long refractory period, and the premature atrial response can block anterogradely in the slow pathway and travel in the fast pathway by using the slow pathway retrogradely, so-called fast-slow AVNR. Finally, some patients can have both anterograde and retrograde conduction over slowly conducting AV nodal fibers, so-called slow-slow AVNR.[183] [184] Some patients may have more than two pathways. The nodal anatomical structure in patients with AVNR appears to be normal.[185] [186]

LOCATION OF AV NODAL PATHWAYS.

While the presence of dual AV nodal pathways in AVNR is indisputable,[24] [25] the question is where are they located--intranodal and caused by longitudinal dissociation or extranodal and involving separate atrial inputs into the AV node? The results of radiofrequency catheter abiation,[187] [188] [189] [190] [191] [192] [193] [194] [195] [196] [197] [198] [199] [200] [201] as well as surgery,[202] [203] [204] [205] [206] treating patients with AVNR leaves little doubt that the fast and slow pathways have their origins well outside the limits of the compact portion of the AV node and, at the point that they are interrupted, are composed of ordinary working atrial myocardium. The slow and fast pathways are likely to be atrionodal approaches or connections rather than discrete intranodal pathways.

During the common form of AVNR, anterograde conduction occurs over a posteroinferior atrial approach, or "slow" pathway, whose upper end is posteroinferior to the AV node, toward the coronary sinus orifice. Radiofrequency lesions in this area eliminate AVNR by selectively affecting conduction over the slow pathway. The lower end of this pathway enters the compact portion of the AV node, where the impulse is able to "turn around" and retrogradely enter the "fast" or anterosuperior atrial approach, whose upper end inserts at the apex of the Koch triangle near the His bundle. This pathway can also be selectively ablated (Fig. 22-35) .

During sinus rhythm, anterograde conduction probably occurs over the anterosuperior atrial approaches. A premature atrial impulse can be blocked in this pathway, because of its longer refractory period, and then conduct anterogradely

Figure 22-34 Atrial preexcitation during atrioventricular (AV) nodal reentry. AV nodal reentrant tachycardia is present with a cycle length of 410 milliseconds. A premature ventricular complex (S_2) from the right ventricular outflow tract with a coupling interval of 300 milliseconds is introduced during the tachycardia before His is activated and penetrates the AV node retrogradely to shorten the A-A interval to 395 milliseconds. Shorter V_1 -V_2 intervals decreased the A-A interval to 355 milliseconds. Dual AV nodal pathways best explain how two impulses can travel in opposite directions in the AV node, i.e., the impulse from the tachycardia traveling anterogradely and the impulse from premature ventricular stimulation traveling retrogradely, and not collide. Surface leads I, II, III, V_1 are displayed along with high right atrial (HRA), His bundle (HBE), proximal coronary sinus (PCS), distal coronary sinus (DCS), and right ventricular (RV) electrograms. Numbers are milliseconds. Premature ventricular stimulus is indicated by S_2 . His bundle activation is indicated by H, and atrial activation is indicated by A. Large time = 50 milliseconds; small time = 10 milliseconds (From Miles WM, Yee R, Klein G, et al: The preexcitation index: An aid in determining the mechanism of supraventricular tachycardia and localizing accessory pathways. Circulation 74:493, 1986. By permission of the American Heart Association, Inc.)

Figure 22-35 Schematic diagram of atrial approaches to the atrioventricular (AV) node that constitute the fast and slow pathways. The AV node and pathways are greatly enlarged for graphic purposes. The lower catheter lies posteroinferiorly over the slow pathway, while the upper catheter lies anterosuperiorly over the His bundle. IVC = inferior vena cava; RA = right atrium; RV = right ventricle; SVC = superior vena cava.

Figure 22-36 His-Purkinje block during atrioventricular (AV) nodal reentry. *A,* A spontaneous premature atrial complex (PAC) is followed by PR (A-H) prolongation and the initiation of AV nodal reentry. Retrograde atrial activation (A
) occurs simultaneously with onset of the QRS complex. *B,* A2:1 block distal to the His bundle recording site is present, with continuation of the AV nodal reentry, which indicates that activation of the ventricle is not required for perpetuation of the tachycardia. Such an event could not occur during reciprocating tachycardia with use of an accessory AV connection in the Wolff-Parkinson-White syndrome. Conventions are as listed in Figure 22-34 .

over the posteroinferior approaches and cause the "jump" in the A-H interval. At this point, AVNR can occur. In the less common form of AVNR, anterograde conduction occurs over the fast pathway and retrograde conduction over the slow pathway and, in the slow-slow form, over two slow pathways.

In patients who have dual AV nodal physiology, both pathways exhibit electrophysiological responses in the anterograde direction characteristic of AV nodal fibers. However, the electrophysiological features of the pathway conducting retrogradely during the tachycardia differ from those of the anterogradely conducting pathway in response not only to atrial or ventricular pacing but also to various drugs.[207] For example, drugs such as procainamide prolong conduction time in the retrogradely conducting but not in either anterogradely conducting pathway. Also, pacing at short cycle lengths prolongs anterograde, but not retrograde AV nodal conduction time. Yet verapamil prolongs retrograde AV nodal conduction time, consistent with an effect on nodal fibers. The area of slow conduction in AVNR is located in the same region as the area of slow conduction in atrial flutter.[208]

While it is clear that activation of the ventricle is not necessary for AVNR (Fig. 22-36) and activation of His bundle is also probably not required in some patients, the necessary role of atrial participation in the reentrant circuit is still debated,[175] [176] [182] and it is probably true that some patients have AVNR confined to reentry within the AV node. The obligatory role of the atrium in the reentry is implicit in the diagram in Figure 22-31 *B*. Figure 22-37 provides an example *apparent* dissociation of the atrium with uninterrupted continuation of the supraventricular tachycardia, which leads to the conclusion that the atrium may *not* be a necessary part of the reentrant circuit in humans.

PREEXCITATION SYNDROME (see also Chap. 25) .

In most patients who have reciprocating tachycardias associated with Wolff-Parkinson-White syndrome, the accessory pathway conducts more rapidly than does the normal AV node but takes a longer time to recover excitability; i.e., the anterograde refractory period of the accessory pathway exceeds that of the AV node at long cycles.[209] [210] Consequently, a premature atrial complex that occurs sufficiently early is blocked anterogradely in the accessory pathway and continues to the ventricle over the normal AV node and His bundle. After the ventricles have been excited, the impulse is able to enter the accessory pathway retrogradely and return to the atrium. A continuous conduction loop of this kind establishes the circuit for the tachycardia. The usual (orthodromic) activation wave during such a reciprocating tachycardia in a patient with an accessory pathway occurs in the following manner: anterogradely over the normal AV node-His-Purkinje system and retrogradely over

the accessory pathway, which results in a normal QRS complex (Fig. 22-38) .

Because the circuit requires both atria and ventricles, the term *supraventricular tachycardia* is not precisely correct, and the tachycardia is more accurately called *atrioventricular reciprocating tachycardia* (AVRT). The reentrant loop can be interrupted by ablation of the normal AV node-His bundle pathway *or* the accessory pathway.[211] [212] [213] [214] [215] [216] [217] [218] [219] [220] Occasionally, the activation wave travels in a reverse (antidromic) direction to the ventricles over the accessory pathway and to the atria retrogradely up the AV node.[209] [210] Two accessory pathways can form the circuit in some patients with antidromic AVRT. In some patients, the accessory pathway may be capable of only retrograde conduction ("concealed"), but the circuit and mechanism of AVRT remain the same. Less commonly, the accessory pathway may conduct only anterogradely. The pathway can be localized by analysis of the scalar ECG.[221] [222] [223] [224] [225] [226] [227] Patients can have AF as well as AVRT.[228]

Unusual accessory pathways with AV nodal-like electrophysiological properties, i.e., nodofascicular or nodoventricular fibers, can constitute the circuit for reciprocating tachycardias in patients who have some form of the Wolff-Parkinson-White

Figure 22-37 Dissociation of atria from ventricles without interrupting atrioventricular (AV) nodal reentrant supraventricular tachycardia. During sinus rhythm, a single premature atrial complex (S, *top panel*) was conducted with AV nodal delay (prolonged A-H interval) and initiated an AV nodal reentrant supraventricular tachycardia. Note that retrograde atrial activation (A) occurred prior to onset of the QRS complex. Two premature atrial stimuli (S-S, *bottom panel*) captured the atria on both occasions without altering the regular cycle length of the AV nodal reentrant supraventricular tachycardia. Note that the QRS complex marked by an asterisk has no accompanying atrial complex, which suggests that atrial participation in the reentrant circuit was not required. CS = coronary sinus electrogram; H = His bundle electrogram; RA = right atrial electrogram; V_1 = scalar lead.

syndrome. Tachycardia in patients with nodoventricular fibers can be due to reentry with these fibers used as the anterograde pathway and the His-Purkinje fibers and a portion of the AV node used retrogradely.[210] [211] In the Lown-Ganong-Levine syndrome (short PR interval and normal QRS complex), conduction over a James fiber that connects the atrium to the distal portion of the AV node and His bundle has been *proposed,* although little functional evidence to support the presence of this entity exists.

VENTRICULAR TACHYCARDIA CAUSED BY REENTRY (see also Chap. 25) .

Reentry in the ventricle, both anatomical and functional, as a cause of sustained ventricular tachycardia has been supported by many animal[219] [220] [221] [222] [223] [224] [225] [226] [227] [228] [229] [230] [231] [232] [233] [234] [235] [236] and clinical[237] [238] [239] [240] studies (see Fig. 22-32). Reentry in ventricular muscle, with or without contribution from specialized tissue, is responsible for many or most ventricular tachycardias in patients with ischemic heart disease. The area of micro-reentry appears to be quite small, and less uncommonly, a macro-reentry is found around the infarct scar. Surviving myocardial tissue (Fig. 22-39) separated by connective tissue provides serpentine routes of activation traversing infarcted areas that can establish reentry pathways. Bundle branch reentry can cause sustained ventricular tachycardia, particularly in patients with dilated cardiomyopathy.[239] [241]

Both figure-of-8 [237] (see Fig. 22-32) and single-circle[234] (Fig. 22-40) reentrant loops have been described as circulating around an area of functional block in a manner consistent with the leading circle hypothesis or conducting slowly across an apparent area of block created by anisotropy.[231] When intramural myocardium survives, it may form part of the reentrant loop. Structural discontinuities that separate muscle bundles, e.g., as a result of naturally occurring myocardial fiber orientation and anisotropic conduction, as well as collagen matrices formed from the fibrosis after a myocardial infarction, establish the basis for slowed conduction, fragmented electrograms, and continuous electrical activity that can lead to reentry. After the infarction, action potential recordings from surviving cells return to normal, which suggests that depressed activity in these cells does not account for the slowed conduction. However, ventricular myocardium resected from humans with recurrent ventricular tachycardia demonstrates abnormal action potentials, thus suggesting that causes of depressed conduction in humans may be multifactorial (see Figs. 22-23 and 22-25) . During acute ischemia, a variety of factors, including elevated $[K]_o$ and reduced pH, combine to create depressed action potentials in ischemic cells that retard conduction and can lead to reentry.[231] [240]

Ventricular Tachycardias Caused by Nonreentrant Mechanisms

In some instances of ventricular tachycardia related to coronary artery disease, but especially in patients without coronary artery disease, nonreentrant mechanisms are important causes of ventricular tachycardias. However, in many patients the mechanism of the ventricular tachycardia remains unknown.[242]

Figure 22-38 *A,* Wolff-Parkinson-White syndrome. Following high right atrial pacing at a cycle length of 500 milliseconds (S_1 -S_1), premature stimulation at a coupling interval of 300 milliseconds (S_1 -S_2) produces physiological delay in atrioventricular (AV) nodal conduction resulting in an increase in the A-H interval from 100 to 140 milliseconds but no delay in the AV interval. Consequently, activation of the His bundle occurs following activation of the QRS complex *(second interrupted line)*, and the QRS complex becomes more anomalous in appearance because of increased ventricular activation over the accessory pathway. I, II, III, and V_1 and scalar leads. DCS = distal coronary sinus electrogram; HBE = His bundle electrogram; HRA = high right atrium; PCS = proximal coronary sinus electrogram; RV = right ventricular electrogram. Time lines and 50- and 10-millisecond intervals. S_1 , stimulus of the drive train; S_2 , premature stimulus. A, H-V, atrial His bundle, and ventricular activation during the drive train; A_2 , H_2 , V_2 , atrial His bundle, and ventricular activation during the premature stimulus. *B,* Induction of reciprocating atrioventricular tachycardia. Premature stimulation at a coupling interval of 230 milliseconds prolongs the A-H interval to 230 milliseconds and results in anterograde block in the accessory pathway and normalization of the QRS complex (a slight functional aberrancy in the nature of incomplete right bundle branch block occurs). Note that H_2 precedes onset of the QRS complex *(interrupted line)*. Following V_2 , the atria are excited retrogradely (A) beginning in the distal coronary sinus, followed by atrial activation in leads recording from the proximal coronary sinus, His bundle, and high right atrium. A supraventricular tachycardia is initiated at a cycle length of 330 milliseconds. Conventions are as in panel *A.* (From Zipes DP, Mahomed Y, King RD, et al: Wolff-Parkinson-White syndrome: Cryosurgical treatment. Indiana Med 89:432, 1986.)

TRIGGERED ACTIVITY.

EADs and triggered activity may be responsible for torsades de pointes.[243] A group of probably nonreentrant ventricular tachycardias occurring in the absence of structural heart disease can be initiated and terminated by programmed stimulation. They are catecholamine dependent and are terminated by the Valsalva maneuver, adenosine, and verapamil. These ventricular tachycardias are generally, but not exclusively located in the right ventricular outflow tract and may be due to triggered activity, possibly DADs that are cAMP dependent.[92] [98] [244] [245] [246] EADs have been recorded in this tachycardia as well.[99] Left ventricular fascicular tachycardias can be suppressed by verapamil but not generally by adenosine,[246] and some may be due to triggered activity[247] and others to reentry.[248]

AUTOMATICITY.

Automatic discharge can be responsible for some ventricular tachycardias[249] [250] and does not appear to be suppressed by adenosine.[98] Unless invasive studies are undertaken, mechanisms of ventricular tachycardia can only be conjectured.[251] [252] [253]

Figure 22-39 *Top panel,* Schematic drawing illustrating left ventricular myocardial sections of a human heart studied electrophysiologically and histologically after removal for a cardiac transplant. Dark areas mark surviving cardiac tissue, while light areas point to fibrotic and fatty tissue. Note the irregularity of the surviving cardiac tissue interspersed with fibrotic tissue. The lower two panels are schematic drawings of sections from the lateral left ventricular wall 500 *(left)* and 1000 *(right)* mum, respectively, beneath the level of those shown in the *top panel.* Note that the bulge of viable tissue at the left of the surviving posterior wall (arrow in the *top panel*) becomes isolated in the *lower left panel* (arrow). In the *lower right panel,* this isolated area merges with the bulk of surviving tissue in the lateral wall (arrow). (From deBakken JMT, Coronel R, Tisserons S, et al: Ventricular tachycardia in the infarcted Langendorff-perfused human heart: Role of the arrangement of surviving cardiac fibers. J Am Coll Cardiol 15:1594, 1990. Reprinted with permission from the American College of Cardiology.)

Figure 22-40 Model of anisotropic reentry in the epicardial border zone. *A,* The activation map of the single reentrant circuit is shown. The large arrows point out the general activation pattern; activation appears to occur around a long line of block. However, parallel isochrones adjacent to the line (isochrones 130 and 140) suggest that activation is also occurring across the line and thereby results in the smaller circuit shown by the small arrows. *B,* This circuit is shown enlarged. Rapid activation occurs parallel to the long axis of the fiber orientation (isochrones 10 to 40 and at 130 to 150), whereas very slow activation (closely bunched isochrones 50 to 120) occurs transverse to fiber orientation in the circuit. The dark black rectangle is an area of either functional or anatomical block that forms the fulcrum of the circuit. Chapter 23 - Management of the Patient with Cardiac Arrhythmias

JOHN M. MILLER
DOUGLAS P. ZIPES

Approach to the Diagnosis of Cardiac Arrhythmias

In the management of clinical arrhythmias, the physician must evaluate and treat the whole patient, not just the rhythm disturbance.[1] Some arrhythmias are hazardous to the patient regardless of the clinical setting (e.g., ventricular fibrillation), whereas others are hazardous because of the clinical setting (e.g., rapidly conducted atrial fibrillation in a patient with severe coronary artery stenoses). Evaluation of the patient begins with a careful history[2] and physical examination and should usually progress from the simplest to the most complex test, from the least invasive and safest to the most invasive and risky, and from the least expensive out-of-hospital evaluations to those that require hospitalization and sophisticated, costly procedures. Occasionally, depending on the clinical circumstances, the physician may wish to proceed directly to a high-risk, expensive procedure, such as an electrophysiological study (EPS), before obtaining a 24-hour electrocardiographic (ECG) recording.

Patients with cardiac rhythm disturbances can present with a variety of complaints, but commonly symptoms such as palpitations, syncope, presyncope, or congestive heart failure cause them to seek a physician's help.[3] Their awareness of palpitations and of a regular or irregular cardiac rhythm varies greatly. Some patients perceive slight variations in their heart rhythm with uncommon accuracy, whereas others are oblivious even to sustained episodes of ventricular tachycardia (VT); still others complain of palpitations when they actually have regular sinus rhythm. The following tests can be used to evaluate patients who have cardiac arrhythmias. The physician's choice of which test to use depends on the clinical circumstances. For instance, a patient with multiple daily episodes of presyncope is likely to have an event recorded on a 24-hour Holter monitor, whereas in a patient who complains of infrequent anxiety- or exercise-induced palpitations, exercise stress testing may be more likely to provide a diagnosis.

Exercise Testing (See also Chap. 6.)

Exercise can induce various types of supraventricular and ventricular tachyarrhythmias and, uncommonly, bradyarrhythmias.[4] [5] [6] [7] [8] [9] About one third of normal subjects develop ventricular ectopy in response to exercise testing. Ectopy is more likely to occur at faster heart rates, usually in the form of occasional premature ventricular complexes (PVCs) of constant morphology, or even pairs of PVCs, and is often not reproducible from one stress test to the next. Three to six beats of nonsustained VT can occur in normal patients, especially the elderly, and its occurrence does not establish the existence of ischemic or other forms of heart disease or predict increased cardiovascular morbidity or mortality. Premature supraventricular complexes are often more common during exercise than at rest and increase in frequency with age; their occurrence does not suggest the presence of structural heart disease.

Approximately 50 percent of patients who have coronary artery disease develop PVCs in response to exercise testing. Ventricular ectopy appears in these patients at lower heart rates (less than 130 beats/min) than in the normal population and often occurs in the early recovery period as well. In one study, exercise reproduced sustained VT or ventricular fibrillation (VF) in only 11 percent of patients with spontaneous VT or VF late after myocardial infarction,[5] but

those who had it experienced a worse outcome. The relation of exercise to ventricular arrhythmia in patients with structurally normal hearts has no prognostic implications.[6] Stress testing with Holter recording has been used to assess antiarrhythmic drug efficacy.[10] [11] [12]

Patients who have symptoms consistent with an arrhythmia induced by exercise (e.g., syncope, sustained palpitations) should be considered for stress testing. Stress testing may be indicated to uncover more complex grades of ventricular arrhythmia, to provoke supraventricular arrhythmias, to determine the relationship of the arrhythmia to activity, to aid in choosing antiarrhythmic therapy and uncovering proarrhythmic responses, and possibly to provide some insight into the mechanism of the tachycardia. The test can be performed safely[7] and appears more sensitive than a standard 12-lead resting ECG to detect ventricular ectopy. However, prolonged ambulatory recording is more sensitive than exercise testing in detecting ventricular ectopy. Because either technique may uncover serious arrhythmias that the other technique misses, both examinations may be indicated for selected patients.

Long-Term Electrocardiographic Recording

Prolonged ECG recording in patients engaged in normal daily activities is the most useful noninvasive method to document and quantitate the frequency and complexity of an arrhythmia, correlate the arrhythmia with the patient's symptoms, and evaluate the effect of antiarrhythmic therapy on spontaneous arrhythmia. For example, recording normal sinus rhythm during the patient's typical symptomatic episode effectively excludes cardiac arrhythmia as a cause. In addition, some recorders can document alterations in QRS, ST, and T contours (Fig. 23-1) .

HOLTER RECORDING.

Continuous ECG tape recorders represent the traditional Holter "monitor" and typically record on tape two ECG channels for 24 hours.[13] Interpretative accuracy of long-term tape recordings varies with the system used, but most computers that scan the tapes are sufficiently accurate to meet clinical needs. All systems can potentially record more information than the physician needs or can assimilate.[14] As long as the system detects important episodes of ectopic activity, VT, or asystolic intervals and semiquantitates these abnormalities, the physician probably receives all the clinical information that is needed. Twenty-five to 50 percent of patients experience a complaint during a 24-hour recording, caused by an arrhythmia in 2 to 15 percent (see Fig. 23-1).

Significant rhythm disturbances are fairly uncommon in healthy young persons. However, sinus bradycardia with heart rates of 35 to 40 beats/min, sinus arrhythmia with pauses exceeding 3 seconds, sinoatrial exit block, Wenckebach's second-degree atrioventricular (AV) block (often during sleep), a wandering atrial pacemaker, junctional escape complexes, and premature atrial complexes (PACs) and PVCs are not necessarily abnormal. Frequent and complex atrial and ventricular rhythm disturbances are less commonly observed, however, and type II second-degree AV conduction disturbances (see Chap. 25) are not recorded in normal patients. Elderly patients may have a greater prevalence of arrhythmias, some of which may be responsible for neurological symptoms. The long-term prognosis in asymptomatic healthy subjects with frequent and complex PVCs resembles that of the healthy U.S. population without an increased risk of death.

A majority of patients who have ischemic heart disease, particularly those after myocardial infarction, exhibit PVCs when monitored for periods of 6 to 24 hours.[15] [16]

The frequency of PVCs progressively increases over the first several weeks, decreasing at about 6 months after infarction.

Figure 23-1 Long-term ECG recording in a patient with atypical angina. The top channel reflects an inferior lead, and the bottom channel records an anterior lead. Note progressive ST segment elevation in the inferior lead, eventually resembling a monophasic action potential. Bursts of nonsustained ventricular tachycardia result. Then, sinus slowing and Wenckebach's AV block occur from a vasodepressor reflex response elicited by ischemia of the inferior myocardial wall or possibly caused by ischemia of the sinus and AV nodes. In the bottom tracing, both AV block and ventricular arrhythmias are apparent. Numbers indicate time (e.g., 2:37 P.M.). (Tracing of a patient of D.A. Chilson, M.D.)

Frequent and complex PVCs constitute an independent risk factor and are associated with a two- to fivefold increased risk of cardiac or sudden death in patients after myocardial infarction. Evidence from the Cardiac Arrhythmia Suppression Trial (CAST) raises the possibility that the ventricular ectopy is a marker identifying the patient at risk rather than being causally related to sudden death, because PVC suppression with flecainide, encainide, or moricizine was associated with increased mortality compared with placebo.[17] [18] Thus the PVC may be an "innocent bystander," unrelated to the tachyarrhythmia producing sudden death. Although the mechanism responsible for the drug-induced exacerbation of mortality is not clear, it may relate to an increase in ischemia-produced conduction delay due to sodium channel blocking drugs.[19]

Holter recordings have been used to determine antiarrhythmic drug efficacy. In one study, Holter recordings led to predictions of antiarrhythmic drug efficacy more often than did electrophysiological testing in patients with sustained ventricular tachyarrhythmias, and there was no significant difference in the success of drug therapy as selected by the two methods.[10] The study also found sotalol to be the most efficacious of the seven antiarrhythmic drugs tested.[11] The beneficial results of noninvasive compared with invasive assessment of drug efficacy in this study have been challenged.[20] [21]

Long-term ECG recording also has exposed potentially serious arrhythmias and complex ventricular ectopy in patients with left ventricular hypertrophy,[22] in those with mitral valve prolapse (see Chap. 46), in those who have otherwise unexplained syncope (see Chap. 27) or transient vague cerebrovascular symptoms, and in those with conduction

disturbances, sinus node dysfunction, the bradycardia-tachycardia syndrome, the Wolff-Parkinson-White syndrome, increased QT dispersion,[23] pacemaker malfunction, and after thrombolytic therapy.[24] [25] It has shown that asymptomatic atrial fibrillation occurs far more often than symptomatic atrial fibrillation in patients with that arrhythmia.[26] This has important implications for deciding whether a patient needs chronic anticoagulation based only on recurrent symptoms.

Variations of Holter recording have been used for particular applications. Repeated 24-hour recording periods may be needed to obtain enough episodes of PAC triggering atrial fibrillation to warrant proceeding to EPS and catheter ablation. Some monitoring systems are able to "reconstruct" a full 12-lead ECG from a seven-electrode recording system. This is especially useful when trying to document the ECG morphology of VT before an ablation procedure or a consistent morphology of PACs that may arise from an ablatable focus of atrial fibrillation. Most Holter recording and analysis systems have the ability to place a clearly recognizable deflection on the recording when a pacemaker stimulus is detected. This greatly facilitates diagnosis of potential pacemaker malfunction. Occasionally, ECG artifacts due to alterations in tape recording or playback speed may mimic bradycardias or tachycardias and lead to erroneous therapy. Newer digital Holter systems are less subject to this phenomenon.

EVENT RECORDING.

In many patients, the 24-hour "snapshot" provided by the Holter recording is incapable of documenting the cause of the patient's symptoms. Still longer-term monitoring is necessary in these cases, which occur frequently. This could be effected by simply repeating many 24-hour Holter recordings until symptoms occur, but this is costly, inefficient, and cumbersome. Instead, a transient-event recorder can be used.[27] [28] These devices are roughly the size of a pager and are kept by the patient for 30 days. During that time, digital recordings can be made during symptomatic episodes and transmitted to a receiving station over standard telephone lines at the patient's convenience. Some of these recorders store up to 30 seconds of ECG before the time when the patient activates the recording. These "loop" recorders[29] record continuously but only a small window of time is present in memory at any time; when the event button is pressed by the patient, the current window is "frozen" while the device continues recording for another 30 to 60 seconds, depending on how it is configured. Event recorders are very effective in documenting infrequent events, but the quality of the recordings is more variable than Holter recorders and only one channel can be recorded. In addition, the patient must be able to press the event button to begin recording; if syncope occurs without warning and the patient is not able to actuate the device, it cannot provide diagnostic information.

Some pacemakers and implantable defibrillators are capable of providing Holter-like data on occurrence of premature beats but cannot store ECGs of these events. Some pacemakers have a feature in which the patient waves a special magnet over the device, causing it to freeze 1 to 3 minutes of the intracardiac electrogram corresponding to the symptoms, much as a loop recorder does. The device can then be interrogated later and the electrograms printed for analysis.

IMPLANTABLE LOOP RECORDER.

For patients with very infrequent and transient symptoms, neither Holter recorders nor 30-day event recorders may yield diagnostic information. In such patients, implantable loop recorders may be used. This device (about the size of a pack of chewing gum) is inserted under the skin at about the second rib on the left and is activated by waving a special magnet over the device. It is capable of recording up to 42 minutes of a single ECG channel that can be partitioned for 1 to 3 episodes, with up to 20 minutes of preactivation ECG saved for subsequent downloading to a programming unit for analysis. Both P waves and QRS complexes can usually be identified. In a recent report, this device was implanted in 24 patients with recurrent syncope who had undergone extensive evaluation without determining a cause of syncope. Over a mean 5-month period after implant, 21 patients had recurrent syncope; the device was instrumental in establishing the diagnosis in 18.[30] [30A]

Other Noninvasive Tests

HEART RATE VARIABILITY.

Heart rate variability is used to evaluate vagal and sympathetic influences on the heart and to identify patients at risk for a cardiovascular event or death.[31] [32] [33] [34] [35] [36] [37] [38] Frequency domain analysis resolves parasympathetic and sympathetic influences better than does time domain analysis, but both types of analysis are useful. RR variability predicts all-cause mortality as well as does left ventricular ejection fraction or nonsustained VT in patients after myocardial infarction[39] [40] [41] [42] [43] and can be added to other measures of risk to enhance predictive accuracy.[44] [45] [46] [47] [48] [49] [50] [51] [52] Perceived high- and low-frequency components of RR interval variability suggest that both vagal and sympathetic activities, respectively, are at physiological levels. However, reduced RR interval variability, the marker of increased risk,[53] merely indicates loss or reduction of the physiological periodic fluctuations, which can be due to many different influences and cannot necessarily be interpreted to represent a particular shift in autonomic modulation.[54]

QT DISPERSION.

Heterogeneity in refractoriness and conduction velocity is a hallmark of reentrant arrhythmias. One index of heterogeneity of ventricular refractoriness can be found in differences in length of the QT interval in surface ECG leads.[55] The most commonly used index to calculate this QT dispersion has been the difference between the longest and shortest QT intervals on the 12-lead ECG, which is often adjusted for heart rate as well as number of leads sampled (when the T wave is flat in some). Other indices have been developed. Abnormally high QT dispersion has been correlated with risk of arrhythmic death in a variety of disorders,[55] [56] [57] although results are not consistent.[58] QT dispersion has been correlated with efficacy and proarrhythmic potential of drug therapy.[59] [60] Different techniques exist for determining dispersion (including automated algorithms), and the results of one study are often difficult to compare with those of another.[23] It remains to be seen whether QT dispersion will be a useful clinical tool.[61] [62]

SIGNAL-AVERAGING TECHNIQUES.

Signal averaging is a method that improves signal-to-noise ratio when signals are recurrent and the noise is random.[63] In conjunction with appropriate filtering and other methods of noise reduction, signal averaging can detect cardiac signals of a few microvolts in amplitude, reducing noise amplitude, such as muscle potentials that are typically 5 to 25 muV, to less than 1 muV. With this method, very low-amplitude electrical potentials generated by the sinus and AV nodes, His bundle, and bundle branches are detectable at the body surface.

One of the hallmarks of reentrant ventricular arrhythmias in patients with prior myocardial damage is slow conduction. Direct cardiac mapping techniques can record

myocardial activation from damaged areas that occurs after the end of the surface QRS complex. These delayed signals have very low amplitude that cannot be discerned on routine electrocardiography and correspond to the delayed and fragmented conduction in the ventricles recorded with direct mapping techniques[64] [65] [66] [67] (Fig. 23-2) . Signal averaging has been applied clinically most often to detect such late ventricular potentials of 1 to 25 muV. Criteria for late potentials are (1) filtered QRS complex duration greater than 114 to 120 milliseconds, (2) less than 20 muV of signal in the last 40 milliseconds of the filtered QRS complex, and (3) the terminal filtered QRS complex remains below 40 muV for

Figure 23-2 Signal-averaged ECG showing the presence of prolonged QRS duration due to late potentials (dark-filled components in the terminal portion of the complex) present preoperatively but not postoperatively. RMS = root mean square (in muV); IN = integral of waveform delineated by the onset and offset markers; LAS = low amplitude signal; MN = mean value in the terminal QRS. Arrow indicates the 40-muV mark, after which the presence of low-amplitude signals is determined. Scale = number of muV per notch.

longer than 39 milliseconds. These late potentials have been recorded in 70 to 90 percent of patients with sustained and inducible VT after myocardial infarction, in only 0 to 6 percent of normal volunteers, and in 7 to 15 percent of patients after myocardial infarction who do not have VT. Late potentials can be detected as early as 3 hours after the onset of chest pain, increase in prevalence in the first week after infarction, and disappear in some patients after 1 year. If not present initially, late potentials usually do not appear later. Early use of thrombolytic agents may reduce the prevalence of late potentials after coronary occlusion.

Late potentials also have been recorded in patients with VT not related to ischemia, such as dilated cardiomyopathies. Successful surgical resection of the VT can eliminate late potentials but is not necessary to cause tachycardia suppression. Antiarrhythmic drug therapy, on the other hand, decreases the amplitude of the late potentials without abolishing them. Late potentials after myocardial infarction constitute an independent risk factor that identifies patients prone to develop VT and can be combined with other data, such as ejection fraction, spontaneous ventricular ectopy on a 24-hour ECG recording, or response to stress testing, to recognize with high sensitivity and specificity patients at risk for VT or sudden cardiac death. It also can be used to identify patients with nonsustained VT or syncope who may develop sustained VT at EPS.

The high-pass filtering used to record late potentials meeting the criteria just noted is called time domain analysis because the filter output corresponds in time to the input signal. Because late potentials are high-frequency signals, Fourier transform can be applied to extract high-frequency content from the signal-averaged ECG, called frequency domain analysis. Some data suggest that frequency domain analysis provides useful information not available in the time domain analysis. The preferable choice has not been determined.[68] [69]

Signal averaging has been applied to the P wave to determine risk for developing postoperative atrial fibrillation[70] as well as maintenance of sinus rhythm after cardioversion.[71] The overall use of the technique remains limited at present.

T WAVE ALTERNANS.

Beat-to-beat alternation in the amplitude and/or morphology of the ECG measurement of repolarization, the ST segment and T wave, has been found in conditions favoring the development of ventricular tachyarrhythmias such as ischemia[72] [73] [74] [75] [76] and long QT interval syndrome[77] [78] [79] [80] and in patients with ventricular arrhythmias.[75] [76] The electrophysiological basis of the alternation is not entirely clear. In the presence of a long QT interval, the cellular basis of alternation has been shown to be due to beat-to-beat repolarization changes in midmyocardial cells (M cells).[81] Whether this mechanism applies to different disease states is not known. T wave alternans may represent a fundamental marker of an electrically unstable myocardium prone to developing VT or VF, and, as such, ST-T wave analysis for alternans may be useful in the future as a method to risk-stratify patients (Fig. 23-3) .

BARORECEPTOR REFLEX SENSITIVITY TESTING.

Acute blood pressure elevation triggers a baroreceptor reflex that augments vagal "tone" to the heart and slows the sinus rate. The increase in sinus cycle length per millimeter of

Figure 23-3 T wave alternans. Reports of T wave alternans analysis from two patients are shown, displaying heart rate (HR) in beats per minute (BPM), proportion of beats rejected from analysis (% Bad), ECG noise level (in muV), and selected precordial leads (V_2 and V_3) as a function of time. Records in the left panel are from a patient with no structural heart disease; the amplitude of T wave alternans was minimal. The study in the right panel, from a patient hospitalized for sustained ventricular tachycardia after myocardial infarction, shows T wave alternans (shaded area, arrow).

mercury systolic blood pressure increase is a measure of the sensitivity of the baroreceptor reflex and, when reduced, identifies patients susceptible to developing VT and VF.[31] [77] The mechanism of the reduction in baroreceptor reflex sensitivity is not known. However, this test may be useful to identify patients at risk for developing a serious ventricular arrhythmia after myocardial infarction.

BODY SURFACE MAPPING.

Isopotential body surface maps are used to provide a complete picture of the effects of the currents from the heart on the body surface. The potential distributions are represented by contour lines of equal potential, and each distribution is displayed instant by instant throughout activation or recovery, or both.[82] [83] [84]

Body surface maps have been used clinically to localize and size areas of myocardial ischemia, localize ectopic foci or accessory pathways, differentiate aberrant supraventricular conduction from ventricular origin, recognize the patient prone to developing arrhythmias, and possibly understand the mechanisms involved.[85] [86] [87] [88] [89] [90] [91] [92] [93] Although these procedures are of interest, their clinical utility has not yet been established. In addition, the technique is cumbersome and the analysis is complex.

UPRIGHT TILT-TABLE TESTING (see also Chap. 27).

The tilt-table test is used to identify patients who have a vasodepressor and/or a cardioinhibitory response as a cause of syncope.[94] [95] Patients are positioned on a tilt table in the supine position and are tilted upright to a maximum of 60 to 80 degrees for 20 to 45 minutes, or longer if necessary (Fig. 23-4) . Isoproterenol, [96] [97] [98] as a bolus or an infusion, may provoke syncope in patients asymptomatic after initial upright tilt-table testing or after just several minutes of tilt to shorten the time of the test necessary to produce a positive response. An initial intravenous isoproterenol dose of 1 mug/min can be increased in 0.5-mug/min steps until symptoms occur or a maximum of 4 mug/min is given. Isoproterenol induces a vasodepressor response in upright, susceptible patients generally consisting of a decrease in heart rate and blood pressure along with near-syncope or syncope. Intravenous edrophonium chloride,[99] nitroglycerin,[95] and esmolol withdrawal[100] have been used. Atropine can block the early bradycardia but not the hypotension. Beta blockers[101] [102] can inhibit the latter. Tilt-table test results are positive in two thirds to three fourths of patients susceptible to neurally mediated syncope and are reproducible in about 80 percent,[103] [104] [105] [106] but have a 10 to 15 percent false-positive response rate. Repeating an initially negative tilt-table test on a subsequent day rarely yields a positive result.[107] Positive responses can be divided into cardioinhibitory, vasodepressor, and mixed categories.[108] Therapy with beta blockers,[101] [102] [109] disopyramide,[110] theophylline, midodrine,[111] and salt loading or fludrocortisone[112] have each been reported to be successful.

MECHANISM.[113]

Vasodepressor reactions, which are thought to be caused by activation of unmyelinated left ventricular vagal C fibers, can be triggered by a variety of events, including increased left ventricular pressure. Stimulation of C fibers from vigorous left ventricular contraction on a relatively empty cavity reduces efferent sympathetic tone while increasing efferent vagal tone, possibly producing vasodepression and paradoxical bradycardia. Isoproterenol increases left ventricular contractility while reducing left ventricular volume. A passive upright tilt exaggerates these responses because the tilt also reduces venous return and prevents isoproterenol from increasing cardiac output. Some patients may experience profound bradycardia, whereas others may have a prominent vasodepressor component (see Chap. 27). Dual-chamber pacing has been shown to benefit some patients with refractory neurocardiogenic syncope.[114] [115] Before pacemaker implantation, some investigators have advocated

performing a tilt-table test with temporary pacing catheters in place to simulate how a permanent pacing system would perform; however, correlation between this type of acute testing and long-term pacing results has not been proven.

A variant of the neurocardiogenic response, the postural orthostatic tachycardia syndrome, is characterized by dramatic increases in heart rate during the first 10 minutes of tilt-table testing.[116] This syndrome appears to be distinct from simple orthostatic hypotension as well as standard neurocardiogenic responses and is thought to be due to various forms of autonomic imbalance. Relief of symptoms has been effected with fludrocortisone, beta blockers, or combinations.

ESOPHAGEAL ELECTROCARDIOGRAPHY.

Esophageal electrocardiography is a useful noninvasive technique to diagnose arrhythmias.[117] [118] The esophagus is located immediately behind the left atrium, between the left and right pulmonary veins. An electrode in the lumen of the esophagus can record atrial potentials. Bipolar recording is superior to unipolar recording because the former can record far-field ventricular events that can lead to possible diagnostic confusion. In addition, atrial and occasionally ventricular

Figure 23-4 Head-up tilt-table testing. Surface ECG leads and an arterial blood pressure (BP) tracing are shown. After 8 minutes of head-up tilt at 80 degrees *(left)*, heart rate and BP were normal and the patient was asymptomatic. Four minutes later *(right)*, systolic BP dropped precipitously to 80 mm Hg, the heart rate fell to 50/min, and the patient lost consciousness. ECG artifact at right is seizure activity.

pacing can be performed by means of a catheter electrode inserted into the esophagus, and initiation and termination of tachycardias can be accomplished. Optimal electrode position for atrial pacing correlates with patient height and is within about 1 cm of the site at which the maximum amplitude of the atrial electrogram is recorded. No serious immediate complications of transesophageal pacing have been reported. A capsule electrode that is easily swallowed has been used to record continuous atrial electrograms from the esophagus.

When recorded simultaneously with the surface ECG, the esophageal atrial electrogram can be used to differentiate supraventricular tachycardia (SVT) with aberrancy from VT and to define the mechanism of SVTs. For example, if atrial and ventricular depolarizations occur simultaneously during a narrow QRS tachycardia, reentry utilizing an accessory AV pathway (Wolff-Parkinson-White syndrome) can be excluded, and AV nodal reentry is the most likely mechanism for the tachycardia (see Chap. 25).

Invasive Electrophysiological Studies

An invasive EPS involves introducing multipolar catheter electrodes into the venous and/or arterial system and positioning the electrodes at various intracardiac sites to record electrical activity. The heart is stimulated from portions of the atria or ventricles and from the region of the His bundle, bundle branches, accessory pathways, and other structures. Such studies are performed diagnostically to provide information on the type of rhythm disturbance and insight into its electrophysiological mechanism. They are used therapeutically to terminate a tachycardia by electrical stimulation or electroshock, to evaluate the effects of therapy by determining whether a particular intervention modifies or prevents electrical induction of a tachycardia or whether an electrical device properly senses and terminates an induced tachyarrhythmia, and to ablate myocardium involved in the tachycardia to prevent further episodes. Finally, these tests have been used prognostically to identify patients at risk for sudden cardiac death. The study may be helpful in patients who have AV block, intraventricular conduction disturbance, sinus node dysfunction, tachycardia, and unexplained syncope or palpitations.[119]

The EPS is quite good at initiating VT or SVT when these have occurred spontaneously. This enables the use of similar stimulation techniques after an intervention (drug therapy or surgical or catheter ablation) to assess treatment efficacy. However, false-negative responses (not finding a particular electrical abnormality known to be present) as well as false-positive ones (induction of a nonclinical arrhythmia) may complicate interpretation of the results, as many lack reproducibility. Altered autonomic tone in a supine patient undergoing study, hemodynamic or ischemic influences, changing anatomy (e.g., new infarction) after the study, day-to-day variability, and the fact that the test employs

an artificial "trigger" (electrical stimulation) to induce the arrhythmia are several of many factors that may explain the occasional disparity between test results and spontaneous clinical occurrences. Overall, the diagnostic validity and reproducibility of these studies are quite good, and they are very safe when performed by skilled clinical electrophysiologists.

AV Block (See also Chap. 25.)

In patients with AV block, the site of block usually dictates the clinical course of the patient and whether a pacemaker is needed.[120] Generally, the site of AV block can be determined from an analysis of the scalar ECG. When the site of block cannot be determined from such an analysis, and when knowing the site of block is imperative for patient management, an invasive EPS is indicated. Candidates include symptomatic patients in whom His-Purkinje block is suspected but not established and patients with AV block treated with a pacemaker who continue to be symptomatic in whom a causal ventricular tachyarrhythmia is sought. Possible candidates are those with second- or third-degree AV block in whom knowledge of the site of block or its mechanism may help direct therapy or assess prognosis and patients suspected of having concealed His bundle extrasystoles. Patients with block in the His-Purkinje system more commonly become symptomatic because of periods of bradycardia or asystole and more commonly require pacemaker implantation than do patients who have AV nodal block.[121] Wenckebach's (type I) AV block in older patients may have clinical implications similar to type II AV block. The results of EPS for evaluating the conduction system must be interpreted with caution, however. In rare cases, the process of recording conduction intervals alters their values. For instance, catheter pressure on the AV node or His bundle can cause a prolongation of the atrial-His (AH) or His-ventricular (HV) interval and lead to erroneous diagnosis and therapy.

Intraventricular Conduction Disturbance

For patients with an intraventricular conduction disturbance, an EPS provides information on the duration of the HV interval, which can be prolonged with a normal PR interval or normal with a prolonged PR interval. A prolonged HV interval (>55 msec) is associated with a greater likelihood of developing trifascicular block (but the rate of progression is slow, 2 to 3 percent annually), having structural disease, and higher mortality. Finding very long HV intervals (>80 to 90 msec) identifies patients at increased risk of developing AV block. The HV interval has a high specificity (about 80 percent) but low sensitivity (about 66 percent) for predicting the development of complete AV block. During the study, atrial pacing is used to uncover abnormal His-Purkinje conduction.[122] A positive response is provocation of distal His block during 1:1 AV node conduction. Once again, sensitivity is low but specificity is high. Functional His-Purkinje block due to normal HisPurkinje refractoriness is not a positive response. Drug infusion, such as that with procainamide or ajmaline, sometimes exposes abnormal His-Purkinje conduction (Fig. 23-5) . Ajmaline (not available in the United States) can cause arrhythmias and should be used cautiously.

An EPS is indicated in the patient with symptoms (syncope or presyncope) that appear to be related to a bradyarrhythmia or tachyarrhythmia when no other cause of symptoms

Figure 23-5 Testing the His-Purkinje system. A 43-year-old woman with sarcoid underwent electrophysiological study after a syncopal episode. Surface leads 1, 2, V_1 , and V_6 are shown with intracardiac recordings from catheters in the high right atrium (HRA), proximal (prox) and distal (dist) electrode pairs of a catheter at the atrioventricular junction to record the His potential, and right ventricular apex (RVA). A = atrial electrogram; H = His potential; V = ventricular electrogram. During baseline recording, the HV interval is only slightly prolonged (62 msec). After infusion of intravenous procainamide, the HV is longer and infra-His Wenckebach is present. Arrow denotes "missing" QRS complex due to infra-His block.

is found. For many of these patients, ventricular tachyarrhythmias rather than AV block can be the cause of their symptoms.[123]

Sinus Node Dysfunction

The demonstration of slow sinus rates, sinus exit block, or sinus pauses temporally related to symptoms suggests a causal relationship and usually obviates further diagnostic studies.[124] [125] [126] [127] [128] Carotid sinus pressure that results in several seconds of complete cardiac asystole or AV block and reproduces the patient's usual symptoms exposes the presence of a hypersensitive carotid sinus reflex (see Chap. 22). Carotid sinus massage must be done cautiously. Rarely, carotid sinus massage can precipitate a stroke. Neurohumoral agents, adenosine,[129] or stress testing can be employed to evaluate the effects of autonomic tone on sinus node automaticity and sinoatrial conduction time. EPS should be considered in patients who have symptoms attributable to bradycardia or asystole, such as presyncope or syncope, and for whom noninvasive approaches have provided no explanation for the symptoms.[130]

SINUS NODE RECOVERY TIME (SNRT).

This technique can be a useful test to evaluate sinus node function. The interval between the last paced high right atrial response and the first spontaneous (sinus) high right atrial response after termination of pacing is measured to determine the SNRT. Because the spontaneous sinus rate influences the SNRT, the value is corrected by subtracting the spontaneous sinus node cycle length (C) (before pacing) from the SNRT (Fig. 23-6) . This value, the CSNRT, is generally less than 525 milliseconds. Prolonged CSNRT has been found in patients suspected of having sinus node dysfunction. Direct recordings of the sinus node electrogram have documented that SNRT is influenced by prolongation of sinoatrial conduction time (the time from the onset of the sinus impulse to the onset of activation of surrounding atrial myocardium), as well as by changes in sinus node automaticity, especially in the first beat after cessation of pacing. After cessation of pacing, the first return sinus cycle can be normal and can be followed by secondary pauses. Secondary pauses appear to be more common in patients whose sinus node dysfunction is caused by sinoatrial exit block. Sinoatrial exit block can cause some sinus pauses. Finally, it is important to evaluate AV node and His-Purkinje function in patients with sinus node dysfunction, because many also exhibit impaired AV conduction.

SINOATRIAL CONDUCTION TIME (SACT).

This time can be estimated using simple pacing techniques based on the assumptions that (1) conduction times into and out of the sinus node are equal, (2) no depression of sinus node automaticity occurs, and (3) the pacemaker site does not shift after premature stimulation. These assumptions may be erroneous, particularly in patients with sinus node dysfunction. SACT can also be measured directly with extracellular electrodes placed in the region of the sinus node. This direct measurement correlates well with the SACT measured indirectly in patients with normal sinus node function. The sensitivity of the SACT and SNRT tests is only about 50 percent for each test alone and about 65 percent when combined. The specificity, when combined, is about 88 percent, with a low predictive value. Thus, if they are abnormal, the likelihood of the patient having sinus node dysfunction is great. However, if they are normal, that does not exclude the possibility of sinus node disease. Candidates for invasive EPS to evaluate sinus node function are symptomatic patients in whom sinus node dysfunction has not been established as a cause of the symptoms. Potential candidates are those requiring pacemakers to determine the pacing modality, patients with sinus node dysfunction to determine the mechanism and response to therapy, and patients

Figure 23-6 Abnormal sinus node function. Recordings are similar to those in Figure 23-3 . The last five complexes of a 1-minute burst of atrial pacing (S) at a cycle length of 400 msec are shown, after which pacing is stopped. The sinus node does not spontaneously discharge (sinus node recovery time) until 6.2 seconds later (arrow). Three junctional escape beats occurred before this time.

in whom other causes of symptoms (e.g., tachyarrhythmias) are to be excluded.

Tachycardia

In patients with tachycardias, an EPS may be used to diagnose the arrhythmia, determine and deliver therapy, determine the anatomical site(s) involved in the tachycardia, identify patients at high risk for developing serious arrhythmias, and gain insights into mechanisms responsible for the arrhythmia. The study can differentiate aberrant supraventricular conduction from ventricular tachyarrhythmias when standard ECG criteria are equivocal in making the differentiation.[131] [132]

An SVT is recognized electrophysiologically by the presence of an HV interval equaling or exceeding that recorded during normal sinus rhythm (Fig. 23-7) . In contrast, during VT, the HV interval is shorter than normal or the His deflection cannot be recorded clearly owing to superimposition of the larger ventricular electrogram. Only two situations exist when a consistently short HV interval occurs: during retrograde activation of the His bundle from activation originating in the ventricle (i.e., PVC or tachycardia) (see Chap. 25) or during conduction over an accessory pathway (preexcitation syndrome; see Chap. 25). Atrial pacing at rates exceeding the tachycardia rate can demonstrate the ventricular origin of the wide QRS tachycardia by producing fusion and capture beats and normalization of the HV interval. The only VT that exhibits an HV interval equal to or slightly exceeding the normal sinus HV interval is bundle branch reentry (see Chap. 25), but His activation will be in the retrograde direction.

INDICATIONS FOR EPS IN PATIENTS WITH TACHYCARDIA.

An EPS should be considered (1) in patients who have symptomatic, recurrent, or drug-resistant supraventricular or ventricular tachyarrhythmias to help select optimal therapy; (2) in patients with tachyarrhythmias occurring too

Figure 23-7 Bundle of His recordings in different situations. Recordings similar to prior figures; CS = coronary sinus. *A,* Baseline sinus rhythm with normal AV conduction. *B,* Orthodromic supraventricular tachycardia with retrograde conduction over a left-sided accessory pathway throughout the tracing. The first three beats have a narrow QRS complex with a normal HV interval; the last three QRS complexes represent a fusion of conduction over the AV node-His and a slowly conducting right-sided accessory pathway. The His potential occurs after the onset of the wide QRS complex (dashed lines). In *C,* three paced ventricular beats are shown with a retrograde His potential (H
), followed by initiation of AV node reentrant supraventricular tachycardia (atrial depolarization near the end of the QRS complex, as seen in HRA tracing). *D,* Ventricular tachycardia with delayed activation of the His potential and complete retrograde AV node block (dissociated atrial complexes).

infrequently to permit adequate diagnostic or therapeutic assessment; (3) to differentiate SVT and aberrant conduction from VT; (4) whenever nonpharmacological therapy such as the use of electrical devices, catheter ablation, or surgery is contemplated; (5) in patients surviving an episode of cardiac arrest (occurring 48 hours after an acute myocardial infarction or without evidence of an acute Q-wave myocardial infarction); and (6) in assessing risk of sustained VT in patients with a prior myocardial infarction, ejection fraction less than 0.4 and nonsustained VT on ECG.[133] Generally, EPS is not indicated in patients with the long QT syndrome and torsades de pointes, although recent information about early afterdepolarizations (see Chap. 22) may make such studies useful in the future.

The process of initiation and termination of SVT or VT with programmed electrical stimulation to test the potential efficacy of pharmacological, electrical, or surgical therapy represents an important application of EPS in patients with tachycardia. Arrhythmia-free survival is higher among patients in whom a drug prevents electrical reinitiation of a sustained monomorphic VT that was induced during the predrug control state. Among patients in whom VT remains inducible, characteristics of the induced arrhythmia predict features of future recurrences. When the tachycardia and its hemodynamic response are not altered, an adverse risk for recurrence and mortality is predicted. When the tachycardia cycle length is prolonged more than 100 milliseconds and stable hemodynamics result, survival improves.[134]

Determination of drug efficacy based on results from long-term ECG recordings may be insufficient to predict a patient's therapeutic response when a low frequency of spontaneous ventricular arrhythmias is present. Two studies have concluded that noninvasive assessment of drug efficacy testing using beta blockers[135] or amiodarone[136] may be superior to the results of programmed electrical stimulation using conventional antiarrhythmic agents. Another controlled, randomized study comparing invasive and noninvasive assessments of conventional drugs[11] found both techniques to be equivalent.[10] Both invasive and noninvasive methods should be considered appropriate approaches for guiding drug therapy.

Patients with Unexplained Syncope (See Chap. 27.)

The three common arrhythmic causes of syncope include sinus node dysfunction, tachyarrhythmias, and AV block. Of the three, tachyarrhythmias are most reliably initiated in the electrophysiology laboratory, followed by sinus node abnormalities and then His-Purkinje block.[137]

The cause of syncope goes undetected in up to 50 percent of patients, depending in part on the extent of the evaluation. A careful, accurately performed history and physical examination begin the evaluation,[1] [138] [139] followed by noninvasive tests, including a 12-lead and 24-hour ECG recording, and can lead to a diagnosis in half or more of the patients.[137] [140] [141] [142] [143] The 1-year mortality is about 6 percent in patients with unknown causes, and 1 to 12 percent in patients with noncardiovascular causes but 19 to 30 percent in patients with cardiovascular causes. The incidence of sudden death is also higher in patients with a cardiovascular cause of syncope. A small percentage (< 5 percent) of patients develop an arrhythmia coincident with syncope or presyncope during a 24-hour ECG recording, whereas a larger percentage (15 percent) have symptoms without an arrhythmia, excluding an arrhythmic cause. Prolonged ECG monitoring with patient-activated transtelephonic event recorders that have memory loops may increase the yield. Signal averaging has a high sensitivity (about 75 percent) and specificity (about 90 percent) for predicting patients with syncope in whom VT can be induced at EPS.[144] Tilt-table testing[108] [145] [146] [147] and stress testing[148] can be useful in some patients, as can long-term ECG recordings.[149]

The EPS helps explain the cause of syncope or palpitations when it induces an arrhythmia that replicates the patient's symptoms. Syncopal patients with a nondiagnostic EPS have a low incidence of sudden death and 80 percent remission rate. In those with recurrent syncope, the test is falsely negative in 20 percent, owing to failure to find AV block or sinus node dysfunction. On the other hand, in many patients with structural heart disease, several abnormalities that could account for syncope may be diagnosed at EPS. Deciding which among these abnormalities is responsible for syncope and therefore requires therapy can be difficult. Mortality and incidence of sudden cardiac death are mainly determined by the presence of underlying heart disease.[150]

Syncopal patients considered for EPS are those whose spells remain undiagnosed despite general, neurological, and noninvasive cardiac evaluation, particularly if the patient has structural heart disease. The diagnostic yield is about 70 percent in that group but only about 12 percent in patients without structural heart disease. Therapy for a putative cause found during EPS prevents recurrence of syncope in about 80 percent of patients. Among arrhythmic causes of syncope, intermittent conduction disturbances are the most difficult to diagnose. EPS is poor at establishing this diagnosis despite an array of provocative tests that can be applied. When tachyarrhythmias have been thoroughly sought and excluded and the clinical suspicion of intermittent heart block is high (e.g., bundle branch block or long HV interval), empirical pacing may be justified.

Palpitations

An EPS is indicated in patients with palpitations[2] [3] [151] who have had a pulse documented by medical personnel to be inappropriately rapid without ECG recording or in those suspected of having clinically significant palpitations without ECG documentation.

In patients with syncope or palpitation, the sensitivity of the EPS may be very low but may be increased at the expense of specificity. For example, more aggressive pacing techniques (e.g., using three or four premature stimuli), administration of drugs (e.g., isoproterenol), or left ventricular pacing can increase the success rate of VT induction, but by precipitating nonclinical ventricular tachyarrhythmias such as nonsustained polymorphic or monomorphic VT or VF. Similarly, aggressive techniques during atrial pacing can induce nonspecific episodes of atrial flutter or atrial fibrillation. A diagnostic dilemma arises when the patient's clinical, symptom-producing arrhythmia is one of these nonspecific arrhythmias that can be produced in the normal patient who has no arrhythmia. In most patients, these arrhythmias are regarded as "nonclinical" (i.e., nonspecific responses to intense stimulation). In other patients, such as those with hypertrophic or dilated nonischemic cardiomyopathy, these may be clinically relevant arrhythmias. Induction of sustained SVT (e.g., AV nodal reentry, AV reciprocating tachycardia) or monomorphic VT in patients who are not subject to the spontaneous development of the tachycardia appears to be uncommon and provides important information that the induced tachyarrhythmia may be clinically significant and responsible for the patient's symptoms. Generally, other abnormalities, such as prolonged sinus pauses after overdrive atrial pacing or His-Purkinje AV block, are not induced in patients who do not or may not experience these abnormalities spontaneously. Induction of these arrhythmias has a high degree of specificity.

Direct Cardiac Mapping: Recording Potentials Directly from the Heart

Cardiac mapping is a method whereby potentials recorded directly from the heart are spatially depicted as a function

Figure 23-8 Endocardial catheter recordings during ventricular tachycardia (VT) in two patients. Dashed lines denote onset of QRS complexes. In *A,* a woman without structural heart disease had a sustained VT arising from the left ventricular outflow tract (LVOT). Note unipolar (uni) electrogram with a sharp "QS" complex and the onset (arrow) distal bipolar recording ($LVOT_{1-2}$) preceding right ventricular recordings. They also precede recordings from a multielectrode catheter advanced along the coronary sinus and down the great cardiac vein (GCV) on the epicardial surface opposite the endocardial recording. Retrograde 1:1 conduction is present. Ablation at this site (LVOT) terminated the VT. In *B,* a patient with reentrant VT due to a prior inferior wall infarction underwent mapping. The ablation catheter on the inferomedial wall shows a very prolonged, fragmented electrogram indicative of slow conduction. The electrogram spans all of the diastolic interval between QRS complexes. Ablation at this site eliminated the VT.

of time in an integrated manner (Fig. 23-8) . The location of recording electrodes (epicardial, intramural, or endocardial) and the recording mode used (unipolar vs. bipolar) as well as the method of display (isopotential vs. isochrone maps) depend on the problem under consideration. Special electrodes can record monophasic action potentials.[152]

Direct cardiac mapping by means of catheter electrodes or at the time of cardiac surgery can be used to identify and localize the areas responsible for rhythm disturbances in patients with supraventricular and ventricular tachyarrhythmias for electrical or surgical ablation, isolation, or resection. Disorders amenable to this approach include accessory pathways associated with the Wolff-Parkinson-White syndrome, the pathway(s) in AV node reentry, His bundle ablation, sites of origin of automatic atrial and VTs, and isolated pathways essential for maintenance of reentrant atrial or ventricular tachycardias. Mapping can also be used to delineate the anatomical course of the His bundle to avoid injury during open-heart surgery (usually for congenital heart surgery or septal accessory pathway ablation). These approaches are discussed in greater detail later in this chapter and in Chapter 25 under the individual arrhythmias.

Complications of Electrophysiological Studies

The risks of undergoing only an EPS are small.[153] Because most procedures do not involve left-sided heart access, risk of stroke, systemic embolism, or myocardial infarction is less than that of coronary arteriography. Myocardial perforation with cardiac tamponade, pseudoaneurysms at arterial access sites, and provocation of nonclinical arrhythmias can occur, each with less than 1/500 incidence. Adding therapeutic maneuvers (e.g., ablation) to the procedure increases the incidence of complications.[153A] In a European survey[154] based on 4398 patients reported from 68 institutions, procedure-related complications ranged from 3.2 to 8 percent. Five deaths occurred within the perioperative period of the ablation. In a North American Society of Pacing and Electrophysiology (NASPE) survey[155] of 164 hospitals reporting in 1994 on over 10,000 patients who received RF ablation, complications ranged from 1 to 3 percent, with procedure-related deaths of about 0.2 percent. The most recent data come from a multicenter study using a single type of temperature-controlled ablation system. In this study of 1050 patients undergoing ablation for supraventricular arrhythmias, 32 (3%) had a major complication. Predictors of major complications were ejection fraction less than 0.35 and multiple ablation targets.[156] The improvement in the complication rate probably reflects the learning curve for radio frequency ablation.

Therapy for Cardiac Arrhythmias

PHARMACOLOGICAL THERAPY

PRINCIPLES OF CLINICAL PHARMACOKINETICS

Pharmacological treatment of a patient with a cardiac arrhythmia has as its primary objective to reach an effective and well-tolerated plasma drug concentration as rapidly as possible and to maintain this concentration for as long as required without producing adverse effects. In many but not all situations and not with all drugs, plasma concentration after equilibration correlates with the pharmacodynamic as well as adverse effects of the drug. Therapeutic serum concentrations for the most important available antiarrhythmic agents are listed in Table 23-1 and are based on concentrations of drugs that exert therapeutic effects on often benign arrhythmias such as PVCs without adverse effects in a majority of patients. However, the therapeutic concentration for any individual patient is the amount of drug required *for that patient* to suppress or terminate the specific cardiac arrhythmia requiring treatment without producing adverse effects.

For a specific patient, one must consider the response both of the patient and of the arrhythmia to the drug; the actual plasma concentration of the drug is often of secondary importance. Low drug concentrations can exert a therapeutic or toxic effect in some patients, whereas drug concentrations higher than the normal range may be needed and tolerated in other patients. In some patients, measured plasma concentrations can be useful to establish concentrations needed for arrhythmia prophylaxis, to judge the sensitivity or resistance of the arrhythmia to the drug, and to evaluate symptoms that suggest drug toxicity. Plasma concentrations also can be used to determine the effects of changing physiological states on drug concentrations, establish drug compliance or abuse, search for drug interactions that affect the pharmacokinetics, and establish the importance of physiologically active metabolites of the parent compound.[157] [158] Active metabolites may be suspected when the clinical effect of the drug outlasts the therapeutic serum concentration of the parent compound or when results immediately after intravenous drug administration differ from those after oral administration of the drug.

Normally, because antiarrhythmic agents have a narrow toxic-therapeutic relationship, important complications of therapy can result from amounts of drug that only slightly exceed the amount necessary to produce beneficial effects; lesser concentrations are often subtherapeutic. It is obvious that careful dosing with these agents is essential to maintain adequate but nontoxic amounts of drug in the body, a task facilitated by understanding drug *pharmacokinetics.*[159] [160] [161] The latter consists of a quantitative assessment of drug dose concentration factors, including drug absorption, distribution, metabolism, and excretion. Alterations in the rate of any of these processes can account for significant intrapatient and interpatient variations in plasma concentrations. In addition, changes in the functional status of any of the organs involved (e.g., the heart, liver, or kidneys) can significantly alter dose requirements in a given patient. The latter concerns a study of *pharmacodynamics,* or drug concentration response issues.[158] [162] *Pharmacogenetics* refers to the influence of genetics on drug metabolism and action. Examples of pharmacogenetic effects include whether procainamide is extensively metabolized to *N*-acetylprocainamide (NAPA), as well as the bimodal population distribution of the oxidative cytochrome P450 enzyme (important in antiarrhythmic drug metabolism). The low activity of this enzyme leads to accumulation of the parent compound, whereas patients with high enzyme activity metabolize drugs more extensively, leading to an altered drug effect.

ABSORPTION.

Drug absorption from the intestinal tract occurs for most drugs with a half-life of absorption in the range of 20 to 30 minutes. completeness of absorption can vary between 50 and over 90 percent, depending on the drug, with most absorption occurring in the small intestine. Different preparations of the same drug can undergo different rates of absorption in the same patient because the tablet preparations have different dissolution rates. Thus, different brands of drug may not result in the same serum concentration. By altering the properties of the tablet, a slow-release form of a drug ordinarily rapidly absorbed and metabolized, such as procainamide, can be developed. Large amounts of some orally administered drugs, such as propranolol or verapamil, are transformed into inactive metabolites in the liver before they reach the systemic circulation (the so-called first-pass hepatic effect).[161] For such an agent, much more drug must be administered orally than intravenously to achieve the same physiological effect.

Absorption Abnormalities.

Disease states and other factors can alter the rate and completeness of drug absorption. For example, heart failure can cause mucosal edema of the gut and impair absorption of orally administered drugs, as can decreased intestinal blood flow. Renal or hepatic hypoperfusion can reduce drug elimination and metabolism. Reduced volume of distribution and impaired clearance can increase elimination half-life, requiring a reduction in loading and maintenance doses (see Tables 23-1 and 23-2). Malabsorption syndromes, concomitant use of other drugs, or changes in gut motility or flora caused by diarrheal states, antibiotics, or the use of cathartics can alter absorption. Because most antiarrhythmic agents are basic compounds, they are ionized and poorly absorbed at normal gastric pH, and some drugs can decompose at gastric pH. Conditions that delay gastric emptying increase the absorption lag phase between ingestion of these drugs and their arrival in the small intestine, where most absorption takes place, and therefore can delay absorption. In patients with severe hypotension, shock, or cardiac arrest, impaired tissue perfusion prevents reliable absorption of intramuscularly administered agents; these patients should receive all medications by the intravenous (IV) route.

BIOAVAILABILITY.

The rate of drug absorption, which is determined by the time required to achieve maximum plasma concentration, and the fraction of drug absorbed influence the drug's *bioavailability,* which is a measure of the amount of drug that reaches the systemic circulation intact. Bioavailability of a drug is influenced by factors such as pill dissolution, absorption, metabolism by gut mucosa, hepatic metabolism, and plasma protein binding.

The fraction of an orally administered drug reaching the systemic circulation intact, or *systemic availability,* can be calculated (assuming equal clearances for IV and oral forms of drug) by comparing the areas under the plasma concentration curve achieved with oral and IV administrations using the following relationship. Systemic availability equals the area under the plasma concentration curve after oral administration divided by the area under the plasma concentration curve after IV administration times 100 (assuming equal IV and oral doses).

DRUG DISTRIBUTION

Most antiarrhythmic drugs in the therapeutic range are eliminated according to *first-order kinetics,* which means that the amount of drug eliminated per unit of time is directly proportional to the amount (or concentration) of drug in the body. More drug in the body results in more drug excreted by the kidneys or metabolized by the liver so that the *fraction* of drug eliminated per unit of time remains constant regardless of the amount of drug in the body. For example, one half the drug may be eliminated in 6 hours whether the total amount of drug in the body is 4 g or 10 g, resulting in elimination of 2 g in the first example and 5 g in the second. As a consequence, the elimination half-life, or time required to eliminate half the body load (or to halve the plasma concentration) of such a drug, is constant and independent of the total-body load. The following discussion will assume first-order kinetics unless otherwise stated. (*Zero-order kinetics* indicates that the reaction occurs at a constant, usually maximal, rate and cannot increase further despite increased drug concentrations. Such nonlinear or saturable kinetics can occur at high concentrations of a drug that at usual concentrations exhibits first-order kinetics.[158])

THE ONE-COMPARTMENT MODEL.

Generally, two models, a *one-compartment open model* and a *two-compartment open model,* are used with relative accuracy to describe and predict serum concentrations at a given time for a variety of dose regimens. Even though these models are oversimplified representations of drug disposition, they provide guidelines for choosing loading doses and maintenance dose schedules for a given patient. In the one-compartment open model, drugs are considered to enter and to be eliminated from a single homogeneous unit that represents the entire body. Drugs entering the compartment are considered to be distributed immediately throughout the compartment, making the concentration of the drug equal to the amount of drug in the compartment divided by the volume of the compartment. The latter equals the amount of the drug in the compartment divided by the drug concentration.

In reality, a one-compartment open model is not entirely appropriate because a certain amount of time is needed to distribute the drug throughout the volume of the compartment. However, the one-compartment model predicts plasma concentration as a function of time and dose if distribution is significantly faster than the rate of administration or excretion, which is the case for many antiarrhythmic drugs.

THE TWO-COMPARTMENT MODEL.

If the rate of drug administration is rapid in relation to drug distribution (e.g., IV administration), a two-compartment open model more accurately predicts drug concentrations (Fig. 23-9) . In this model the drug enters the system by the central compartment and can leave the system only by distribution into a peripheral compartment or elimination from the central compartment. The central compartment, in dynamic equilibrium with the more slowly equilibrating peripheral compartment, is assumed to consist of the blood volume and extracellular fluid of highly perfused tissues such as the heart, lungs, kidneys, and liver, whereas the peripheral compartment, acting as a reservoir, consists of less well perfused tissue such as muscle, skin, and adipose tissue. The first-order

Results presented may vary according to doses, disease state, and intravenous or oral administration.

*Intravenous use investigational.

TABLE 23-2 -- KNOWN INFLUENCE OF DISEASE STATES AND OTHER CONDITIONS ON ANTIARRHYTHMIC DRUG PHARMACOKINETICS

DISEASE OR CONDITION	EFFECTS
Congestive heart failure	Reduced clearance of:
	Lidocaine
	Procainamide
	Flecainide
	Reduced volume of distribution of:
	Lidocaine
Liver disease	Reduced clearance of:
	Lidocaine
	Disopyramide
	Phenytoin
	Propranolol
Renal disease	Reduced clearance of:
	Disopyramide
	Procainamide
	Bretylium
	Flecainide
	Altered protein binding (with usually unchanged drug requirements) of:
	Phenytoin
Post-myocardial infarction	Reduced clearance of:
	Procainamide
	Altered protein binding of:
	Lidocaine
	Quinidine
Prolonged administration	Reduced clearance of:
	Lidocaine
Obesity	Increased volume of distribution of:
	Lidocaine

From Roden D: New concepts in antiarrhythmic drug pharmacokinetics. Prog Cardiovasc Dis 15:19, 1987.

rate constants $K_{1\text{-}2}$ and $K_{2\text{-}1}$ determine the rate of transfer of drug between the central and peripheral compartments or vice versa, with Ke representing the overall elimination rate constant. Ke relates the sum of all methods of irreversible drug elimination from the central compartment to the concentration of drug in that compartment (see Fig. 23-9).

For antiarrhythmic drugs, the peripheral compartment is generally larger than the central compartment. The concepts of distribution volumes and drug movement are more complex in the two-compartment open model than in the one-compartment open model. The two-compartment model may behave similarly to the one-compartment model when drugs are infused slowly or given orally and K_1 approximates K_2 , but pronounced differences exist when injections are given rapidly.

DISTRIBUTION AND ELIMINATION PHASES.

After administration of drugs for which the kinetics are described by a two-compartment

Figure 23-9 Two-compartment open model. A smaller central compartment into which drug is administered and from which it is eliminated (Ke) connects in dynamic equilibrium with a larger peripheral compartment.

model, the curve of plasma drug concentration demonstrates two distinct phases: (1) an early phase (alpha, or distribution, phase), characterized by rapidly falling plasma drug concentrations due to distribution between the central compartment and the peripheral compartment, and (2) a second phase (beta, or elimination, phase) of slower decline in plasma drug concentration, representing primarily elimination of drugs from the central compartment (Fig. 23-10) . *Alpha* is often referred to as the *rate constant for distribution* and *beta* as the *rate constant for elimination.* During the latter beta phase, when the drug is in distribution equilibrium, serum concentrations correlate with the pharmacological effects of the drug. The distribution of quinidine is shown in Figure 23-11 .

VOLUME OF DISTRIBUTION.

The extent of extravascular distribution of a drug is obtained by measuring the apparent *volume of distribution* (V_d), which is the hypothetical volume into which a dose of drug would have to be diluted to give the observed plasma concentration. It is determined by the dose administered divided by the plasma concentration at time 0. The latter equals the sum of A and B on the logarithmic plasma concentration axis obtained by extrapolating the alpha and beta phases back to 0 time (see Fig. 23-10). It is also calculated by dividing the systemic clearance of the drug by beta, the rate constant of elimination. A large volume of distribution indicates a wide distribution and extensive tissue uptake of the drug and often exceeds by several times the actual amount of total-body water. The large volume of distribution for most antiarrhythmic agents indicates that they are present in higher concentrations in some tissues than in the plasma. The volume of distribution is dependent on the relative serum and tissue binding characteristics of the drug and can be constricted in some patients, such as those with renal failure, during which a change in serum protein or tissue binding can occur. Quinidine decreases the volume of distribution of digoxin, probably as a result of a decrease in tissue binding of digoxin, and thereby causes an increase in serum digoxin concentration.

DRUG METABOLISM AND EXCRETION.

Serum elimination half-life is defined as the time interval for 50 percent of the drug present in the body at the beginning of the interval to be eliminated. After one half-life, 50 percent of the drug remains in the body (assuming no further drug is administered), after two half-lives 25 percent remains, after three half-lives 12.5 percent remains, and so forth. Approximately 97 percent of the dose of any drug is removed from the body after five half-lives. Half-life is determined from the relationship $t_{1/2}$ = 0.693/beta for a two-compartment model (see Fig. 23-10). Because changes in drug distribution influence elimination half-life, the equation can be rewritten as

DRUG CLEARANCE.

This is analogous to renal clearance and is the volume of blood totally cleared of drug per unit of time. It is the sum of the clearances for each process by which the drug is eliminated and can be calculated from the relationship

Figure 23-10 Schematic diagram of the semilogarithmic plot of drug plasma concentration as a function of time after rapid intravenous injection, according to the principles outlined for a two-compartment open model. *(From Gibaldi M, Perrier D: Drugs and the pharmaceutical sciences. In Pharmacokinetics, vol 1. New York, Marcel Dekker, 1975.)*

Figure 23-11 *A,* Changes in plasma concentration over time after beginning treatment with quinidine. *Top,* Quinidine plasma concentration over time, with the dashed line indicating the therapeutic range. *Bottom,* The hatched bars represent the body load immediately after each dose of quinidine, expressed as a percentage of the load after a dose when a steady state has been achieved. Quinidine is administered every 6 hours (the half-life in this case). Four half-lives, or 24 hours, are required to achieve a body load of quinidine that exceeds 90 percent of the load at steady state. *B, top,* Plasma concentrations produced by administering a full intravenous loading dose of quinidine as a bolus, with the therapeutic range shown by a dashed line. *Bottom,* The numbered vertical boxes indicate the volume of distribution of quinidine. Just after the drug is given, it is dissolved only in the small central compartment, as in box 1, and very high peak concentrations are achieved (in the toxic range). The drug then distributes throughout the rest of the body. Distribution has a half-life of about 8 minutes and is complete by 30 minutes (box 3). Quinidine concentration is now in the therapeutic range, and further decreases in plasma concentration are due solely to drug elimination. *(From Nattel S, Zipes DP: Clinical pharmacology of old and new antiarrhythmic drugs. Cardiovasc Clin 11:221, 1980.)*

Expressed differently,

A larger volume of distribution increases the elimination half-life at a given clearance. The larger volume of distribution of antiarrhythmic drugs accounts for the relatively long half-life despite their high clearance rates. Administration of one drug may alter the half-life of another; for example, quinidine prolongs digoxin's half-life by decreasing total-body clearance. Clearance of drugs with high extraction ratios strongly depends on blood flow to the organ from which they are eliminated, such as propranolol, verapamil, or lidocaine in the liver. For antiarrhythmic drugs that have a high renal extraction ratio, such as procainamide and quinidine, reduction of renal flow decreases their clearance.

ELIMINATION HALF-LIFE.

The function of the organ system that eliminates a given drug from the body determines the elimination half-life. Primary routes of elimination are hepatic metabolism and renal clearance. The kidneys can remove unchanged drug or metabolites. For drugs rapidly metabolized in the liver, hepatic blood flow limits the rate of drug elimination. Disorders that reduce liver blood flow (e.g., low cardiac output, hepatic disease with portacaval shunting) markedly slow the elimination of such drugs. Drugs with a short half-life are convenient to use by intravenous infusion but not by chronic oral dosing, since the short half-life requires frequent oral doses to maintain a fairly constant plasma concentration. Generally, maintenance dosing involves giving a certain amount of the drug at a time interval that equals the elimination half-life. However, with drugs that have very long half-lives, such as 12 hours, this can result in excessive peak values shortly after administration and consequent side effects. Maintaining constant plasma concentrations is necessary because of the narrow toxic-therapeutic ratios exhibited by antiarrhythmic agents.

Some drugs have active metabolites with half-lives considerably longer than the parent compound, allowing dosing intervals to be more widely spaced than those predicted by the half-life of the parent drug. The active metabolite of procainamide, NAPA, is eliminated unchanged by the kidneys and can accumulate in high concentrations in patients with renal disease. The rate and extent of metabolism of the same drug can vary greatly from patient to patient owing to a variety of factors, including environment, genetics, age, disease states, and influence of other drugs given concomitantly. A genetically determined acetyltransferase enzyme system influences the metabolism of some drugs, making about half the American population "rapid" and half "slow acetylators." Rapid acetylators metabolize a greater proportion of a drug dose than do slow acetylators, who may require less drug to achieve any desired serum level or pharmacological effect. Also, rapid acetylators may be more prone to develop reactions from the metabolites of drugs or are less likely to develop side effects from the parent compound for a constant drug dose.

DRUG BINDING

Drugs exist in plasma both in the free form and bound to plasma proteins. Only free drug is capable of distributing into tissues and exerting a pharmacological action. Some drugs (e.g., verapamil, sotalol, and disopyramide) have optical isomers, with different potencies and effects. Virtually all assays for drug concentration in the blood measure *both* free and protein-bound drug. For antiarrhythmic drugs, the fraction of drug that is bound varies greatly among the different agents but is fairly constant for individual drugs over the clinically relevant range of plasma concentrations, with the exception of phenytoin, lidocaine, propafenone, and disopyramide. With these drugs, binding sites become saturated at high concentrations; therefore, a doubling of total drug concentration represents more than a doubling of unbound drug. Total plasma concentrations of a given drug generally correlate well with its clinical effects, and it has not been necessary to develop assays to measure free drug concentrations

for antiarrhythmic agents. Some drugs, such as quinidine and lidocaine, bind to an $alpha_1$ -acid glycoprotein that increases in acute disease states such as myocardial infarction, which may decrease the concentration of free drug.

When a constant dose of a drug is administered repeatedly (orally or parenterally) at a constant dosing interval, accumulation occurs until drug concentration approaches a constant steady-state level, at which time the rate of drug administration equals the rate of drug elimination. The time it takes to reach steady state is a function of the half-life of the drug; 94 percent of steady state is achieved after four half-lives and 99 percent after seven half-lives. A drug with a long half-life takes longer to reach steady state than does one with a short half-life. The average steady-state concentration of a drug equals the fraction of the dose absorbed (F) × the maintenance dose ($dose_m$) divided by the total-body clearance (Cl_s) × the dosing interval (tau).

If the drug is given intravenously,

Finally, it is important to stress that drug pharmacokinetics may differ in normal, healthy volunteers compared with patients who have a variety of illnesses. Therefore, information derived from patients as well as normal subjects must be considered when one is planning dosing regimens.

General Considerations Regarding Antiarrhythmic Drugs

Most of the available antiarrhythmic drugs (Table 23-3) can be classified according to whether they exert blocking actions predominantly on sodium, potassium, or calcium channels and whether they block beta-adrenoceptors.[162] [163]

TABLE 23-3 -- CLASSIFICATION OF DRUG ACTIONS ON ARRHYTHMIAS BASED ON MODIFICATION OF VULNERABLE PARAMETER

MECHANISM	ARRHYTHMIA	VULNERABLE PARAMETER (EFFECT)	DRUGS (EFFECT)
Automaticity			
Enhanced normal	Inappropriate sinus tachycardia	Phase 4 depolarization (decrease)	Beta-adrenergic blocking agents
	Some idiopathic ventricular tachycardias		Na^+ channel blocking agents
Abnormal	Atrial tachycardia	Maximum diastolic potential (hyperpolarization)	M_2 agonist
		Phase 4 depolarization (decrease)	Ca^{2+} or Na^+ channel blocking agents
			M_2 agonist
	Accelerated idioventricular rhythms	Phase 4 depolarization (decrease)	Ca^{2+} or Na^+ channel blocking agents
Triggered Activity			
EAD	Torsades de pointes	Action potential duration (shorten)	Beta-adrenergic agonists; vagolytic agents (increase rate)
		EAD (suppress)	Ca^{2+} channel blocking agents; Mg^{2+} ; beta-adrenergic blocking agents
DAD	Digitalis-induced arrhythmias	Calcium overload (unload)	Ca^{2+} channel blocking agents
		DAD (suppress)	Na^+ channel blocking agents
	Right ventricular outflow tract ventricular tachycardia	Calcium overload (unload)	Beta-adrenergic blocking agents
		DAD (suppress)	Ca^{2+} channel blocking agents; adenosine
Reentry-Na^+ Channel-Dependent			
Long excitable gap	Typical atrial flutter	Conduction and excitability (depress)	Type IA, IC Na^+ channel blocking agents
	Circus movement tachycardia in WPW	Conduction and excitability (depress)	Type IA, IC Na^+ channel blocking agents
	Sustained uniform ventricular tachycardia	Conduction and excitability (depress)	Na^+ channel blocking agents
Short excitable gap	Atypical atrial flutter	Refractory period (prolong)	K^+ channel blocking agents
	Atrial fibrillation	Refractory period (prolong)	K^+ channel blocking agents
	Circus movement tachycardia in WPW	Refractory period (prolong)	Amiodarone, sotalol
	Polymorphic and uniform ventricular tachycardia	Refractory period (prolong)	Type IA Na^+ channel blocking agents
	Bundle branch reentry	Refractory period (prolong)	Type IA Na^+ channel blocking agents; bretylium
	Ventricular fibrillation	Refractory period (prolong)	
Reentry-Ca^{2+} Channel-Dependent			
	AV nodal reentrant tachycardia	Conduction and excitability (depress)	Ca^{2+} channel blocking agents
	Circus movement tachycardia in WPW	Conduction and excitability (depress)	Ca^{2+} channel blocking agents
	Verapamil-sensitive ventricular tachycardia	Conduction and excitability (depress)	Ca^{2+} channel blocking agents

WPW = Wolff-Parkinson-White syndrome.

Reproduced with permission from Task Force of the Working Group on Arrhythmias of the European Society of Cardiology: The Sicilian Gambit: A new approach to the classification of antiarrhythmic drugs based on their actions on arrhythmogenic mechanisms. Circulation 84:1831, 1991. Copyright 1991, American Heart Association.

The commonly used Vaughan Williams classification is limited because it is based on the electrophysiological effects exerted by an arbitrary concentration of the drug, generally on normal cardiac tissue. Actually, the actions of these drugs are quite complex and depend on tissue type, species, the degree of acute or chronic damage, heart rate, membrane potential, the ionic composition of the extracellular milieu, and other factors (see Table 23-3). Many drugs exhibit actions that belong in multiple categories or operate indirectly, such as by altering hemodynamics, myocardial metabolism, or autonomic neural transmission. Some drugs have active metabolites that exert effects different from those exerted by the parent compound. Not all drugs in the same class have identical effects (e.g., bretylium, sotalol, and amiodarone). Whereas all class III agents are dramatically different, some drugs in different classes have overlapping actions (e.g., Class IA and IC drugs). In vitro studies on healthy fibers usually establish the properties of antiarrhythmic agents rather than their actual antiarrhythmic properties.

Despite these limitations, the Vaughan Williams classification[164] is widely known and provides a useful communication shorthand. It is listed here, but the reader is cautioned that drug actions are more complex than those depicted by the classification. A more realistic view of antiarrhythmic agents is provided by the "Sicilian gambit."[165] [166] [167] This approach to drug classification is an attempt to identify the mechanisms of a particular arrhythmia, determine the vulnerable parameter of the arrhythmia most susceptible to modification, define the target most likely to affect the vulnerable parameter, and then select a drug that will modify the target. This concept provides a framework in which to consider antiarrhythmic drugs (see Tables 23-3 and 23-4).

DRUG CLASSIFICATION.

According to the Vaughan Williams classification, *Class I* drugs predominantly block the fast sodium channel (they can also block potassium channels). They, in turn, are divided into three subgroups:

Class IA. Drugs that reduce
max (rate of rise of action potential upstroke [phase 0]) and prolong action potential duration (see Chap. 22): quinidine, procainamide, disopyramide; kinetics of onset and offset in blocking the Na^+ ; channel are of intermediate rapidity (<5 seconds).

Class IB. Drugs that do not reduce
max and that shorten action potential duration: mexiletine, phenytoin, and lidocaine; fast onset and offset kinetics (<500 milliseconds).

Class IC. Drugs that reduce
max, primarily slow conduction, and can prolong refractoriness minimally: flecainide, propafenone, and moricizine; slow onset and offset kinetics (10 to 20 seconds).

Class II. Drugs that block beta-adrenergic receptors and include propranolol, timolol, metoprolol, and others.

Class III. Drugs that predominantly block potassium channels (such as I_{Kr}) and prolong repolarization. They include sotalol, amiodarone, bretylium, and NAPA.

Class IV. Drugs that predominantly block the slow calcium channel ($I_{Ca\text{-}L}$) and include verapamil, diltiazem, nifedipine, and others (felodipine blocks $I_{Ca\text{-}T}$).

A recently proposed model suggests that antiarrhythmic drugs cross the cell membrane and interact with receptors in the membrane channels when the latter are in the rested, activated, or inactivated state (see Table 23-4) and that each of these interactions is characterized by different association and dissociation rate constants (see Chap. 22) Such interactions are voltage and time dependent. Transitions among rested, activated, and inactivated states are governed by standard Hodgkin-Huxley-type equations. When the drug is bound (associated) to a receptor site at or very close to the ionic channel (the drug probably does not actually "plug" the channel), the latter cannot conduct, even in the activated state.

USE-DEPENDENCE.

Some drugs exert greater inhibitory effects on the upstroke of the action potential at more rapid rates of stimulation and after longer periods of stimulation, a characteristic called *use-dependence.* Use-dependence means that depression of
max is greater after the channel has been "used" (i.e., after action potential depolarization rather than after a rest period). It is possible that this use-dependence results from preferential interaction of the antiarrhythmic drug with either the open or the inactive channel, and there is little interaction with the resting channels of the unstimulated cell. Agents in Class IB exhibit fast kinetics of onset and offset or use-dependent block of the fast channel; that is, they bind and dissociate quickly from the receptors. Class IC drugs have slow kinetics, and Class IA drugs are intermediate. With increased time spent in diastole (slower rate), a greater proportion of receptors become drug free, and the drug exerts less effect. Cells with reduced membrane potentials recover more slowly from drug actions than cells with more negative membrane potentials (see Chap. 22).

REVERSE USE-DEPENDENCE.

Some drugs exert greater effects at slow rates than at fast rates, a property known as *reverse use-dependence.* This is particularly true for drugs that lengthen repolarization. The QT interval becomes prolonged more at slow than fast rates. This is opposite to what the ideal antiarrhythmic agent would do, because prolongation of refractoriness should be increased at fast rates so as to interrupt or prevent a tachycardia and should be minimal at slow rates to avoid precipitating torsades de pointes.[168]

MECHANISMS OF ARRHYTHMIA SUPPRESSION.

Given the fact that enhanced automaticity, triggered activity, or reentry can cause cardiac arrhythmias (see Chap. 22), mechanisms by which antiarrhythmic agents suppress arrhythmias can be postulated.[165] [166] Antiarrhythmic agents can slow the spontaneous discharge frequency of an automatic pacemaker by depressing the slope of diastolic depolarization, shifting the threshold voltage toward zero, or hyperpolarizing the resting membrane potential. Mechanisms by which different drugs suppress normal or abnormal automaticity may not be the same. In general, however, most antiarrhythmic agents in therapeutic doses depress the automatic firing rate of spontaneously discharging ectopic sites while minimally affecting the discharge rate of the normal sinus node. Slow-channel blockers like verapamil, beta blockers like propranolol, and some antiarrhythmic agents like amiodarone also depress spontaneous discharge of the normal sinus node, whereas drugs that exert vagolytic effects, such as disopyramide or quinidine, can increase the sinus discharge rate. Drugs can also suppress early or delayed afterdepolarizations (see Chap. 22) and eliminate triggered arrhythmias due to these mechanisms.

As mentioned earlier (see Chap. 22), reentry depends critically on the timing interrelationships between refractoriness and conduction velocity, the presence of unidirectional block in one of the pathways, and other factors that influence refractoriness and conduction, such as excitability. An antiarrhythmic agent can stop reentry that is already present or prevent it from starting if the drug improves or depresses conduction. For example, *improved conduction* can (1) eliminate the unidirectional block so that reentry cannot begin or (2) facilitate conduction in the reentrant loop so that the returning wavefront reenters too quickly, encroaches on fibers still refractory, and becomes extinguished. A drug that *depresses conduction* can transform the unidirectional block to bidirectional block and thus terminate reentry or prevent it from occurring by creating an area of complete block in the reentrant pathway.

TABLE 23-4 -- ACTIONS OF ANTIARRHYTHMIC DRUGS

DRUG	CHANNELS						RECEPTORS				PUMPS	CLINICAL EFFECTS			ECG INTERVALS

Adapted from Schwartz PJ, Zaza A: The Sicilian Gambit revisited--theory and practice. Eur Heart J 13:26, 1992.

*Fast, Med (medium), and Slow refer to kinetics of recovery from sodium channel blockade.

Conversely, a drug that slows conduction without producing block or lengthening refractoriness significantly can promote reentry. Finally, most antiarrhythmic agents share the ability to prolong refractoriness relative to their effects on action potential duration (APD); that is, the ratio of effective refractory period (ERP) to APD exceeds 1.0. If a drug *prolongs refractoriness* of fibers in the reentrant pathway, the pathway may not recover excitability in time to be depolarized by the reentering impulse and the reentrant propagation ceases. The different types of reentry (see Chap. 22) influence the effects and effectiveness of a drug.

When one is discussing any of the properties of a drug, it is important that the situation and/or model from which conclusions are drawn be defined with care. Electrophysiological, hemodynamic, autonomic, pharmacokinetic, and adverse effects all may differ in normal subjects compared with patients, in normal tissue compared with abnormal tissue, in cardiac muscle compared with specialized conduction fibers, in atrium as opposed to ventricular muscle, and in different species.

STEREOSELECTIVITY.

Drug interactions with a channel, receptor, or enzyme may depend on the three-dimensional geometry of the drug.[169] Many drugs have stereoisomers (molecules with the same atomic composition but different spatial arrangement) that can influence drug effects, metabolism, binding, clearance, and excretion. Most drugs of this type are prescribed as 50/50 mixtures of their two forms (racemates), which may make 50 percent of the dose ineffective for some drugs. Except for timolol, virtually all beta blockers are racemates. *d*-Propranolol exerts antiarrhythmic actions unrelated to beta-adrenoceptor blockade, whereas *l*-propranolol blocks the beta receptor. Both enantiomers (mirror images) of sotalol block the potassium channel to prolong APD and suppress arrhythmias equally, but *d*-sotalol does not block the beta adrenoceptor. Racemic propafenone exhibits beta-blocking actions due to the S enantiomer. Other drugs with notable stereoselective differences include disopyramide, with one form (S [+]) prolonging repolarization and having greater antiarrhythmic effects than R (-), which shortens repolarization. The latter form has fewer anticholinergic effects. The (-) enantiomer of verapamil exerts much more negative inotropic and dromotropic effects than does the (+) form and may have more potent antiarrhythmic actions. Stereoselectivity affects sodium channel blocking drugs less than it affects beta-adrenoceptor, potassium, and calcium blockers.

DRUG METABOLITES.

Drug metabolites may add to or alter the effects of the parent compound by exerting similar actions, competing with the parent compound, or mediating drug toxicity. Quinidine has at least four active metabolites but none with a potency exceeding the parent drug and none preliminarily implicated in causing torsades de pointes. About 50 percent of procainamide is metabolized to NAPA. Only the parent drug blocks cardiac sodium channels and slows impulse propagation in the His-Purkinje system. NAPA prolongs repolarization and is a less effective antiarrhythmic drug but competes with procainamide for renotubular secretory sites and can increase the parent drug's elimination half-life. Lidocaine's metabolite can compete with lidocaine for sodium channels and partially reverse block produced by lidocaine.

PHARMACOGENETICS.

Genetically determined metabolic pathways account for many of the differences in patients' responses to some drugs. The genetically determined activity of hepatic *N*-acetyltransferase regulates the development of antinuclear antibodies and development of the lupus syndrome in response to procainamide. Slow acetylator phenotypes appear more prone to develop lupus than do rapid acetylators.[170] [171] [172] About 7 percent of white and black subjects lack debrisoquin 4-hydroxylase. This enzyme is needed to metabolize debrisoquine (an antihypertensive drug) and propafenone, to hydroxylate several beta blockers, and to biotransform flecainide. The gene coding for this enzyme (termed $P450_{dbl}$) is on human chromosome 22. Lack of this enzyme reduces metabolism of the parent compound, leading to increased plasma concentrations of the parent drug and reduced concentrations of metabolites. Propafenone is metabolized by this enzyme to a compound with slightly less antiarrhythmic and beta-adrenergic blocking effects, as well as fewer central nervous system side effects. Thus, poor metabolizers may experience more heart rate slowing and neurotoxicity than extensive metabolizers. Quinidine in low doses can inhibit this enzyme and thereby alter concentrations of the drugs and metabolites given in combination that are affected by the $P450_{dbl}$ enzyme, such as propafenone or flecainide.

Understanding stereoselectivity and pharmacogenetics can provide major clues to understanding differences in drug efficacy and toxicity from one patient to the next. Cimetidine and ranitidine also affect drug metabolism, probably by inhibiting hepatic P450-metabolizing enzymes (Table 23-5) . Other commonly used noncardiovascular medications affect this important metabolic pathway. Drugs such as rifampin, phenobarbital, and phenytoin induce synthesis of larger amounts of cytochrome $P450_{dbl}$, leading to lower concentrations of parent drugs that are extensively metabolized, whereas erythromycin, clarithromycin, fluoxetine, and grapefruit juice inhibit enzyme activity, leading to accumulation of the parent compound. This effect is thought to explain why cisapride, an agent used to increase gastric motility, can cause QT interval prolongation and torsades de pointes in isolated cases. Cisapride is a potent blocker of the delayed rectifier current I_{kr} but does not prolong the QT interval significantly in the majority of patients, presumably owing to extensive metabolism. In patients who take an inhibitor of cytochrome P450 (such as erythromycin) along with cisapride, the latter drug can accumulate, leading to QT prolongation and torsades de pointes.[173]

SIDE EFFECTS.

Antiarrhythmic drugs produce one group of side effects that relate to excessive dosage and plasma concentrations, resulting in both noncardiac (e.g., neurological defects) and cardiac (e.g., heart failure, some arrhythmias) toxicity and another group of side effects unrelated to plasma concentrations, which is termed *idiosyncratic.* Examples of the latter include procainamide-induced lupus syndrome, amiodarone-induced pulmonary toxicity (although some evidence relates maintenance dose to this side effect), and some arrhythmias such as quinidine-induced torsades de pointes. The latter phenomenon can occur in individuals with a "forme fruste" of the long

QT syndrome (i.e., normal QT interval at rest but markedly prolonged in the presence of certain medications).[174]

PROARRHYTHMIA.

Drug-induced or drug-aggravated cardiac arrhythmias (proarrhythmia) constitute a major clinical

problem. [175] [176] [177] [178] [179] [180] Proarrhythmia can be manifested as an increase in frequency of a preexisting arrhythmia, sustaining of a previously nonsustained arrhythmia (even making it incessant), or development of arrhythmias the patient has not previously experienced. Electrophysiological mechanisms probably relate to prolongation of repolarization, the development of early afterdepolarizations to cause torsades de pointes,[181] [182] [183] [184] [185] [186] [187] [188] [189] [190] and alterations in reentry pathways[191] to initiate or sustain ventricular tachyarrhythmias. Proarrhythmic events can occur in as many as 5 to 10 percent of patients. Heart failure increases proarrhythmic risk. Patients with atrial fibrillation treated with antiarrhythmic agents had a 4.7 relative risk of cardiac death if they had a history of heart failure compared with patients not so treated who had a 3.7 relative risk of arrhythmic death. Patients without a history of congestive heart failure had no increased risk of cardiac mortality during antiarrhythmic drug treatment.[192] Reduced left ventricular function, treatment with digitalis and diuretics, and longer pretreatment QT interval characterize patients who develop drug-induced VF. The more commonly known proarrhythmic events occur within several days of beginning drug therapy or changing dosage and are represented by such developments as incessant VT, long QT syndrome, and torsades de pointes. However, in CAST,[18] [193] [194] researchers found that encainide and flecainide reduced spontaneous ventricular arrhythmias but were associated with a total mortality of 7.7 percent, in comparison with 3.0 percent of the group receiving placebo. Deaths were equally distributed throughout the treatment period, raising the important consideration that another kind of proarrhythmic response can occur some time after the beginning of drug therapy. Such late proarrhythmic effects may relate to drug-induced exacerbation of regional myocardial conduction delay due to ischemia and heterogeneous drug concentrations that may promote reentry. Moricizine also increased mortality, leading to termination of CAST II.[17] [195]

CLASS IA ANTIARRHYTHMIC AGENTS

Quinidine

Quinidine and quinine are isomeric alkaloids isolated from the cinchona bark.[196] Although quinidine shares the antimalarial, antipyretic, and vagolytic actions of quinine, the latter lacks the significant electrophysiological and antiarrhythmic effects of quinidine.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Quinidine exerts little effect on automaticity of the isolated or denervated normal sinus node but suppresses automaticity in normal Purkinje fibers, especially in ectopic pacemakers, by decreasing the slope of phase 4 diastolic depolarization and shifting threshold voltage toward zero. In patients with the sick sinus syndrome, quinidine can depress sinus node automaticity. It does not affect abnormal automaticity in partially depolarized Purkinje fibers. Quinidine produces early afterdepolarizations in experimental preparations and in humans, which may be responsible for torsades de pointes.[181] [182] [183] [184] [185] [186] [187] [188] [189] [190] Because of its significant anticholinergic effect and reflex sympathetic stimulation resulting from alpha-adrenergic blockade that causes peripheral vasodilation, quinidine can increase sinus node discharge rate and can improve AV node conduction in the innervated heart in vivo. Direct myocardial effects can prolong AV node and His-Purkinje conduction times and refractoriness in an AV accessory pathway. Quinidine slightly prolongs the APD of atrial and ventricular muscle and Purkinje fibers (quinine shortens it) while also prolonging the ERP without significantly changing resting membrane potential. Prolongation of repolarization is more prominent at slow heart rates (reverse use-dependence)[197] [198] owing to block of I_{Kr} .[199] Action potential amplitude, overshoot, and

max of phase 0 are reduced, more so during ischemia, hypoxia, and in partially depolarized fibers, especially at fast rates. The open channel has a high affinity for quinidine, resulting in block of a fraction of sodium channels with each action potential upstroke.[200] The time for unblocking by Class IA drugs (about 4 seconds) is slower than for Class IB drugs but faster than for Class IC drugs. For the duration of the plateau of the action potential (inactivated state) or in depolarized fibers, the rate of unblocking is slow, proceeding much faster in polarized fibers. Therefore, faster rates result in more block of sodium channels and less unblocking because of a lesser percentage of time spent in a polarized state (use-dependence). Isoproterenol can modulate the effects of quinidine on reentrant circuits in humans.[201] [202] Quinidine's effect on I_{to} (but not I_k) varies according to patient age and may account for its lower efficacy in children than adults.[203]

*With a background of sympathetic activity.

HEMODYNAMIC EFFECTS.

Quinidine decreases peripheral vascular resistance and can cause significant hypotension because of its alpha-adrenergic receptor blocking effects. Concomitant administration of vasodilators can exaggerate the potential for hypotension. In some patients, quinidine can increase cardiac output, possibly by reducing afterload and preload. No significant direct myocardial depressant action occurs unless large doses are given rapidly by intravenous infusion. Most of the adverse effects of intravenous quinidine are probably the result of excessive vasodilation.

PHARMACOKINETICS (see Table 23-1).

Although orally administered quinidine sulfate and quinidine gluconate exhibit similar degrees of systemic availability, plasma quinidine concentrations peak at about 90 minutes after oral administration of quinidine sulfate and at 3 to 4 hours after oral administration of quinidine gluconate. Intramuscular quinidine produces a higher and an earlier peak plasma concentration but results in incomplete absorption and tissue necrosis. Quinidine may be given intravenously if it is infused slowly. Approximately 80 percent of plasma quinidine is protein bound, especially to $alpha_1$ -acid glycoprotein, which increases in heart failure. Both the liver and the kidneys remove quinidine, and dose adjustments may be made according to the creatinine clearance.[204] [205] Metabolism is by means of the P450 cytochrome system. Approximately 20 percent is excreted unchanged in the urine. Because congestive heart failure, hepatic disease, or poor renal function can reduce quinidine elimination and increase plasma concentration, the dosage probably should be reduced and the drug given cautiously to patients with these disorders while serum quinidine concentration is monitored. Elimination half-life is 5 to 8 hours after oral administration. Quinidine can increase plasma concentrations of flecainide by inhibiting the P450 enzyme system.[169] Quinidine's effect on repolarization and overall efficacy vary directly with left ventricular function.[206]

DOSAGE AND ADMINISTRATION (see Table 23-1).

The usual oral dose of quinidine sulfate for an adult is 300 to 600 mg four times daily, which results in a steady-state level within about 24 hours. A loading dose of 600 to 1000 mg produces an earlier effective concentration. Similar doses of quinidine gluconate are used intramuscularly, whereas the IV dose of quinidine gluconate is about 10 mg/kg given at a rate of about 0.5 mg/kg/min as blood pressure and ECG parameters are checked frequently. Oral doses of the gluconate are about 30 percent greater than those of sulfate. Important interactions with other drugs occur (see Tables 23-2 and 23-5).

INDICATIONS.

Quinidine is a versatile antiarrhythmic agent, useful for treating premature supraventricular and ventricular complexes and sustained tachyarrhythmias. It may prevent spontaneous recurrences or electrical induction of AV node reentrant tachycardia (AVNRT) by prolonging atrial and ventricular refractoriness and depressing conduction in the retrograde fast pathway. In patients with the Wolff-Parkinson-White syndrome, quinidine prolongs the ERP of the accessory pathway and, by so doing, can prevent reciprocating tachycardias and slow the ventricular response from conduction over the accessory pathway during atrial flutter or atrial fibrillation. Quinidine and other antiarrhythmic agents also can prevent recurrences of tachycardia by suppressing the "trigger" (i.e., the PAC or PVC that initiates a sustained tachycardia).

Quinidine successfully terminates atrial flutter or atrial fibrillation in 20 to 60 percent of patients, with higher success rates if the arrhythmia is of more recent onset and if the atria are not enlarged.[207] Before quinidine is administered to these patients, the ventricular response should be slowed sufficiently with digitalis, propranolol, or verapamil, because quinidine-induced slowing of the atrial flutter rate (e.g., from 300 to 230 beats/min), and its vagolytic effect on AV node conduction may convert a 2:1 AV response (two atrial impulses for each QRS complex, ventricular rate 150 beats/min) to a 1:1 AV response, with an *increase* in the ventricular rate (to 230 beats/min). If quinidine is going to be used to try to maintain sinus rhythm after elective cardioversion of patients with atrial fibrillation, it probably should be given for 1 to 2 days before planned cardioversion, because this regimen restores sinus rhythm in some patients (thus obviating the need for direct-current cardioversion) and helps maintain sinus rhythm once it is achieved. In addition, early toxicity or patient intolerance to the drug may be observed and changes made in drug therapy before attempting cardioversion. A meta-analysis of six studies testing the effects of quinidine versus control in maintaining sinus rhythm in patients with atrial fibrillation showed that quinidine-treated patients remained in sinus rhythm longer than did the control group but had an increased total mortality over the same period. This important conclusion needs to be verified in a controlled, prospective study.

Quinidine has prevented sudden death in some patients resuscitated after out-of-hospital cardiac arrest and may be combined with other antiarrhythmic agents for increased efficacy in suppressing ventricular tachyarrhythmias. It is important to stress that no published data from controlled, randomized studies indicate improved survival in quinidine-treated patients after myocardial infarction (see Fig. 23-5). Cardiac arrest can occur despite quinidine therapy.[208] [209] Because it crosses the placenta, quinidine can be used to treat arrhythmias in the fetus.

ADVERSE EFFECTS.

The most common adverse effects of chronic oral quinidine therapy are gastrointestinal and include nausea, vomiting, diarrhea, abdominal pain, and anorexia. Gastrointestinal side effects may be milder with the gluconate form. Central nervous system toxicity includes tinnitus, hearing loss, visual disturbances, confusion, delirium, and psychosis. *Cinchonism* is the term usually applied to these side effects. Allergic reactions may be manifested as rash, fever, immune-mediated thrombocytopenia, hemolytic anemia, and, rarely, anaphylaxis. Thrombocytopenia is due to the presence of antibodies to quinidine-platelet complexes, causing platelets to agglutinate and lyse. In patients receiving oral anticoagulants, quinidine may cause bleeding. Side effects may preclude long-term administration of quinidine in 30 to 40 percent of patients.

Quinidine can slow cardiac conduction, sometimes to the point of block, manifested as prolongation of the QRS duration or sinoatrial (SA) or AV node conduction disturbances. Quinidine-induced cardiac toxicity can be treated with molar sodium lactate. Quinidine can prolong the QT interval and cause torsades de pointes in 1 to 3 percent of patients.[178] [179] [180] [181] [182] [183] [184] [185] [186] [187] [188] [189]

Quinidine can produce syncope in 0.5 to 2.0 percent of patients, most often the result of a self-terminating episode of torsades de pointes (see Chaps. 22 and 25). Torsades de pointes may be due to the development of early afterdepolarizations, as noted earlier. Quinidine prolongs the QT interval in most patients, whether or not ventricular arrhythmias occur, but significant QT prolongation (QT interval of 500 to 600 msec) is often a characteristic of patients with quinidine syncope. Many of these patients are also receiving digitalis or diuretics; women are more susceptible than men.[210] Syncope is unrelated to plasma concentrations of quinidine or duration of therapy, although the majority of episodes occur within the first 2 to 4 days of therapy (often after conversion of atrial fibrillation to sinus rhythm). Hypokalemia often is a prominent feature. Therapy for quinidine syncope requires immediate discontinuation of the drug and avoidance of other drugs that have similar pharmacologic effects, such as disopyramide, because cross-sensitivity exists in some patients. Magnesium given intravenously (2 gm over 1 to 2 minutes, followed by an

infusion of 3 to 20 mg/min) is the initial drug treatment of choice. Atrial or ventricular pacing can be used to suppress the ventricular tachyarrhythmia and may act by suppressing early afterdepolarizations. For some patients, drugs that do not prolong the QT interval, such as lidocaine or phenytoin, can be tried. When pacing is not available, isoproterenol can be given *with caution.*

Drugs that induce hepatic enzyme production, such as phenobarbital and phenytoin, can shorten the duration of quinidine's action by increasing its rate of elimination.

Quinidine may elevate serum digoxin and digitoxin concentrations by decreasing total-body clearance of digitoxin and by decreasing the clearance, volume of distribution, and affinity of tissue receptors for digoxin.

Procainamide

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

The cardiac actions of procainamide on automaticity, conduction, excitability, and membrane responsiveness resemble those of quinidine. Procainamide predominantly blocks the inactivated state of I_{Na} . It also blocks I_{Kr} and I_{KATP} .[211] Like quinidine, procainamide usually prolongs the ERP more than it prolongs the APD and thus prevents early responses from occurring, arising from less negative resting potentials that might conduct slowly or block and cause an arrhythmia. Compared with disopyramide and quinidine, procainamide exerts the least severe anticholinergic effects but does produce more local anesthetic effects than quinidine. It does not affect normal sinus node automaticity. In vitro, procainamide decreases abnormal automaticity, with less effect on triggered activity or catecholamine-enhanced normal automaticity.

The electrophysiological effects of NAPA,[212] procainamide's major metabolite, differ from those of the parent compound. NAPA (10 to 40 mg/liter) does not suppress the rate of phase 4 diastolic depolarization of Purkinje fibers and does not alter resting membrane potential, action potential amplitude, or $\dot{V}_{max}$ of phase 0 of the action potential of Purkinje fibers or ventricular muscle. However, NAPA, a K^+ channel blocker (I_{Kr}), exerts a Class III action and prolongs the APD of ventricular muscle and Purkinje fibers in a dose-dependent manner. Toxic doses produce early afterdepolarizations, triggered activity, and ventricular tachyarrhythmias, including torsades de pointes. Procainamide appears to exert greater electrophysiological effects than NAPA.

HEMODYNAMIC EFFECTS.

Procainamide can depress myocardial contractility in high doses. It does not produce alpha blockade but can result in peripheral vasodilation, possibly through antisympathetic effects on brain or spinal cord that can impair cardiovascular reflexes.[213]

PHARMACOKINETICS (see Table 23-1).

Oral administration produces peak plasma concentration in about 1 hour. Absorption may be reduced in the first week after myocardial infarction. Approximately 80 percent of oral procainamide is bioavailable, with 20 percent bound to serum proteins. The overall elimination half-life for procainamide is 3 to 5 hours, with 50 to 60 percent of the drug eliminated by the kidney and 10 to 30 percent eliminated by hepatic metabolism. Prolonged-release forms of procainamide given every 6 hours provides steady-state plasma levels of the drug equivalent to an equal total daily dose of short-acting procainamide given every 4 hours.

The drug is acetylated to NAPA, which is excreted almost exclusively by the kidneys. As renal function decreases and in patients with heart failure, procainamide levels--particularly NAPA levels--increase and, because of the risk of serious cardiotoxicity, need to be carefully monitored in such situations. NAPA has an elimination half-life of 7 to 8 hours but exceeds 10 hours if high doses of procainamide are used. Small amounts of NAPA are converted back to procainamide by deacetylation. Increased age, congestive heart failure, and reduced creatinine clearance lower the procainamide clearance and necessitate reduced dosage.

DOSAGE AND ADMINISTRATION (see Table 23-1).

Procainamide can be given by the oral, intravenous, or intramuscular route to achieve plasma concentrations in the range of 4 to 10 mg/ml that produce an antiarrhythmic effect. Occasionally, plasma concentrations exceeding 10 mg/ml have been required, but the probability of adverse effects at these higher plasma concentrations generally precludes long-term administration. Several IV regimens have been used to administer procainamide. Twenty-five to 50 mg can be given over a 1-minute period and then repeated every 5 minutes until the arrhythmia is controlled, hypotension results, or the QRS complex is prolonged more than 50 percent. Doses of 10 to 15 mg/kg at 50 mg/min are commonly used during EPS.[214] [215] Using this method, plasma concentration falls rapidly during the first 15 minutes after the loading dose, with parallel effects on refractoriness and conduction. A constant-rate IV infusion of procainamide can be given at a dose of 2 to 6 mg/min. The upper limits regarding total IV dose are flexible and range between 1000 and 2000 mg, depending on the patient's response.

Oral administration of procainamide requires a 3- to 4-hour dosing interval at a total daily dose of 2 to 6 gm, with a steady state reached within 1 day. When a loading dose is used, it should be twice the maintenance dose. Frequent dosing is required because of the short elimination half-life in normal subjects. For the prolonged-release forms of procainamide, dosing is at 6- to 12-hour intervals.[216] Although a longer half-life may be seen in some cardiac patients, allowing longer intervals between drug administration, this needs to be documented for the individual patient. Procainamide is well absorbed after intramuscular injection, with virtually 100 percent of the dose bioavailable.

INDICATIONS.

Procainamide is used to treat both supraventricular and ventricular arrhythmias in a manner comparable with that of quinidine.[217] Although both drugs have similar electrophysiological actions, either drug can effectively suppress a supraventricular or ventricular arrhythmia that is resistant to the other drug.

Procainamide can be used to convert atrial fibrillation of recent onset to sinus rhythm.[218] As with quinidine, prior treatment with digitalis, propranolol, or verapamil is recommended to prevent acceleration of the ventricular response after procainamide therapy. In patients with paroxysmal SVT, procainamide can inhibit the induction of sustained AVNRT as a result of selective depression of retrograde AV node conduction in the fast pathway. Procainamide can block conduction in the accessory pathway of patients with the Wolff-Parkinson-White syndrome and is particularly useful in patients with atrial fibrillation and a rapid ventricular response due to conduction over the accessory pathway. Whether it can be used intravenously to identify those patients who have a short anterograde ERP is not resolved. It can produce His-Purkinje block (see Fig. 23-5) and is sometimes administered during EPS to "stress" the His-Purkinje system in evaluating the need for a pacemaker. However, it should be used with caution in patients with evidence of His-Purkinje disease (bundle branch block) in whom a ventricular pacemaker is not readily available.

Procainamide is more effective than lidocaine in preventing the induction of VT by programmed stimulation[219] and in acutely terminating sustained VT. The electrophysiological response to procainamide given intravenously appears to predict the response to the drug given orally. Patients with ejection fractions greater than 40 percent whose VT is rendered noninducible by procainamide have a high

likelihood of responding to the drug given orally. High doses, 500 to 1000 mg orally every 4 hours, resulting in a plasma concentration exceeding 10.0 mg/ml, may be necessary to suppress VT in some patients. Most consistently, procainamide slows the rate of the induced VT, a change correlated with the increase in QRS duration. Adding amiodarone to procainamide slows the VT cycle length further but increases the noninducibility success rate only slightly. Procainamide appears to preferentially affect the reentrant circuit of the VT compared with other areas of myocardium. The antiarrhythmic response to procainamide does not predict the response to NAPA.

ADVERSE EFFECTS.

Multiple adverse noncardiac effects have been reported with procainamide administration and include rashes, myalgias, digital vasculitis, and Raynaud's phenomenon. Fever and agranulocytosis may be due to hypersensitivity reactions, and white blood cell and differential blood cell counts should be performed at regular intervals. Gastrointestinal side effects are less frequent than with quinidine, and adverse central nervous system side effects are less frequent than with lidocaine. Procainamide can cause giddiness, psychosis, hallucinations, and depression. Toxic concentrations of procainamide can diminish myocardial performance and promote hypotension. A variety of conduction disturbances or ventricular tachyarrhythmias[220] can occur similar to those produced by quinidine, including prolonged QT syndrome and polymorphic VT. NAPA also can induce QT prolongation and torsades de pointes. In the absence of sinus node disease, procainamide does not adversely affect sinus node function. In patients with sinus dysfunction, procainamide tends to prolong corrected SNRT and can worsen symptoms in some patients who have the bradycardia-tachycardia syndrome. Procainamide does not increase the serum digoxin concentration.

Arthralgia, fever, pleuropericarditis, hepatomegaly, and hemorrhagic pericardial effusion with tamponade have been described in a systemic lupus erythematosus (SLE)-like syndrome related to procainamide administration. The syndrome can occur more frequently and earlier in patients who are "slow acetylators" of procainamide and is influenced by genetic factors.[170] The aromatic amino group on procainamide appears important for induction of SLE syndrome, because

acetylating this amino group to form NAPA appears to block the SLE-inducing effect. Sixty to 70 percent of patients who receive procainamide on a chronic basis develop antinuclear antibodies, with clinical symptoms in 20 to 30 percent, but this is reversible when procainamide is stopped. When symptoms occur, SLE cell preparations are often positive. Positive serological tests are not necessarily a reason to discontinue drug therapy; however, the development of symptoms or a positive anti-DNA antibody is, except for patients whose life-threatening arrhythmia is controlled only by procainamide. Corticosteroid administration in these patients may eliminate the symptoms. In contrast to naturally occurring SLE, the brain and kidney are spared and there is no predilection for females.

Disopyramide

Disopyramide has been approved in the United States for oral but not IV administration to treat patients with ventricular arrhythmias.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Although structurally different from quinidine and procainamide, disopyramide produces similar electrophysiological effects in vitro. It causes use-dependent block of I_{Na} and non-use-dependent block of I_{Kr} .[199] Along with quinidine, low concentrations tend to prolong APD and induce early afterdepolarizations just as do higher concentrations.[190] Disopyramide also inhibits I_{KATP} .[211] It decreases the slope of phase 4 diastolic depolarization in Purkinje fibers, produces a rate-dependent depression of
max of phase 0, prolongs the ERP more than it prolongs the APD, lengthens conduction time in normal and depolarized Purkinje fibers, and does not affect calcium-dependent action potentials, except possibly at very high concentrations, or suppress late potentials in the signal-averaged ECG. Disopyramide, like procainamide, reduces the differences in APD between normal and infarcted tissue by lengthening the action potential of normal cells more than it lengthens the action potential of cells from infarcted regions of the heart.

Stereochemical properties influence the effects of disopyramide. Racemic (clinically used) and (+)-disopyramide prolong canine Purkinje fiber action potential, whereas (-)-disopyramide shortens it. The (+) isomer exerts approximately three times more vagolytic effects than does the (-) isomer. Disopyramide, as a muscarinic blocker, can speed the sinus node discharge rate and shorten AV node conduction time and refractoriness when the nodes are restrained by cholinergic influences. Disopyramide also can slow the sinus node discharge rate by a direct action when given in high concentration and can significantly depress sinus node activity in patients with sinus node dysfunction. Disopyramide exerts greater anticholinergic effects than quinidine and does not appear to affect alpha- or beta-adrenoceptors.

Atrial and ventricular refractory periods increase, as do conduction time and refractoriness of the accessory pathway in patients with the Wolff-Parkinson-White syndrome. Disopyramide's effect on AV node conduction and refractoriness in vivo is not consistent. Disopyramide prolongs His-Purkinje conduction time, but infra-His block results infrequently. Disopyramide can be administered safely to patients who have first-degree AV block and narrow QRS complexes.

HEMODYNAMIC EFFECTS.

Disopyramide administered intravenously reduces systemic blood pressure and cardiac and stroke indexes and increases right atrial pressures and total peripheral resistance. Profound hemodynamic deterioration can occur, and patients who have abnormal ventricular function tolerate the negative inotropic effects of IV and oral disopyramide quite poorly. In these patients, the drug should be used with extreme caution or not at all.

PHARMACOKINETICS (see Table 23-1).

Disopyramide is 80 to 90 percent absorbed, with a mean elimination half-life of 8 to 9 hours in healthy volunteers but almost 10 hours in patients with heart failure and sometimes longer in some patients with ventricular arrhythmias. Total-body clearance and volume of distribution decrease in patients, and mean serum concentration is higher than that reported in normal subjects. Renal insufficiency prolongs the elimination time. Thus, in patients who have renal, hepatic, or cardiac insufficiency, loading and maintenance doses need to be reduced. Peak blood levels after oral administration result in 1 to 2 hours, and bioavailability exceeds 80 percent. The fraction of disopyramide bound to serum protein varies inversely with the total plasma concentration of the drug but may be more stable (30 to 40 percent) at clinically relevant concentrations of 3 mg/ml. It is bound to $alpha_1$ -acid glycoprotein and passes through the placenta. About half an oral dose is recovered unchanged in the urine, with about 30 percent as the mono-*N*-dealkylated metabolite. The metabolites appear to exert less effect than the parent compound. Erythromycin inhibits its metabolism.[221]

DOSAGE AND ADMINISTRATION (see Table 23-1).

Doses are generally 100 to 200 mg orally every 6 hours, with a range of 400 to 1200 mg/d. A controlled-release preparation can be given as 200 to 300 mg every 12 hours. The IV (investigational) dose is 1 to 2 mg/kg as an initial bolus given over 5 to 10 minutes, which may be followed by an infusion of 1 mg/kg/hr.

INDICATIONS.

Disopyramide appears comparable to quinidine and procainamide in reducing the frequency of

PVCs and effectively preventing recurrence of VT in selected patients. Disopyramide has been combined with other drugs such as mexiletine to treat patients who do not respond or only partially respond to one drug.

Disopyramide terminates and prevents recurrent episodes of paroxysmal SVT due to AV and AV nodal reentry. It prolongs the anterograde and retrograde refractory periods of the accessory pathway in patients with the Wolff-Parkinson-White syndrome, helps prevent recurrence of atrial fibrillation after successful cardioversion as effectively as quinidine, and may terminate atrial flutter. In treating patients with atrial fibrillation, particularly atrial flutter, the ventricular rate must be controlled before administering disopyramide, or the atrial rate may decrease sufficiently, aided by the vagolytic effects of disopyramide, to create 1:1 conduction during atrial flutter. Disopyramide may be useful in preventing inducible and spontaneous neurally mediated syncope.

ADVERSE EFFECTS.

Three categories of adverse effects follow disopyramide administration. The most common relates to the drug's potent parasympatholytic properties and includes urinary hesitancy or retention, constipation, blurred vision, closed-angle glaucoma, and dry mouth. Symptoms may be minimized by concomitant administration of pyridostigmine. Second, disopyramide can produce ventricular tachyarrhythmias that are commonly associated with QT prolongation and torsades de pointes. Some patients can have "cross-sensitivity" to both quinidine and disopyramide and develop torsades de pointes while receiving either drug. When drug-induced torsades de pointes occurs, agents that prolong the QT interval should be used very cautiously or not at all. Finally, disopyramide can reduce contractility of the normal ventricle, but the depression of ventricular function is much more pronounced in patients with preexisting ventricular failure. Occasionally, cardiovascular collapse can result.

CLASS IB ANTIARRHYTHMIC AGENTS

Lidocaine

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Lidocaine blocks I_{Na} , predominantly in the open or possibly inactivated state.[222] It has rapid onset and offset kinetics and does not affect normal sinus node antomaticity but does depress both normal and abnormal forms of automaticity, as well as early and late afterdepolarizations in Purkinje fibers in vitro. Lidocaine exhibits only a modest depressant effect on
and has no effect on maximal diastolic potential of normal muscle and specialized tissue in concentrations of about 1.5 mg/ml. However, faster rates of stimulation, reduced pH,[223] increased extracellular K^+ concentration, and reduced membrane potential--all changes that can result from ischemia--increase the ability of lidocaine to block I_{Na} . Lidocaine reduces the magnitude of the transient inward current responsible for some forms of afterdepolarization. Intracellular calcium activity may be reduced because of the sodium-calcium exchange mechanism. Lidocaine can convert areas of unidirectional block into bidirectional block during ischemia and prevent development of VF by preventing fragmentation of organized large wavefronts into heterogeneous wavelets. Lidocaine may be arrhythmogenic if it depresses

conduction but not to the point of bidirectional block, but this does not appear to be an important clinical problem.

Lidocaine, except in very high concentrations, does *not* affect slow-channel-dependent action potentials despite its moderate suppression of the slow inward current. In fact, its depressant effect on electrical potentials from ischemic myocardium supports the notion that these ischemic potentials are depressed fast responses rather than slow responses. Lidocaine significantly reduces the APD and the ERP of Purkinje fibers and ventricular muscle owing to blocking of tetrodotoxin-sensitive sodium channels and decreasing entry of sodium into the cell. It has little effect on atrial fibers and does not affect conduction in accessory pathways. In some in vitro preparations, lidocaine can improve conduction by hyperpolarizing tissues depolarized as a result of stretch or low external potassium concentration.

In vivo, lidocaine has a minimal effect on automaticity or conduction except in unusual circumstances. Patients with preexisting sinus node dysfunction, abnormal His-Purkinje conduction, or junctional or ventricular escape rhythms can develop depressed automaticity or conduction. Part of its effects may be to inhibit cardiac sympathetic nerve activity.

HEMODYNAMIC EFFECTS.

Clinically significant adverse hemodynamic effects are rarely noted at usual drug concentrations unless left ventricular function is severely impaired.

PHARMACOKINETICS (see Table 23-1).

Lidocaine is used only parenterally because oral administration results in extensive first-pass hepatic metabolism and unpredictable, low plasma levels with excessive metabolites that can produce toxicity. Hepatic metabolism of lidocaine depends greatly on hepatic blood flow, so clearance of this drug almost equals (and can be approximated by) measurements of this flow. Severe hepatic disease or reduced hepatic blood flow, as in heart failure or shock, can markedly decrease the rate of lidocaine metabolism. Beta-adrenoceptor blockers can decrease hepatic blood flow and increase lidocaine serum concentration. Prolonged infusion can reduce lidocaine clearance. Its elimination half-life averages 1 to 2 hours in normal subjects, more than 4 hours in patients after relatively uncomplicated myocardial infarction, more than 10 hours in patients after myocardial infarction complicated by cardiac failure, and even longer in the presence of cardiogenic shock. Maintenance doses should be reduced by one third to one half for patients with low cardiac output. Lidocaine is 50 to 80 percent protein bound and binds to alpha1-acid glycoprotein, which may increase in heart failure and myocardial infarction. Intravenous infusions should be discontinued as far in advance of EPS as possible to avoid residual lidocaine effects. A two-compartment model accurately predicts serum concentrations.[224]

DOSAGE AND ADMINISTRATION (see Table 23-1).

Although lidocaine can be given intramuscularly, the IV route is most commonly used (Fig. 23-12) . Intramuscular lidocaine is given in doses of 4 to 5 mg/kg (250 to 350 mg), resulting in effective serum levels at about 15 minutes and lasting for about 90 minutes. Intravenously, lidocaine is given as an initial bolus of 1 to 2 mg/kg of body weight at a rate of 20 to 50 mg/min, with a second injection of one half of the initial dose 20 to 40 minutes later. Patients treated with an initial bolus followed by a maintenance infusion may experience transient subtherapeutic plasma concentrations at 30 to 120 minutes after initiation of therapy. A second bolus of about 0.5 mg/kg without increasing the maintenance infusion rate reestablishes therapeutic serum concentrations.

If recurrence of arrhythmia appears after a steady state has been achieved (e.g., 6 to 10 hours after starting therapy), a similar bolus should be given and the maintenance infusion rate increased. Increasing the maintenance infusion rate alone without an additional bolus results in a very slow increase in plasma lidocaine concentrations, reaching a new plateau in over 6 hours (four elimination half-lives), and is therefore not recommended. Another recommended IV dosing is 1.5 mg/kg initially and 0.8 mg/kg at 8-minute intervals for three doses. Doses are reduced by about 50 percent for patients with heart failure.

If the initial bolus of lidocaine is ineffective, up to two more boluses of 1 mg/kg may be administered at 5-minute

Figure 23-12 *A, top,* Plasma concentrations after a bolus of lidocaine, with the therapeutic range indicated by a dashed line. *Bottom,* The disposition of the drug in the body, with the larger box indicating the total volume of distribution and the smaller box the central compartment. The bolus initially produces therapeutic lidocaine concentrations in the small central compartment. Rapid distribution of the drug to the rest of the body produces subtherapeutic concentrations within 15 minutes. *B,* Lidocaine is administered by an initial bolus as in *A,* with a maintenance infusion begun just after the bolus. The maintenance infusion replaces drug eliminated from the body, but drug is also lost from the central compartment by distribution, which is more rapid than elimination. As a result, plasma concentrations decrease transiently. In this instance, lidocaine concentration is subtherapeutic between 30 and 70 minutes after initiation of therapy. *C,* Subtherapeutic lidocaine concentrations after an initial bolus (as in *B*) can be prevented by giving a second lidocaine bolus 10 minutes after the first. A maintenance infusion should be started after the second bolus rather than after the first, as shown here. This will prevent excessive lidocaine concentrations after the second bolus. *D,* An alternative method to produce therapeutic lidocaine concentrations rapidly. This illustration indicates plasma concentrations after the administration of a loading dose of lidocaine given over 10 minutes. A maintenance infusion is begun after the loading dose has been given. *(From Nattel S, Zipes DP: Clinical pharmacology of old and new antiarrhythmic drugs. Cardiovasc Clin 11:221, 1980.)*

intervals. Patients who require more than one bolus to achieve a therapeutic effect have arrhythmias that respond only to higher lidocaine plasma concentrations, and a greater maintenance dose may be necessary to sustain these higher concentrations. Patients requiring only a single initial bolus of lidocaine should probably receive a maintenance infusion of 30 mu/kg/min, whereas those requiring two or three boluses may need infusions at 40 to 50 mug/kg/min.

Loading doses also may be administered by rapid infusion, and a constant-rate IV infusion may be used to maintain an effective concentration. Maintenance infusion rates in the range of 1 to 4 mg/min produce steady-state plasma levels of 1 to 5 mg/ml in patients with uncomplicated myocardial infarction, but these rates must be reduced during heart failure or shock because of concomitant reduced hepatic blood flow. A loading dose of approximately 75 mg followed by an initial infusion rate of 5.33 mg/min that declines exponentially to 2 mg/min with a half-life of 25 minutes also has been recommended.

INDICATIONS.

Lidocaine demonstrates efficacy against ventricular arrhythmias of diverse etiology, the ability to achieve effective plasma concentrations rapidly, and a fairly wide toxic-to-therapeutic ratio with a low incidence of hemodynamic complications and other side effects. However, its first-pass hepatic effect precludes oral use, and it is generally ineffective against supraventricular arrhythmias. In patients with the Wolff-Parkinson-White syndrome, for whom the ERP of the accessory pathway is relatively short, lidocaine generally has no significant effect and may even accelerate the ventricular response during atrial fibrillation.

Lidocaine is used primarily for patients with acute myocardial infarction[225] [226] or recurrent ventricular tachyarrhythmias. It has been effective in patients resuscitated from out-of-hospital VF[227] and in patients after coronary revascularization.[228] Lidocaine prophylaxis in patients with acute myocardial infarction is controversial. However, most data suggest that the benefits of prophylactic lidocaine therapy in reducing the incidence of VF in hospitalized patients who have had acute myocardial infarction have not been clearly established.[225] [226] Drug-induced side effects and a possible increase in the risk of developing asystole led to the conclusion that prophylaxis is probably not indicated for all patients. Subcutaneous lidocaine given for local anesthesia during EPS can affect inducibility of ventricular arrhythmias by programmed electrical stimulation.[229]

ADVERSE EFFECTS.

The most commonly reported adverse effects of lidocaine are dose-related manifestations of central nervous system toxicity: dizziness, paresthesias, confusion, delirium, stupor, coma, and seizures.[230] Occasional sinus node depression and His-Purkinje block have been reported. In patients with atrial tachyarrhythmias, ventricular rate acceleration has been noted. Rarely, lidocaine can cause malignant hyperthermia.[231] Both lidocaine and procainamide can elevate defibrillation thresholds.[232]

Mexiletine

Mexiletine, a local anesthetic congener of lidocaine with anticonvulsant properties, is used for oral treatment of patients with symptomatic ventricular arrhythmias.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Mexiletine is similar to lidocaine in many of its electrophysiological actions. In vitro, mexiletine

shortens the APD and ERP of Purkinje fibers and, to a lesser extent, of ventricular muscle. It depresses
max of phase 0 by blocking I_{Na} , especially at faster rates, and depresses automaticity of Purkinje fibers but not of the normal sinus node. Its onset and offset kinetics are rapid. Hypoxia or ischemia can increase its effects on
max.

Mexiletine can result in severe bradycardia and abnormal SNRT in patients with sinus node disease but not in patients with a normal sinus node. It does not affect AV nodal conduction and can depress His-Purkinje conduction, but not greatly, unless conduction was abnormal initially. Mexiletine does not appear to affect the ERP of human atrial and ventricular muscle. The duration of the QT interval does not increase. Because of its rate-dependent effects, theoretically, mexiletine might be expected to suppress closely coupled rather than late-coupled ventricular extrasystoles or faster tachycardias.

HEMODYNAMIC EFFECTS.

Mexiletine exerts no major hemodynamic effects. It does not depress myocardial performance when given orally, although IV administration can produce hypotension.

PHARMACOKINETICS (see Table 23-1).

Mexiletine has been reported to be rapidly and almost completely absorbed after oral ingestion by volunteers, with peak plasma concentrations attained in 2 to 4 hours. Elimination half-life in healthy subjects is approximately 10 hours, and in patients after myocardial infarction it is 17 hours. Therapeutic plasma levels of 1 to 2 mg/ml are maintained by oral doses of 200 to 300 mg every 6 to 8 hours. Absorption with less than a 10 percent first-pass hepatic effect occurs in the upper small intestine and is delayed and incomplete in patients who have myocardial infarction and in patients receiving narcotic analgesics, antacids, or atropine-like drugs that retard gastric emptying. Bioavailability of orally administered mexiletine is approximately 90 percent, and about 70 percent of the drug is protein bound. The apparent volume of distribution is large, reflecting extensive tissue uptake. Normally, mexiletine is eliminated metabolically by the liver, with less than 10 percent excreted unchanged in the urine. Doses probably should be reduced in patients with cirrhosis and those with left ventricular failure. Renal clearance of mexiletine decreases as urinary pH increases. Known metabolites exert no electrophysiological effects. Metabolism can be increased by phenytoin, phenobarbital, and rifampin and reduced by cimetidine. It is influenced by the genotype for the CYP206 gene.[159]

DOSAGE AND ADMINISTRATION (see Table 23-1).

The recommended starting dose is 200 mg orally every 8 hours when rapid arrhythmia control is not essential. Doses may be increased or decreased by 50 to 100 mg every 2 to 3 days and are better tolerated when given with food. Total daily dose should not exceed 1200 mg. In some patients, administration every 12 hours can be effective. For rapid loading, 400 mg followed in 8 hours by a 200-mg dose is suggested.

INDICATIONS.

Mexiletine is an effective antiarrhythmic agent for treating patients with both acute and chronic ventricular tachyarrhythmias but not with SVTs. Success rates vary from 6 to 60 percent and can be increased in some patients if mexiletine is combined with other drugs such as procainamide, beta blockers, quinidine, disopyramide, or amiodarone. Most studies show no clear superiority of mexiletine over other Class I agents. In the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) investigation, sotalol was more effective than mexiletine.[11] [20] It may be very useful in children with congenital heart disease and serious ventricular arrhythmias. In treating patients with a long QT interval, mexiletine may be safer than drugs such as quinidine that increase the QT interval further. Limited experience in treating subsets of patients with long QT syndrome (LQT3, which is related to the SCN5A gene for the cardiac sodium channel) suggests a beneficial role. It does not appear to alter the prognosis of patients with inducible ventricular tachyarrhythmias after myocardial infarction. It may be effectively combined with propafenone.[233] [234]

ADVERSE EFFECTS.

Thirty to 40 percent of patients may require a change in dose or discontinuation of mexiletine therapy as a result of adverse effects, including tremor, dysarthria, dizziness, paresthesia, diplopia, nystagmus, mental confusion, anxiety, nausea, vomiting, and dyspepsia. Cardiovascular side effects are seen most often after IV dosing and include hypotension, bradycardia, and exacerbation of arrhythmia. Adverse effects of mexiletine appear to be dose related, and toxic effects occur at plasma concentrations only slightly higher than therapeutic levels. Therefore, effective use of this antiarrhythmic drug requires careful titration of dose and monitoring of plasma concentration. Lidocaine should be avoided, or dose reduced, in patients also receiving lidocaine congeners like mexiletine.[235]

Phenytoin

Phenytoin was employed originally to treat seizure disorders. Its value as an antiarrhythmic agent remains limited.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Therapeutic concentrations of phenytoin do not alter the discharge rate of rabbit sinus node tissue but may depress normal automaticity in cardiac Purkinje fibers in vitro or spontaneous ventricular rate in vivo. Phenytoin effectively abolishes abnormal automaticity caused by digitalis-induced delayed afterdepolarizations in cardiac Purkinje fibers and suppresses certain digitalis-induced arrhythmias in humans. Similar to lidocaine, phenytoin abbreviates Purkinje fiber APD more than it shortens the ERP, thus increasing the ratio of ERP to APD. Phenytoin can cause depolarized cells to repolarize by increasing potassium conductance and, in so doing, may increase the
max of phase 0 in Purkinje fibers, particularly when these are depressed by digitalis.

The rate of rise of action potentials initiated early in the relative refractory period is increased, as is membrane responsiveness, possibly reducing the chance for impaired conduction and block. Phenytoin may slow conduction at high potassium concentrations but minimally affects sinus discharge rate and AV conduction in humans. As with other Class IB agents, phenytoin has little effect on
max in normally polarized fibers at slow rates and shows use-dependence and rapid kinetics for onset and termination of effects.

Some of phenytoin's antiarrhythmic effects may be neurally mediated, because phenytoin may reduce the increase in impulse traffic in cardiac sympathetic nerves caused by ouabain toxicity and protect against some arrhythmias when it is injected into the central nervous system. The drug also may modulate vagal efferent activity centrally. It has no peripheral cholinergic or beta-adrenergic blocking actions. Phenytoin exerts minimal hemodynamic effects.

PHARMACOKINETICS (see Table 23-1).

The pharmacokinetics of phenytoin are less than ideal. Absorption after oral administration is incomplete and varies with the brand of drug. Plasma concentrations peak 8 to 12 hours after an oral dose. Ninety percent of the drug is protein bound. Phenytoin has limited solubility at physiological pH, and intramuscular administration is associated with pain, muscle necrosis, sterile abscesses, and variable absorption. Therapeutic serum concentrations of phenytoin (10 to 20 mg/ml) are similar for treating both cardiac arrhythmias and epilepsy. Lower concentrations can suppress certain digitalis-induced arrhythmias or other arrhythmias when decreased plasma protein binding occurs (as in uremia), because a larger fraction of drug is free and pharmacologically active.

METABOLISM.

Over 90 percent of a dose is hydroxylated in the liver to presumably inactive compounds. Some families have a genetically determined inability to hydroxylate phenytoin, whereas others have a higher than usual capability for hydroxylation. Elimination half-time is about 24 hours and can be slowed in the presence of liver disease or when phenytoin is administered concomitantly with drugs such as phenylbutazone, dicumarol, isoniazid, chloramphenicol, and phenothiazines that compete with phenytoin for hepatic enzymes (see Table 23-3). Because of the large number of medications that can increase or decrease phenytoin levels during chronic therapy, phenytoin plasma concentration should be determined frequently when changes are made in other medications. In some patients, maintenance dose regimens

of phenytoin are difficult to predict because the enzyme system that metabolizes phenytoin becomes saturated at plasma concentrations within the therapeutic range. The half-life then increases with increasing phenytoin load. Above the saturation point, phenytoin elimination follows zero-order kinetics, so only a fixed amount of drug is eliminated per unit of time. These concentration-dependent

kinetics for elimination can cause unexpected toxicity, because disproportionately large changes in plasma concentration can follow dose increases.

DOSAGE AND ADMINISTRATION (see Table 23-1).

To achieve therapeutic plasma concentration rapidly, 100 mg of phenytoin should be administered intravenously every 5 minutes until the arrhythmia is controlled, about 1 gm has been given, or adverse side effects result. Generally, 700 to 1000 mg will control the arrhythmia. A large central vein should be used to avoid pain and development of phlebitis produced by the extremely alkalotic (pH 11.0) vehicle in which phenytoin is dissolved. Orally, phenytoin is given as a loading dose of approximately 1000 mg the first day, 500 mg on the second and third days, and 300 to 400 mg daily thereafter. All maintenance doses can be given once or twice daily, depending on the brand, because of the long half-life of elimination.

INDICATIONS.

Phenytoin has been used successfully to treat atrial and ventricular arrhythmias caused by digitalis toxicity but is much less effective in treating ventricular arrhythmias in patients with ischemic heart disease or with atrial arrhythmias not due to digitalis toxicity. The drug has been somewhat more successful in treating ventricular arrhythmias associated with general anesthesia and cardiac surgery. It can be tried in patients with the long QT syndrome.

ADVERSE EFFECTS.

The most common manifestations of phenytoin toxicity are central nervous system effects of nystagmus, ataxia, drowsiness, stupor, and coma. Progression of such symptoms can be correlated with increases in plasma drug concentration. Neurological signs, such as nystagmus on lateral gaze, develop at plasma drug levels of about 20 mg/ml. Nausea, epigastric pain, and anorexia are also relatively common effects of phenytoin. Long-term administration can result in hyperglycemia, hypocalcemia, rashes, megaloblastic anemia, gingival hypertrophy, lymph node hyperplasia (a syndrome resembling malignant lymphoma), peripheral neuropathy, pneumonitis,[236] and drug-induced systemic lupus erythematosus (SLE). Birth defects also can result.[237] [238]

CLASS IC ANTIARRHYTHMIC AGENTS

Flecainide

Flecainide is approved by the U.S. Food and Drug Administration (FDA) to treat patients with life-threatening ventricular arrhythmias as well as a variety of supraventricular arrhythmias.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Flecainide exhibits marked use-dependent depressant effects on the rapid sodium channel,[239] decreasing
$\dot{V}_{max}$ with slow onset and offset kinetics. Drug dissociation from the sodium channel is very slow, with time constants of 10 to 30 seconds (compared with 4 to 8 seconds for quinidine and less than 1 second for lidocaine). Thus, marked drug effects can occur at physiological heart rates. Flecainide shortens the duration of Purkinje fiber action potential but prolongs it in ventricular muscle, actions that, depending on the circumstances, could enhance or reduce electrical heterogeneity and create or suppress arrhythmias. Flecainide profoundly slows conduction in all cardiac fibers and, in high concentrations, inhibits the slow Ca^{2+} channel. Conduction time in the atria, ventricles, AV node, and His-Purkinje system is prolonged. It can terminate experimental atrial reentry by causing conduction block in the reentry pathway[240] [241] [242] and eliminate atrial tachycardia by producing exit block from the focus.[243] Flecainide also can promote reentry.[244] Minimal increases in atrial or ventricular refractoriness or in the QT interval result. Anterograde and retrograde refractoriness in accessory pathways can increase significantly in a use-dependent fashion.[245] Normal sinus node function remains unchanged, but abnormal sinus node discharge may be depressed. Pacing thresholds are increased.

HEMODYNAMIC EFFECTS.

Flecainide depresses cardiac performance, particularly in patients with compromised myocardial function. Left ventricular ejection fraction decreases after oral (single dose of 200 to 250 mg) or IV (1 mg) administration. Caution is warranted, particularly in patients with a history of heart failure. Flecainide should be used cautiously, if at all, in patients with severely compromised cardiac function.

PHARMACOKINETICS (see Table 23-1).

Flecainide is at least 90 percent absorbed, with peak plasma concentrations in 3 to 4 hours. Elimination half-life in patients with ventricular arrhythmias is 20 hours, 85 percent of the drug being excreted unchanged or as an inactive metabolite in urine. Two major metabolites exert fewer effects than the parent drug. Rate of elimination is slower in patients with renal disease and heart failure, and doses should be reduced in these situations. Therapeutic plasma concentrations range from 0.2 to 1.0 mg/ml. About 40 percent of the drug is protein bound. Increases in serum concentrations of digoxin (15 to 25 percent) and propranolol (30 percent) result during coadministration with flecainide. Propranolol, quinidine, and amiodarone may increase flecainide serum concentrations. Five to 7 days of dosing may be required to reach steady state in some patients.

DOSAGE AND ADMINISTRATION (see Table 23-1).

The starting dose is 100 mg every 12 hours, increased in increments of 50 mg twice daily, no sooner than every 3 to 4 days, until efficacy is achieved, an adverse effect is noted, or to a maximum of 400 mg/d. Cardiac rhythm and QRS duration should be monitored.

INDICATIONS.

Flecainide is indicated for the treatment of life-threatening ventricular tachyarrhythmias, SVTs, and paroxysmal atrial fibrillation.[246] [247] [248] Therapy should begin in the hospital while the ECG is being monitored because of the high incidence of proarrhythmic events (see later). Serum concentration should not exceed 1.0 mg/ml. Flecainide is particularly effective, more so than quinidine, in almost totally suppressing PVCs and short runs of nonsustained VT, although the importance of such a response on the subsequent outcome of the patient has not been established. As with other Class I antiarrhythmic drugs, there are no data from controlled studies to indicate that the drug favorably affects survival or sudden cardiac death, and data from CAST (see later) indicate an increased mortality in patients with coronary artery disease. Flecainide prevents electrical induction of ventricular tachyarrhythmias in a small percentage of patients (10 to 30 percent) and eliminates recurrence of life-threatening ventricular tachyarrhythmias in about 40 percent. However, it produces a use-dependent prolongation of VT cycle length that improves hemodynamic tolerance.[247]

Flecainide is also very useful in a variety of SVTs[249] [250] [251] [252] such as atrial flutter[253] and atrial fibrillation,[249] [254] [255] [256] in Wolff-Parkinson-White syndrome,[257] and for atrial tachycardia.[258] Isoproterenol can reverse some of these effects. Flecainide may be more effective than procainamide in the acute termination of atrial fibrillation.[249] It is important to slow the ventricular rate before treating with flecainide to avoid 1:1 conduction.[259] Flecainide has been used to treat fetal arrhythmias[260] [261] and arrhythmias in children.[262] It may increase defibrillation thresholds.[263]

ADVERSE EFFECTS.

Proarrhythmic effects are some of the most important adverse effects of flecainide. Its marked slowing of conduction precludes its use in patients with second-degree AV block without a pacemaker and warrants cautious administration in patients with intraventricular conduction disorders. Aggravation of existing ventricular arrhythmias or onset of new ventricular arrhythmias can occur in 5 to 30 percent of patients, the increased percentage in patients with preexisting sustained VT, cardiac decompensation, and higher doses of the drug. Failure of the flecainide-related arrhythmia to respond to therapy, including electrical cardioversion-defibrillation, may result in mortality as high as 10 percent in patients who develop proarrhythmic events. Negative inotropic effects can cause or worsen heart failure. Patients with sinus

node dysfunction may experience sinus arrest, and those with pacemakers may develop an increase in pacing threshold. In CAST, patients treated with flecainide had 5.1 percent mortality or nonfatal cardiac arrest compared with 2.3 percent in the

placebo group over 10 months.[18] [193] Mortality was highest in those with non-Q-wave infarction, frequent PVCs, and faster heart rates, raising the possibility of drug interaction with ischemia and electrical instability.[17] [264] [265] Exercise can amplify the conduction slowing in the ventricle produced by flecainide and in some cases can precipitate a proarrhythmic response. Therefore, exercise testing has been recommended to screen for proarrhythmia. Central nervous system complaints, including confusion and irritability, represent the most frequent noncardiac adverse effect. The safety of flecainide during pregnancy has not been determined. It is concentrated in breast milk to levels 2.5- to 4-fold higher than plasma.

Propafenone

Propafenone has been approved by the FDA for treatment of patients with life-threatening ventricular tachyarrhythmias.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Propafenone blocks the fast sodium current in a use-dependent manner, as well as at rest, in Purkinje fibers and to a lesser degree in ventricular muscle. Use-dependent effects contribute to its ability to terminate experimental atrial fibrillation.[266] The dissociation constant is slow, like that of flecainide. Effects are greater in ischemic than normal tissue and at reduced membrane potentials. Propafenone decreases excitability and suppresses spontaneous automaticity and triggered activity. It terminates experimental VT by producing conduction block or by collision of the impulse with an echo wave.[267] Effects on APD are variable in that guinea pig APD is shortened, whereas rabbit APD is prolonged. Propafenone is a weak blocker of I_{Kr} .[268] Although ventricular refractoriness increases, conduction slowing is the major effect. The active metabolites of propafenone exert important actions, reducing
max, action potential amplitude, and duration in canine Purkinje fibers. In contrast to propafenone and the *N*-depropylpropafenone metabolite, the 5-hydroxypropafenone metabolite suppressed VT in the postinfarct canine model. Propafenone depresses sinus node automaticity. In patients, the AH, HV, PR, and QRS intervals increase, as do refractory periods of the atria, ventricles, AV node, and accessory pathways. The corrected QT interval increases only as a function of increased QRS duration.

HEMODYNAMIC EFFECTS.

Propafenone and 5-hydroxypropafenone exhibit negative inotropic properties at high concentrations in vitro, and large doses depress left ventricular function in vivo.[269] In patients with ejection fractions exceeding 40 percent, the negative inotropic effects are well tolerated, but patients with preexisting left ventricular dysfunction and congestive heart failure may have symptomatic worsening of their hemodynamic status.

PHARMACOKINETICS (see Table 23-1).

With more than 95 percent of the drug absorbed, propafenone's maximum plasma concentration occurs in 2 to 3 hours. Systemic bioavailability is dose dependent and ranges from 3 to 40 percent due to variable presystemic clearance. Bioavailability increases as the dose increases, and plasma concentration is therefore nonlinear. A threefold increase in dosage (300 to 900 mg/d) results in a tenfold increase in plasma concentration, presumably due to saturation of hepatic metabolic mechanisms. Propafenone is 97 percent bound to alpha1-acid glycoprotein, with an elimination half-life of 5 to 8 hours. Maximum therapeutic effects occur at serum concentrations of 0.2 to 1.5 mg/ml. Marked interpatient variability of pharmacokinetics and pharmacodynamics may be due to genetically determined differences in metabolism. About 93 percent of the population are extensive metabolizers and exhibit shorter elimination half-lives (5 to 6 hours), lower plasma concentrations of the parent compound, and higher concentrations of metabolites. Poor metabolizers, due to diminished capacity of the microsomal cytochrome P450 enzyme system in the liver (see earlier), exhibit an elimination half-life of 15 to 20 hours for the parent compound and virtually no 5-hydroxypropafenone.[159] Low-dose quinidine may inhibit the metabolism of propafenone, and stereoselectivity may be important with the (+) enantiomer, providing nonspecific beta-adrenergic receptor blockade 2.5 to 5 percent the potency of propranolol. Poor metabolizers have a greater beta-adrenergic receptor blocking effect than extensive metabolizers. Because plasma propafenone concentrations may be 50 times or more propranolol levels, these beta-blocking properties may be relevant.[270] Propafenone also blocks the slow calcium channel to a degree about 100 times less than verapamil.

DOSAGE AND ADMINISTRATION (see Table 23-1).

Most patients respond to oral doses of 150 to 300 mg every 8 hours, not exceeding 1200 mg/d. Doses are similar for patients of both phenotypes. Concomitant food administration increases bioavailability, as does hepatic dysfunction. No good correlation between plasma propafenone concentration and arrhythmia suppression has been shown. Doses should not be increased more often than every 3 to 4 days. Propafenone increases plasma concentrations of warfarin, digoxin, and metoprolol.

INDICATIONS.

Propafenone is indicated for the treatment of SVTs, paroxysmal atrial fibrillation, and life-threatening ventricular tachyarrhythmias and effectively suppresses spontaneous PVCs[271] and nonsustained and sustained VT.[272] Propafenone has also been approved for use in patients with atrial tachycardia,[272] [273] AV node reentry, AV reentry,[274] and atrial flutter[253] or fibrillation.[271] [275] [276] [277] [278] Acute termination of atrial fibrillation episodes was effected with a single 600-mg oral dose of propafenone in 76 percent of patients given the drug, compared with 37 percent of those given placebo.[279] It has been used effectively in the pediatric age group.[280] [281] [282] [283] Propafenone increases the pacing threshold[284] [285] but minimally affects the defibrillation threshold. Spontaneous sinus rate during exercise is reduced. Propafenone use is associated with a higher mortality in cardiac arrest survivors compared with an implantable defibrillator.[286] Sotalol was more effective than propafenone in the ESVEM trial.[11] Propafenone has been combined effectively with mexiletine.[233] [234]

ADVERSE EFFECTS.

Minor noncardiac effects occur in about 15 percent of patients, with dizziness, disturbances in taste, and blurred vision the most common and gastrointestinal side effects next. Exacerbation of bronchospastic lung disease can occur due to mild beta-blocking effects. Cardiovascular side effects occur in 10 to 15 percent of patients, including conduction abnormalities such as AV block, sinus node depression, and worsening of heart failure. Proarrhythmic responses, which occur more often in patients with a history of sustained VT and decreased ejection fractions, appear less commonly than with flecainide and may be in the range of 5 percent. The applicability of data from CAST about flecainide to propafenone is not clear, but limiting propafenone's application in a manner similar to other Class IC drugs seems prudent at present until more information is available. Its beta-blocking actions may make it different, however.[270] The safety of propafenone administration during pregnancy has not been established.

Moricizine (Ethmozine)

Moricizine is a phenothiazine derivative used for treatment of patients with ventricular tachyarrhythmias. It was formerly discussed as a Class IB antiarrhythmic drug because it shortens Purkinje fiber action potential. However, the intensity of its effect on the Na^+ channel is more like

that of a Class IA antiarrhythmic drug, whereas the time constants for onset and offset resemble those of Class IC agents.

ELECTROPHYSIOLOGICAL ACTIONS.

Moricizine decreases I_{Na} predominantly in the inactivated state, with a resultant decrease in
max of phase 0, action potential amplitude, and APD in canine cardiac Purkinje fibers (see Tables 23-4 , 23-6 , and 23-7).[287] Maximum diastolic potential is not changed. Moricizine blocks $I_{Ca\text{-}L}$ and I_K and prolongs AV node and His-Purkinje conduction times and QRS duration. The JT interval shortens slightly, whereas the QTc is prolonged 5 percent owing to QRS prolongation. Ventricular refractoriness is prolonged slightly, with no consistent atrial change. No alterations in sinus node automaticity result. In vitro, moricizine slows spontaneous automaticity in normal Purkinje fibers and suppresses abnormal automaticity arising from depolarized fibers

and delayed afterdepolarizations. It terminates experimental flutter by causing block in the area of slow conduction.[288] Moricizine decreases RR interval variability, which does not predict mortality.[289] Moricizine minimally raises the defibrillation threshold.[290]

HEMODYNAMIC EFFECTS.

Moricizine exerts minimal effects on cardiac performance in patients with impaired left ventricular function. Exercise tolerance and ejection fraction do not change. A small but consistent increase in blood pressure and heart rate results. An occasional patient with significant left ventricular dysfunction may have worsening of heart failure.

PHARMACOKINETICS (see Table 23-1).

After oral ingestion, moricizine undergoes extensive first-pass metabolism, resulting in absolute bioavailability of 35 to 40 percent. Peak plasma concentrations are reached in 0.5 to 2 hours and later if the drug is taken after meals. Extent of absorption is not changed. Proportionality exists between dose and plasma concentrations in the therapeutic range. Protein binding is 95 percent to alpha1-acid glycoprotein and albumin. Antiarrhythmic and electrophysiological actions do not relate to plasma concentrations or to any identified metabolite, of which there are more than 20. At least two metabolites are pharmacologically active but are in small concentrations. Moricizine induces its own metabolism,[291] and plasma concentrations decrease with multiple dosing. Plasma elimination half-life is 1.5 to 3.5 hours, with slightly more than half the drug excreted in the feces and slightly less than half excreted in the urine.

DOSAGE AND ADMINISTRATION (see Table 23-1).

The usual adult dose is 600 to 900 mg/d, given every 8 hours in three equally divided doses. Increments of 150 mg/d at 3-day intervals can be tried. Some patients may be treated every 12 hours. Dose reductions in patients with hepatic or neural disease, AV conduction disturbances, or sick sinus syndrome without a pacemaker and with significant congestive heart failure should be observed.

INDICATIONS.

Moricizine is indicated for prevention of life-threatening ventricular arrhythmias and exerts an efficacy that is about comparable with those of quinidine and disopyramide.[292] It is less effective in preventing VT initiation at EPS and may have proarrhythmic effects.[293] [294] [295] It caused an increase in mortality compared with placebo during initial treatment of patients who had symptomatic or minimally symptomatic ventricular arrhythmias after myocardial infarction.[17] [194] [195] Risk was greater in patients taking diuretics.[194]

ADVERSE EFFECTS.

Usually the drug is well tolerated. Noncardiac adverse effects primarily involve the nervous system and include tremor, mood changes, headache, vertigo, nystagmus, and dizziness. Gastrointestinal side effects include nausea, vomiting, and diarrhea. Worsening of congestive heart failure is uncommon but can happen. Proarrhythmic effects have been reported in 3 to 15 percent of patients[296] [297] and appear to be more common in patients with severe ventricular arrhythmias. Advancing age increases the susceptibility to adverse effects.[298] Moricizine appears to be relatively safe to use during pregnancy and is present in small amounts in breast milk.

CLASS II ANTIARRHYTHMIC AGENTS

Beta-Adrenoceptor Blocking Agents

Although many beta-adrenoceptor blocking drugs have been approved for use in the United States (see Table 23-8), acebutolol (PVCs), esmolol (SVT), metoprolol (post-myocardial infarction), atenolol (post-myocardial infarction), propranolol (post-myocardial infarction, SVT, VT), and timolol (post-myocardial infarction) have been approved to treat arrhythmias or to prevent sudden death after myocardial infarction.[163] It is generally considered that no beta blocker offers distinct advantages over the others and that, when titrated to the proper dose, all can be used effectively to treat cardiac arrhythmias, hypertension, or other disorders. However, differences in pharmacokinetic or pharmacodynamic properties that confer safety, reduce adverse effects, or affect dosing intervals or drug interactions influence the choice of agent. Also, some beta blockers such as sotalol exert unique actions.

Beta receptors can be separated into those that affect predominantly the heart ($beta_1$) and those that affect predominantly

TABLE 23-8 -- PHARMACODYNAMIC PROPERTIES OF BETA-ADRENOCEPTOR BLOCKING DRUGS

DRUG	$BETA_2$ BLOCKADE POTENCY RATIO (PROPRANOLOL = 1.0)	RELATIVE $BETA_2$ SELECTIVITY	INTRINSIC SYMPATHOMIMETIC ACTIVITY	CLASS I ACTIVITY

*Bucindolol and labetalol have additional $beta_1$ -adrenergic blocking activity and direct vasodilatory actions ($beta_2$ -agonism).

Carvedilol has additional $beta_1$ -adrenergic blocking activity without peripheral $beta_2$ -agonism.

Celiprolol may have additional peripheral $beta_2$ -adrenergic blocking activity at high doses.
§Dilevalol is an isomer of labetalol with peripheral $beta_2$ -agonism but no $beta_1$ -blocking activity.

Sotalol has an additional type of antiarrhythmic activity.

blood vessels and the bronchi (beta$_2$). In low doses, selective beta blockers can block beta$_1$ receptors more than they block beta$_2$ receptors and might be preferable for treating patients with pulmonary or peripheral vascular diseases. In high doses, the selective beta$_1$ blockers also block beta$_2$ receptors.

Some beta blockers exert intrinsic sympathomimetic activity; that is, they slightly activate the beta receptor. These drugs appear to be as efficacious as beta blockers without intrinsic sympathomimetic actions and may cause less slowing of heart rate at rest and less prolongation of AV nodal conduction time. They have been shown to induce less depression of left ventricular function than beta blockers without intrinsic sympathomimetic activity. Only nonselective beta blockers without intrinsic sympathomimetic activity have been demonstrated to reduce mortality in patients after myocardial infarction[299] (Fig. 23-13) .

The following discussion will concentrate on the use of propranolol as a prototypical antiarrhythmic agent.

ELECTROPHYSIOLOGICAL ACTIONS.

Beta blockers exert an electrophysiological action by competitively inhibiting catecholamine binding at beta-adrenoceptor sites, an effect almost entirely due to the (-)-levorotatory stereoisomer, or by their quinidine-like or direct membrane-stabilizing action (see Tables 23-4 , 23-6 , and 23-7). The latter is a local anesthetic effect that depresses I_{Na} and membrane responsiveness in cardiac Purkinje fibers, occurs at concentrations generally 10 times that necessary to produce beta blockade, and most likely plays an insignificant antiarrhythmic role. Thus, major effects of beta blockers will take place in cells most actively stimulated by adrenergic actions. At beta-blocking concentrations, propranolol slows spontaneous automaticity in the sinus node or in Purkinje fibers that are being stimulated by adrenergic tone, producing

Figure 23-13 Metaanalytical data from randomized clinical trials of antiarrhythmic drugs in survivors of acute myocardial infarction. The relative risk is compared with placebo therapy (mean and 95 percent confidence interval) for death during therapy with various electrophysiological classes of compounds. Class I agents, particularly IC, and sotalol increase mortality, whereas beta blockers and amiodarone decrease mortality. Numbers under each drug class refer to number of patients involved in the trials. *(Modified from Teo KK, Yusuf S: In Singh BN, Dzau VJ, Vanhoutte PM, Woosley RL [eds]: Cardiovascular Pharmacology and Therapeutics. New York, Churchill Livingstone, 1994, pp 631-643, and Waldo AL, Camm AJ, deRuyter H, et al: Effect of d-sotalol on mortality in patients with left ventricular dysfunction after recent and remote myocardial infarction: The SWORD Investigators. Survival With Oral d-Sotalol. Lancet 348:7, 1996.)*

block of I_f (see Chap. 22). Beta blockers also block $I_{Ca\text{-}L}$ stimulated by beta agonists. In the absence of adrenergic stimulation, only high concentrations of propranolol slow normal automaticity in Purkinje fibers, probably by a direct membrane action.

Concentrations that cause beta-receptor blockade but no local anesthetic effects do not alter the normal resting membrane potential, maximum diastolic potential amplitude,
max, repolarization, or refractoriness of atrial, Purkinje, or ventricular muscle cells when these tissues are not being superfused with catecholamines. However, in the presence of isoproterenol, a pure beta-receptor stimulator, beta blockers reverse isoproterenol's accelerating effects on repolarization; in the presence of norepinephrine, beta blockade permits unopposed alpha-adrenoceptor stimulation to prolong APD in Purkinje fibers. Propranolol (2×10^{-6} M) reduces the amplitude of digitalis-induced delayed afterdepolarizations and suppresses triggered activity in Purkinje fibers.

Propranolol upregulates beta adrenoceptors in part by externalizing receptors from a light vesicle fraction to the sarcolemma. Beta blockers do not blunt heart rate variability in dogs after myocardial infarction.[44]

Concentrations exceeding 3 mg/ml are required to depress
max action potential amplitude, membrane responsiveness, and conduction in normal atrial, ventricular, and Purkinje fibers without altering resting membrane potential. These effects probably result from depression of I_{Na} . Propranolol shortens the APD of Purkinje fibers and, to a lesser extent, of atrial and ventricular muscle fibers. Long-term administration of propranolol may lengthen APD. Similar to the effects of lidocaine, acceleration of repolarization of Purkinje fibers is most marked in areas of the ventricular conduction system in which the APD is greatest. The reduction in refractory period is not as great as the reduction in APD (ERP/APD>1.0). At least one beta blocker, sotalol, markedly increases the time course of repolarization in Purkinje fibers and ventricular muscles. Smaller doses of propranolol are required to prevent sympathetically induced shortening of ventricular refractoriness than are required to prevent sympathetically induced sinus acceleration.

Propranolol slows the sinus discharge rate in humans by 10 to 20 percent, whereas severe bradycardia occasionally results if the heart is particularly dependent on sympathetic tone or if sinus node dysfunction is present. The slowing is probably due to beta blockade because *d*-propranolol does not significantly slow the sinus discharge rate in doses comparable to the racemic mixture. The PR interval lengthens, as do AV node conduction time and effective and functional refractory periods (if the heart rate is maintained constant), but refractoriness and conduction in the normal His-Purkinje system remain unchanged even after high doses of propranolol. Therefore, therapeutic doses of propranolol in humans do not exert a direct depressant or "quinidine-like" action but influence cardiac electrophysiology through a beta-blocking action. Beta blockers do not affect conduction in normal ventricular muscle, as evidenced by their lack of effect on the QRS complex, and they insignificantly prolong the right ventricular ERF and uncorrected QT interval.

Because administration of beta blockers that do not have direct membrane action prevents many arrhythmias resulting from activation of the autonomic nervous system, it is thought that the beta-blocking action is responsible for their antiarrhythmic effects.[300] [301] [302] [303] [304] Nevertheless, the possible importance of the direct membrane effect of some of these drugs cannot be discounted totally because beta blockers with direct membrane actions can affect transmembrane potentials of diseased cardiac fibers at much lower concentrations than are needed to affect normal fibers directly. However, indirect actions on arrhythmogenic effects of ischemia are probably quite important. Beta blockers reduce myocardial injury during experimental cardiopulmonary resuscitation.[305]

HEMODYNAMIC EFFECTS.

Beta blockers exert negative inotropic effects and can precipitate or worsen heart failure. However, beta blockers clearly improve survival in heart failure patients (see Chap. 18). By blocking beta receptors, these drugs may cause peripheral vasoconstriction and exacerbate coronary artery spasm in some patients.

PHARMACOKINETICS (see Table 23-1).

Although various types of beta blockers exert similar pharmacological effects, their pharmacokinetics differ substantially. Propranolol is almost 100 percent absorbed, but the effects of first-pass hepatic metabolism reduce bioavailability to about 30 percent and produce significant interpatient variability of plasma concentration for a given dose. Reduction in hepatic blood flow, as in patients with heart failure, decreases the hepatic extraction of propranolol; in these patients propranolol may further decrease its own elimination rate by reducing cardiac output and hepatic blood flow. Beta blockers eliminated by the kidney tend to have longer half-lives and exhibit less interpatient variability of drug concentration than do those beta blockers metabolized by the liver.

DOSAGE AND ADMINISTRATION (see Tables 23-1 and 23-8).

The appropriate dose of propranolol is best determined by a measure of the patient's physiological response, such as changes in resting heart rate or in the prevention of exercise-induced tachycardia, because wide individual differences exist between the observed physiological effect and plasma concentration. For example, intravenous dosing is best achieved by titrating the dose to a clinical effect, beginning with doses of 0.25 to 0.50 mg, increasing to 1.0 mg if necessary, and administering doses every 5 minutes until either a desired effect or toxicity is produced or a total of 0.15 to 0.20 mg/kg has been given. In many instances, the short-acting effects of esmolol are preferred. Orally, propranolol is given in four divided doses, usually ranging from 40 to 160 mg/d to more than 1 gm/d. A once-daily long-acting propranolol preparation is available. Generally, if one agent in adequate doses proves to be ineffective, other beta blockers will be ineffective also.

INDICATIONS.

Arrhythmias associated with thyrotoxicosis, pheochromocytoma, and anesthesia with cyclopropane or halothane or arrhythmias largely due to excessive cardiac adrenergic stimulation, such as those initiated by exercise, emotion, or cocaine, often respond to beta-blocker therapy. Beta-blocking drugs usually do not convert chronic atrial flutter or atrial fibrillation to normal sinus rhythm but may do so if the arrhythmia is of recent onset and in patients who have recently undergone cardiac surgery. The atrial rate during flutter/fibrillation is not changed, but the ventricular response decreases because beta blockade prolongs AV node conduction time and refractoriness. Esmolol combined with digoxin has been useful.[306] In the absence of heart failure, beta blockers can be more effective than digoxin to control the rate.[307] For reentrant SVTs using the AV node as one of the reentrant pathways, such as AVNRT[308] [309] and orthodromic reciprocating tachycardias in the Wolff-Parkinson-White syndrome or inappropriate sinus tachycardia,[310] [311] or for SNRT, beta blockers can slow or terminate the tachycardia and be used prophylactically to prevent a recurrence. Combining beta blockers with digitalis, quinidine, or a variety of other agents may be effective when the beta blocker as a single agent fails. *Metoprolol* and *esmolol* may be useful in patients with multifocal atrial tachycardia.[312] These agents must be used with caution in this arrhythmia, however, because a common setting for it is advanced lung disease, often with a bronchospastic component.

Beta blockers may be effective for digitalis-induced arrhythmias such as atrial tachycardia, nonparoxysmal AV junctional tachycardia, PVCs, or VT. If a significant degree of AV block is present during a digitalis-induced arrhythmia, lidocaine or phenytoin may be preferable to propranolol. Beta blockers also may be useful to treat ventricular arrhythmias associated with the prolonged QT interval syndrome[313] [314] [315] and with mitral valve prolapse. For patients with ischemic heart disease, beta blockers generally do not prevent episodes of chronic recurrent monomorphic ventricular tachycardia that occur in the absence of acute ischemia but may be effective in some patients, usually at a beta-blocking concentration. It is well accepted that propranolol, timolol, and metoprolol reduce the incidence of overall death and sudden cardiac death after myocardial infarction.[316] [317] [318] The mechanism of this reduction in mortality is not entirely clear and may relate to reduction in the extent of ischemic damage, autonomic effects, a direct antiarrhythmic effect, or combinations of these factors. Beta blockers may have been protective against proarrhythmic responses in CAST[319] and may be more effective in some patients than electrophysiologically guided antiarrhythmic drug therapy[135] for ventricular tachyarrhythmias. Labetalol has been used for ventricular arrhythmias in eclampsia.[320]

Labetalol is an alpha$_1$ - and beta-blocking drug. Carvedilol, another alpha- and beta-blocking agent, has been shown to improve survival in moderate to severe heart failure (see Chap. 15).[321] *Esmolol* is an ultra-short-acting (elimination half-life, 9 minutes), cardioselective beta-adrenoceptor blocker that is useful for the rapid control of the ventricular rate in patients with atrial flutter/fibrillation.[322] Its withdrawal has been used in tilt-table testing.[100]

ADVERSE EFFECTS.

Adverse cardiovascular effects from beta blockers include unacceptable hypotension, bradycardia, and congestive heart failure. The bradycardia may be due to sinus bradycardia or AV block. Sudden withdrawal of propranolol in patients with angina pectoris can precipitate or worsen angina and cardiac arrhythmias and cause an acute myocardial infarction, possibly owing to heightened sensitivity to beta agonists caused by previous beta blockade (upregulation). Heightened sensitivity may begin several days after cessation of beta-blocker therapy and may last 5 or 6 days. Other adverse effects of beta blockers include worsening of asthma or chronic obstructive pulmonary disease, intermittent claudication, Raynaud's phenomenon, mental depression, increased risk of hypoglycemia among insulin-dependent diabetic patients, easy fatigability, disturbingly vivid dreams or insomnia, and impaired sexual function. Many of these side effects were noted less frequently when using beta$_1$ -selective agents, but even so-called cardioselective beta blockers can exacerbate asthma or diabetic control in individual patients.

CLASS III ANTIARRHYTHMIC AGENTS

Amiodarone

Amiodarone is a benzofuran derivative approved by the FDA for the treatment of patients with life-threatening ventricular tachyarrhythmias when other drugs are ineffective or are not tolerated.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

When chronically given orally, amiodarone prolongs APD and refractoriness of all cardiac fibers without affecting resting membrane potential. When acute effects are evaluated, amiodarone and its metabolite, desethylamiodarone, prolong the APD of ventricular muscle but shorten the APD of Purkinje fibers. Injected into the sinus and AV node arteries, amiodarone reduces sinus and junctional discharge rates and prolongs AV node conduction time. It decreases the slope of diastolic depolarization of the sinus node and markedly depresses
max in guinea pig papillary muscle in a rate- or use-dependent manner. Such depression of
max is caused by blocking of inactivated sodium channels, an effect that is accentuated by depolarized and reduced by hyperpolarized membrane potentials. Amiodarone also inhibits depolarization-induced automaticity. Amiodarone depresses conduction at fast rates more than at slow rates (use or frequency dependence),[323] [324] [325]

not only by depressing
max but also by increasing resistance to passive current flow. It does not prolong repolarization more at slow than fast rates (i.e., does not demonstrate reverse use or frequency dependence) but does exert time-dependent effects on refractoriness, which may in part explain the low incidence of torsades de pointes and high efficacy.[323] [324]

Desethylamiodarone has relatively greater effects on fast-channel tissue and probably contributes importantly to antiarrhythmic efficacy. The delay to build up adequate concentrations of this metabolite may explain in part the delay in amiodarone's antiarrhythmic action.

In vivo, amiodarone noncompetitively antagonizes alpha and beta receptors and blocks conversion of thyroxine (T_4) to triiodothyronine (T_3), which may account for some of its electrophysiological effects. Amiodarone exhibits slow-channel blocking effects, and chronic oral therapy slows the spontaneous sinus node discharge rate in anesthetized dogs even after pretreatment with propranolol and atropine. With oral administration it prolongs the QT interval, at times changing the contour of the T wave and producing U waves, and slows the sinus rate by 20 to 30 percent.

ERPs of all cardiac tissues are prolonged. His-Purkinje conduction time increases and QRS duration lengthens, especially at fast rates. Amiodarone given intravenously modestly prolongs the refractory period of atrial and ventricular muscle. The PR interval and AV node conduction time lengthen. The duration of the QRS complex lengthens at increased rates but less than after oral amiodarone. Thus, far less increase in prolongation of conduction time (except for the AV node), duration of repolarization, and refractoriness occurs after IV administration compared with the oral route. Considering these actions, it is clear that amiodarone has Class I (blocks I_{Na}), Class II (antiadrenergic), and Class IV (blocks $I_{Ca\text{-}L}$) actions, in addition to Class III effects (blocks I_K). Amiodarone's actions approximate those of a theoretically ideal drug that exhibits use-dependence of Na^+ channels with fast diastolic recovery from block and use-dependent prolongation of APD. It does not increase[60] and may decrease[326] QT dispersion. Catecholamines can partially reverse some of the effects of amiodarone.[202] [323]

HEMODYNAMIC EFFECTS.

Amiodarone is a peripheral and coronary vasodilator. When administered intravenously in doses of 2.5 to 10 mg/kg, amiodarone decreases heart rate, systemic vascular resistance, left ventricular contractile force, and left ventricular dP/dt (see Chaps. 11 , 14 , and 15). Left ventricular output may increase. Oral doses of amiodarone sufficient to control cardiac arrhythmias do not depress left ventricular ejection fraction, even in patients with reduced ejection fractions measured by radionuclide ventriculography. However, because antiadrenergic actions of amiodarone may block I_{si} to some degree, and because it does exert some negative inotropic action, it should be given cautiously, particularly intravenously, to patients with marginal cardiac compensation.

PHARMACOKINETICS (see Table 23-1).

Amiodarone is slowly, variably, and incompletely absorbed, with systemic bioavailability of 35 to 65 percent. Plasma concentrations peak 3 to 7 hours after a single oral dose. There is minimal first-pass effect, indicating little hepatic extraction. Elimination is by hepatic excretion into bile with some enterohepatic recirculation. Extensive hepatic metabolism occurs with desethylamiodarone as a major metabolite. The plasma concentration ratio of parent to metabolite is 3:2. Both extensively accumulate

in the liver, lung, fat, "blue" skin, and other tissues. Myocardium develops a concentration 10 to 50 times that found in the plasma. Plasma clearance of amiodarone is low, and renal excretion is negligible. Doses need not be reduced in patients with renal disease. Amiodarone and desethylamiodarone are not dialyzable. Volume of distribution is large but variable, averaging 60 liters/kg. Amiodarone is highly protein bound (96 percent), crosses the placenta (10 to 50 percent), and is found in breast milk.

The onset of action after IV administration is generally within 1 to 2 hours. After oral administration, the onset of action may require 2 to 3 days, often 1 to 3 weeks, and, on occasion, even longer. Loading doses reduce this time interval. Plasma concentrations relate well to oral doses during chronic treatment, averaging about 0.5 mg/ml for each 100 mg/d at doses between 100 and 600 mg/d. Elimination half-life is multiphasic with an initial 50 percent reduction in plasma concentration 3 to 10 days after cessation of drug ingestion (probably representing elimination from well-perfused tissues) followed by a terminal half-life of 26 to 107 days (mean 53 days), with most patients in the 40- to 55-day range. To achieve steady state without a loading dose takes about 265 days. Interpatient variability of these pharmacokinetic parameters mandates close monitoring of the patient. Therapeutic serum concentrations range from 1 to 2.5 mg/ml. Greater suppression of arrhythmias may occur up to 3.5 mg/ml, but the risk of side effects increases.

DOSAGE AND ADMINISTRATION (see Table 23-1).

An optimal dosing schedule for all patients has not been achieved.[327] [328] [329] [330] One recommended approach is to treat with 800 to 1600 mg/d for 1 to 3 weeks,[331] reduced to 800 mg/d for the next 2 to 4 weeks, then 600 mg/d for 4 to 8 weeks, and finally, after 2 to 3 months of treatment, a maintenance dose of 300 mg or less per day. Maintenance drug can be given once or twice daily and should be titrated to the *lowest effective dose* to minimize the occurrence of side effects.[332] Doses as low as 100 mg/d can be effective in some patients.[333] Regimens must be individualized for a given patient and clinical situation. Amiodarone may be administered intravenously[334] [335] to achieve more rapid loading and an effect in emergencies at initial doses of 15 mg/min for 10 minutes, followed by 1 mg/min for 6 hours and then 0.5 mg/min for the remaining 18 hours and for the next several days, as necessary. Supplemental infusions of 150 mg over 10 minutes can be used for breakthrough VT or VF. IV infusions can be continued safely for 2 to 3 weeks. IV amiodarone is generally well tolerated even in patients with left ventricular dysfunction.[336] Patients with depressed ejection fractions should receive IV amiodarone with great caution because of hypotension. High-dose oral loading (800 to 2000 mg two or three times a day to maintain trough serum concentrations of 2 to 3 mg/ml) may suppress ventricular arrhythmias in 1 to 2 days.

INDICATIONS.

Amiodarone has been used to suppress a wide spectrum of supraventricular and ventricular tachyarrhythmias in utero,[337] [338] in adults,[332] and in children,[339] [340] including AV node and AV entry, junctional tachycardia,[341] atrial flutter and fibrillation,[342] [343] [344] [345] [346] [347] [347A] VT and VF associated with coronary artery disease,[348] [349] [350] [351] and hypertrophic cardiomyopathy. Success rates vary widely depending on patient population,[352] arrhythmia, underlying heart disease, length of follow-up, definition and determination of success, and other factors. In general, however, amiodarone's efficacy equals or exceeds that of all other antiarrhythmic agents and may be in the range of 60 to 80 percent for most supraventricular tachyarrhythmias (including those associated with the Wolff-Parkinson-White syndrome) and 40 to 60 percent for ventricular tachyarrhythmias. Amiodarone may be useful in improving survival in patients with hypertrophic cardiomyopathy, nonischemic dilated cardiomyopathy,[353] asymptomatic ventricular arrhythmias after myocardial infarction, and ventricular tachyarrhythmia after resuscitation. Amiodarone given before open-heart surgery,[354] as well as postoperatively,[355] has been shown to decrease the incidence of postoperative atrial fibrillation. Amiodarone is superior to Class I antiarrhythmic agents in maintaining sinus rhythm in patients with recurrent atrial fibrillation.[356]

Patients who have an internal cardioverter-defibrillator (ICD) receive fewer shocks if they are treated with amiodarone compared with conventional drugs.[357] Amiodarone

may facilitate defibrillation experimentally[358] but typically increases the electrical defibrillation threshold.[359] [360]

A number of prospective, randomized, controlled trials have demonstrated improved survival with amiodarone therapy compared with placebo[361] [362] [363] [364] [365] or metoprolol[366] in patients after myocardial infarction (Table 23-9) . Amiodarone was found to improve survival in patients resuscitated from VF compared with conventional drugs.[367] [368] In patients with congestive heart failure, amiodarone therapy improved survival in one study,[353] whereas no benefit was observed in another.[369] The Antiarrhythmics Versus Implantable Defibrillator (AVID) trial was designed to compare mortality between patients treated with antiarrhythmic drugs (empirical amiodarone or EPS- or Holter-guided sotalol) versus an ICD, in patients with ejection fraction less than 0.40 who had suffered spontaneous hypotensive VT or cardiac arrest.[370] This study was stopped prematurely when interim analysis showed that ICD-treated patients survived better after 1 year of treatment.[371]

Some controversy exists regarding the ability to predict the effectiveness of amiodarone in patients with ventricular tachyarrhythmias. Clinical assessment, suppression of spontaneous ventricular arrhythmias as documented by 24-hour ECG recordings, and response to EPS have served as endpoints to judge therapy. In the patient with a history of sustained VT or VF and minimal spontaneous ventricular arrhythmias in between symptomatic episodes, an invasive EPS is indicated to judge drug efficacy. The answer to when, after amiodarone therapy is started, such a study should be done is still not entirely resolved but probably should be 1 week or longer. In the 10 to 20 percent of patients whose electrically induced, clinical, ventricular tachyarrhythmias become no longer inducible while they are receiving amiodarone, the chances for a spontaneous recurrence of the arrhythmias are low while the patients are taking amiodarone, probably less than 5 to 10 percent at 1 year. For those patients whose ventricular tachyarrhythmias are still inducible, the recurrence rate is 40 to 50 percent at 1 year. However, in this latter group, greater difficulty in inducing the arrhythmias may predict a less likely possibility of a recurrence.

Patients' hemodynamic responses to the induced arrhythmia also may predict how they tolerate a spontaneous recurrence. Amiodarone slows the VT,[372] [373] but it is important to remember that the supine patient in the electrophysiology laboratory may tolerate the same tachycardia better than when in an erect position. An ejection fraction greater than 0.4 may predict a good response to amiodarone in patients with VT or VF.[374]

Because of the serious nature of the arrhythmias being treated, the unusual pharmacokinetics of the drug, and its adverse effects (see later), amiodarone therapy should be started with the patient hospitalized and monitored for at least several days. Combining other antiarrhythmic agents with amiodarone may improve efficacy in some patients.[375] [376]

ADVERSE EFFECTS.

Adverse effects are reported by about 75 percent of patients treated with amiodarone for 5 years but compel stopping the drug in 18 to 37 percent. The most frequent side effects requiring drug discontinuation involve pulmonary and gastrointestinal complaints.[332] [377] Most adverse effects are reversible with dose reduction or cessation of treatment. Adverse effects become more frequent when therapy is continued long term. Of the noncardiac adverse reactions, pulmonary toxicity is the most serious; in one study it occurred between 6 days and 60 months of treatment in 33 of 573 patients, with three deaths. The mechanism is unclear but may relate to a hypersensitivity reaction and/or widespread phospholipidosis.[378] Dyspnea, nonproductive cough, and fever are common symptoms, with rales, hypoxia, a positive gallium scan, reduced diffusion capacity,[379] [380] and radiographic evidence of pulmonary infiltrates noted. Amiodarone must be discontinued if such pulmonary inflammatory changes occur. Corticosteroids can be tried, but no controlled studies have been done to support their use. A 10 percent mortality results in patients with pulmonary inflammatory changes, often in patients with unrecognized pulmonary involvement that is allowed to progress. Chest radiographs and pulmonary function tests, including diffusion capacity (DL_{CO}), at 3-month intervals for the first year and then twice a year for several years have been recommended. At maintenance doses less than 300 mg/d, pulmonary toxicity is uncommon. Advanced age, high drug maintenance dose, and reduced predrug diffusion capacity are risk factors for developing pulmonary toxicity. An unchanged DL_{CO}may be a negative predictor of pulmonary toxicity.

Although asymptomatic elevations of liver enzymes are

TABLE 23-9 -- CLINICAL TRIALS EVALUATING USE OF AMIODARONE TO PREVENT DEATH

STUDY (NO. OF SUBJECTS)	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
CASCADE (228)	Resuscitated cardiac arrest	Cardiac death	Empirical amiodarone	39% reduction in cardiac death at 2 years, 22% reduction at 6 years
		Resuscitated cardiac arrest	EP- or Holter-guided drug therapy	
		ICD shock after syncope		
GESICA (516)	Heart failure (Classes II-IV)	Sudden death	Amiodarone	27% reduction in sudden death

	Enlarged heart (CXR) or EF<0.35	Total mortality	Standard therapy	28% reduction in total mortality
CHF-STAT (674)	Heart failure (Classes II-IV)	Total mortality	Amiodarone	No difference in total mortality
	EF<0.40		Placebo	
	> 10 VPC/hr			
EMIAT (1486)	Recent MI	Sudden death	Amiodarone	50% reduction in sudden death
	EF<0.40	Total mortality	Placebo	No difference in total mortality
CAMIAT (1202)	Recent MI	Sudden death/resuscitated cardiac arrest	Amiodarone	48% reduction in sudden death
	> 10 VPC/hr or NSVT		Placebo	
AVID (1016)	Cardiac arrest/severely symptomatic sustained VT	Total mortality	Empirical amiodarone or EP/Holter-guided sotalol	
	No acutely reversible cause		ICD	
	EF<0.40			

ICD=implantable cardioverter-defibrillator; EP=electrophysiology; CXR=chest X-ray; EF=ejection fraction; VPC=ventricular premature complex; MI=myocardial infarction; NSVT=nonsustained ventricular tachycardia.

found in most patients, the drug is not stopped unless values exceed two or three times normal in a patient with initially abnormal values. Cirrhosis occurs uncommonly but may be fatal. Neurological dysfunction, photosensitivity (perhaps minimized by sunscreens), bluish skin discoloration, gastroenterological disturbances, and hyperthyroidism[381] [382] (1 to 2 percent) or hypothyroidism (2 to 4 percent) can occur. Amiodarone appears to inhibit the peripheral conversion of T_4 to T_3 so that chemical changes result, which are characterized by a slight increase in T_4 , reverse T_3 and thyroid-stimulating hormone (TSH), and a slight decrease in T_3 . Reverse T_3 concentration has been used as an index of drug efficacy. During hypothyroidism, TSH increases greatly, whereas T_3 increases in hyperthyroidism. Corneal microdeposits occur in almost 100 percent of adults receiving the drug more than 6 months; more serious ocular reactions, including optic neuritis and/or atrophy with visual loss, have been reported[383] but are rare.

Cardiac side effects include symptomatic bradycardias in about 2 percent; aggravation of ventricular tachyarrhythmias (with occasional development of torsades de pointes) in 1 to 2 percent,[384] possibly higher in women[210] ; and worsening of congestive heart failure in 2 percent. Possibly due to interactions with anesthetics, complications after open-heart surgery, including pulmonary dysfunction, hypotension, hepatic dysfunction, and low cardiac output, have been noted by some,[385] but not all,[386] investigators.

In general, the lowest possible maintenance dose of amiodarone that is still effective should be used to avoid significant adverse effects. Many supraventricular arrhythmias can be successfully managed with dally doses of 200 mg or less,[386A] whereas ventricular arrhythmias generally require higher doses. Adverse effects are uncommon at doses of 200 mg/d or less but still occur.[387] Because of potential toxicity in a variety of organ systems, special multidisciplinary amiodarone clinics have been used by some to attempt to prevent adverse outcomes when using the drug.[388]

Important interactions with other drugs occur, and when given concomitantly with amiodarone, the doses of warfarin, digoxin, and other antiarrhythmic drugs should be reduced by one third to one half and the patient watched closely. Drugs with synergistic actions, such as beta blockers or calcium channel blockers, must be given cautiously. Amiodarone's safety during pregnancy has not been established, and it should be used in the pregnant patient only if no alternatives exist.

Bretylium Tosylate

Bretylium is a quaternary ammonium compound that is approved by the FDA for parenteral use only in patients with life-threatening ventricular tachyarrhythmias.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Bretylium is selectively concentrated in sympathetic ganglia and their postganglionic adrenergic nerve terminals. After initially *causing* norepinephrine release, bretylium *prevents* norepinephrine release by depressing sympathetic nerve terminal excitability without depressing preganglionic or postganglionic sympathetic nerve conduction, impairing conduction across sympathetic ganglia, depleting the adrenergic neuron of norepinephrine, or decreasing the responsiveness of adrenergic receptors. It produces a state resembling chemical sympathectomy. During chronic bretylium treatment, the beta-adrenergic responses to circulating catecholamines are increased. The initial release of catecholamines results in several transient electrophysiological responses, such as an increase in the discharge rates of the isolated, perfused sinus node and of in vitro Purkinje fibers, often making quiescent fibers automatic.

Bretylium initially increases conduction velocity and excitability and decreases refractoriness in the rabbit atrium, and partially depolarized fibers may hyperpolarize. Pretreatment with reserpine or propranolol prevents these early changes. Initial catecholamine release can aggravate some arrhythmias, such as those caused by digitalis excess or myocardial infarction. Prolonged drug administration lengthens the duration of the action potential and refractoriness of atrial and ventricular muscle and Purkinje fibers, possibly by blocking one or more repolarizing potassium currents. The ratio of ERP to APD does not change, nor do membrane responsiveness and conduction velocity. Bretylium exerts little effect on diastolic excitability but increases VF thresholds in some studies[389] [390] but not others.[391] It is not clear whether the chemical sympathectomy-like state alone or together with other actions exerts the antifibrillatory effect. Reduced disparity between APD and ERP in regions of normal and infarcted myocardium may account for some of its antifibrillatory effects. Bretylium has no effect on vagal reflexes and does not alter the responsiveness of cholinergic receptors in the heart.

HEMODYNAMIC EFFECTS.

Bretylium does not depress myocardial contractility. After an initial increase in blood pressure, the drug can cause significant hypotension by blocking the efferent limb of the baroreceptor reflex. Hypotension results most commonly when patients are sitting or standing but also can occur in the supine position in seriously ill patients. Bretylium reduces the extent of the vasoconstriction and tachycardia reflexes during standing. Orthostatic hypotension can persist for several days after the drug has been discontinued.

PHARMACOKINETICS (see Table 23-1).

Bretylium is effective orally as well as parenterally, but it is absorbed poorly and erratically from the gastrointestinal tract. Bioavailability may be less than 50 percent, and elimination is almost exclusively by renal excretion without significant metabolism or active metabolites being recognized. Elimination half-life is 5 to 10 hours but with fairly wide variability. Doses should be reduced in patients with renal insufficiency. In survivors of VT or VF, bretylium had an elimination half-life of 13.5 hours after single IV dosing, which was similar to previous results in normal subjects. Renal clearance accounted for virtually all elimination. Onset of action after IV administration occurs within several minutes, but full antiarrhythmic effects may not be seen for 30 minutes to 2 hours.

DOSAGE AND ADMINISTRATION (see Table 23-1).

Bretylium can be given intravenously in doses of 5 to 10 mg/kg of body weight diluted in 50 to 100 ml of 5 percent dextrose in water and administered over 10 to 20 minutes or more quickly in a life-threatening state. This dose can be repeated in 1 to 2 hours if the arrhythmia persists. The total daily dose probably should not exceed 30 mg/kg. A similar initial dose, but undiluted, can be given intramuscularly. The maintenance IV dose is 0.5 to 2.0 mg/min. Intramuscular injection during cardiopulmonary resuscitation from cardiac arrest and in shock states should be avoided because of unreliable absorption during reduced tissue perfusion. In this situation, bretylium should be given intravenously.

INDICATIONS.

Bretylium is used in patients who are in an intensive care setting and who have life-threatening, recurrent ventricular tachyarrhythmias that have not responded to other

antiarrhythmic drugs. Bretylium has been effective in treating some patients with drug-resistant tachyarrhythmias and in treating victims of out-of-hospital VF.

ADVERSE EFFECTS.

Hypotension, most prominently orthostatic but also supine, appears to be the most significant side effect and can be prevented with tricyclic drugs such as protriptyline. Transient hypertension, increased sinus rate, and worsening of arrhythmias, often those due to digitalis excess or ischemia, may follow initial drug administration and may be due to initial release of catecholamines. Bretylium should be used cautiously or not at all in patients who have a relatively fixed cardiac output, such as those with severe aortic stenosis. Vasodilators or diuretics can enhance these hypotensive effects. Nausea and vomiting can occur after parenteral administration. Parotid pain primarily during meals commonly occurs after 2 to 4 months of oral therapy and is associated with increased salivation without parotid swelling or inflammation.

Sotalol

Sotalol is a nonspecific beta-adrenoceptor blocker without intrinsic sympathomimetic activity that prolongs repolarization. It was approved in 1992 by the FDA to treat patients with life-threatening ventricular tachyarrhythmias.[350] [392] [392A]

ELECTROPHYSIOLOGICAL ACTIONS (Tables 23-4 , 23-6 , and 23-7).

Both *d*- and *l*-isomers have similar effects on prolonging repolarization, whereas the *l*-isomer is responsible for virtually all the beta-blocking activity. Sotalol does not block alpha adrenoceptors and does not block the sodium channel (no membrane-stabilizing effects) but does prolong atrial and ventricular repolarization times[393] by reducing I_{Kr} , thus prolonging the plateau of the action potential. Action potential prolongation is greater at slower rates (reverse use-dependence). Resting membrane potential, action potential amplitude, and
max are not significantly altered. Sotalol prolongs atrial and ventricular refractoriness, AH and QT intervals, and sinus cycle length. It narrows the excitable gap in reentrant VT.[394]

HEMODYNAMICS.

Sotalol exerts a negative inotropic effect only through its beta-blocking action. It can increase the strength of contraction by prolonging repolarization, which will occur maximally at slow heart rates. In patients with reduced cardiac function, sotalol can cause a decrease in cardiac index, an increase in filling pressure, and overt heart failure. Therefore, it must be used cautiously in patients with marginal cardiac compensation but appears to be well tolerated in patients with normal cardiac function.[395] [396] [397] .

PHARMACOKINETICS (see Table 23-1).

Sotalol is completely absorbed and not metabolized, making it 90 to 100 percent bioavailable. It is not bound to plasma proteins, is excreted unchanged primarily by the kidneys, and has an elimination half-life of 10 to 15 hours. Peak plasma concentrations occur 2.5 to 4.0 hours after oral ingestion, with steady state attained after five or six doses. Effective antiarrhythmic plasma concentration is in the range of 2.5 mg/ml. There is very little intersubject variability in plasma levels. Over the dose range of 160 to 640 mg, sotalol displays dose proportionality with plasma concentration. The dose must be reduced in patients with renal disease. The beta-blocking effect is half maximal at 80 mg/d and maximal at 320 mg/d. Significant beta-blocking action occurs at 160 mg/d.

DOSAGE (see Table 23-1).

The typical oral dose is 80 to 160 mg every 12 hours, allowing 2 to 3 days between dose adjustments to attain steady state and monitor the ECG for arrhythmias and QT prolongation. Doses exceeding 320 mg/d can be used in patients when the potential benefits outweigh the risk of proarrhythmia.

INDICATIONS.

Approved by the FDA only to treat patients with ventricular tachyarrhythmias,[398] [399] [400] sotalol is also useful to prevent recurrence of a wide variety of SVTs, including atrial flutter and fibrillation,[266] [401] atrial tachycardia, AV node reentry, and AV reentry. It also shows the ventricular response to atrial tachyarrhythmias.[402] It appears to be more effective than conventional antiarrhythmic drugs and comparable with amiodarone in treating patients with ventricular tachyarrhythmias.[11] Sotalol has been shown to be superior to lidocaine for acute termination of sustained VT[403] and is useful in patients with arrhythmogenic right ventricular dysplasia.[404] It can prolong the duration of late potentials.[405] Sotalol may be effective in pediatric patients.[406] It may decrease the frequency of ICD discharges[407] and reduce the defibrillation threshold.[359]

ADVERSE EFFECTS.

Proarrhythmia is the most serious adverse effect. Overall, new or worsened ventricular tachyarrhythmias occur in about 4 percent, and this response is due to torsades de pointes in about 2.5 percent. The incidence of torsades de pointes increases to 4 percent in patients with a history of sustained VT and is dose related, reportedly only 1.6 percent at 320 mg/d but 4.4 percent at 480 mg/d.[408] This proarrhythmic effect is probably the cause of excess mortality in patients given *d*-sotalol (the enantiomer lacking a beta-blocking effect) after an acute myocardial infarction in the Survival With Oral *d*-Sotalol (SWORD) trial.[409] Other adverse effects commonly seen with other beta blockers also apply to sotalol. Sotalol should be used with caution or not at all in combination with other drugs that prolong the QT interval. However, such combinations have been used successfully.[410]

Ibutilide

Ibutilide is a relatively new agent released for use in acutely terminating episodes of atrial flutter and fibrillation.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Like other Class III agents, ibutilide prolongs repolarization. Although it is like other Class III agents that block outward potassium currents such as I_{Kr} , ibutilide is unique in that it also appears to activate a slow inward sodium current (see Chap. 22).[411] Administered intravenously, ibutilide causes mild slowing of the sinus rate and has minimal effects on AV conduction or QRS duration, but the QT interval is characteristically prolonged. Ibutilide has no significant effect on hemodynamics.

PHARMACOKINETICS (see Table 23-1).

Ibutilide is administered intravenously and has a large volume of distribution. Clearance is predominantly renal, with a drug half-life averaging 6 hours (but with considerable interpatient variability). Protein binding is approximately 40 percent. One of the drug's metabolites has weak Class III effects.

DOSAGE AND ADMINISTRATION (see Table 23-1).

Ibutilide is given as an IV rapid infusion of 1 mg over 10 minutes. It should not be given in the presence of a QTc interval greater than 440 milliseconds or other drugs that prolong the QT interval or of uncorrected hypokalemia or bradycardia. A second 1-mg dose may be given if the arrhythmia persists. Patients must be on continuous ECG monitoring throughout the dosing period and for 6 to 8 hours thereafter because of the risk of ventricular arrhythmias (see later). Up to 60 percent of patients with atrial fibrillation and 70 percent of those with atrial flutter will convert to sinus rhythm after 2 mg of ibutilide.[412]

INDICATIONS.

Ibutilide is indicated for termination of an established episode of atrial flutter or fibrillation. It should not be used in patients with frequent, short paroxysms of atrial fibrillation because it merely terminates episodes and is not useful for prevention. Patients whose condition is hemodynamically unstable should proceed to direct-current cardioversion (see later). Ibutilide has been administered at the time of transthoracic electrical cardioversion to increase the likelihood of termination of

atrial fibrillation. Oral and associates found that all 50 patients given ibutilide before attempted electrical cardioversion achieved sinus rhythm, whereas only 34 of 50 who did not receive the drug converted to sinus rhythm.[413] Of note, all 14 patients who failed electrical cardioversion without ibutilide were successfully electrically cardioverted to sinus rhythm when a second attempt was made after ibutilide pretreatment.

ADVERSE EFFECTS.

The most significant adverse effect of ibutilide is torsades de pointes, which occurs in approximately 2 percent of patients given the drug. This occurs within the first 4 to 6 hours of dosing, after which the risk is negligible. Thus, patients in whom the drug is used must undergo ECG monitoring for up to 8 hours after dosing. This can make ibutilide's use in emergency departments or private offices problematic. Ibutilide's safety during pregnancy is not well studied. Its use should be restricted to cases in which no safer alternative exists.

Dofetilide

Dofetilide is a relatively new agent (approved by the FDA in early 2000) for acute conversion of atrial fibrillation into sinus rhythm as well as chronic suppression of recurrent atrial fibrillation.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

The sole electrophysiological effect of dofetilide appears to be block of the rapid component of the delayed rectifier potassium current (I_{Kr}), which is important in repolarization (see Chap. 22). This effect is more prominent in the atria than in the ventricles (30 percent increase in atrial refractory periods vs. 20 percent in the ventricles).[414] Dofetilide's effect on I_{Kr} prolongs refractoriness without slowing conduction, which is believed to be largely responsible for its antiarrhythmic effect. It is also responsible for the prolongation of the QT interval on the ECG, which averages 11 percent but can be much greater. This effect on the QT interval is dose dependent and linear. No other important ECG changes are observed with the

drug. It has no significant hemodynamic effects.[415] Dofetilide has been shown to be more effective than quinidine at converting atrial fibrillation to sinus rhythm.[416]

PHARMACOKINETICS (see Table 23-1).

Orally administered dofetilide is absorbed well, with over 90 percent bioavailability. Fifty to 60 percent of the drug is excreted unchanged in urine, with a mean elimination half-life of 7 to 13 hours. [417] [418] The remainder of the drug undergoes hepatic metabolism to inert compounds. There have been no significant drug interactions yet reported. Dofetilide appears to exert no adverse effect on hemodynamics.

DOSAGE AND ADMINISTRATION (see Table 23-1).

At the time of this writing, dofetilide is available only as an oral preparation. Dosing is from 0.01 to 0.5 mg twice daily.

INDICATIONS.

Intravenous dofetilide has been used for termination of an established episode of atrial flutter, fibrillations, or other types of SVT.[419] [420] Oral dofetilide is indicated for prevention of episodes of supraventricular tachyarrhythmias, particularly atrial flutter and fibrillation.[420A] Dofetilide's role in therapy for ventricular arrhythmias is less clear. Dofetilide has been shown to have a neutral effect on mortality when given to patients after myocardial infarction.[421]

ADVERSE EFFECTS.

The most significant adverse effect of dofetilide is QT interval prolongation with torsades de pointes, occurring in 2 to 4 percent of patients given the drug.[420] Risk is highest in patients with a baseline prolonged QT interval, those who are hypokalemic, those taking some other agent that prolongs repolarization, and after conversion from atrial fibrillation to sinus rhythm.[422]

Azimilide

Azimilide is a new agent (not yet approved by the FDA at the time of this writing) for use in the treatment of atrial flutter and fibrillation.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Unlike dofetilide, which blocks the rapid component of the delayed rectifier potassium current, azimilide produces a more balanced blockade of both rapid and slow components of I_K (see Chap. 22).[423] [424] It is presumed that this effect is responsible for the lower rate of proarrhythmia as well as better preservation of drug efficacy at higher heart rates with this agent compared with purer I_{Kr} blockers. Azimilide produces a mild prolongation of the QT interval but no other meaningful ECG changes. Unlike dofetilide and sotalol, which have greater effects on atrial than ventricular refractoriness, azimilide exerts a similar effect on each.

PHARMACOKINETICS (see Table 23-1).

Azimilide's pharmacokinetic profile is relatively simple and predictable.[425] It can be taken orally once a day, and its absorption is nearly complete and unaffected by food intake. Few drug interactions have been reported. Azimilide is cleared by the kidney; some metabolism of the drug to inactive compounds occurs.[426] The drug has no significant adverse hemodynamic effects.

DOSAGE AND ADMINISTRATION (see Table 23-1).

Azimilide can be taken by mouth once a day at a dose of 100 to 200 mg. The drug is well tolerated, and dosing need not be adjusted in the presence of renal or hepatic disease.

INDICATIONS.

Azimilide is indicated for IV administration to terminate an established episode of atrial flutter or fibrillation, as well as orally for long-term prevention of these arrhythmias. Studies are under way to evaluate its efficacy in ventricular arrhythmias.[427]

ADVERSE EFFECTS.

The drug is generally well tolerated. As with other Class III agents, the most significant adverse effect of azimilide is torsades de pointes, although this arrhythmia appears to be less common with this agent than with other Class III medications (occurring in approximately 1 percent of patients given the drug).

CLASS IV ANTIARRHYTHMIC AGENTS

Calcium Channel Antagonists: Verapamil and Diltiazem

Verapamil, a synthetic papaverine derivative, is the prototype of a class of drugs that block the slow calcium channel and reduce $I_{Ca\text{-}L}$ in cardiac muscle. *Diltiazem* has electrophysiological actions similar to those of verapamil.[163] *Nifedipine* (see Chap. 37) exhibits minimal electrophysiological effects at clinically used doses and will not be discussed here. *Felodipine* blocks the T-type calcium current (see Chap. 22), and its clinical application has not been established. Neither of these drugs is

discussed here.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

By blocking $I_{Ca\text{-}L}$ in all cardiac fibers, verapamil reduces the plateau height of the action potential, slightly shortens muscle action potential, and slightly prolongs total Purkinje fiber action potential. It does not appreciably affect the action potential amplitude, max of phase 0, or resting membrane voltage in cells that have fast-response characteristics due to I_{Na} (atrial and ventricular muscle, the His-Purkinje system). Verapamil suppresses slow responses elicited by a variety of experimental methods as well as triggered sustained rhythmic activity and early and late afterdepolarizations (see Chap. 22). Verapamil and diltiazem suppress electrical activity in the normal sinus and AV nodes in concentrations that do not suppress action potentials of fast-channel-dependent cells. Verapamil depresses the slope of diastolic depolarization in sinus node cells, max of phase 0, maximum diastolic potential, and action potential amplitude in the sinus and AV node cells and prolongs conduction time and the effective and functional refractory periods of the AV node. The AV node blocking effects of verapamil and diltiazem[428] are more apparent at faster rates of stimulation (use-dependence) and in depolarized fibers (voltage-dependence). Verapamil slows the activation and delays recovery from inactivation of the slow channel. Unbinding of the drug from its receptor occurs more rapidly in tissue that is hyperpolarized.

Verapamil does exert some local anesthetic activity because the dextrorotatory stereoisomer of the clinically used racemic mixture exerts slight blocking effects on I_{Na} . The levorotatory stereoisomer blocks the slow inward current carried by calcium, as well as other ions, traveling through the slow channel. Verapamil does not modify calcium uptake, binding, or exchange by cardiac microsomes, nor does it affect calcium-activated adenosine triphosphatase. Verapamil does not block beta receptors and may block alpha receptors and potentiate vagal effects on the AV node. Verapamil also may cause other effects that indirectly alter cardiac electrophysiology, such as decreasing platelet adhesiveness or reducing the extent of myocardial ischemia.

In vivo, both in experimental animals and in humans, verapamil prolongs conduction time through the AV node (the AH interval) without affecting the P wave onset to atrial (PA), HV, or QRS interval and lengthens the anterograde and retrograde functional refractory periods and ERPs of the AV node. Spontaneous sinus rate may decrease slightly, an event only partially reversed by atropine. More commonly, the sinus rate does not change significantly in vivo because verapamil causes peripheral vasodilation, transient hypotension, and reflex sympathetic stimulation that mitigates any direct slowing effect verapamil may exert on the sinus node. If verapamil is given to a patient who is also receiving a beta blocker, the sinus node discharge rate

may slow because reflex sympathetic stimulation is blocked. Verapamil does not exert a significant direct effect on atrial or ventricular refractoriness or on anterograde or retrograde properties of accessory pathways. However, reflex sympathetic stimulation may increase the ventricular response over the accessory pathway during atrial fibrillation in patients with the Wolff-Parkinson-White syndrome.

HEMODYNAMIC EFFECTS.

Because verapamil interferes with excitation-contraction coupling, it inhibits vascular smooth muscle contraction and causes marked vasodilation in coronary and other peripheral vascular beds. Propranolol does not block the vasodilation produced by verapamil. Reflex sympathetic effects may reduce in vivo the marked negative inotropic action of verapamil on isolated cardiac muscle, but the direct myocardial depressant effects of verapamil may predominate when the drug is given in high doses. In patients with well-preserved left ventricular function, combined therapy with propranolol and verapamil appears to be well tolerated, but beta blockade can accentuate the hemodynamic depressant effects produced by oral verapamil. Patients who have reduced left ventricular function may not tolerate the combined blockade of beta receptors and of slow channels, and the combined use of verapamil and propranolol in these patients must be undertaken cautiously or not at all. Verapamil decreases myocardial oxygen demand while decreasing coronary vascular resistance and reduces the extent of ischemic damage in experimental preparations. Such changes may be antiarrhythmic. Diltiazem also reduces ventricular arrhythmias during coronary occlusion in the dog, possibly by preventing calcium overload.

Peak alterations in hemodynamic variables occur 3 to 5 minutes after completion of the verapamil injection, the major effects being dissipated within 10 minutes. Mean arterial pressure decreases and left ventricular end-diastolic pressure increases; systemic resistance decreases and left ventricular dP/dt max decreases. Heart rate, cardiac index, left ventricular minute work, and mean pulmonary artery pressure do not change significantly. Thus, afterload reduction produced by verapamil significantly minimizes its negative inotropic action so that the cardiac index may not be reduced. In addition, when verapamil slows the ventricular rate in a patient with a tachycardia, cardiac slowing also may improve hemodynamics. Nevertheless, caution should be exercised when giving verapamil to patients with severe myocardial depression or those receiving beta blockers or disopyramide because hemodynamic deterioration may progress in some patients.

PHARMACOKINETICS (see Table 23-1).

After single oral doses of verapamil, measurable prolongation of AV node conduction time occurs in 30 minutes and lasts 4 to 6 hours. After IV administration, AV node conduction delay occurs within 1 to 2 minutes and AH interval prolongation is still detectable after 6 hours. Effective plasma concentrations necessary to terminate SVT are in the range of 125 ng/ml after doses of 0.075 to 0.150 mg/kg. After oral administration, absorption is almost complete, but an overall bioavailability of 20 to 35 percent suggests substantial first-pass metabolism in the liver, particularly of the *l* isomer. The elimination half-life of verapamil is 3 to 7 hours, with up to 70 percent of the drug excreted by the kidneys. Norverapamil is a major metabolite that may contribute to verapamil's electrophysiological actions. Serum protein binding is approximately 90 percent. With diltiazem, the percentage of heart rate reduction in atrial fibrillation relates to plasma concentration.[429]

DOSAGE AND ADMINISTRATION (see Table 23-1).

The most commonly used IV dose of verapamil is 10 mg infused over 1 to 2 minutes while cardiac rhythm and blood pressure are monitored. A second injection of equal dose may be given 30 minutes later. The initial effect achieved with the first bolus injection, such as slowing of the ventricular response during atrial fibrillation, may be maintained by a continuous infusion of the drug at a rate of 0.005 mg/kg/min. The oral dose is 240 to 480 mg/d in divided doses. Diltiazem is given intravenously at a dose of 0.25 mg/kg as a bolus over 2 minutes, with a second dose in 15 minutes if necessary. Orally, doses must be adjusted to the patient's needs, with a 120- to 360-mg range. Various long-acting preparations exist for verapamil and diltiazem.

INDICATIONS.

After simple vagal maneuvers have been tried and adenosine given, IV verapamil or diltiazem[430] is the next treatment of choice for terminating sustained sinus node reentry, AV node reentry, or orthodromic AV reciprocating tachycardia associated with the Wolff-Parkinson-White syndrome. Verapamil is as effective as adenosine for termination of these arrhythmias.[431] Verapamil should definitely be tried before attempting termination by digitalis administration, pacing, electrical direct-current cardioversion, or acute blood pressure elevation with vasopressors. Verapamil and diltiazem terminate 60 to more than 90 percent of episodes of paroxysmal SVTs within several minutes. Verapamil may be of use in some fetal SVTs as well. Although IV verapamil has been given along with IV propranolol, this combination should be used only with great caution.

Verapamil and diltiazem decrease the ventricular response over the AV node during atrial fibrillation or atrial flutter, possibly converting a small number of episodes to sinus rhythm, particularly if the atrial flutter or fibrillation is of recent onset.[288] Some patients who exhibit atrial flutter may develop atrial fibrillation after verapamil administration. Quinidine, flecainide, and esmolol appear to be more effective than verapamil in establishing and maintaining sinus rhythm in patients with atrial fibrillation. As noted earlier, in patients with atrial fibrillation associated with the Wolff-Parkinson-White syndrome, intravenous verapamil may *accelerate* the ventricular response; therefore, the intravenous route is contraindicated in this situation. Verapamil can terminate some atrial tachycardias. Even though verapamil terminates a left septal VT,[432] hemodynamic collapse can occur if intravenous verapamil is given to patients with the more common forms of VT. A general rule to avoid complications, however, is to not give intravenous verapamil to any patient with wide QRS tachycardia unless one is absolutely certain of the nature of the tachycardia and its response to verapamil.

Orally, verapamil or diltiazem can prevent the recurrence of AV node reentrant and orthodromic AV reciprocating tachycardias[430] [431] [433] associated with the WolffParkinson-White syndrome as well as help maintain a decreased ventricular response during atrial flutter or atrial fibrillation in patients without an accessory pathway.[434] [435] [436] In this regard, the effectiveness of verapamil appears to be enhanced when given concomitantly with quinidine, and that of diltiazem is enhanced when given with digoxin.[322] Verapamil generally has not been effective in treating patients who have recurrent ventricular tachyarrhythmias, although it may suppress some forms of VT such as a left septal VT,[432] [437] [438] [439] [440] [441] as noted earlier. It may be useful in about two thirds of patients with idiopathic VT that has a left bundle branch block morphology,[437] in patients with hypertrophic cardiomyopathy who have experienced cardiac arrest,[148] in patients with a short-coupled variant of torsades de pointes,[442] in patients with right ventricular dysplasia,[404] and in patients with ventricular arrhythmias due to coronary artery spasm.[443] Whereas data from animal

models suggest that verapamil may be useful in reducing or preventing ventricular arrhythmias due to acute myocardial ischemia, calcium antagonists have not been shown to reduce mortality or prevent sudden cardiac death in patients

after acute myocardial infarction, except for diltiazem in patients with non-Q-wave infarctions. Verapamil abolishes the wall motion abnormality found in patients with the long QT syndrome.[77]

ADVERSE EFFECTS.

Verapamil must be used cautiously in patients with significant hemodynamic impairment or in those receiving beta blockers, as previously noted. Hypotension, bradycardia, AV block, and asystole are more likely to occur when the drug is given to patients who are already receiving beta-blocking agents. Hemodynamic collapse has been noted in infants, and verapamil should be used cautiously in patients younger than 1 year old. Verapamil also should be used with caution in patients with sinus node abnormalities, because marked depression of sinus node function or asystole can result in some of these patients. Isoproterenol, calcium, glucagon infusion, dopamine, or atropine (which may be only partially effective) or temporary pacing may be necessary to counteract some of the adverse effects of verapamil. Isoproterenol may be more effective for treating bradyarrhythmias and calcium for treating hemodynamic dysfunction secondary to verapamil. AV node depression is common in overdoses.[444] Contraindications to the use of verapamil and diltiazem include the presence of advanced heart failure, second- or third-degree AV block without a pacemaker in place, atrial fibrillation and anterograde conduction over an accessory pathway, significant sinus node dysfunction, most VTs, cardiogenic shock, and other hypotensive states. While the drugs probably should not be used in patients with manifest heart failure, if the latter is due to one of the supraventricular tachyarrhythmias noted earlier, verapamil or diltiazem may restore sinus rhythm or significantly decrease the ventricular rate, leading to hemodynamic improvement. Finally, it is important to note that verapamil can decrease the excretion of digoxin by about 30 percent. Hepatotoxicity may occur on occasion. Verapamil crosses the placental barrier; its use in pregnancy has been associated with impaired uterine contraction, fetal bradycardia, and, possibly, fetal digital defects. It should thus be used only if no good alternatives exist.

OTHER ANTIARRHYTHMIC AGENTS

Adenosine

Adenosine is an endogenous nucleoside present throughout the body and has been approved by the FDA to treat patients with SVTs.[445]

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Adenosine interacts with A_1 receptors present on the extracellular surface of cardiac cells, activating K^+ channels ($I_{K\ Ach}$, $I_{K\ Ado}$) in a fashion similar to that produced by acetylcholine. The increase in K^+ conductance shortens atrial APD, hyperpolarizes the membrane potential, and decreases atrial contractility. Similar changes occur in the sinus and AV nodes. In contrast to these direct effects mediated through the guanine nucleotide regulatory proteins G_i and G_o , adenosine antagonizes catecholamine-stimulated adenylate cyclase to decrease cyclic adenosine monophosphate accumulation and to decrease $I_{Ca\text{-}L}$ and the pacemaker current I_f in sinus node cells (see Chap. 22).
max is reduced. Shifts in pacemaker site within the sinus node and sinus exit block may occur. Reflex-mediated sinus tachycardia can follow adenosine administration. In the N region of the AV node, conduction is depressed, along with decreases in action potential amplitude, duration, and
max. Adenosine slows the sinus rate in humans, which is followed by a reflex increase in sinus discharge. Transient prolongation of the AH interval results, often with transient first-, second-, or third-degree AV node block. Delay in AV node conduction is rate dependent.[446] His-Purkinje conduction is generally not directly affected. Adenosine does not affect conduction in normal accessory pathways. Conduction may be blocked in accessory pathways that have long conduction times or decremental conduction properties. Patients with heart transplants exhibit a supersensitive response to adenosine.[446] Adenosine may mediate the phenomenon of ischemic preconditioning.[445]

PHARMACOKINETICS (see Table 23-1).

Adenosine is removed from the extracellular space by washout, enzymatically by degradation to inosine, by phosphorylation to adenosine monophosphate, or by reuptake into cells through a nucleoside transport system. The vascular endothelium and the formed blood elements contain these elimination systems, which result in very rapid clearance of adenosine from the circulation. Elimination half-life is 1 to 6 seconds. Most of adenosine's effects are produced during its first passage through the circulation. Important drug interactions occur. Methyl xanthines are competitive antagonists, and therapeutic concentrations of theophylline totally block the exogeneous adenosine effect. Dipyridamole is a nucleoside transport blocker that blocks reuptake of adenosine, delaying its clearance from the circulation or interstitial space and potentiating its effect. Smaller adenosine doses should be used in patients receiving dipyridamole.

DOSAGE AND ADMINISTRATION (see Table 23-1).

To terminate tachycardia, a bolus of adenosine is rapidly injected intravenously into a central vein (if possible) at doses of 6 to 12 mg. Pediatric dosing should be 0.1 to 0.3 mg/kg.[447] When given into a central vein and in patients after heart transplantation or in patients receiving dipyridamole, the initial dose should be reduced to 3 mg.[448] [449] Transient sinus slowing or AV node block results.

INDICATIONS.

Adenosine has become the drug of first choice to terminate acutely an SVT such as AV node or AV reentry.[450] [451] [452] [453] [454] It is useful in pediatric patients[447] [455] and to judge the effectiveness of ablation of accessory pathways.[456] Adenosine can produce AV block or terminate atrial tachycardias[457] [458] and sinus node reentry. It results in transient AV block during atrial flutter or fibrillation. Adenosine terminates a group of VTs whose maintenance depends on adrenergic drive, which is most often located in the right ventricular outflow tract but found at other sites as well.[438] [439] [459] [460] Adenosine has less potential than verapamil for lowering the blood pressure should tachycardia persist after injection.

Doses as low as 2.5 mg terminate some tachycardias; doses of 12 mg or less terminate 92 percent of SVTs, usually within 30 seconds. Successful termination rates with adenosine are comparable with those achieved with verapamil. Because of its effectiveness and extremely short duration of action, adenosine is preferable to verapamil in most instances, particularly in patients who previously have received intravenous beta-adrenoceptor blockers, in those having poorly compensated heart failure or severe hypotension, and in neonates. Verapamil might be chosen first in patients receiving drugs such as theophylline, which is known to interfere with adenosine's actions or metabolism; in patients with active bronchoconstriction; and in those with inadequate venous access. Adenosine produces transient AV nodal block in patients with atrial flutter, atrial fibrillation, and some types of atrial tachycardia, facilitating the diagnosis by exposing the atrial rhythm.

Adenosine may be useful to help differentiate among causes of wide QRS tachycardias[460] because it terminates many SVTs with aberrancy or reveals the underlying atrial mechanism, and it does not block conduction over an accessory pathway or terminate most VTs. Adenosine does in

rare cases terminate some VTs (characteristically those of right ventricular outflow tract origin), and therefore tachycardia termination is not completely diagnostic for an SVT.[461] This agent may predispose to the development of atrial fibrillation and possibly can increase the ventricular response in patients with atrial fibrillation conducting over an accessory pathway. Adenosine also may be useful in differentiating conduction over the AV node versus an accessory pathway during ablative procedures designed to interrupt the accessory pathway. However, this distinction is not absolute because adenosine can block conduction in slowly conducting accessory pathways and does not always effect block in the AV node.[462] Endogenously released adenosine may be important in ischemia and hypoxia-induced AV node block and in postdefibrillation bradyarrhythmias.

ADVERSE EFFECTS.

Transient side effects occur in almost 40 percent of patients with SVT given adenosine and are most commonly flushing, dyspnea, and chest pressure. These symptoms are fleeting, lasting less than 1 minute, and are well tolerated. PVCs, transient sinus bradycardia, sinus arrest, and AV block are common when an SVT

abruptly terminates. Atrial fibrillation is occasionally observed (12 percent in one study) with adenosine administration,[463] perhaps owing to the drug's effect in shortening atrial refractoriness.[464] Induction of atrial fibrillation can be problematic in patients with the Wolff-Parkinson-White syndrome or rapid AV conduction.[465] [466]

Digoxin

Cardiac actions of digitalis glycosides have been recognized for centuries. Digoxin is used for control of supraventricular arrhythmias, mainly control of ventricular rate during atrial fibrillation. The use of digoxin has decreased in recent years owing to the availability of agents with greater potency and a wider therapeutic-to-toxic drug concentration range.

ELECTROPHYSIOLOGICAL ACTIONS (see Tables 23-4 , 23-6 , and 23-7).

Digoxin acts mainly through the autonomic nervous system, in particular by enhancing both central and peripheral vagal tone. These actions are largely confined to slowing the sinus node discharge rate, shortening atrial refractoriness, and prolonging AV node refractoriness.[445] Electrophysiological effects on the His-Purkinje system and ventricular muscle are minimal except in toxic concentrations. In studies on denervated hearts, digoxin has relatively little effect on the AV node and causes a mild increase in atrial refractoriness. Digoxin has a mild antiadrenergic effect in low doses but may enhance central sympathetic tone at higher concentrations, which may be important in the development of digitalis-toxic arrhythmias.

The sinus rate and P wave duration are minimally changed in most patients taking digoxin. The sinus rate may decrease in patients with heart failure whose left ventricular performance is improved by the drug; individuals with significant underlying sinus node disease also have slower sinus rates or even sinus arrest. Similarly, the PR interval is generally unchanged except in patients with underlying AV node disease. QRS and QT intervals are unaffected. The characteristic ST and T wave abnormalities seen with digoxin use do not represent toxicity.

PHARMACOKINETICS (see Table 23-1).

Intravenously administered digoxin yields some electrophysiological effect within minutes, with a peak effect occurring after 1.5 to 3 hours. After oral dosing, the peak effect occurs in 4 to 6 hours. The extent of digoxin absorption after oral administration varies depending on the preparation: Tablet forms are 60 to 75 percent absorbed, whereas encapsulated gel forms are almost completely absorbed. Ingestion of cholestyramine or antacid preparation at the same time as digoxin ingestion decreases its absorption. The serum half-life of digoxin is 36 to 48 hours, and the drug is excreted unchanged by the kidneys.[445]

DOSAGE AND ADMINISTRATION (see Table 23-1).

In acute loading doses of 0.5 to 1.0 mg, digoxin may be given intravenously or by mouth. Chronic daily oral dosing should be adjusted based on clinical indications and the extent of renal dysfunction. Most patients require from 0.125 to 0.25 mg/d as a single dose; however, as little as 0.125 mg every other day is needed in some patients on renal dialysis, whereas young patients may require as much as 0.5 mg/d. Serum digoxin levels may be used to monitor compliance with therapy as well as to determine whether digitalis toxicity is the cause of new symptoms compatible with the diagnosis. However, routine monitoring of digoxin levels is not warranted in patients whose ventricular rate is controlled during atrial fibrillation and who have no symptoms of toxicity.

A large number of pharmacokinetic interactions have been described for digoxin, the most important being with quinidine (which increases serum digoxin concentrations by displacing the drug from tissue binding sites and decreasing renal clearance).

INDICATIONS.

Digoxin can be used intravenously to slow the ventricular rate during atrial fibrillation and flutter; it has been used in the past to attempt to convert SVTs to sinus rhythm, but its onset of action is much slower and its success rate less than adenosine, verapamil, or beta blockers; thus it is rarely used in this way at present. Digoxin is more commonly used orally to control the ventricular rate in chronic atrial fibrillation. When the patient with atrial fibrillation is at rest and vagal tone predominates, the ventricular rate can be maintained between 60 and 100 beats/min in 40 to 60 percent of cases. However, when the patient begins to exercise, the decrease in vagal tone and increase in adrenergic tone combine to diminish digoxin's beneficial effects on AV node conduction.[307] Patients may experience a marked increase in ventricular rate with even mild exertion. Thus, digoxin is rarely used as a single agent to control the ventricular rate in chronic atrial fibrillation. The drug has little capacity to prevent episodes of *paroxysmal* atrial fibrillation or to control ventricular rate during episodes. Finally, digoxin is no more effective than placebo at terminating episodes of acute- or recent-onset atrial fibrillation.[467]

ADVERSE EFFECTS.

One of the main reasons that digoxin use has decreased is the potential for serious adverse effects and the narrow window between therapeutic and toxic concentrations. Digitalis toxicity produces a variety of symptoms and signs, including headache, nausea and vomiting, altered color perception and halo vision, and generalized malaise. More serious than these are digitalis-related arrhythmias. These include bradycardias due to a markedly enhanced vagal effect (sinus bradycardia or arrest, AV node block) and tachyarrhythmias that may be due to delayed afterdepolarization-mediated, triggered activity (atrial, junctional, and fascicular/ventricular tachycardia; see Chap. 22). Worsening renal function, advanced age, hypokalemia, chronic lung disease, hypothyroidism, and amyloidosis increase the patient's sensitivity to digitalis-related arrhythmias. The diagnosis can be confirmed using serum digoxin levels. Therapy for most bradycardias consists of withdrawal of digoxin; atropine or temporary pacing may be needed in symptomatic patients. Phenytoin can be used for control of atrial tachyarrhythmias, whereas lidocaine has been successful in treating infranodal tachycardias. Life-threatening arrhythmias can be treated with digoxin-specific antibody fragments. Electrical direct-current cardioversion should be performed only when absolutely necessary in the digitalis-toxic patient, because life-threatening VT or VF can result that can be very difficult to control.

Electrotherapy of Cardiac Arrhythmias

Direct-Current Electrical Cardioversion

Electrical cardioversion offers obvious advantages over drug therapy in terminating tachycardia. Under conditions optimal for close supervision and monitoring, a precisely regulated "dose" of electricity can restore sinus rhythm immediately and safely. The distinction between supraventricular and ventricular tachyarrhythmias--crucial to the proper medical management of arrhythmias--becomes less significant, and the time-consuming titration of drugs with potential side effects is obviated.[468]

MECHANISMS.

Electrical cardioversion appears to most effectively terminate those tachycardias due to reentry, such as atrial flutter and atrial fibrillation, AV node reentry, reciprocating tachycardias associated with the WolffParkinson-White syndrome, most forms of VT, ventricular flutter, and VF. The electrical shock, by depolarizing all excitable myocardium and possibly by prolonging refractoriness, interrupts reentrant circuits and establishes electrical homogeneity that terminates reentry. The mechanism by which a shock successfully terminates VF has not been completely explained, although recent evidence suggests that hyperpolarization of cell membranes is an important effect.[469] If the precipitating factors are no longer present, interrupting the tachyarrhythmia for only the brief time produced by the shock may prevent its return for long periods even though the anatomical and electrophysiological substrates required for the tachycardia are still present.

Tachycardias thought to be due to disorders of impulse formation (automaticity) include parasystole, some forms of atrial tachycardia, nonparoxysmal AV junctional tachycardia, and accelerated idioventricular rhythms. An attempt to cardiovert these tachycardias electrically is not indicated in most instances, because they typically recur within seconds after the shock. It has not been established whether cardioversion can terminate tachycardias due to enhanced automaticity or triggered activity.

TECHNIQUE.

Before elective cardioversion, a careful physical examination, including palpation of all pulses, should be performed. A 12-lead ECG is obtained before and after cardioversion, as well as a rhythm strip during the electroshock. The patient, who should be informed completely about what to expect, is in a fasting state and "metabolically balanced"; that is, blood gases, pH, and electrolytes should be normal with no evidence of drug toxicity. Withholding digitalis for several days before elective cardioversion in patients without clinical evidence of digitalis toxicity is not necessary, although patients in whom digitalis toxicity is suspected should not be electrically cardioverted until this situation is corrected. Maintenance antiarrhythmic drug administration 1 to 2 days before electrical cardioversion of patients with atrial fibrillation can revert some patients to sinus rhythm, help prevent recurrence of atrial fibrillation once sinus rhythm is restored, and help determine patient tolerance to the drug.

Self-adhesive pads applied in the standard apex-anterior or apex-posterior paddle positions have transthoracic impedances similar to paddles and are very useful in elective cardioversions or other situations in which there is time for their application, such as at the start of an EPS.[470] [471] Paddles 12 to 13 cm in diameter can be used to deliver maximum current to the heart, but the benefits of these paddles compared with those of 8 to 9 cm in diameter have not been clearly established. Larger paddles may distribute the intracardiac current over a wider area and may reduce shock-induced myocardial necrosis.

A synchronized shock (i.e., one delivered during the QRS complex) is used for all cardioversions except for very rapid ventricular tachyarrhythmias, such as ventricular flutter or VF (Fig. 23-14) . Data suggest that for internal cardioversion, shocks delivered late in the QRS complex during VT are more effective and have a lower risk of acceleration than those delivered near QRS onset.[472] Because myocardial damage increases directly with increases in applied energy, the minimum effective energy should be used. Therefore, shocks are "titrated" when the clinical situation permits. Except for atrial fibrillation, shocks in the range of 25 to 50 joules successfully terminate most SVTs and should be tried initially. If unsuccessful, a second shock of higher energy can be delivered. The starting level to terminate atrial fibrillation should be no less than 100 joules.[472A] If this fails, up to 360 joules can be used safely. Anteroposterior pads may have a higher efficacy rate by placing more of the atrial mass in the shock vector than is the case for apical-anterior pads. If 360 joules fails to convert the rhythm, repeated shocks at the same energy

Figure 23-14 *Top,* A synchronized shock (note synchronization marks in the apex of the QRS complex [arrow]) during ventricular tachycardia is followed by a single repetitive ventricular response and then normal sinus rhythm. *Bottom,* A shock synchronized to the terminal portion of the QRS complex (arrow) in a patient with atrial fibrillation and conduction to the ventricle over an accessory pathway (Wolff-Parkinson-White syndrome) results in ventricular fibrillation that was promptly terminated by a 400-joule shock. Recording was lost for 1.5 seconds (arrow) owing to baseline drift after the shock.

may succeed by decreasing chest wall impedance; reversing pad polarity can occasionally help as well.[472B] Administration of ibutilide has been shown to facilitate electrical cardioversion of atrial fibrillation to sinus rhythm.[413] Intracardiac defibrillation can be tried if all attempts at external cardioversion fail.[473] [474] [475] For patients with stable VT, starting levels in the range of 25 to 50 joules can be employed. If there is some urgency to terminate the tachyarrhythmia, one can begin with higher energies. To terminate VF, 200 to 360 joules generally is used, although much lower energies (< 100 joules) terminate VF when the shock is delivered at the *very onset* of the arrhythmia, using adhesive pads in the electrophysiology laboratory, for example.[476] [477] [478] [479]

During elective cardioversion, a short-acting barbiturate such as methohexital, a sedative such as propofol, or an amnesic such as diazepam or midazolam can be used. A physician skilled in airway management should be in attendance, an IV route should be established, and monitoring of pulse oximetry, ECG, and blood pressure should be operating. All equipment necessary for emergency resuscitation should be immediately accessible. Before cardioversion, 100 percent oxygen may be administered for 5 to 15 minutes by nasal cannula or face mask and is continued throughout the procedure. Manual ventilation of the patient may be necessary to avoid hypoxia during periods of deepest sedation. Adequate sedation of the patient undergoing cardioversion is essential; some patients who have needlessly been shocked while awake (due to uneasiness of the physician with the arrhythmia) have declined further medical care for their arrhythmias after this experience out of concern they will again undergo cardioversion without appropriate sedation.

In 2 to 5 percent of patients with atrial fibrillation, sinus rhythm cannot be restored by external countershock, despite all the above measures including ibutilide pretreatment.[413] Very obese patients or those with severe obstructive lung disease are most frequently affected. In such cases, internal cardioversion can be performed using specially configured catheters with multiple large electrodes covering several centimeters of the distal portion of the catheter for distributing shock energy. Using standard percutaneous access, these catheters can be situated in the lateral right atrium and coronary sinus to achieve a shock vector across most of the atrial mass. With such configurations, internal shocks of from 2 to 15 joules are able to terminate atrial fibrillation in more than 90 percent of patients whose arrhythmia was refractory to transthoracic shock.

INDICATIONS.

As a rule, any tachycardia that produces hypotension, congestive heart failure, or angina and does not respond promptly to medical management should be terminated

electrically. Very rapid ventricular rates in patients with atrial fibrillation and the Wolff-Parkinson-White syndrome are often best treated by electrical cardioversion. In almost all instances, the patient's hemodynamic status improves after cardioversion. An occasional patient may develop hypotension, reduced cardiac output, or congestive heart failure after the shock. This may be related to complications of the cardioversion, such as embolic events, myocardial depression resulting from the anesthetic agent or the shock itself,[480] [481] hypoxia, lack of restoration of left atrial contraction despite return of electrical atrial systole,[482] or postshock arrhythmias. Direct-current countershock of digitalis-induced tachyarrhythmias is contraindicated.

Favorable candidates for electrical cardioversion of atrial fibrillation include those patients who (1) have symptomatic atrial fibrillation of less than 12 months' duration and derive significant hemodynamic benefits from sinus rhythm, (2) have embolic episodes, (3) continue to have atrial fibrillation after the precipitating cause has been removed (e.g., after treatment of thyrotoxicosis), and (4) have a rapid ventricular rate that is difficult to slow.[482A]

Unfavorable candidates include patients with (1) digitalis toxicity, (2) no symptoms and a well-controlled ventricular rate without therapy, (3) sinus node dysfunction and various unstable supraventricular tachyarrhythmias or bradyarrhythmias (often the bradycardia-tachycardia syndrome) who finally develop and maintain atrial fibrillation (which in essence represents a "cure" for the sick sinus syndrome), (4) little or no benefit from normal sinus rhythm who promptly revert to atrial fibrillation after cardioversion despite drug therapy, (5) a large left atrium and long-standing atrial fibrillation, (6) infrequent episodes of atrial fibrillation that revert spontaneously to sinus rhythm, (7) no mechanical atrial systole after the return of electrical atrial systole, (8) atrial fibrillation and advanced heart block, (9) cardiac surgery planned in the near future, and (10) antiarrhythmic drug intolerance. Atrial fibrillation is likely to recur after cardioversion in patients who have significant chronic obstructive lung disease, congestive heart failure, mitral valve disease (particularly mitral regurgitation), atrial fibrillation longer than 1 year, and an enlarged left atrium (>4.5 cm by echocardiography).

In patients with atrial flutter, slowing the ventricular rate by administering digitalis or terminating the flutter with an antiarrhythmic agent may be difficult, so electrical cardioversion is often the initial treatment of choice. For the patient with other types of SVT, electrical cardioversion may be employed when (1) vagal maneuvers or simple medical management (e.g., intravenous adenosine and verapamil) has failed to terminate the tachycardia and (2) the clinical setting indicates that fairly prompt restoration of sinus rhythm is desirable because of hemodynamic decompensation or electrophysiological consequences of the tachycardia. Similarly, in patients with VT, the hemodynamic and electrophysiological consequences of the arrhythmias determine the need and urgency for direct-current cardioversion. Electrical countershock is the *initial* treatment of choice for ventricular flutter or VF.[468] [483] [484] Speed is essential.

If, after the first shock, reversion of the arrhythmia to sinus rhythm does not occur, a higher energy level should be tried. When transient ventricular arrhythmias result after an unsuccessful shock, a bolus of lidocaine can be given before delivering a shock at the next energy level. If sinus rhythm returns only transiently and is promptly supplanted by the tachycardia, a repeat shock can be tried, depending on the tachyarrhythmia being treated and its consequences. Administration of an antiarrhythmic agent intravenously may be useful before delivering the next cardioversion shock (such as ibutilide in resistant atrial fibrillation). After cardioversion, the patient should be monitored at least until full consciousness has been restored and preferably for several hours thereafter.

RESULTS.

Cardioversion restores sinus rhythm in 70 to 95 percent of patients, depending on the type of tachyarrhythmia. However, sinus rhythm remains after 12 months in less than one third to one half of the patients with chronic atrial fibrillation. Thus, maintenance of sinus rhythm, once established, is the difficult problem, not the immediate termination of the tachycardia. The likelihood of maintaining sinus rhythm depends on the particular arrhythmia, the presence of underlying heart disease, and the response to antiarrhythmic drug therapy. Atrial size decreases after termination of atrial fibrillation and restoration of sinus rhythm,[485] [486] and functional capacity improves.[487] [488] [489]

COMPLICATIONS.

Arrhythmias induced by electrical cardioversion generally are caused by inadequate synchronization, with the shock occurring during the ST segment or T wave. Occasionally, a properly synchronized shock can produce VF (see Fig. 23-14). Postshock arrhythmias usually are transient and do not require therapy. Embolic episodes are reported to occur in 1 to 3 percent of the patients converted from atrial fibrillation to sinus rhythm. Prior anticoagulation

for 2 to 3 weeks should be employed for patients who have no contraindication to such therapy and have had atrial fibrillation present for longer than 2 to 3 days or is of indeterminate duration. This is particularly true for those who are at high risk for emboli, such as those with mitral stenosis and atrial fibrillation of recent onset, a history of recent or recurrent emboli, a prosthetic mitral valve, an enlarged heart (including left atrial enlargement), or congestive heart failure. Anticoagulation with warfarin for at least 4 weeks *afterward* is recommended because restoration of mechanical function lags behind that of electrical systolic function, and thrombi can still form in largely akinetic atria, although they are electrocardiographically in sinus rhythm. Importantly, exclusion of left atrial thrombus by transesophageal echocardiography may not always preclude embolism after cardioversion of atrial fibrillation.[490] [491] [492] [493] Atrial thrombi may be present in patients with nonfibrillation atrial tachyarrhythmias such as atrial flutter and congenital heart disease.[494] The same pre-cardioversion and postcardioversion anticoagulation recommendations apply to these patients as well as to those with atrial fibrillation. Although direct-current shock has been demonstrated in animals to cause myocardial injury, studies in humans indicate that elevations of myocardial enzymes after cardioversion are not common. ST segment elevation can occur immediately after elective direct-current cardioversion, although cardiac enzymes and myocardial scintigraphy may be unremarkable. A decrease in serum K^+ and Mg^{2+} can occur after cardioversion of VT.[495]

Cardioversion of VT also can be achieved by a chest thump. Its mechanism of termination probably relates to a mechanically induced PVC that interrupts a tachycardia. The thump cannot be timed very well and is probably only effective when delivered during a nonrefractory part of the cardiac cycle. The thump can alter a VT and possibly induce ventricular flutter or VF if it occurs during the vulnerable period of the T wave. Because there may be a slightly greater likelihood of converting a stable VT to VF than of terminating VT to sinus rhythm, the thump version should not be attempted unless a defibrillator is simply unavailable.

Implantable Electrical Devices for Treatment of Cardiac Arrhythmias

Implantable devices that monitor the cardiac rhythm and can deliver competing pacing stimuli and low- and high-energy shocks have been used effectively in selected patients and are discussed fully in Chapter 24 .

Ablation Therapy for Cardiac Arrhythmias

The purpose of catheter ablation is to destroy myocardial tissue by delivering electrical energy over electrodes on a catheter placed next to an area of the endocardium integrally related to the onset and/or maintenance of the arrhythmia. The first catheter ablation procedures were performed using direct-current shocks, but this energy source has been almost wholly supplanted by radio frequency (RF) energy, which is delivered from an external generator and destroys tissue by controlled heat production.[496] Lasers, cryothermy, and microwave energy sources have been used, but not commonly. Once a target tissue has been identified, the tip of the ablation catheter is maneuvered into apposition with this tissue. After stable catheter position and recordings have been assured, RF energy is delivered between the catheter tip and an indifferent electrode, usually an electrocautery-type grounding pad on the skin of the

Figure 23-15 Radio frequency lesion in human ventricular myocardium (explanted heart at the time of transplantation). A 30-second application of energy was made at the location denoted by arrows using the tip of the catheter shown. The lesion is 5 mm in diameter and has a clear border. A central depression in the lesion results from partial desiccation of tissue.

patient's thigh. Because energies in the RF portion of the electromagnetic spectrum are not conducted by cardiac tissue, RF energy instead causes resistive heating in the cells in close proximity to the catheter tip (i.e., these cells transduce the electrical energy into thermal energy). Once tissue temperature exceeds 50°C, irreversible cellular damage and tissue death occur. An expanding front of conducted heat emanates from the region of resistive heating while RF delivery continues, resulting in production of a homogenous hemispheric lesion of coagulative necrosis 3 to 5 mm in radius (Fig. 23-15) . RF-induced heating of tissue that has inherent automaticity (His bundle, foci of automatic tachycardias) results in acceleration of a rhythm, whereas RF delivery during a reentrant arrhythmia typically causes slowing and termination of the arrhythmia. In most cases, RF delivery is painless, although ablation of atrial or RV tissue can be uncomfortable for some patients.

Radio Frequency Catheter Ablation of Accessory Pathways

LOCATION OF PATHWAYS.

The safety, efficacy, and cost-effectiveness of RF catheter ablation of an accessory AV pathway[496] [497] [498] [499] [500] [501] [502] have made ablation the treatment of choice in most adult and many pediatric patients who have AV reentrant tachycardia (AVRT)[503] or atrial flutter/fibrillation associated with a rapid ventricular response over the accessory pathway.[504] [505] [506] [507] However, the fact that the lesion size, when RF energy is delivered to an immature heart, can increase as the heart grows makes the long-term outlook for ablation less certain in the very young.[508] [509] [510] [511] [512] RF energy has replaced direct-current shock as the optimal energy source.[513] [514] [515]

An EPS is performed initially to determine that the accessory pathway is part of the tachycardia circuit or capable of rapid AV conduction during atrial fibrillation and to localize the accessory pathway (the optimal site for ablation). Pathways can exist in the right or left free wall or septum of the heart (Fig. 23-16) . Septal accessory pathways are further classified as anteroseptal, midseptal, and posteroseptal.[516] [517] [518] [519] Rare parahissian pathways can be distinguished from anteroseptal pathways.[517] Midseptal locations are true septal pathways, whereas those classified as anteroseptal generally have no septal connection but are located anteriorly along the central fibrous body or the right fibrous trigone at the right anterior free wall. Pathways classified as

Figure 23-16 Locations of accessory pathways by anatomic region. Tricuspid and mitral valve annuli are depicted in a left anterior oblique view. Locations of coronary sinus, AV node, and bundle of His are shown. Accessory pathways may connect atrial to ventricular myocardium in any of the regions shown.

posteroseptal are located posterior to the central fibrous body within the so-called pyramidal space, which is bounded by the posterior superior process of the left ventricle and the inferomedial aspects of both atria. Anteroseptal pathways are found near the His bundle, and accessory pathway activation potential as well as His bundle potential can be recorded simultaneously from a catheter placed at the His bundle region. Midseptal pathways are classified as right midseptal if an accessory pathway potential is recorded through a catheter located in an area bounded anteriorly by the tip electrode of the His bundle catheter and posteriorly by the coronary sinus ostium. Pathways located in a similar region but which can be ablated only from a left-sided approach are called left midseptal pathways. Right posteroseptal pathways insert along the tricuspid ring in the immediate vicinity of the coronary sinus ostium, whereas left posteroseptal pathways are close to the terminal portion of the coronary sinus and may be located at a subepicardial site around the proximal coronary sinus, within a middle cardiac vein or coronary sinus diverticulum, or subendocardially along the ventricular aspect of the mitral annulus. Pathways at all locations and in all age groups can be ablated successfully.[520] [521] Multiple pathways are present in about 5 percent of patients.[522] [523] Occasional epicardial locations may be more easily approached from within the coronary sinus.[524] Conduction block after ablation usually occurs between the local atrial electrogram and the accessory pathway potential.[525]

ABLATION SITE.

The optimal ablation site can be found by direct recordings of the accessory pathway (Fig. 23-17) , although deflections that mimic accessory pathway potentials can be recorded at other sites. The ventricular insertion site can be determined by finding the site of the earliest onset of the ventricular electrogram in relation to the onset of the delta wave. Other helpful guidelines are unfiltered unipolar recordings that register a QS wave and the

Figure 23-17 Wolff-Parkinson-White syndrome. *A,* Two beats of atrial pacing are conducted over the accessory pathway (dark arrow in Abl_{bi} recording, from the site of the accessory pathway) resulting in a delta wave on the ECG; a premature atrial stimulus (center) encounters accessory pathway refractoriness (white arrow) instead conducting over the AV node and bundle of His, resulting in a narrow QRS complex and starting an episode of AVRT. After each narrow QRS complex is an atrial deflection, the earliest of which is recorded at the ablation site (gray arrow). *B,* Ablation of this pathway is accomplished by delivery of radio frequency (RF) energy from the ablation catheter tip. Dark arrow denotes onset of RF energy delivery; two QRS complexes later, the delta wave is abruptly lost (gray arrow) owing to elimination of conduction over the accessory pathway. T wave inversion in lead 3 is due to "memory" (see Chap. 22).

shortest AV conduction time during maximal preexcitation. A major ventricular potential synchronous with the onset of the delta wave can be a target site in left-sided preexcitation, whereas earlier ventricular excitation in relation to the delta wave is to be found for right-sided preexcitation. The atrial insertion site of manifest or concealed pathways (i.e., delta wave present or absent, respectively) can be found by locating the site showing the shortest ventriculoatrial interval during retrograde conduction over the pathway. Reproducible mechanical inhibition of accessory pathway conduction during catheter manipulation[526] and subthreshold stimulation [527] also have been used to determine the optimal site. Accidental catheter trauma should be avoided, however, because this can "hide" the target for prolonged periods.[528] Intracardiac echocardiography can be helpful at times in delineating unusual anatomy, guiding transseptal puncture, and determining adequacy of catheter contact at ablation sites.[529] [530]

Accessory pathways often cross the left AV groove obliquely, with the atrial insertion site located closer to the ostium of the coronary sinus.[531] Consequently, the earliest site of retrograde atrial activation and the earliest site of anterograde ventricular activation are not directly across the AV groove from each other. Ablation from the atrial aspect is from a site more proximal along the coronary sinus than is the ablation site from a ventricular approach. Identification of the earliest site of atrial activation is usually performed during orthodromic AVRT or during relatively rapid ventricular pacing, such that retrograde conduction using the AV node does not confuse assessment of location of the earliest atrial activation.

Successful ablation sites should exhibit stable fluoroscopic and electrical characteristics. During orthodromic AVRT, the interval between the onset of ventricular activation in any lead and local atrial activation is usually 70 to 90 milliseconds at the successful ablation site (see Fig. 23-17). When thermocouple- or thermistor-tipped ablation catheters are used, a stable rise in catheter tip temperature is a helpful indicator of catheter stability and adequate contact between the catheter and tissue. In such an instance, the tip temperature generally exceeds 50°C.[532] The retrograde transaortic and transseptal approaches have been used with equal success to ablate accessory pathways located on the left side of the heart.[533] [534] Routine EPS performed weeks after the ablation procedure is generally not indicated but should be considered in patients who have recurrent delta wave or symptoms of tachycardia.[535] [536]

Patients with atriofascicular accessory pathways have connections consisting of a proximal portion responsible for conduction delay and decremental conduction properties and a long distal segment located along the endocardial surface of the right ventricular free wall that has electrophysiological properties similar to the right bundle branch. The distal end of the right atriofascicular accessory pathway can insert into the apical region of the right ventricular free wall close to the distal right bundle branch or can actually fuse with the latter.[537] Right atriofascicular accessory pathways actually may represent a duplication of the AV conduction system and can be localized for ablation by recording potentials from the rapidly conducting distal component crossing the tricuspid annulus (analogous to the His bundle) and extending to the apical region of the right

Figure 23-18 AV node reentry. *A,* Two atrial paced complexes from the coronary sinus (CS) are followed by an atrial premature stimulus at coupling interval 260 msec, resulting in an AH interval of 145 msec. *B,* The same atrial drive train is followed by an atrial extrastimulus 10 msec earlier than before (250 msec). This results in a marked increase in the AH interval to 210 msec, after which AVNRT ensues, because the extrastimulus encounters block in a "fast" AV node pathway, conducts down a "slow" pathway, and then conducts back up the "fast" pathway in a repeating fashion. Dark arrows denote atrial electrograms coincident with QRS complexes, characteristic of the most common type of AV node reentry.

ventricular free wall.[538] Ablation attempts should be performed more proximally to avoid inadvertently ablating the distal right bundle branch, which could actually be proarrhythmic and create incessant tachycardia by lengthening the reentrant circuit.[452] [539] [540]

INDICATIONS.

Ablation of accessory pathways is indicated in patients with symptomatic AVRT that is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy. It is also indicated in patients with atrial fibrillation (or other atrial tachyarrhythmias) and a rapid ventricular response by means of an accessory pathway when the tachycardia is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy. Other candidates might include patients with AVRT or atrial fibrillation with rapid ventricular rates identified during EPS of another arrhythmia; asymptomatic patients with ventricular preexcitation whose livelihood, profession, important activities, insurability, mental well-being, or the public safety would be affected by spontaneous tachyarrhythmias or by the presence of the ECG

abnormality; patients with atrial fibrillation and a controlled ventricular response by means of the accessory pathway; and patients with a family history of sudden cardiac death.[119] Not all patients with accessory pathways need treatment; however, ablation has such a high success rate and low complication rate that in many centers patients who need any form of therapy are referred for catheter ablation.

RESULTS.

From the results of a survey conducted by the North American Society of Pacing and Electrophysiology (NASPE),[155] successful ablation of left free wall accessory pathways was obtained in 2312 of 2527 (91 percent) patients; for septal accessory pathways, 1115 of 1279 (87 percent); and for right free wall accessory pathways, 585 of 715 (82 percent). Significant complications were reported in 94 of 4521 patients (2.1 percent), and there were 13 procedure-related deaths in 4521 patient studies (0.2 percent). In Europe, the complication rate was 4.4 percent, with three deaths in 2222 patients.[154] A large study of patients using a temperature-controlled ablation system had similar success rates (overall success, 398/465 [93 percent] with an 8 percent recurrence rate).[541]

Radio Frequency Catheter Modification of the AV Node for AVNRTs

Atrioventricular node reentry is a very common cause of SVT episodes. Although controversy still exists as to the exact nature of the tachycardia circuit, abundant evidence indicates that two pathways in the region of the AV node participate, one with relatively fast conduction but long refractoriness and the other with shorter refractoriness but slower conduction. PACs can encounter refractoriness in the fast pathway, conduct down the slow pathway, and reenter the fast pathway retrogradely, initiating AV node reentrant SVT (Fig. 23-18) . Although this is the most common presentation of AV node reentry, some patients have what appears to be propagation in the opposite direction in this circuit (anterograde fast, retrograde slow) as well as a "slow-slow" variant. Two or more of these variants can exist in the same patient (Fig. 23-19) .

FAST-PATHWAY ABLATION.

Ablation can be performed to eliminate conduction in the fast pathway or the slow pathway.[542] [543] [544] [545] [546] [547] [548] [549] [550] [551] [552] [553] [554] [555] For fast-pathway ablation, the electrode tip is positioned along the AV node-His bundle axis in the anterosuperior portion of the tricuspid annulus. The catheter is gradually withdrawn until the atrial electrogram amplitude equals or exceeds that of the ventricular electrogram and the His bundle recording is either absent or extremely small (0.05 mV). During energy delivery, the ECG is monitored for PR prolongation and/or the occurrence of AV block. If accelerated junctional rhythm is noted during delivery of RF energy, the atrium can be paced at a faster rate to ensure integrity of AV conduction. The initial RF pulse is

Figure 23-19 Three variants of AV node reentrant supraventricular tachycardia (SVT) in the same patient. Recordings as in other figures; CL = cycle length. The left panel shows the most common type of AV node SVT (anterograde slow pathway, retrograde fast); atrial activation is coincident with ventricular activation. The center panel shows "atypical" AV node reentry, with anterograde fast pathway conduction and retrograde conduction over a slow pathway. A rare variety is shown in the right panel, with anterograde conduction over a slow pathway and retrograde conduction over a second slow pathway. Note the similar atrial activation sequences in the latter two (coronary sinus before right atrium), as distinct from that of "slow-fast" AV node reentry (coronary sinus and right atrial activation nearly simultaneous). Note also the different P-QRS relationships, from simultaneous activation (left panel, short RP interval) to P in front of the QRS (middle panel, long RP interval) and P midway in the cardiac cycle (right panel).

delivered at 15 to 20 watts for 10 to 15 seconds and gradually increased. Endpoints are PR prolongation, elimination of retrograde fast-pathway conduction, and noninducibility of AVNRT. An alternative approach is to apply RF current at the site of earliest retrograde atrial activation during tachycardia. RF current should be discontinued if the PR interval is prolonged by more than 50 percent or if AV block results.[542] [543] [555]

The major electrophysiological effects of fast-pathway ablation are elimination or marked attenuation of ventriculoatrial conduction, an increase in the AH interval, and elimination of dual AV node physiology. Titrating the energy may reduce the risk of complete AV block, which is the most important complication associated with ablation of the fast pathway. If it is going to occur, complete AV block usually occurs during the ablation procedure, but some episodes have occurred 24 hours or more after the procedure, possibly as a result of the extension of the RF lesion over time. The tachycardia recurrence rate after successful fast-pathway ablation is 10 to 15 percent.[542] [543] [555]

SLOW-PATHWAY ABLATION.

The slow pathway can be located by mapping along the posteromedial tricuspid annulus close to the coronary sinus os. Electrogram recordings are obtained with an atrial-to-ventricular electrogram ratio of less than 0.5 and either a multicomponent atrial electrogram or a recording of possible slow-pathway potential.[547] [548] In the anatomical approach,[542] [549] target sites are selected fluoroscopically. Serial RF lesions are created in each region, starting at the most posterior site (near the coronary sinus os) and progressing to the more anterior locus (closer to the His bundle recording site). Finally, the slow pathway can be localized during ventricular pacing, seeking the site of earliest atrial activation when conducting over the slow pathway. An accelerated junctional rhythm (Fig. 23-20) usually occurs when RF energy is applied at a site that will result in successful elimination of SVT. The success rate with the anatomical or electrogram mapping approach is equivalent, and, most often, combinations of both are used, yielding success rates approaching 100 percent, with less than a 1 percent chance of complete heart block.

Slow-pathway ablation results in an increase in the anterograde AV block cycle length and AV node ERP without a change in the AH interval or retrograde conduction properties of the AV node (see Chap. 25). Approximately 40 percent of patients can have evidence of residual slow-pathway function after successful elimination of sustained AVNRT, usually manifested as persistent dual AV node physiology and single AV node echoes during atrial extrastimulation. The endpoint for slow-pathway ablation is the elimination of sustained AVNRT both with and without an infusion of isoproterenol.[544] [551] [553]

AVNRT recurs in about 5 percent of patients after slow-pathway ablation. In some patients, the ERP of the fast pathway decreases after slow-pathway ablation, possibly due to electrotonic interaction between the two pathways.[308] [556] Atypical forms of reentry can result after ablation,[557] as can apparent parasympathetic denervation, resulting in inappropriate sinus tachycardia.[558]

At present, the fast-pathway approach is appropriate when the slow-pathway approach has been found unsuccessful and perhaps in some patients in whom the induction of AVNRT is not reproducible, because fast-pathway ablation provides a reliable endpoint of PR prolongation, in contrast to slow-pathway ablation, for which the only reliable endpoint is elimination of tachycardia. Ablation of the slow pathway is a safe and effective means for treating atypical AVNRT. In patients with AVNRT undergoing slow-pathway ablation, junctional ectopy during application of RF energy is a sensitive but nonspecific marker of successful ablation,[559] [560] [561] occurring in longer bursts at effective target sites than at ineffective sites. Ventriculoatrial conduction should be expected during the junctional ectopy, and poor ventriculoatrial conduction or actual block is a predictor of AV block in patients undergoing RF ablation of the slow pathway.

INDICATIONS.

RF catheter ablation for AV node reentrant tachycardia can be considered in patients with symptomatic, sustained AVNRT that is drug resistant or when the patient is drug intolerant or does not desire long-term drug treatment. The procedure also can be considered in patients with sustained AVNRT identified during EPS or catheter ablation of another arrhythmia or when finding dual AV node pathway physiology and atrial echoes but without AVNRT during EPS in a patient suspected of having AVNRT clinically.[119]

RESULTS.

Results of the NASPE survey indicate that 3052 patients had slow-pathway ablation with a 96 percent reported success rate, whereas 255 had fast-pathway ablation that was successful in 229 (90 percent). Significant complications occurred in 0.96 percent, but no procedure-related deaths were reported.[155] In Europe, the complication rate was 8.0 percent, mostly due to AV block after fast-pathway ablation, and there were no deaths in 815 patients.[154] [562] Most centers currently employ slow-pathway ablation, resulting in a procedural success rate of 98 percent, recurrence rate of less than 2 percent and incidence of heart block requiring permanent pacing of less than 1 percent.[541]

Radio Frequency Catheter Ablation of Atrial Tachycardia, Sinus Node Reentry/Inappropriate Sinus Tachycardia, and Atrial Flutter

Atrial arrhythmias amenable to catheter ablation include atrial tachycardias that are automatic or reentrant,[457] [563] [564] [565] sinus node reentry,[566] incessant/inappropriate

sinus tachycardia, junctional tachycardias,[567] and typical and atypical atrial flutter.[568] [569] [570] In "focal" atrial tachycardias (automatic

Figure 23-20 AV node slow pathway modification for cure of AV node reentrant SVT. Recordings as in prior figures. The ablation recording (gray arrow) shows a slurred deflection between atrial and ventricular electrogram components; this may represent the AV node slow pathway deflection (but it is not the bundle of His deflection, which is instead recorded from a separate catheter 15 mm away). Shortly after the onset of RF delivery (dark arrow), an accelerated junctional rhythm begins and gradually speeds up further. Retrograde conduction is present during the junctional rhythm.

Figure 23-21 Atrial tachycardias. *A,* Automatic atrial tachycardia arising in the left inferior pulmonary vein (LIPV). A sinus beat is shown at left, followed by a fusion beat (F) of sinus and tachycardia activation. The last three beats in the panel are atrial tachycardia. The ablation catheter was within the LIPV and recorded a sharp potential (gray arrow) 40 msec before the P wave onset (dashed line). Ablation at this site terminated the tachycardia. *B,* Intraatrial reentrant tachycardia in a patient who had undergone atrial septal defect repair years earlier. The ablation catheter is in the posterior right atrium (PRA), where a fragmented signal is recorded. A portion of this electrogram (dark arrow) precedes the P wave onset during tachycardia (dashed line) by 70 msec. Ablation at this site terminated the tachycardia.

or triggered foci), activation mapping is used to determine the site of the atrial tachycardia by recording the earliest onset of local activation. Ten to 15 percent of patients can have multiple atrial foci. Sites tend to cluster near the pulmonary veins in the left atrium and the mouths of the atrial appendages and along the crista terminalis on the right (Fig. 23-21 *A*). Reentrant atrial tachycardia appears to occur more commonly in the setting of structural heart disease, in particular after prior atrial surgery. The region of slow conduction is not in a constant anatomical location but varies from patient to patient depending on the operation performed. Therefore, careful review of operative reports and electrophysiological mapping is essential. The atriotomy scar often plays an important role in the genesis of the tachycardia. The ablation strategy is to identify regions with diastolic atrial activation during tachycardia that can be proven by pacing techniques to be integral to the tachycardia (see Fig. 23-21 *B*). Focal ablation of these sites can then be performed, but in many cases tachycardia can still be initiated (often at a slower rate) or it recurs after the procedure. Because these sites are typically located at the ends of prior scars or surgical incisions, another technique is to make a line of ablation lesions from the end of the scar to the nearest electrical barrier, such as the tricuspid annulus or a caval orifice. Reentry can thus be prevented. This technique is analogous to that used in curing atrial flutter (see later).

SINUS NODE ABLATION.

When the sinus node area is to be ablated, it can be identified anatomically as well as electrophysiologically, and ablation lesions are usually placed between the superior vena cava and crista terminalis. Care must be taken in applying RF energy at the most cephalad sites first; initial ablation performed farther down the crista terminalis does not alter the atrial rate but may damage subsidiary pacemaker regions that may be needed after the sinus node is eventually ablated. Recurrence rates are high after sinus node modification (up to 30 percent), and in other cases pacemaker therapy is required after ablation because of inadequate atrial rates at rest or with exercise.

ATRIAL FLUTTER.

Understanding the reentrant pathway for typical atrial flutter (negative sawtooth waves in leads II, III, and aVF at a rate of about 300 beats/min) has been essential for developing an ablation approach. Reentry in the right atrium, with the left atrium passively activated, constitutes the mechanism of typical atrial flutter, with a caudocranial activation along the right atrial septum and a craniocaudal activation of the right atrial free wall (Fig. 23-22 *A*). In some cases a zone of slow conduction exists in the low right atrium, which is typically bounded by the tricuspid annulus, the inferior vena cava, and the coronary sinus.[571] [572] [573] In other cases, conduction velocity is more uniform throughout the large circuit. Placing an ablative lesion between any two anatomical barriers that transect a portion of the circuit necessary for perpetuation of reentry can be curative. Typically, this is across the isthmus of atrial tissue between the tricuspid annulus and inferior vena caval orifice, a relatively narrow point in the circuit. Successful ablation can be accomplished where the advancing flutter wavefront enters this zone in the low inferolateral right atrium, near the exit of this zone at the inferomedial right atrium, or in between these sites. Lesions can be guided anatomically or electrophysiologically. Less commonly, the direction of wavefront propagation in this large right atrial circuit is reversed ("clockwise" flutter proceeding cephalad up the right atrial free wall and caudad down the septum, with upright flutter waves in the inferior leads [see Fig. 23-22 *A*]). This arrhythmia, which has been called "atypical atrial flutter," may also be ablated using the same techniques as with more typical atrial flutter. These two arrhythmias constitute "isthmus-dependent" flutter and are distinct from other rapid atrial arrhythmias that may have similar ECG appearance but utilize different (and often multiple) circuits in other parts of the right or left atrium. Ablation can be more difficult in these cases, which often occur in the setting of advanced lung disease or after cardiac surgery.

The endpoint of flutter ablation procedures was initially termination of flutter with RF application and noninducibility of the arrhythmia. However, using these criteria, up to 30 percent of patients had recurrent flutter. In the last several years, the endpoint of ablation has changed to ensuring a line of bidirectional block in the tricuspid-inferior vena caval isthmus by pacing from opposite sides of the isthmus (see Fig. 23-22 *B*). With the use of these criteria, recurrence rates have fallen to less than 5 percent.

INDICATIONS.

Candidates for RF catheter ablation include patients with atrial tachycardia, sinus node reentry, inappropriate sinus tachycardia, or atrial flutter that is drug resistant; those who are drug intolerant; or those who do not desire long-term drug therapy.[119]

Figure 23-22A Two forms of atrial flutter are shown from the same patient (see also Fig. 23-22 *B*). A "halo" catheter with 10 electrode pairs is situated on the atrial side of the tricuspid annulus (TA), with recording sites displayed from the top of the annulus ("12:00") to the inferomedial aspect ("5:00"), as shown in fluoroscopic views in *B.* On the left, the wavefront of atrial activation proceeds in a "clockwise" fashion (arrows) along the annulus, whereas in the right panel the direction of propagation is the reverse.

RESULTS.

From the U.S. NASPE survey, 371 patients underwent ablation for atrial tachycardia and atrial flutter with a success rate of 75 percent with three significant complications (0.8 percent) and no deaths.[155] The complication rate was 5 percent in the European survey, and there were no deaths in 141 patients.[154]

Ablation and Modification of Atrioventricular Conduction for Atrial Tachyarrhythmias

In some patients with atrial tachyarrhythmias who have rapid ventricular rates despite optimal drug therapy, RF ablation can be used to modify AV conduction to control the ventricular rates. To achieve RF catheter ablation of AV conduction, a catheter is placed across the tricuspid valve and positioned to record the largest His bundle electrogram associated with the largest atrial electrogram. RF energy is applied until complete AV block is achieved and is continued for an additional 30 to 60 seconds. If no change in AV conduction is observed after 15 seconds of RF ablation, the catheter is repositioned and the attempt is repeated. In occasional patients, attempts at RF ablation using this right-sided heart approach fail to achieve heart block. These patients can undergo an attempt from the left ventricle with a catheter positioned along the posterior interventricular septum just beneath the aortic valve to record a large His bundle electrogram. Energy is applied between the catheter electrode and the skin patch or between catheters in the left and right ventricles. Success rates approach 100 percent in most studies today, with recurrence of AV conduction in less than 5 percent.[541] [574] Improved left ventricular function can result from both control of ventricular rate during atrial fibrillation, as well as withdrawal of rate-controlling medications with negative inotropic action.[575]

In some cases, the AV junction can be modified to merely slow the ventricular rate without producing complete AV block by ablation in the region of the slow pathway, as described under AV node modification for AV node reentry. Initial success rates for slowing the ventricular response are quite good; however, long-term results are less consistent.[576] Some patients have a gradual increase in ventricular rate to nearly preablation levels, whereas late complete heart block may occur in others. Nonetheless, this procedure can be tried before producing complete AV block.[577] [578] [579]

INDICATIONS.

Ablation and modification of AV conduction can be considered in (1) patients with symptomatic atrial tachyarrhythmias who have inadequately controlled ventricular rates unless primary ablation of the atrial tachyarrhythmia is possible; (2) similar patients when drugs are not tolerated or the patient does not wish to take them, even though the ventricular rate can be controlled; (3) patients with symptomatic, nonparoxysmal, junctional tachycardia that is drug resistant or by whom drugs are not tolerated or are not desired; (4) patients resuscitated from sudden cardiac death due to atrial flutter or atrial fibrillation

Figure 23-22B Ablation of the isthmus of atrial tissue between the tricuspid annulus and inferior vena caval orifice for cure of atrial flutter. Recordings are displayed from the multipolar catheter around much of the circumference of the tricuspid annulus (see left anterior oblique fluoroscopy images). Ablation of this isthmus is performed during coronary sinus pacing. In the two beats on the left, atrial conduction proceeds in two directions around the tricuspid annulus, as indicated by arrows and recorded along the halo catheter. In the two beats on the right, ablation has interrupted conduction in the floor of the right atrium, eliminating one path for transmission along the tricuspid annulus. The halo catheter now records conduction proceeding all the way around the annulus. This demonstrates unidirectional block in the isthmus; block in the other direction may be demonstrated by pacing from one of the halo electrodes and observing a similar lack of isthmus conduction. (The bundle of His recording in the right panel is lost owing to catheter movement.)

with a rapid ventricular response in the absence of an accessory pathway; and (5) patients with a dual-chamber pacemaker and a pacemaker-mediated tachycardia that cannot be treated effectively by drugs or by reprogramming the pacemaker.[119] The last three situations are rarely encountered.

RESULTS.

Results from the U.S. survey indicated that the procedure was successful in producing complete AV block in 95 percent of 1600 patients, with significant complications occurring in 21 (1.3 percent) and two procedure-related deaths (0.1 percent).[155] In Europe, the complication rate was 3.2 percent, and there was 1 death in 900 patients.[154] In early studies, up to 4 percent of patients had an episode of sudden death after AV junction ablation despite adequate pacemaker function, presumably due to relative bradycardia after long periods of rapid ventricular rates.[541] In one study, 6 of 100 patients died suddenly when the initial pacing rate was set to 60 beats/min, but none of 135 died suddenly when the rate was set to 90 beats/min for 1 to 3 months after ablation.[580]

Radio Frequency Catheter Ablation of Atrial Fibrillation

In recent years, considerable progress has been made in understanding the pathophysiology of atrial fibrillation. The

use of this information has translated directly into therapeutic advances. For example, it is now recognized that a significant proportion of patients with paroxysmal atrial fibrillation in the absence of structural heart disease have a focal origin of the arrhythmia; that is, very rapid discharges from a focal source (often in a pulmonary vein or on the crista terminalis) drive the atrium more rapidly than it can uniformly conduct, leading to the ECG appearance of atrial fibrillation.[581] [582] [583] [584] If this focus can be located and successfully ablated, recurrences of atrial fibrillation are prevented. Patients in this group typically have frequent isolated PACs that can be detected with ambulatory ECG monitoring. In some, the onset of spontaneous atrial fibrillation can be observed after one or more PACs. A significant problem with focal atrial fibrillation ablation is that some patients do not have a sufficient amount of PACs to allow mapping. In some cases, burst pacing, isoproterenol infusion, and removal of sedation during the procedure may allow expression of PACs and atrial fibrillation.

The surgical Maze procedure (see later) has become established as a successful technique for permanently restoring sinus rhythm. In 1994, the first human reports appeared of replicating the surgically induced lines of block in the atria using catheter ablation.[585] The intent of the procedure is to compartmentalize the atrial muscle into segments too small to support fibrillation wavefronts yet have the segments connected enough to participate in contraction. Several techniques have been used, including creation of long, linear RF lesions limited to either the right or left atrium or both. It appears that the procedure is capable of restoring sinus rhythm, but many patients have recurrences of atrial fibrillation, atrial flutter, or rapid, regular tachycardias arising in the left atrium ("left atrial flutter") and require subsequent left atrial procedures to eliminate these arrhythmias.[586] Procedure durations can exceed 8 hours, and fluoroscopy times more than 90 minutes are not uncommon. Because of the length of time spent in the left atrium and the large areas of endocardial damage produced to successfully make the lines of block, patients must be vigorously anticoagulated during the procedures. This increases the risk of bleeding complications and still has not entirely prevented thromboemboli related to the procedure. In addition, there have been reports of pulmonary vein stenosis with consequent pulmonary venous hypertension after extensive ablations within the pulmonary veins.[586A]

INDICATIONS.

Candidates for focal atrial fibrillation ablation have paroxysmal atrial fibrillation in the absence of structural heart disease, and frequent PACs on monitoring, and include those whose atrial fibrillation is either refractory to medications or who prefer not to take medications. Patients in whom linear ablation for atrial fibrillation might be considered are those with some degree of structural heart disease and persistent or chronic atrial fibrillation for whom maintenance of sinus rhythm is important and in whom atrial fibrillation recurs despite standard antiarrhythmic drugs or in whom drug therapy is not tolerated or preferred.

RESULTS.

Success rates of ablation for focal atrial fibrillation range from 40 to 85 percent. As noted earlier, the inability to observe and map PACs is a major limitation of this procedure. Procedures for making linear ablations in the left or right atrium are still undergoing refinement. Preliminary data suggest a success rate of about 30 percent in preventing recurrences of atrial fibrillation for right atrial-only procedures and up to 80 percent success for primarily left atrial procedures (often including a "flutter lesion" in the floor of the right atrium, because many patients undergoing a purely left atrial procedure have subsequent episodes of flutter). The risk of stroke related to extensive left atrial ablation is approximately 5 percent even with rigorous anticoagulation regimens. Although surgical procedures involving incision and isolation of atrial myocardium have been devised to eliminate atrial fibrillation and their feasibility has been demonstrated, catheter techniques for

Figure 23-23 Ventricular tachycardia and pacemapping. All 12 surface ECG leads are shown along with intracardiac recordings during VT. The Abl_{1-2} recording shows a small deflection occurring early in electrical diastole (arrow) 110 msec before the onset of the QRS (dashed line). In the right panel, pacing is performed from this site. This produces an identical QRS complex in each lead, with a stimulus-QRS onset interval similar to the electrogram-QRS onset interval during VT. Ablation at this site eliminated VT in 2 seconds. RVOT = right ventricular outflow tract.

eliminating atrial fibrillation are in the relatively early stage of development, but preliminary success has been reported.[585] [587] [588] [589] [590] [591] [591A] [592] [593] [593A]

Other nonpharmacological modalities for the treatment of atrial fibrillation, such as preventive pacing[594] and implantable atrial defibrillators/atrial rhythm management devices,[595] are discussed in Chapter 24 .

Radio Frequency Catheter Ablation of Ventricular Tachycardia

In general, the success rate for ablation of VTs is lower than for AV node or AV reentry.[439] [440] [596] [597] [598] [599] [600] [601] [602] [603] [604] [605] [606] [607] [608] [609] This may be related to the fact that this procedure is often a last resort in patients with drug-resistant VTs but also relates to more difficult mapping in the ventricles. Furthermore, the VT induction must be reproducible, uniform in QRS morphology from beat to beat, sustained, and hemodynamically stable so that the patient can tolerate the VT long enough during the procedure to undergo the extensive mapping necessary to localize optimal ablation target sites. (Patients with several electrocardiographically distinct, uniform morphologies of VT can still be candidates for ablation, because in many instances a common reentrant pathway is shared by two or more VT morphologies.[610]) Also, the origin of the VT must be fairly circumscribed and endocardially situated (rare cases of successful ablation only from the epicardial aspect

have been reported[611]). Very rapid VT, polymorphic VT, and infrequent, nonsustained episodes are not amenable to this form of therapy at this time.[596] [609]

RF catheter ablation of VT can be divided into idiopathic VT that occurs in patients with essentially normal hearts,[439] [440] [596] [599] [600] [603] [605] [609] VT that occurs in a variety of disease settings but without coronary artery disease, and VT in patients with coronary artery disease and prior myocardial infarction.[597] [601] [602] [604] [605] [606] [609] In the first group, the VTs arise most commonly in the right ventricular outflow tract and less often in the inflow tract. Initiation of tachycardia can be facilitated by catecholamines. The majority of left VTs are septal in origin and have a characteristic QRS configuration (right bundle branch block, superior axis); other VTs occur less commonly and arise from other areas of the left ventricle, including the left ventricular outflow tract, that have similar ECG appearance and clinical behavior to those arising in the right ventricular outflow tract (see Fig. 23-8). Abnormal patterns of sympathetic innervation may be present in some.[612] VTs in abnormal hearts without coronary artery disease can be due to bundle branch reentry, a characteristic of dilated cardiomyopathies. In these patients, ablation of the right bundle branch eliminates the tachycardia.[613] VT can occur in right ventricular dysplasia, sarcoidosis, Chagas' disease, hypertrophic cardiomyopathy, and a host of other noncoronary disease problems (see Chap. 25).

Activation mapping[598] [602] and pace mapping are effective in patients with idiopathic VTs to locate the site of origin of the VT. In activation mapping, the timing of sampled endocardial electrograms from the mapping catheter is compared with the onset of the surface QRS complex. Sites that are activated before the surface QRS onset are near the origin of the VT (see Figs. 23-8 and 23-23). In idiopathic VT, ablation at a site at which the unipolar electrogram shows a "QS" complex may yield greater success than if an "rS" potential is observed (Fig. 23-24) . Pace mapping involves stimulation of various ventricular sites to initiate a QRS contour that duplicates the QRS contour of the spontaneous VT, thus establishing the apparent site of origin of the arrhythmia (see Fig. 23-23). This technique is limited by several methodological problems but may be useful when the tachycardia cannot be initiated and when a 12-lead ECG has been obtained during the spontaneous VT. Purkinje potentials can be recorded during VT from sites at which ablation will cure VT in most patients with left VTs that have right bundle branch block/superior axis.[440] [596] [609] Localization of optimal ablation sites for VT in patients with coronary artery disease and prior infarction is more difficult than in patients with structurally normal hearts because of the altered anatomy and electrophysiology. [614] Pace mapping has lower sensitivity and specificity than it does for idiopathic VT. Furthermore, reentry circuits can sometimes be large and resistant to the relatively small lesions produced by RF catheter ablation in scarred endocardium. Finding a protected region of diastolic activation used as a critical part of the reentrant circuit is desirable, because ablation at this site has a good chance of eliminating the tachycardia (Fig. 23-25) . Because of the extensive derangement in electrophysiology caused

Figure 23-24 Recordings from unsuccessful and successful ablation sites in a patient with idiopathic ventricular tachycardia arising in the inferior right ventricular wall. In the recordings from the unsuccessful ablation site, the unipolar signal (arrow) has a small "r" wave, indicating that a portion of the wavefront from the focus of tachycardia was approaching the site from elsewhere. At the successful site, the unipolar recording has a "QS" configuration, indicating all depolarization was emanating from this site. In each site, the bipolar recording (Abl_{1-2}) occurs an identical 43 msec before QRS onset (dashed lines).

Figure 23-25 Radio frequency ablation of postinfarct ventricular tachycardia (VT). Recordings are as in previous figures. The electrogram in the ablation recording (vertical arrow) precedes the QRS onset (dashed line) by 131 msec. Ablation here (RF on at diagonal arrow) results in slight deceleration of VT before termination in 1.3 seconds. Temperature monitored from the catheter tip had just peaked (approximately 70°C) at the time VT terminated.

by the infarction, many areas of the ventricle may have diastolic activation but not be relevant to the perpetuation of the VT. These "bystander sites" make activation mapping more difficult.

In patients without structural heart disease, only a single VT is usually present, and catheter ablation of that VT is curative. In patients with extensive structural heart disease, especially those with prior myocardial infarction, multiple VTs are usually present. Catheter ablation of a single VT in such patients may only be palliative and may not eliminate the need for further antiarrhythmic therapy. The genesis of multiple tachycardia morphologies is not clear, although in some cases they are merely different manifestations of one circuit (e.g., different directions of wavefront propagation or exit to the ventricle as a whole), and ablation of one may prevent recurrence of others. The presence of multiple VT morphologies contributes to the difficulties in mapping and ablation of VT in these patients, because pacing techniques employed to validate recordings at potential sites of ablation may result in a change in morphology to another VT that does not arise in the same region.

After ablation of VT, repeat ventricular stimulation is performed to assess efficacy. In some cases, rapid polymorphic VT or fibrillation is initiated. The clinical significance of these arrhythmias is unclear, but some evidence suggests that they have a low likelihood of spontaneous occurrence during follow-up.

INDICATIONS.

Patients considered for RF catheter ablation of VT are those with symptomatic, sustained, monomorphic VT when the tachycardia is drug resistant, when the patient is drug intolerant, or when the patient does not desire long-term drug therapy; patients with bundle branch reentrant VT; and patients with sustained monomorphic VT and an ICD who are receiving multiple shocks not manageable by reprogramming or concomitant drug therapy.[607] Occasionally, nonsustained VT or even severely symptomatic PVCs require RF catheter ablation.[119]

RESULTS.

In the U.S. NASPE survey, 429 patients underwent ablation, with an overall success rate of 71 percent. In 224 patients with structurally normal hearts, the success rate was 85 percent. The success rate was 54 percent in 115 patients with VT due to ischemic heart disease and 61 percent in 90 patients with idiopathic cardiomyopathy. There were 13 significant complications (3.0 percent) and, interestingly, considering the nature of the disease, no procedure-related deaths.[155] The complication rate was 7.5 percent in the European survey, and there was 1 death in 320 patients.[154] More recent series suggest a 30 percent "cure" rate for patients (no inducible ventricular arrhythmia of any type, no recurrences), whereas over 70 percent of patients no longer have recurrences of VT after the procedure, despite inducibility of rapid VT or VF.[606] [607] [615]

New Mapping and Ablation Technologies

MULTIELECTRODE MAPPING SYSTEMS.

As noted earlier, many of the limitations of ablation are related to inadequate mapping. These problems include only isolated premature complexes during the EPS as opposed to sustained tachycardias (in idiopathic atrial and ventricular tachycardias), nonsustained episodes of VT, poor hemodynamic tolerance of VT, and multiple VT morphologies. Standard mapping techniques sample single sites sequentially and are poorly suited to these situations listed earlier. New mapping systems are available that enable sampling of many sites simultaneously and incorporate sophisticated computer algorithms for analysis and display of global maps. These mapping systems use a variety of technologies, ranging from multiple electrodes situated on each of several splines of a "basket" catheter,[616] to use of low-intensity magnetic fields to localize the catheter tip in the heart and record and plot activation times on a contour map of the chamber,[617] to use of complex mathematics to compute "virtual" electrograms recorded from a mesh electrode situated in the middle of a chamber cavity.[618] [619] Some of these systems are capable of generating activation maps of an entire chamber using only one complex, an obvious advantage in patients with only premature complexes, nonsustained arrhythmias, or poor hemodynamic tolerance. Although these mapping systems offer great promise in selected cases, they are complex and expensive to use.

COOLED-TIP RF ABLATION.

There are situations in which the catheter can be delivered to the correct location but conventional RF energy delivery is unable to eliminate the tachycardia. In some such cases, the amount of damage (either depth or breadth) caused by standard RF is inadequate. Using standard RF, power delivery is usually regulated to maintain a preset catheter tip temperature (typically 70°C). Tip temperatures greater than 90°C are associated with coagulation of blood elements on the electrode that preclude further energy delivery and could also become detached and embolize. Cooling the catheter tip, either by an internal circulation of liquid or continuous fluid infusion through the tip electrode, can prevent excessive heating of the tip and allow greater power delivery, thus effecting larger lesion size and potentially enhancing efficacy. Preliminary studies have shown the safety of this technology, but efficacy has yet to be demonstrated.[156]

CHEMICAL ABLATION.

Chemical ablation with alcohol or phenol of an area of myocardium involved in a tachycardia has been used to create AV block in patients not responding to catheter

ablation and to eliminate atrial and ventricular tachycardias.[620] [621] Recurrences of tachycardia several days after apparently successful ablation are common. Excessive myocardial necrosis is the major complication, and alcohol ablation should be considered only when other ablative approaches fail or cannot be done.

Surgical Therapy for Tachyarrhythmias

The objectives of a surgical approach to treating a tachycardia are to excise, isolate, or interrupt tissue in the heart critical for the initiation, maintenance, or propagation of the tachycardia while preserving or even improving myocardial function. In addition to a direct surgical approach to the arrhythmia, indirect approaches such as aneurysmectomy, coronary artery bypass grafting, and relief of valvular regurgitation or stenosis can be useful in selected patients by improving cardiac hemodynamics and myocardial blood flow. Cardiac sympathectomy alters adrenergic influences on the heart and has been effective in some patients, particularly those who have recurrent VT with the long QT syndrome.

Supraventricular Tachycardias

Surgical procedures[622] [623] [624] [625] [626] [627] exist for patients (adults and children) with atrial tachycardias,[625] atrial flutter, AV node reentry,[623] and AV reentry,[624] [628] [629] (Fig. 23-26) . RF catheter ablation adequately treats the majority of these patients except for those with atrial fibrillation. Therefore, RF catheter ablation has replaced direct surgical intervention except for the occasional patient in whom RF catheter ablation fails or who is having concomitant cardiovascular surgery. In some instances, a prior attempt at RF catheter ablation complicates surgery by obliterating the normal tissue planes that exist in the AV groove of the heart or by rendering tissues too friable. Occasionally, patients with atrial tachycardias have multiple foci that require surgical intervention.[625]

The Maze procedure,[626] [630] [631] [631A] developed to treat patients with atrial fibrillation (see Chap. 25), eliminates the arrhythmia by reducing atrial tissue mass to a size at any instant in time too small to perpetuate the reentrant circuits responsible for atrial fibrillation. It forces atrial activation to proceed along a surgically determined pathway, thus maintaining sinus rhythm with AV node conduction. The Maze procedure permits organized electrical depolarization of the atria, restores atrial transport function, and in so doing decreases the risk of thromboembolism. Maintenance of sinus rhythm more than 3 months after the procedure approaches 100 percent, although up to 10 percent of patients require pacemakers because of chronotropic incompetence of the sinus node (either due to the surgery or the preexisting atrial pathology). The advent of minimally invasive endoscopic and endovascular techniques may make it possible to perform an equivalent of the Maze procedure without thoracotomy in the future. The Maze procedure is currently most commonly performed concomitantly with mitral valve surgery rather than as a primary indication. In some centers, intraoperative RF ablation has replaced surgical incisions for performing the Maze procedure.[632]

Ventricular Tachycardia

In contrast to patients with supraventricular arrhythmias, candidates for surgical therapy for ventricular arrhythmias often have severe left ventricular dysfunction, which is generally caused by coronary artery disease. The cause of the underlying heart disease influences the type of surgery performed. Candidates are patients with drug-resistant, symptomatic, recurrent ventricular tachyarrhythmias who ideally have a segmental wall motion abnormality (scar or aneurysm) with preserved residual left ventricular function. Poorer surgical results are obtained in patients with a history of congestive heart failure and left ventricular dysfunction.

Ischemic Heart Disease

In almost all patients who have VT associated with ischemic heart disease, the arrhythmia, regardless of its configuration on the surface ECG, arises in the left ventricle or on the left ventricular side of the interventricular septum. The ECG contour of the VT can change from a right bundle branch block to a left bundle branch block pattern without

Figure 23-26 Schematic diagram showing the two approaches for surgical interruption of an accessory pathway. The left panel depicts the left atrioventricular groove and its vascular contents, the coronary sinus (C.S.) and circumflex coronary artery (C.A.). Multiple accessory pathways (AP) course through the fat pad. The middle panel shows the epicardial dissection approach, whereas the right panel exhibits the endocardial dissection. Both approaches clear out the fat pad and interrupt any accessory pathways. *(From Zipes DP: Cardiac electrophysiology: Promises and contributions. J Am Coll Cardiol 13:1329, 1989. Reprinted by permission of the American College of Cardiology.)*

a change in the site of earliest diastolic activation, suggesting that the left ventricular site of origin remains the same, often near the septum, but its exit pathway is altered.

Indirect surgical approaches, including cardiothoracic sympathectomy, coronary artery bypass grafting, and ventricular aneurysm or infarct resection with or without coronary artery bypass grafting, have been successful in 20 to 30 percent of reported cases. Coronary artery bypass grafting as a primary therapeutic approach generally has only been successful in rare patients who experience VT during ischemia as well as patients with ischemia-related VF but can sometimes be useful in patients with coronary disease resuscitated from sudden death who have no inducible arrhythmias at EPS. Patients with sustained monomorphic VT or only polymorphic VT rarely have their arrhythmias affected by coronary bypass surgery, although the latter can reduce the frequency of the arrhythmic episodes in some patients and prevent new ischemic events.

SURGICAL TECHNIQUES.

Generally, two types of direct surgical procedures are used: resection and ablation (Fig. 23-27) . The first direct surgical approach to VT was *encircling endocardial ventriculotomy,* using a transmural ventriculotomy to isolate areas of endocardial fibrosis that were recognized visually; this procedure is rarely employed now. The rationale for *subendocardial resection* is based on animal and clinical data indicating that arrhythmias after myocardial infarction arise mostly at the subendocardial borders between normal and infarcted tissue. Subendocardial resection involves peeling off a 1- to 3-mm-thick layer of endocardium, often near the rim of an aneurysm, that has been demonstrated by means of mapping procedures to be the site of earliest activation recorded during the VT. Some VTs can arise from the epicardium. Tachycardias arising from near the base of the papillary muscles are cryoablated using a 1.5-cm flat probe cooled to -70°C. Cryoablation also can be used to isolate areas of the ventricle that cannot be resected and is often combined with resection. The neodymium:yttrium-aluminum-garnet laser approaches have been used as well with good success, but the equipment is very expensive and difficult to work with.

RESULTS.

For ventricular tachyarrhythmias, operative mortality ranges from 6 to 23 percent, with success rates defined as absence of recurrence of spontaneous ventricular arrhythmias ranging from 59 to 98 percent. In experienced centers, operative mortality may be as low as 5 percent in stable patients undergoing elective procedures, with 85 to 95 percent of survivors free of inducible or spontaneous ventricular tachyarrhythmias. Long-term recurrence rates range from 2 to 38 percent and correlate with results of the patient's postoperative electrophysiological stimulation

Figure 23-27 Schematic diagram showing surgical procedures for treatment of postinfarct ventricular tachycardia with left ventricular aneurysm. A damaged left ventricle is depicted as opened along the lateral wall and viewing the septum and papillary muscles. The tachycardia circuit (arrow) takes a meandering course near where the aneurysm meets normal myocardium and at times is superficial, other times coursing deeper (dashed line). Simple aneurysmectomy that leaves a portion of the aneurysm for suturing often misses the circuit and thus does not cure the arrhythmia. Using subendocardial resection, a layer of endocardium and subjacent tissue is removed, including at least some of the tachycardia circuit. This results in elimination of tachycardia. Encircling endocardial ventriculotomy attempts to electrically isolate the circuit without removing tissue, but it probably actually works by incising portions of the circuit. Cryoablation can be used either to encircle the infarct zone or in combination with resection to damaged tissue too deep in the wall to safely resect.

study. Operative survival is strongly influenced by the degree of left ventricular dysfunction. Patients with less favorable anatomy who are poor surgical candidates and who fail drug treatment are generally considered for an ICD. By no longer having to operate on these sicker patients, surgeons have improved the overall operative mortality.[627] [633] [634]

Operative mortality for nonthoracotomy ICD implantation is less than 1 percent, with an annual sudden cardiac death mortality rate of less than 1 percent.[635] Because of the difference in operative survival and shorter hospital stay with ICD therapy compared with direct surgery for VT, relatively few curative surgical procedures are now performed. Nevertheless, ICD patients are relegated to a form of therapy that, naturally, does not prevent the arrhythmia but only terminates it after its onset. Some experts recommend surgery for patients with VT who have discrete aneurysms that are amenable to intraoperative mapping and resection because such patients have a very high probability for cure of their arrhythmias.[636]

Electrophysiological Studies

PREOPERATIVE ELECTROPHYSIOLOGICAL STUDY.

In patients for whom direct surgical therapy for VT is planned, a preoperative EPS is usually warranted. This involves initiation of the VT and electrophysiological mapping to localize the area to be resected, as is done with catheter ablation. A resolution of 4 to 8 cm^2 of ventricular endocardium is thereby achieved, although more accurate anatomical localization of the mapping electrode tip in the ventricle may be possible. Tachycardias that are too rapid, short in duration, or polymorphic cannot be mapped accurately unless multiple catheters or a multielectrode array is used. Administering a drug such as procainamide may slow the VT and transform a nonsustained polymorphic VT into a sustained VT of uniform contour that can be mapped.

INTRAOPERATIVE VENTRICULAR MAPPING.

Electrophysiological mapping is also performed at the time of surgery, with the surgeon using a hand-held probe or an electrode array coupled with on-line computer techniques that instantaneously provide an overall activation map cycle by cycle. The sequence of activation during VT can be plotted and the area of earliest activation determined.

During VT, the origin of the arrhythmia is generally ascribed to electrical activity recorded more than 50 milliseconds before the onset of the QRS complex (ideally, isolated mid-diastolic potentials). Generally, potentials recorded before the onset of the surface QRS complex suggest that the origin of the tachycardia is nearby. Resection or cryoablation of tissue from which these recordings are made usually cures the VT, indicating that they represent a critical portion of the reentrant circuit. However, it is quite clear that such electrical activity can be late following the preceding cycle or early in advance of the next cycle. When the earliest recordable endocardial electrical activity occurs less than 30 milliseconds before the onset of the QRS complex, the critical portions of the circuit may be in the interventricular septum or near the epicardium of the free wall.

The area of earliest recorded electrical activity during VT may not actually represent a critical portion of the tachycardia circuit, because the latter may be several centimeters away (e.g., in a small, scarred area). The impulse may then conduct very slowly until it reaches more normally excitable tissue, where it exits and spreads rapidly to the rest of the endocardium to generate a QRS complex. However, this area of early activation is probably closely related to the origin of the tachycardia that, based on the present state of knowledge and results from surgery, warrants surgical intervention at that site. Finding an area from which "continuous electrical activity" is recorded rarely if ever indicates that the entire circuit is being recorded. However, it is likely that a critical portion of the tachycardia circuit is close to the area of continuous electrical activity. In some patients, intramural mapping using a plunge needle electrode can be useful, particularly if the origin of the tachycardia is not located in the subendocardium. Most centers now employ a strategy of "sequential" subendocardial resection, in which VT is initiated, mapped, and ablated (resected or cryoablated) and stimulation is immediately repeated. If VT can still be initiated, mapping and resection are also repeated until VT can no longer be initiated.

GUIDELINES
AMBULATORY MONITORING AND ELECTROPHYSIOLOGICAL TESTING

Thomas H. Lee

This appendix summarizes guidelines from American College of Cardiology/American Heart Association (ACC/AHA) task forces on ambulatory monitoring published in 1999[1] and electrophysiological testing and cardiac ablation procedures published in 1995. Information on guidelines for implantable cardioverter-defibrillators (ICDs) is included in the Guidelines in Chapter 24 .

AMBULATORY MONITORING

Guidelines for the use of ambulatory electrocardiography (ECG) continue to evolve with advances in technology of the monitoring devices, as well as other medical devices and clinical research. An ACC/AHA task force issued updated guidelines for the use of this technology in 1999,[1] a decade after its first guidelines in this area.[2] Particularly important progress was made during this period in several areas, including

- Understanding of the limited usefulness of suppression of ventricular ectopy with drug therapy as a predictor of prognosis[3]
- Solid-state digital technology that facilitates transtelephonic transmission of ECG data
- Technical advances in long-term event recorders
- Improved signal quality and interpretation
- Improved computer arrhythmia interpretation
- Increasingly sophisticated monitoring capacity of pacemakers and implantable defibrillators

As result of progress in these areas, ambulatory ECG is now considered to be of uncertain appropriateness for many indications for which it was an accepted strategy in prior guidelines.

ACC/AHA guidelines on the appropriateness of ambulatory ECG for various clinical settings are summarized in Table 23-G-1 . As is the case for other ACC/AHA guidelines, the indications are divided into classes.

Class I
: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective

Class II
: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment

Class IIa
: Weight of evidence/opinion in favor of usefulness/efficacy

Class IIb
: Usefulness/efficacy less well established by evidence/opinion

Class III
: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful.

DIAGNOSIS.

In the assessment of symptoms that may be related to arrhythmias, ambulatory ECG is most clearly established for evaluation of syncope. The ability of 24-hour ambulatory ECG to capture rare events such as syncope is low; however, the rhythm during asymptomatic periods may be useful. When continuous ambulatory ECG is not diagnostic, intermittent recorders may be useful. The guidelines note that data on the use of ambulatory ECG for near syncope or dizziness are insufficient to describe the diagnostic performance of this technology for those indications.

A second Class I indication is the use of ambulatory ECG in patients with recurrent palpitations. This test is considered useful in this setting because the frequency of recurrence of palpitations makes it more likely that ECG data will be captured during episodes of palpitations than during syncope.

Other indications for ambulatory ECG for diagnostic purposes are of uncertain appropriateness at best. The ACC/AHA guidelines explicitly discourage use of this technology for patients with syncope, near syncope, dizziness, or palpitations in whom another cause has been identified. Also considered inappropriate was ambulatory ECG for patients with cerebrovascular accidents and no other evidence of arrhythmia. Thus, these guidelines discourage performance of ambulatory ECG for "completeness" of an evaluation in such patients.

ASSESSMENT OF RISK.

The ACC/AHA guidelines are not generally encouraging of the use of ambulatory ECG for either arrhythmia detection or analysis of heart rhythm variability if the goal is risk assessment among patients without symptoms of arrhythmia (see Table 23-G-1). No clinical indications were considered Class I or Class IIa. In certain patients at high risk for arrhythmias, the ACC/AHA guidelines considered ambulatory ECG Class IIb (i.e., controversial, without the weight of evidence or opinion in support of appropriateness). Such "marginal" indications include patients with left ventricular dysfunction after myocardial infarction, congestive heart failure, or idiopathic hypertrophic cardiomyopathy. However, data from Multicenter Automatic Defibrillator Implantation Trial (MADIT) and Multicenter Unsustained Tachycardia Trial (MUSTT) suggest that documenting nonsustained ventricular tachycardia in patients after myocardial infarction who have reduced ejection fractions identifies a high-risk group who may benefit from ICD implantation. Ambulatory ECG may be indicated in this population.

EFFICACY OF ANTIARRHYTHMIC THERAPY.

Ambulatory ECG is considered appropriate for assessment of the efficacy of antiarrhythmic therapy in some patients with frequent, reproducible arrhythmia (see Table 23-G-1) but the ACC/AHA guidelines recognize the lack of correlation between arrhythmia suppression after an intervention and subsequent clinical outcome. In the absence of clinical trial data demonstrating that antiarrhythmic agents that suppress arrhythmia

TABLE 23--G-1 -- ACC/AHA GUIDELINES FOR AMBULATORY ELECTROCARDIOGRAPHY

Indication	Class I	Class IIa	Class IIb	Class III
To assess symptoms possibly related to rhythm disturbances	Patients with unexplained syncope, near syncope, or episodic dizziness in whom the cause is not obvious Patients with unexplained recurrent palpitations		Patients with episodic shortness of breath, chest pain, or fatigue that is not otherwise explained Patients with neurological events when transient atrial fibrillation or flutter is suspected Patients with symptoms such as syncope, near syncope, episodic dizziness, or palpitations in whom a probable cause other than arrhythmia has been identified but in whom symptoms persist despite treatment of this other cause	Patients with symptoms such as syncope, near syncope, episodic dizziness, or palpitations in whom other causes have been identified by history, physical examination, or laboratory tests Patients with recurrent cerebrovascular accidents, without other evidence of arrhythmia
Use of ambulatory electrocardiography for arrhythmia detection to assess risk for future cardiac events in patients without symptoms from arrhythmia	None		Post-MI patients with LV dysfunction Patients with CHF Patients with idiopathic hypertrophic cardiomyopathy	Patients who have sustained myocardial contusion Systemic hypertensive patients with LV hypertrophy Post-MI patients with normal LV function Preoperative arrhythmia evaluation of patients for noncardiac surger Patients with sleep apnea Patients with valvular heart disease
Use of HRV to assess risk for future cardiac events in patients without symptoms from arrhythmia	None		Post-MI patients with LV dysfunction Patients with CHF Patients with idiopathic hypertrophic cardiomyopathy	Post-MI patients with normal LV function Diabetic subjects to evaluate for diabetic neuropathy Patients with rhythm disturbances that preclude HRV analysis (i.e., atrial fibrillation)
To assess antiarrhythmic therapy	To assess antiarrhythmic drug response in individuals in whom baseline frequency of arrhythmia has been well characterized as reproducible and of sufficient frequency to permit analysis	To detect proarrhythmic responses to antiarrhythmic therapy in high-risk patients	To assess rate control during atrial fibrillation To document recurrent symptomatic or asymptomatic nonsustained arrhythmias during therapy in the outpatient setting	None
For ischemia monitoring	None	Patients with suspected variant angina	Evaluation of patients with chest pain who cannot exercise Preoperative evaluation for vascular surgery in patients who cannot exercise Patients with known CAD and atypical chest pain syndrome	Initial evaluation of patients with chest pain who are able to exercise Routine screening of asymptomatic patients

Implantable loop recorders are just being evaluated and may cause modifications of the above recommendations.

ACC/AHA = American College of Cardiology/American Heart Association; CAD = coronary artery disease; CHF = congestive heart failure; HRV = heart rate variability; LV = left ventricular; MI = myocardial infarction.

From Crawford MH, Bernstein SJ, Deedwania PC, et al: ACC/AHA guidelines for ambulatory electrocardiography: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the Guidelines for Ambulatory Electrocardiography. J Am Coll Cardiol 34:913, 1999. Reprinted with permission from the American College of Cardiology.

also improve survival, the usefulness of a test that documents arrhythmia suppression is moot at best. ICDs offer an alternative strategy for treatment of life-threatening arrhythmias, and ambulatory ECG is rarely needed to assess the function of these devices.

Although the role of antiarrhythmic drugs for the treatment of supraventricular tachycardia is more clear, the role of ambulatory ECG in such patients is limited by the fact that most patients do not have episodes of sustained arrhythmia every day. However, event recorders

can be useful for documenting the relationship between recurrent arrhythmia and the interval between episodes, which is a useful measure of drug efficacy.

The ACC/AHA guidelines reflect some support for the use of ambulatory ECG for detection of proarrhythmic responses to drug therapy in patients at high risk for such complications. However, patients at high risk for proarrhythmia frequently undergo initiation of therapy as inpatients with continuous ECG monitoring.

ASSESSMENT OF PACEMAKER AND ICD FUNCTION.

The role of ambulatory ECG for assessment of the function of pacemakers and ICDs is being eroded by the increasingly sophisticated diagnostic and monitoring functions of these devices themselves. However, ambulatory ECG can provide useful information by correlating symptoms with device activity and by detecting abnormalities in sensing and capture during chronic follow-up. For example, ambulatory ECG can help prolong the longevity of devices by assessing function after reprogramming of output parameters. Nevertheless, in the long run, ambulatory ECG will probably be used even more rarely for assessment of these devices.

MONITORING FOR MYOCARDIAL ISCHEMIA.

The 1999 ACC/AHA guidelines do not unequivocally support any indications for routine clinical use of ambulatory ECG monitoring for myocardial ischemia. The only indication that was rated as high as Class IIa was detection of ischemia in patients with suspected variant angina. The guidelines gave particular emphasis to the multiple causes of false-positive test results, as well as the marked day-to-day variability in the frequency and duration of ST depression and ischemic episodes. Because of complex technical requirements and diagnostic criteria, the guidelines recommend that ambulatory ECG to detect myocardial ischemia be performed only by laboratories and personnel with specific training in this area.

ELECTROPHYSIOLOGICAL PROCEDURES

ACC/AHA guidelines for the use of intracardiac electrophysiological procedures were first published in 1989[4] and, because of rapid evolution in this field, were revised in 1995.[5] The more recent version of these guidelines reflects the emerging importance of catheter ablation as a therapeutic strategy and primary treatment option for most forms of paroxysmal supraventricular tachycardia and preexcitation syndromes and in patients with monomorphic ventricular tachycardia and structurally normal hearts. The new guidelines also reflect progress in understanding the role of electrophysiological studies for risk stratification of patients with tachyarrhythmias and emphasize consideration of whether the test is likely to influence management decisions.

The ACC/AHA task force used a three-category system for assessment of appropriateness (see below).

The ACC/AHA guidelines identified a narrow list of indications for which electrophysiological testing was clearly appropriate for guiding drug therapy: sustained ventricular tachycardia or cardiac arrest, especially among patients with prior myocardial infarction, and supraventricular tachyarrhythmias associated with reentry loops and/or accessory pathways. However, the ACC/AHA guidelines reflect the increasing importance of electrophysiological testing as a prelude to interventions such as implantable electrical devices and catheter ablation.

EVALUATION OF SINUS NODE FUNCTION

Clinical evaluation of sinus node dysfunction is often difficult because of the episodic nature of symptomatic abnormalities and the finding that asymptomatic patients frequently have wide variability in sinus node rates. Invasive tests of sinus node function can test the ability of the sinus node to recover from overdrive suppression (sinus node recovery time) and assess sinoatrial conduction by introducing atrial extrastimuli or by atrial pacing. These tests can be used to complement data from noninvasive testing, including ambulatory ECG, exercise testing, and tilt-table testing to assess chronotropic incompetence.

The ACC/AHA guidelines considered electrophysiological studies of sinus node function most appropriate for patients in whom dysfunction was suspected but not proved despite a noninvasive evaluation; conversely, such studies would be inappropriate (Class III) when bradyarrhythmias had been proved to be the cause of symptoms and electrophysiological studies would not alter treatment. When bradyarrhythmias were recognized as the cause of the patient's symptoms, electrophysiological studies were considered to have possible, but uncertain appropriateness (Class II) when data might refine treatment choices. These procedures were deemed inappropriate for asymptomatic patients who have bradyarrhythmias observed only during sleep.

ACQUIRED ATRIOVENTRICULAR BLOCK

Electrophysiological studies permit evaluation of conduction above, within, and below the His bundle. This information can be useful to clinicians because patients with atrioventricular (AV) block that is lower in the conduction system tend to have a worse prognosis. However, both prognosis and the level at which AV block is occurring can often be predicted from ECG data.

Therefore, the ACC/AHA guidelines emphasized that electrophysiological studies are inappropriate (Class III) when ECG findings correlate with symptoms and the findings from electrophysiological studies are unlikely to alter therapy. For example, if a patient warrants implantation of a pacemaker because of documented symptomatic advanced AV block, documentation of His bundle conduction will rarely contribute to management. Similarly, electrophysiological studies are not appropriate for asymptomatic patients with mild degrees of AV block who are not likely to warrant pacemaker implantation. According to these guidelines, electrophysiological studies of AV conduction should be performed when a relationship between symptoms and AV block has not been proved; in such patients, another arrhythmia could be the cause of symptoms.

CHRONIC INTRAVENTRICULAR CONDUCTION DELAY

Patients who have prolonged H-V intervals have an increased risk for the development of complete trifascicular block, but the specificity of the H-V interval for predicting the development of complete block among patients with bifascicular block is only about 63%.[5] The use of rapid atrial pacing can improve the specificity of this test, but the annual incidence of progression to complete trifascicular block is low unless patients are exposed to intervening events (e.g., drugs) that adversely affect intracardiac conduction. Therefore, the main role for electrophysiological testing in this population, according to the ACC/AHA guidelines, is not to predict future complications but to determine whether the symptoms of arrhythmia are due to conduction delay versus some other arrhythmia.

The only Class I (clearly appropriate) indication for electrophysiological testing in patients with intraventricular conduction delay according to the ACC/AHA guidelines is determination of the cause of symptoms. These guidelines discouraged the use of electrophysiological testing in asymptomatic patients with conduction system delay. Testing of asymptomatic patients in whom treatment with drugs that could increase conduction delay is being considered was regarded as being of uncertain appropriateness (Class II).

NARROW AND WIDE COMPLEX QRS TACHYCARDIAS.

In narrow QRS tachycardia, the site of abnormal impulse formation or the reentry circuit can be located in the sinus node, in the atria, in the AV node-His bundle axis, or in the accessory pathway. The correct diagnosis can often be made from information from the 12-lead ECG, particularly when the ECG is combined with vagal maneuvers. In contrast, wide QRS tachycardias can be caused by ventricular or supraventricular arrhythmias, and identifying the site of origin of the tachycardia is frequently impossible with ECG tracings alone.

As a result, electrophysiological testing plays different roles in these two types of tachycardias. In patients with wide complex tachycardias, electrophysiological testing permits accurate diagnosis in virtually all patients. Since knowledge of the mechanism of the arrhythmia is essential for selection of the best therapeutic strategy, use of electrophysiological testing was considered appropriate (Class I) for the diagnosis of wide complex tachycardias by the ACC/AHA task force. However, when the diagnosis is already clear from other data, electrophysiological testing is unlikely to influence therapy, and these procedures are not generally useful.

In patients with narrow QRS tachycardias, electrophysiological testing was considered more appropriate as a guide to therapy than as a tool for diagnosis. Therefore, Class I indications for such testing include patients with recurrent tachycardia in whom data from electrophysiological testing may help clinicians choose among drug therapy, catheter ablation, pacing, or surgery. However, the ACC/AHA task force did not believe that electrophysiological testing was useful for patients who have narrow complex tachycardias that are well controlled with medications and who are not candidates for nonpharmacological therapy.

OTHER CONDITIONS

PROLONGED QT INTERVALS.

The ACC/AHA task force concluded that electrophysiological testing has a limited role in the evaluation of congenital or acquired forms of prolonged QT syndrome. Whether catecholamine infusion during testing can unmask patients who are at high risk for complications or whether electrophysiological testing can be used to evaluate proarrhythmic effects in this population is unclear. Therefore, no indication for electrophysiological testing for this problem was called clearly appropriate.

WOLFF-PARKINSON-WHITE SYNDROME.

Electrophysiological studies can be used in patients with this syndrome to determine the mechanism of arrhythmia, assess the electrophysiological properties of the accessory pathway, and evaluate the location and response of accessory pathways to drugs. Therefore, electrophysiological studies were considered appropriate by the ACC/AHA task force for patients who were candidates for catheter or surgical ablation, for those who had had cardiac arrests or unexplained syncope, or for patients whose management might be altered by knowledge of the electrophysiological properties of the accessory pathway and normal conduction system. For asymptomatic patients, however, electrophysiological testing was deemed inappropriate except in special situations, such as patients with high-risk occupations or those with a family history of sudden cardiac death.

NONSUSTAINED VENTRICULAR TACHYCARDIA.

For patients with ventricular premature complexes, couplets, and nonsustained ventricular tachycardia, the usefulness of electrophysiological testing is compromised by the lack of therapeutic strategies that have been shown to improve outcome. There were no indications for which the ACC/AHA task force agreed that electrophysiological testing was clearly useful in this patient population, and these tests were considered inappropriate for patients with no or only mild symptoms. (An exception is a patient who fits the MADIT or MUSTT criteria.) For certain patients with other data suggesting an adverse prognosis, electrophysiological testing was believed to have possible but unproven appropriateness (Class II).

UNEXPLAINED SYNCOPE.

Among patients with structural heart disease, arrhythmia is an important cause of syncope and a worrisome prognostic sign. Therefore, electrophysiological testing is highly useful for the evaluation of syncope in this patient population. In contrast, among patients without structural heart disease, an arrhythmic cause of syncope is uncommon, and the yield of electrophysiological testing is low. Therefore, the ACC/AHA guidelines recommend a higher threshold for the use of electrophysiological testing in patients without known heart disease and suggest that head-up tilt testing may provide more useful data in this population.

SURVIVORS OF CARDIAC ARREST.

Electrophysiological testing is frequently used for patients who have survived cardiac arrest to assess prognosis and identify drugs that suppress inducible arrhythmia. The assumption that these data can be used to improve patient outcome has been called into question by data from the Electrophysiologic Study Versus Electrocardiographic Monitoring Trial.[6] Nevertheless, electrophysiological testing was considered appropriate by the ACC/AHA task force for patients who survived cardiac arrest without evidence that the event was directly provoked by ischemia or myocardial infarction. These tests were deemed inappropriate when the cardiac arrest was closely associated with acute ischemic syndromes or other specific causes.

UNEXPLAINED PALPITATIONS.

The procedure of choice to determine the cause of palpitations, according the ACC/AHA guidelines, is ambulatory ECG. Electrophysiological testing should be reserved for patients with associated syncope or those in whom ECGs have failed to capture a cause of the palpitations but who have been noted to have a rapid pulse rate by medical personnel. Electrophysiological testing is of equivocal value in patients whose symptoms are so sporadic that they cannot be documented while ambulatory ECGs are being performed.

APPROPRIATENESS OF CATHETER ABLATION PROCEDURES

Catheter ablation of the AV junction or accessory pathways is a rapidly advancing technology that has been reviewed in guidelines and position papers from several organizations, including the American Medical Association,[7] the ACC,[8] the North American Society of Pacing and Electrophysiology,[9] and an ACC/AHA task force.[5] The ACC/AHA task force identified several conditions for which they considered catheter ablation an appropriate strategy (Table 23-G-2) . The characteristics that are common among appropriate indications include supraventricular arrhythmias that are symptomatic; that cannot be controlled with medications because of either limited effectiveness, side effects, or inconvenience; or that have caused sudden cardiac death. Catheter ablation is also useful for some patients with ventricular tachycardia, although patients with extensive structural heart disease tend to have multiple sites of origin of their arrhythmia and may therefore be poor candidates for this procedure.

TABLE 23--G-2 -- ACC/AHA GUIDELINES FOR CLINICAL INTRACARDIAC ELECTROPHYSIOLOGICAL STUDIES (1995)

Setting	Class I (Appropriate)	Class II (Equivocal)	Class III (Inappropriate)
Evaluation of sinus node function	Symptomatic patients in whom sinus node dysfunction is suspected to be the cause of symptoms but a casual relation between an arrhythmia and the symptoms has not been established after appropriate evaluation	Patients who have documented sinus node dysfunction in whom evaluation of AV or Va conduction or susceptibility to arrhythmias may aid in selection of the most appropriate pacing modality Patients with ECG-documented sinus bradyarrhythmias to determine whether the abnormalities are due to intrinsic disease, autonomic nervous system dysfunction, or the effects of drugs in order to help select therapeutic options Symptomatic patients with known sinus bradyarrhythmias to evaluate the potential for other arrhythmias as the cause of their symptoms	Symptomatic patients in whom an association between symptoms and a documented bradyarrhythmia has been established and the choice of therapy would not be affected by the results of an EP study Asymptomatic patients with sinus bradyarrhythmias or sinus pauses observed only during sleep, including sleep apnea
Patients with acquired AV block	Symptomatic patients in whom His-Purkinje block, suspected as a cause of symptoms, has not been established Patients with second- or third-degree AV block treated with a pacemaker who remain symptomatic and in whom another arrhythmia is suspected as a cause of symptoms	Patients with second- or third-degree AV block in whom knowledge of the site of block or its mechanism or the response to pharmacological or other temporary intervention may help direct therapy or assess prognosis Patients with premature concealed junctional depolarizations suspected as a cause of the second- or third-degree AV block pattern (i.e., pseudo-AB block)	Symptomatic patients in whom the symptoms and the presence of AV block are correlated by ECG findings Asymptomatic patients with transient AV block associated with sinus slowing (e.g., nocturnal type I second-degree AV block)
Patients with chronic intraventricular conduction delay	Symptomatic patients in whom the cause of the symptoms is not known	Asymptomatic patients with bundle branch block in whom pharmacological therapy is contemplated with a drug that could increase conduction delay or produce a heart attack	Asymptomatic patients with intraventricular conduction delay Symptomatic patients in whom the symptoms can be correlated with or excluded by ECG events

Patients with a narrow QRS tachycardia (QRS complex <0.12 seconds)	Patients with frequent or poorly tolerated episodes of tachycardia not adequately responding to drug therapy in whom information about the site of origin, mechanism, and EP properties of the pathways of the tachycardia is essential for choosing appropriate therapy (drugs, catheter ablation, pacing, or surgery) Patients who prefer ablative therapy to pharmacological management	Patients with frequent episodes of tachycardia requiring drug treatment in whom there is concern about proarrhythmia or the effects of the antiarrhythmic drugs on the sinus node or on AV conduction	Patients whose tachycardias are easily controlled by vagal maneuvers and/or well-tolerated drug therapy and who are not candidates for nonpharmacological forms of therapy
Patients with wide complex tachycardias	Patients with wide QRS tachycardias when the correct diagnosis is unclear after analysis of available ECG tracings and when knowledge of the correct diagnosis is necessary for appropriate patient care	None	Patients with VT or SVT and aberrant conduction or preexcitation syndromes that are diagnosed with certainty by ECG criteria and in whom invasive EP data would not influence therapy. Data obtained at baseline EP study in these patients might be appropriate, however, as a guide to subsequent therapy (see sections on therapy)
Patients with a prolonged QT interval syndrome	None	Identification of a proarrhythmic effect of antiarrhythmics drugs in a patient experiencing sustained VT or cardiac arrest while receiving the drug Patients who have equivocal abnormalities in QT interval duration or TU wave configuration along with syncope or symptomatic arrhythmias and in whom catecholamine effects may unmask a distinct QT abnormality	Patients with clinically manifested congenital QT prolongation with or without symptomatic arrhythmias Patients with acquired prolonged QT syndrome and symptoms closely related to an identifiable cause or mechanism
Patients with the Wolff-Parkinson-White syndrome	Patients being evaluated for catheter ablation or surgical ablation of an accessory pathway Patients with ventricular preexcitation who have survived cardiac arrest or who have unexplained syncope Symptomatic patients in whom determination of the mechanism of arrhythmia or knowledge of the EP properties of the accessory pathway and normal conduction system would help in determining appropriate therapy	Asymptomatic patients with ventricular preexcitation but no spontaneous arrhythmia who engage in high-risk occupations or activities and in whom knowledge of the EP properties of the accessory pathway or inducible tachycardia may help determine the recommendation for further activities or therapy or those who have a family history of sudden cardiac death Patients with ventricular preexcitation who are undergoing cardiac surgery for other reasons	Asymptomatic patients with ventricular preexcitation, except those in Class II
Patients with ventricular premature complexes, couplets, and nonsustained VT	None	Patients with other risk factors for further arrhythmic events, such as a low ejection fraction, positive signal-averaged ECG, and nonsustained VT on ambulatory ECG recordings in whom EP studies will be used for further risk assessment and for guidance of therapy in patients with inducible VT Patients with highly symptomatic, uniform-morphology ventricular premature complexes, couplets, and nonsustained VT who are considered potential candidates for catheter ablation	Asymptomatic or mildly symptomatic patients with premature ventricular complexes, couplets, and nonsustained VT without other risk factors for sustained arrhythmias
Patients with unexplained syncope	Patients with syncope that remains unexplained after appropriate evaluation and who are suspected to have structural heart disease	Patients with recurrent unexplained syncope without structural heart disease and a negative head-up tilt test	Patients with known cause of syncope in whom treatment will be guided by EP testing
Survivors of cardiac arrest	Patients surviving an episode of cardiac arrest without evidence of an acute Q wave myocardial infarction Patients surviving an episode of cardiac arrest occurring 48 hr after acute myocardial infarction	Patients surviving cardiac arrest caused by bradyarrhythmia Patients surviving cardiac arrest thought to be associated with a congenital repolarization abnormality (long QT syndrome) in whom the results of noninvasive diagnostic testing are equivocal	Patients surviving a cardiac arrest that occurred during the acute phase (<48 hr) of myocardial infarction Patients with cardiac arrest resulting from clearly definable specific causes such as reversible ischemia, severe valvular aortic stenosis, or noninvasively defined congenital or acquired long QT syndrome
Patients with unexplained palpitations	Patients with palpitations who have a pulse rate that has been documented by medical personnel to be inappropriately rapid and in whom ECG recordings fail to document the cause of the palpitations Patients with palpitations preceding a syncopal episode	Patient with clinically significant palpitations suspected to be of cardiac origin and in whom the symptoms are sporadic and cannot be documented. Studies are performed to determine the mechanisms of arrhythmias, direct or provide therapy, or assess prognosis	Patients with palpitations documented to be due to extracardiac causes (e.g., hyperthyroidism)
Guidance of drug therapy	Patients with sustained VT or cardiac arrest, especially those with prior myocardial infarction Patients with AVNRT, AV reentrant tachycardia using an accessory pathway, or atrial fibrillation associated with an accessory pathway in whom chronic drug therapy is involved	Patients with sinus node reentrant tachycardia, atrial tachycardia, atrial fibrillation, or atrial flutter without ventricular preexcitation syndrome in whom chronic drug therapy is planned Patients with arrhythmias not inducible during control EP study in whom drug therapy is planned	Patients with isolated atrial or ventricular premature complexes Patients with ventricular fibrillation with a clearly identified reversible cause

Patients who are candidates for or who have implantable electrical devices	In patients with tachyarrhythmias, prior to and during implantation and final (predischarge) programming of an electrical device to confirm the ability of the system to perform as anticipated Patients in whom an electrical device has been implanted and in whom changes in patient status or therapy may have influenced continued safety and efficacy of the device In patients who have a pacemaker to treat a bradyarrhythmia, and receive a cardioverter-defibrillator to test for device interactions	Patients with previously documented indications for pacemaker implantation to test for the most appropriate chronic pacing mode and sites to optimize symptomatic improvement and hemodynamics	Patients who are not candidates for device therapy
Indications for catheter ablation procedures	Patients with symptomatic atrial tachyarrhythmias who have inadequately controlled ventricular rates *unless* primary ablation of the atrial tachyarrhythmia is possible Patients with symptomatic atrial tachyarrhythmias, such as those above, but when drugs are not tolerated or the patient does not wish to take them even though the ventricular rate can be controlled Patients with symptomatic nonparoxysmal junctional tachycardia that is drug resistant, drugs are not tolerated, or the patient does not with to take them Patients resuscitated from sudden cardiac death caused by atrial flutter or atrial fibrillation with a rapid ventricular response in the absence of an accessory pathway	Patients with a dual-chamber pacemaker and pacemaker-mediated tachycardia that cannot be treated effectively by drugs or by reprogramming the pacemaker	Patients with atrial tachyarrhythmias responsive to drug therapy that is acceptable to the patient
Radiofrequency catheter ablation for AVNRT	Patients with symptomatic sustained AVNRT that is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy	Patients with sustained AVNRT identified during EP study or catheter ablation of another arrhythmia The finding of dual--AV nodal pathway physiology and atrial echos but without AVNRT during EP study in a patient suspected to have AVNRT clinically	Patients with AVNRT that is responsive to drug therapy and the therapy is well tolerated and preferred by the patient to ablation The finding of dual--AV nodal pathway physiology (with or without echo complexes) during EP study in a patient in whom AVNRT is not suspected clinically
Ablation of atrial tachycardia, flutter, and fibrillation: Atrium/atrial sites	Patients with atrial tachycardia that is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy Patients with atrial flutter that is drug resistant or when the patient is drug intolerant or not desire long-term drug therapy	Atrial flutter/atrial tachycardia associated with paroxysmal atrial fibrillation when the tachycardia is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy Patients with atrial fibrillation in whom there is evidence of (a) localized site(s) of origin when the tachycardia is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy	Patients with atrial arrhythmia responsive to drug therapy and the therapy is well tolerated and preferable to the patient than ablation Patients with multiform atrial tachycardia
Ablation of atrial tachycardia, flutter, and fibrillation: Accessory pathways	Patients with symptomatic AV reentrant tachycardia that is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy Patients with atrial fibrillation (or other atrial tachyarrhythmia) and a rapid ventricular response via the accessory pathway when the tachycardia is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy	Patients with AV reentrant tachycardia or atrial fibrillation with rapid ventricular rates identified during EP study of another arrhythmia Asymptomatic patients with ventricular preexcitation whose livelihood, profession, important activities, insurability, or mental well-being or the public safety would be affected by spontaneous tachyarrhythmias of by the presence of the ECG abnormality Patients with atrial fibrillation and a controlled ventricular response via the accessory pathway Patients with a family history of sudden cardiac death	Patients who have accessory pathway-related arrhythmias that are responsive to drug therapy and the therapy is well tolerated and preferable to ablation by the patient
Ablation of VT	Patients with symptomatic sustained monomorphic VT when the tachycardia is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy Patient with bundle branch ventricular reentrant tachycardia Patients with sustained monomorphic VT and an ICD who are receiving multiple shocks not manageable by reprogramming or concomitant drug therapy	Nonsustained VT that is symptomatic when the tachycardia is drug resistant or when the patient is drug intolerant or does not desire long-term drug therapy	Patients with Vt that is responsive to drug, ICD, or surgical therapy and that therapy is well tolerated and preferable to ablation by the patient Unstable, rapid, multiple, or polymorphic VT that cannot be adequately localized by present mapping techniques Asymptomatic and clinically benign nonsustained VT

ACC/AHA = American College of Cardiology/American Heart Association; AV = atrioventricular; AVNRT = AV nodal reentrant tachycardia; ECG = electrocardiographic; EP = electrophysiological; ICD = implantable cardioverter-fibrillator; SVT = supraventricular tachycardia; VA = ventriculoatrial; VT = ventricular tachycardia.

Chapter 24 - Cardiac Pacemakers and Cardioverter-Defibrillators

DAVID L. HAYES
DOUGLAS P. ZIPES

Cardiac pacing has evolved rapidly since its inception in the late 1950s. The collective intelligence of creative biomedical engineers and clinicians, coupled with the advent and increasing sophistication of the microprocessor, has made this possible. What began with asynchronous ventricular pacing as a therapy for patients with Stokes-Adams attacks has made momentous strides every decade. Similar to what has happened in other highly technical fields, many times in the past 20 years it was believed that the ultimate pacemaker had been designed and there was little possibility of further improvement. Each time, the "next generation" of devices yielded greater sophistication, more variables, and the ability to better tailor the device to the needs of the patient. Most recently, we have witnessed a number of new indications for pacing that are based not on the need to treat bradycardia but on an attempt to improve hemodynamics. Investigation into the arenas of pacing for hemodynamic improvement is truly in its infancy and, without doubt, will yield even more technological improvements in cardiac pacemakers.

The rapid technological advancements in cardiac pacemakers have, at least to some degree, served as a catalyst for an even faster evolution in implantable cardioverter-defibrillators (ICDs). Considering that the first human cardioverter-defibrillator implantation occurred in 1979, the evolution of this technology has been staggering. The initial implants were large pulse generators capable of defibrillation, but that required open-chest implantation techniques. Only 20 years later, ICDs are now a fraction of the size, implanted almost exclusively by transvenous techniques in the same manner as permanent pacemakers, and capable of many options, including multiple programmable therapies for ventricular tachycardia and ventricular fibrillation, dual-chamber rate-responsive pacing, and atrial defibrillation.

As the technology for both pacemakers and ICDs has evolved and potential indications have expanded, clinical trials have been crucial to prove efficacy. Clinical trials were uncommon in this field before the 1990s but are now an integral part of the discipline of implantable device therapy and will remain so as we see further innovative improvements in the years to come.

PACEMAKER NOMENCLATURE

Current pacemaker nomenclature established by members of the North American Society of Pacing and Electrophysiology (NASPE) and the British Pacing and Electrophysiology Group (BPEG) is designated the NBG code for pacing nomenclature (Table 24-1) .[1] The code has five positions, but the fifth position is restricted to antitachycardia functions and is rarely used. It is a generic code and does not describe specific or unique functional characteristics of each device.

The first position reflects the chamber or chambers in which stimulation occurs: A = atrium; V = ventricle; and D = dual chamber, or both A and V.

The second position refers to the chamber or chambers in which sensing occurs. The letters are the same as those for the first position. (Manufacturers also use "S" in both the first and the second positions to indicate that the device is capable of pacing only a single cardiac chamber.)

TABLE 24-1 -- NBG* CODE

I **Chamber(s) Paced**	II **Chamber(s) Sensed**	III **Response to Sensing**	IV **Programmability, Rate Modulation**
O = None	O = None	O = None	O = None
A = Atrium	A = Atrium	T = Triggered	P = Simple programmable
V = Ventricle	V = Ventricle	I = Inhibited	M = Multiprogrammable
D = Dual (A+V)	D = Dual (A+V)	D = Dual (T+I)	C = Communicating
			R = Rate modulation

Modified from Bernstein AD, Camm AJ, Fletcher RD, et al: The NASPE/BPEG generic pacemaker code for antibradyarrhythmia and adaptive-rate pacing and antitachyarrhythmia devices. Pacing Clin Electrophysiol 10:794, 1987. By permission of Futura Publishing Company.

*The North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group.

The third position refers to the mode of sensing, or how the pacemaker responds to a sensed event. An "I" indicates that a sensed event inhibits the output pulse and causes the pacemaker to recycle for one or more timing cycles. "T" means that an output pulse is triggered in response to a sensed event. "D" means that both "T" and "I" responses can occur. This designation is restricted to dual-chamber systems. An event sensed in the atrium inhibits the atrial output but triggers a ventricular output. Unlike a single-chamber triggered mode (VVT or AAT), in which an output pulse is triggered immediately on sensing, a dual-chamber mode has a delay between the sensed atrial event and the triggered ventricular output to mimic the normal PR interval. If a native ventricular signal or R wave is sensed, the ventricular output and possibly even the atrial output are inhibited, depending on where sensing occurs.

The fourth position of the code reflects both programmability and rate modulation. An "R" in the fourth position indicates that the pacemaker incorporates a sensor to modulate the rate independently of intrinsic cardiac activity, such as with activity or respiration. From a practical standpoint, "R" is the only indicator commonly used in the fourth position. Other indicators are described in Table 24-1 .

INDICATIONS FOR CARDIAC PACING

Criteria established by a joint committee of the American College of Cardiology (ACC) and the American Heart Association (AHA) have established indications for pacing into categories of "generally indicated," "may be indicated," and "not indicated."[2] Although some indications for permanent pacing are relatively certain or unambiguous, others require considerable expertise and judgment.[3] The clinician prescribing permanent pacing systems should be aware of the published indications

and controversies regarding indications.

The clinical need for pacing and appropriate objective data, such as electrocardiographic (ECG) tracings, must be clearly documented in the patient's medical record to ensure reimbursement by Medicare or third-party payers.

Indications are considered in categories of acquired atrio-ventricular (AV) block, congenital AV block, chronic bifascicular and trifascicular block, sinus node dysfunction, and neurocardiogenic syndromes. Currently, sinus node dysfunction is the most frequent indication for pacing, followed by AV node dysfunction. Pacing for tachyarrhythmias and miscellaneous indications comprises a relatively small percentage. Potential hemodynamic indications for permanent pacing are discussed separately.

Acquired AV Block

AV block is classified traditionally into first-, second-, and third-degree (or complete) heart block. Alternatively, it can be defined anatomically as supra-, intra-, or infra-Hisian. If the QRS complex is prolonged more than 0.12 second, there is a greater probability that the conduction disturbance is infra-Hisian. Acquired AV block is most commonly idiopathic and related to aging, but there are many potential causes (Table 24-2) (see Chap. 25). Indications for permanent pacing in acquired AV block are listed in Table 24-3 .

Indications for permanent pacing for AV block that occurs with an acute myocardial infarction are more controversial. A pacemaker is generally considered indicated if complete AV block, Mobitz type II block, or bilateral or alternating bundle branch block persists for more than 72 hours after the acute event. Some clinicians consider new and persistent bifascicular block an indication for pacing, and others consider pacing for a new left anterior or left posterior hemiblock alone (see Chap. 35).

TABLE 24-2 -- CAUSES OF ACQUIRED ATRIOVENTRICULAR (AV) BLOCK

Idiopathic (senescent) AV block
Coronary artery disease
Calcific valvular disease
Postoperative or traumatic
AV node ablation
Therapeutic irradiation of the chest
Infectious
Syphilis
Diphtheria
Chagas' disease
Tuberculosis
Toxoplasmosis
Lyme disease*
Viral myocarditis (e.g., Epstein-Barr, varicella)
Infective endocarditis
Collagen vascular
Rheumatoid arthritis
Scleroderma
Dermatomyositis
Ankylosing spondylitis
Polyarteritis nodosa
Systemic lupus erythematosus
Marfan syndrome
Infiltrative
Sarcoidosis
Amyloidosis
Hemochromatosis
Malignancy (lymphomatous or solid tumor)
Neuromuscular
Progressive external ophthalmoplegia (Kearns-Sayre syndrome)
Myotonic muscular dystrophy
Peroneal muscular atrophy (Charcot-Marie-Tooth disease)
Scapuloperoneal syndrome
Limb-girdle dystrophy
Drug effect
Digoxin
Beta blockers
Calcium-blocking agents
Amiodarone
Procainamide
Class 1C agents: propafenone, encainide, flecainide
Taxol

*Lyme disease may require temporary cardiac pacing. Lyme disease is not usually an indication for permanent pacing.

Congenital Complete Heart Block

Although some controversy remains about when to pace in congenital complete heart block, there is now a tendency to pace in all these patients and to do so earlier, even if they are asymptomatic. This clinical approach has evolved because of recognition of a high incidence of unpredictable syncope with significant mortality from initial attacks, gradual decrease in heart rate, and a high incidence of acquired mitral insufficiency.[4] In pediatric patients with congenital complete heart block, pacemaker implantation is recommended for congestive heart failure, average heart rate of less than 50 beats/min in the awake infant, history of syncope or

presyncope, significant ventricular ectopy, or exercise intolerance.[5]

Chronic Bifascicular and Trifascicular Block

If bifascicular or trifascicular block is associated with transient complete heart block, whether symptomatic or not, pacing is indicated. Pacing in the patient with bifascicular or trifascicular block and syncope that cannot be attributed to any other cause is a Class II ACC/AHA indication. If only fascicular block is noted in the asymptomatic patient, pacing is not indicated.

TABLE 24-3 -- INDICATIONS FOR PERMANENT PACING IN ATRIOVENTRICULAR (AV) BLOCK

TYPE OF AV BLOCK	PACEMAKER NECESSARY	PACEMAKER PROBABLY NECESSARY	PACEMAKER NOT NECESSARY
Third	Symptomatic congenital CHB		
	Acquired symptomatic CHB		
	Atrial fibrillation with CHB		
	Acquired asymptomatic CHB		
Second	Symptomatic, type I	Asymptomatic, type II	Asymptomatic, type I, at supra-His (AV nodal)* level
	Symptomatic, type II	Asymptomatic, type I, at intra-His or infra-His level	
		Hemodynamically symptomatic due to loss of AV synchrony	
First		Hemodynamically symptomatic due to effective loss of AV synchrony with markedly prolonged PR interval (e.g., >300 msec)	Asymptomatic

CHB = complete heart block.

*An exception may be in the elderly with asymptomatic type I AV block.

Sinus Node Dysfunction

Tachycardia-bradycardia syndrome, sick sinus syndrome, symptomatic sinus bradycardia, sinus arrest and sinus pauses, and chronotropic incompetence are all variants of sinus node dysfunction, and often the terms are used synonymously. The definition of bradycardia varies but is generally accepted to be rates of less than 40 beats/min during waking hours. There is disagreement about the absolute cycle length at which pacing should be considered. Although every patient needs to be considered individually, most experts would agree that sinus pauses exceeding 3 seconds during waking hours should be considered abnormal and may warrant pacing. Pauses that occur during sleep are more difficult to categorize. Because of vagal influences, many normal persons display pauses significantly longer than 3 seconds during sleep, and 3-second pauses without symptoms or rhythm disturbances during waking hours should not require treatment. Permanent pacing should be considered for any patient who has symptomatic bradyarrhythmias if the cause of the bradyarrhythmia is not reversible (Table 24-4) .

Permanent pacing for patients with sinus node dysfunction after myocardial infarction is reserved for patients who have symptoms during bradycardia. If drug therapy results in symptomatic bradycardia, criteria for permanent pacing should follow the guidelines given for sinus node dysfunction in Table 24-4 .

Neurocardiogenic Syncope

Permanent pacing may be indicated for some of the several types of neurally mediated syncope.[5A] Neurally mediated syncope includes carotid sinus hypersensitivity and vasovagal syncope (see Chap. 27).

Understanding the physiology involved is crucial to understanding the clinical manifestations.[6] [7] The carotid sinus reflex is the physiological response to pressure exerted on the carotid sinus. Stimulation results in activation of baroreceptors within the wall of the carotid sinus, and they initiate an afferent response. Discharge from vagal efferents then results in cardiac slowing. Although this reflex is physiological, some persons have an exaggerated or even pathological response. This reflex has two components, cardioinhibitory and vasodepressor. A cardioinhibitory response results from increased parasympathetic tone and may be manifested by sinus bradycardia, PR prolongation, or advanced AV block. The vasodepressor response is due to sympathetic withdrawal and secondary hypotension. Although a pure cardioinhibitory or pure vasodepressor response can occur, a mixed response is most common.

Tilt-table testing can provide the physiological environment to reproduce vasovagal syncope. With head-up tilt, susceptible patients have decreased venous return and subsequent decrease in left ventricular filling. This response triggers stimulation of baroreceptors and adrenergic discharge, which can result in efferent vagal discharge and sympathetic withdrawal. Vasodilatation and hypotension as well as cardiac slowing may result. It is important to document whether the predominant cause of symptoms is cardioinhibitory or vasodepressor, because therapy differs. Tilt-table testing is often helpful in determining the predominant cause.

Drugs such as beta blockers are commonly used as first-line therapy. Although significant controversy persists, vasovagal syncope can be aborted or blunted by dual-chamber pacing; and even if syncope does occur, pacing can prolong consciousness to avoid injury.[8] Conversely, the beneficial effect of pacing was challenged in a series of 22 patients with bradycardia during neurocardiogenic syncope in whom pacing failed to prevent a significant drop in blood pressure during a repeat tilt test.[9] Nonetheless, pacing significantly altered symptoms. Of 21 patients with an abnormal response to the initial tilt test, 18 had syncope and 3 had presyncope. During repeat tilt testing, 5 patients experienced syncope, 15 had presyncope, and 1 had no symptoms. Although presyncope was not prevented in most patients, the shift from syncope in 18 patients to syncope in only 5 patients represented significant clinical improvement.

TABLE 24-4 -- INDICATIONS FOR PERMANENT PACING IN SINUS NODE DYSFUNCTION (SND)

PACEMAKER NECESSARY	PACEMAKER PROBABLY NECESSARY	PACEMAKER NOT NECESSARY
Symptomatic sinus bradycardia	Symptomatic patients with SND who have documented rates of <40 beats/min without a clear-cut association between significant symptoms and bradycardia	Asymptomatic SND
Symptomatic sinus bradycardia due to long-term drug therapy of a type and at a dose for which there is no accepted alternative		

TABLE 24-5 -- TRIALS OF PACING THERAPY IN NEUROCARDIOGENIC SYNCOPE

STUDY	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
VPS-1[10]	Six lifetime episodes of syncope *and* Positive HUT test with syncope or presyncope Relative bradycardia	Time to recurrent syncope	Standard drug therapy *vs.* Pacemaker	85% risk reduction for recurrent syncope with pacing
VPS-2	History strongly suggests vasovagal syncope Six lifetime episodes of syncope *or* Three in past 2 yr *or* One episode in past 6 mo *and* Positive HUT test with syncope or presyncope	Time to recurrent syncope Efficacy of rate drop response	Randomization to DDD or no pacing for 6 months or until first episode of syncope Rerandomization to DDD pacing with or without rate drop response	In progress
VASIS[12]	Three syncopal episodes in prior 2 yr Duration of symptoms >6 mo	Recurrence of syncope Recurrence of presyncope Need for secondary PM implant or drug therapy	Dual-chamber pacing with hysteresis *vs.* No pacing (no specific therapy)	In progress
SAFE PACE 2[13]	Age 50 yr Two unexplained falls ±1 syncopal episode in prior 12 mo >3-Sec asystole on CSM No other cause of falls	Recurrent falls Time to first fall Frequency of dizziness or presyncope Health care utilization Quality of life	Pacemaker *vs.* Conventional therapy	In progress
SYDIT[14]	No cardiac disease Age >35 yr Three syncopal spells in preceding 2 yr Positive HUT test with HR 30% and bradycardia 50 beats/min	Recurrence of syncope	Atenolol or etilefrine *vs.* DDD pacing with rate drop response	In progress

CSM, carotid sinus massage; HR
, heart rate decrease; HUT, head-up tilt; PM, pacemaker; SAFE PACE, Syncope and Falls in the Elderly--Pacing and Carotid Sinus Evaluation; SYDIT, Syncope: Diagnosis and Treatment Study; VASIS, Vasovagal Syncope International Study; VPS, North American Vasovagal Pacemaker Study.

In the North American Vasovagal Pacemaker Study (VPS-1),[10] 46 patients with recurrent syncope and a positive tilt test were randomized to dual-chamber pacemaker with a special feature known as "rate drop" or to no pacemaker therapy. (The "rate drop" algorithm allows the pacemaker to pace at a faster rate if bradycardia suddenly occurs.) Stopped prematurely because of the benefit observed with pacemaker therapy, the study revealed that only 17 percent of paced patients had recurrent syncope compared with 59 percent of patients without pacing.

Brignole and coworkers[11] randomized 60 patients with carotid sinus hypersensitivity to pacing or no pacing. At a mean follow-up of 36 months, syncope recurred in 9 percent of paced patients compared with 57 percent of patients without pacing.

Additional trials, North American Vasovagal Pacemaker Study-2 (VPS-2), Vasovagal Syncope International Study (VASIS),[12] and Syncope and Falls in the Elderly-Pacing and Carotid Sinus Evaluation 2 (SAFE PACE 2),[13] are under way to assess pacing therapy in both neurocardiogenic syncope and carotid sinus hypersensitivity (Table 24-5) .

SELECTION OF THE APPROPRIATE PACING MODE

When an indication for pacing has been identified, consideration should be given to selecting the most appropriate pacing mode for the patient. Factors to consider when choosing the pacing mode include

Underlying rhythm disturbance

Overall physical condition

Associated medical problems

Exercise capacity

Chronotropic response to exercise

Effect of pacing mode on long-term morbidity and mortality

Before individual pacing modes and how they can restore rate response or AV synchrony are discussed, the larger issue of the effect of pacing mode on morbidity and mortality should be considered.

An early study by Rosenqvist and associates [15] paved the way for intense clinical interest and subsequent clinical trials on the effect of pacing mode on morbidity and mortality. At 4 years of follow-up, atrial fibrillation had occurred in 47 percent of the patients receiving VVI pacing but in only 7 percent of those receiving AAI pacing (*p*
0.0005); congestive heart failure occurred in 37 percent of the VVI group and in 15 percent of the AAI group (*p*
0.005); and mortality was 23 percent in the VVI group and 8 percent in the AAI group (*p*

0.025).

Many other investigators performed retrospective reviews to assess the effect of pacing mode on mortality. Despite the inherent weaknesses of retrospective analyses, it is difficult to dismiss the similar finding among all the studies of a significantly lower mortality with DDD or AAI pacing than with VVI pacing and significantly lower incidences of atrial fibrillation.[16]

Lamas and associates[17] reported survival in a large population of patients (20,948) with sinus node dysfunction. The population was a random sample of the complete U.S. cohort of Medicare patients paced for sinus node dysfunction in 1988 through 1990. The DDD/DDDR pacing mode was an independent correlate of survival.

A number of prospective trials are now completed or under way.[17A] Results to date are mixed (Table 24-6) . Andersen and colleagues[24] published the first prospective data on pacing mode and survival. In 225 patients (mean age, 76 years) with sinus node dysfunction randomized to AAI or VVI pacing, they demonstrated a higher incidence of atrial fibrillation in the VVI group (14 percent of the AAI group vs. 23 percent of the VVI group; $p = 0.12$) and a higher incidence of thromboembolism in the VVI group than in the AAI group ($p = 0.0083$). Although no difference in mortality could be detected at the initial analysis at 3.3 years, subsequent analysis at 5.5 years showed improved survival and less heart failure in the AAI group.[18] In addition, there was a persistent reduction in the incidences of atrial fibrillation and thromboembolic events.

Lamas and associates[19] subsequently developed a prospective, randomized, single-blind trial, Pacemaker Selection in the Elderly (PASE), to compare DDDR and VVIR pacing modes. There was no statistically significant difference in quality of life between DDDR and VVIR pacing modes, but there was a trend toward improved quality of life in patients with sinus node dysfunction randomized to dual-chamber pacing. Perhaps more significant was a crossover of 26 percent of patients from ventricular pacing to dual-chamber pacing due to pacemaker syndrome.

The PASE study was the template for the subsequent MOST (Mode Selection Trial) study.[21] In this study of 2000 patients with sinus node dysfunction randomized to either VVI or DDD pacing, primary endpoints are all causes of mortality and cerebrovascular accidents. Results are expected in the year 2000.

The Canadian Trial of Physiologic Pacing (CTOPP)[20] compared VVIR with DDDR or AAIR and had primary endpoints of overall mortality and cerebrovascular accidents and secondary endpoints of atrial fibrillation, hospitalizations for congestive heart failure, and death due to a cardiac cause. CTOPP demonstrated that physiological pacing (DDD/AAI) was associated with a reduced rate in the development of chronic atrial fibrillation, from 3.78 to 2.87 percent per year, at the 3-year analysis. However, no difference in quality of life or mortality was demonstrated.

In a smaller trial by Schrepf and coworkers, [25] paroxysmal atrial fibrillation occurred more frequently with VVI pacing than with DDD pacing. However, the Pac-A-Tach trial[26] found no significant difference in recurrence of atrial tachyarrhythmias by intention to treat at 1 year, 48 percent in DDDR and 43 percent in VVI.

TABLE 24-6 -- TRIALS ASSESSING THE EFFECT OF PACING MODE ON MORBIDITY AND MORTALITY

STUDY	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
Danish study[18]	Sick sinus syndrome requiring pacing	Mortality	AAI pacing (n = 110)	Cumulative incidence of cardiovascular death, PAF, chronic AF, and TE events lower with AAI pacing
		Cardiovascular death	*vs.*	Less severe heart failure with AAI
		AF	VVI pacing (n = 115)	Multivariate analysis: AAI associated with freedom from TE events, survival from cardiovascular death
		TE events		
		Heart failure		
		AV block		
PASE[19]	Age 65 yr	QOL	Single-blind, randomized, controlled comparison; VVIR pacing	QOL improved significantly, but no difference between pacing modes
	Need for PPM for prevention or treatment of bradycardia	All-cause mortality	*vs.*	26% pt with VVIR crossover to DDDR due to pacemaker syndrome
		First nonfatal CVA or death		Trends of borderline statistical significance in endpoints favoring DDDR in patient with SND
		First hospitalization for congestive heart failure	DDDR pacing	
		AF		
		Pacemaker syndrome		
CTOPP[20]	Initial pacemaker	Cardiovascular mortality or stroke	DDD/R or AAI/R pacing	No difference in QOL, VVI vs. DDD/AAI
	Life expectancy >1 yr	Paroxysmal or chronic AF	*vs.*	No statistically significant difference in mortality or stroke
	Not in chronic AF	Hospitalization for congestive heart failure	VVI/R pacing	No difference in hospitalizations
			QOL	24% incidence of chronic or paroxysmal AF with DDD/AAI
		6-Minute walk		
MOST[21]	SND requiring pacemaker	Stroke	DDDR	In progress
	NSR or atrial standstill at time of implantation	Health status	*vs.*	
		Cost effectiveness	VVIR	
		Total mortality		
		Cardiovascular mortality		
		AF		
		Heart failure score		
		PM syndrome		
UKPACE[22]	Age 70 yr	All-cause mortality	DDDR (50%)	In progress
	High-grade AV block requiring PPM		*vs.*	
			VVIR (25%)	
			vs.	

			VVI (25%)	
DANPACE[23]	Tachycardia-bradycardia syndrome with normal AV conduction	All-cause mortality	AAIR	In progress
		Cardiovascular mortality	*vs.*	
		Incidence of AF and TE events	DDDR	
		QOL		
		Cost-effectiveness		

AF = atrial fibrillation; AV = atrioventricular; CHF = congestive heart failure; CTOPP = Canadian Trial of Physiologic Pacing; CVA = cardiovascular accident; DANPACE = Danish Pacing Trial; MOST = Mode Selection Trial; NSR = normal sinus rhythm; PAF = paroxysmal atrial fibrillation; PASE = Pacemaker Selection in the Elderly; PPM = permanent pacemaker; QOL = quality of life; SND = sinus node dysfunction; TE = thromboembolic; UKPACE = United Kingdom Pacing and Cardiovascular Events.

Figure 24-1 The VVI timing cycle consists of a defined lower rate limit (LR) and a ventricular refractory period (VRP, represented by triangle). When the LR timer is complete, a pacing artifact is delivered in the absence of a sensed intrinsic ventricular event. If an intrinsic QRS occurs, the LR timer is started from that point. A VRP begins with any sensed or paced ventricular activity.

A prospective, randomized British trial, U.K. PACE, has been initiated to compare DDD with VVI pacing modes in 2000 patients 70 years of age and older requiring permanent pacing for second- or third-degree AV block.[22]

The prospective data to date are inconsistent. Although later analyses of initially negative trial results could potentially minimize the current inconsistencies, definitive statements are difficult to make on the basis of current information.

MODES AND TIMING CYCLES

The advantages and disadvantages of each pacing mode cannot be completely comprehended unless the timing cycle of each is understood.

Single-Chamber Triggered Pacing

Single-chamber triggered pacing (AAT and VVT) releases an output pulse every time a native event is sensed. This feature increases the current drain on the battery, accelerating its rate of depletion, and deforms the inscription of the intrinsic spontaneous complex on the ECG. However, it can serve as an excellent marker for the site of sensing within an intrinsic complex and can prevent inappropriate inhibition from oversensing when the patient does not have a stable escape rhythm. Triggered pacing is used infrequently.

VENTRICULAR INHIBITED PACING (VVI).

This pacing mode incorporates sensing on the ventricular channel, enabling a sensed ventricular event to inhibit pacemaker output (Fig. 24-1) . VVI pacemakers are refractory for an interval after a paced or sensed ventricular event, the ventricular refractory period (VRP). Any ventricular event occurring within the VRP is not sensed and does not reset the ventricular timer.

VVI pacing remains the most commonly used pacing mode worldwide. Although VVI pacing protects the patient from lethal bradycardias, it is significantly limited because it does not restore or maintain AV synchrony and does not provide rate responsiveness in the chronotropically incompetent patient, that is, the patient in whom the spontaneous sinus heart rate does not increase in response to a physiological demand. In addition, some patients with VVI pacing experience symptomatic hemodynamic deterioration during ventricular pacing.[27] [28] Adverse hemodynamics associated with a normally functioning pacing system that cause overt symptoms or limit the patient's ability to achieve optimal functional status are referred to as "pacemaker syndrome" (Fig. 24-2) . Pacemaker syndrome was initially recognized with ventricular (VVI) pacing but can occur with any pacing mode if there is AV dissociation. The incidence of pacemaker syndrome is difficult to determine and depends on how the syndrome is defined. If the definition is restricted to patients with clinical limitations during any pacing mode that results in AV dissociation, the incidence is

Figure 24-2 Hemodynamic tracing from a patient with pacemaker syndrome. In the initial portion of the tracing there is sinus rhythm with intrinsic atrioventricular node conduction with a systolic arterial pressure of approximately 125 mm Hg. This is followed by fusion beats and a progressive decrease in systolic pressure. When the ventricle is completely depolarized by the pacemaker, the systolic pressure decreases to approximately 80 mm Hg. This hemodynamic response is compatible with pacemaker syndrome.

Figure 24-3 The AAI timing cycle consists of a defined lower rate limit (LR) and an atrial refractory period (ARP). When the LR cycle is complete, a pacing artifact is delivered in the atrium in the absence of a sensed atrial event. If an intrinsic P wave occurs, the LR timer is started from that point. An ARP begins with any sensed or paced atrial activity. The AAI timing cycle should not be affected by events in the ventricle. In this schematic example, a premature ventricular contraction (PVC) occurs. Appropriately, it is not sensed by the AAI pacemaker, and the atrial pacing artifact occurs in the T wave of the PVC. Even though atrial capture presumably would occur, there is no ventricular event after the paced atrial event because the ventricle is still refractory. However, the timing cycle will be reset by anything that is sensed on the atrial sensing circuit. In this schematic example, a premature ventricular contraction occurs. It is appropriately not sensed, and the pacing artifact is delivered after the PVC. Even though there appears to be atrial depolarization, no intrinsic ventricular depolarization occurs because the ventricle is refractory.

probably in the range of 7 to 10 percent of patients with VVI pacing.[27] In a study of patients with DDD pacemakers who were randomized to DDD or VVI pacing mode, some degree of pacemaker syndrome was thought to be present in 83 percent.[29] The most common symptoms reported were shortness of breath, dizziness, fatigue, pulsations in the neck or abdomen, cough, and apprehension. It can be concluded from this study that if patients with VVI pacing have some basis for comparison, they may be more aware of symptoms with VVI pacing.

ATRIAL INHIBITED PACING (AAI).

This pacing mode incorporates the same timing cycles, with the obvious difference that pacing and sensing occur from the atrium and pacemaker output is inhibited by a sensed atrial event (Fig. 24-3) . An atrial paced or sensed event initiates a refractory period during which no spontaneous event is sensed by the pacemaker. When the atrial timing cycle ends, the atrial pacing artifact is delivered regardless of ventricular events, because an AAI pacemaker should not sense ventricular events. The single exception to this rule is far-field sensing; that is, the ventricular signal is large enough to be inappropriately sensed by the atrial lead. In this situation, the atrial timing cycle is reset by events sensed in the ventricle. Sometimes this abnormality can be corrected by making the atrial channel less sensitive or by lengthening the refractory period.

AAI pacing is appropriate for patients with sinus node dysfunction and normal AV conduction. The obvious disadvantage of atrial pacing is lack of ventricular support should AV block occur. If the patient with sinus node dysfunction is assessed carefully for AV node disease at the time of pacemaker implantation, the occurrence of clinically significant AV nodal disease is very low, that is, less than 2 percent per year.[30] Assessment before use of an AAI system should include incremental atrial pacing at the time of pacemaker implantation. Although criteria vary among institutions and implanting physicians, the adult patient should be capable of 1-to-1 AV nodal conduction to rates of 120 to 140 beats/min.

Dual-Chamber Pacing

AV sequential, ventricular inhibited pacing (DVI) is rarely used as the preimplantation pacing mode of choice. By definition, DVI provides pacing in both the atrium and the ventricle (D) but sensing only in the ventricle (V). The pacemaker is inhibited and reset by sensed ventricular activity but ignores all intrinsic atrial complexes and therefore prevents atrial tracking. In addition, lack of atrial sensing may lead to competitive atrial pacing and initiation of atrial rhythm disturbances.

AV SEQUENTIAL, NON-P-SYNCHRONOUS PACING.

This pacing mode with dual-chamber sensing (DDI) incorporates atrial sensing, as well as ventricular sensing, which prevents competitive atrial pacing (Fig. 24-4) . The DDI mode of response is inhibition only; that is, no tracking of P waves can occur. Therefore, the programmed rate, which by definition is the lower rate, because only a single rate exists, is the fastest paced rate that can be seen. DDI is rarely the preimplantation mode of choice but remains a programmable option in most dual-chamber pacemakers.[31] The DDI pacing mode could be considered in patients with intermittent atrial tachyarrhythmias, but DDD or DDDR pacing with mode switching is preferable.

ATRIAL SYNCHRONOUS PACING (VDD).

These pacemakers pace only in the ventricle, sense in both chambers, and respond both by inhibition of ventricular output due to intrinsic ventricular activity and by ventricular tracking of P waves. The VDD mode has become increasingly available as a single-lead pacing system. In this system, a single lead is capable of pacing in the ventricle in response to sensing atrial activity by way of a remote electrode situated on the intra-atrial portion of the ventricular pacing lead.[32]

In the VDD mode, sensed atrial events initiate the AV interval (AVI). If an intrinsic ventricular event occurs before the termination of the AVI, ventricular output is inhibited

Figure 24-4 The timing cycle in DDI pacing consists of a lower rate limit, an atrioventricular (AV) interval, a ventricular refractory period (VRP), and an atrial refractory period (ARP). The VRP is initiated by any sensed or paced ventricular activity, and the ARP is initiated by any sensed or paced atrial activity. The lower rate limit cannot be violated even if the sinus rate is occurring at a faster rate. PVARP = postventricular atrial refractory period; VA = ventriculoatrial.

Figure 24-5 The timing cycle of VDD consists of a lower rate limit (LRL), an atrioventricular interval (AVI), a ventricular refractory period, a postventricular atrial refractory period (PVARP), and an upper rate limit. A sensed P wave initiates the AVI (during the AVI the atrial sensing channel is refractory). At the end of the AVI a ventricular pacing artifact is delivered if no intrinsic ventricular activity has been sensed; this represents P-wave tracking pacing. Ventricular activity, paced or sensed, initiates the PVARP and the ventriculoatrial interval (the LRL interval minus the AVI). If no P-wave activity occurs, the pacemaker escapes with a ventricular pacing artifact at the LRL. PV = interval from intrinsic atrial event to paced ventricular event; TARP = total atrial refractory period.

and the lower rate timing cycle is reset (Fig. 24-5) . If a paced ventricular beat occurs at the end of the AVI, this beat resets the lower rate. If no atrial event occurs, the pacemaker escapes with a paced ventricular event at the lower rate limit; that is, the pacemaker displays VVI activity in the absence of a sensed atrial event. VDD pacing may be appropriate for the patient with normal sinus node function and conduction disease of the AV node.

DUAL-CHAMBER PACING AND SENSING WITH INHIBITION AND TRACKING (DDD).

In this mode the basic timing circuit associated with lower rate pacing is divided into two sections, the VA interval and the AVI. The AVI may be defined by AV sequential pacing initiated by pacing with subsequent intrinsic ventricular conduction or initiated by a native P wave with subsequent ventricular pacing (Fig. 24-6) .

The postventricular atrial refractory period, or PVARP, is the period after a sensed or paced ventricular event during which the atrial sensing circuit is refractory. Any atrial event occurring during the PVARP is not sensed by the atrial sensing circuit. If a P wave occurs after the PVARP and is sensed, no atrial pacing artifact is delivered at the end of the VA interval (Fig. 24-6) . Because the maximum tracking rate of the pacemaker is determined by the total atrial refractory period (TARP), the PVARP is a significant determinant of the upper rate limit. The PVARP is *especially important for the prevention of endless-loop, or pacemaker-mediated, tachycardia*.

Four different rhythms can result in normal DDD function: (1) normal sinus rhythm, (2) atrial pacing, (3) AV sequential pacing, and (4) P-synchronous pacing.

DDD pacing mode is most appropriate for patients with normal sinus node function and AV block. DDD pacing is often considered the mode of choice in neurocardiogenic syndromes with symptomatic cardioinhibition.

DDD pacing has limitations in the patient with sinus node dysfunction, because P-synchronous pacing is not possible in chronic atrial fibrillation or in patients with a paralyzed or nonexcitable atrium. Also, DDD pacing does not restore rate response in the chronotropically incompetent patient.

Figure 24-6 The timing cycle in DDD consists of a lower rate limit (LR), an atrioventricular interval (AVI), a postventricular atrial refractory period (PVARP), and an upper rate limit. The AVI and PVARP together comprise the total atrial refractory period (TARP). If intrinsic atrial and ventricular activity occur before the LR times out, both channels are inhibited and no pacing occurs. If no intrinsic atrial or ventricular activity occurs, there is AV sequential pacing (first sequence). If no atrial activity is sensed before the ventriculoatrial (VA) interval is completed, an atrial pacing artifact is delivered, which initiates the AVI. If intrinsic ventricular activity occurs before the termination of the AVI, the ventricular output from the pacemaker is inhibited, that is, atrial pacing (second sequence). If a P wave is sensed before the VA interval is completed, output from the atrial channel is inhibited. The AVI is initiated; and if no ventricular activity is sensed before the AVI terminates, a ventricular pacing artifact is delivered, that is, P-synchronous pacing (third sequence). ID = intrinsic deflection.

Figure 24-7 Electrocardiographic (ECG) example of pacemaker-mediated tachycardia (PMT) in a patient whose device is programmed to the DDD pacing mode. The ECG tracing demonstrates atrial pacing with a long AR interval. The second QRS complex is followed by a paced ventricular beat that is followed by continuous ventricular pacing at a rate of approximately 100 beats/min. This appearance is consistent with PMT, or endless-loop tachycardia. It is unclear what initiates the PMT, although the most likely explanation is a retrograde P wave after the intrinsic QRS.

In any pacemaker capable of P-synchronous pacing, endless-loop tachycardia, also called "pacemaker reentrant tachycardia" or "pacemaker-mediated tachycardia," can result.[33] If AV synchrony is dissociated by any event, most commonly a premature ventricular complex (PVC), retrograde ventriculoatrial (VA) conduction can result in a retrograde P wave (Fig. 24-7) . If the retrograde P wave is sensed by the atrial sensing circuit of the pacemaker, the AVI is initiated, resulting in a paced ventricular complex at a cycle length approximately equal to the maximum tracking rate. The paced ventricular event may again result in retrograde VA conduction, perpetuating this rapid reentrant circuit. Endless-loop tachycardia can be prevented by a PVARP that is long enough to prevent sensing of the retrograde P wave. Most pacemakers also have specific algorithms that attempt to recognize and abort endless-loop tachycardia.

INDICATIONS FOR RATE-ADAPTIVE PACING

Rate-adaptive pacemakers have the ability to increase the pacing rate through sensors that monitor physiological processes such as activity and minute ventilation. Single-chamber rate-adaptive pacing (AAIR, VVIR) has timing cycles that are not significantly different from those of its non-rate-adaptive counterparts. The difference lies in the potential variability of the paced rate (Fig. 24-8) . Depending on the sensor incorporated and the level of exertion of the patient, the basic interval shortens from the programmed lower rate limit to an upper rate limit programmed to define the absolute shortest cycle length allowable.

VVIR pacing, like VVI, is generally contraindicated if ventricular pacing results in retrograde (VA) conduction or a decrease in blood pressure. Also, if the sinus node is normal, P-synchronous pacing should be considered the optimal rate-adaptive mode and used when possible.

AAIR pacing can be considered in the patient with sinus node dysfunction and normal AV node function, because this mode restores rate responsiveness and maintains AV synchrony. If AAIR pacing is contemplated, normal AV node conduction must first be determined, as previously discussed for AAI pacing.

Dual-chamber rate-adaptive (DDDR) pacemakers are capable of all the variations described for DDD pacemakers. In addition to using P-synchronous pacing as a method for increasing the heart rate, the sensor incorporated in the pacemaker may also drive the increase in heart rate. The resulting rhythm may be sinus driven (alternatively called "atrial-driven" or "P-synchronous") or sensor driven. The ideal patient for DDDR pacing is one with combined sinus node and AV node dysfunction, because this mode allows restoration of rate responsiveness and AV synchrony.

Algorithms for determining the appropriate pacing mode for patients with sinus node disease and AV node disease are shown in Figure 24-8 . In Figure 24-8 *A*, a more complex algorithm, most of the available pacing modes are considered. The second algorithm is simpler and assumes that a pacemaker capable of rate adaptation is used (Fig. 24-8 *B*).

Selecting the Appropriate Sensor for Rate-Adaptive Pacing

In an effort to classify sensors on the basis of their response to physiological variables, Rossi[34] divided sensors into five orders (Table 24-7) . A variety of sensors appropriate for

Figure 24-8 Algorithms for pacemaker mode selection. *A*, Choice of VVI, VVIR, AAI, AAIR, DDD, or DDDR is allowed. *B*, Only VVIR or DDDR is selected.

rate-adaptive pacing have been developed and are displayed in Figure 24-9 as endpoints of some physiological response.[34A]

ACTIVITY SENSORS.

Activity sensing with vibration detection (piezoelectric crystal or accelerometer) has been the most widely used form of rate adaptation because it is simple, easy to apply clinically, and rapid in onset of rate response.[35] [36] The main difference between the piezoelectric crystal sensor and the accelerometer is that the former senses vibration from "up and down" motion and the latter in addition senses anterior and posterior motion. Accelerometers have been shown to have a slightly more physiological response than piezoelectric crystal sensors and specifically to have a more appropriate rate response to stair walking.[37]

Subsequent variations include a gravitational sensor able to discriminate changes in vertical gravitational acceleration[38] and a moving magnetic ball that measures electrical signals.[39]

MINUTE-VENTILATION SENSORS.

The minute volume (respiratory rate times tidal volume) sensor has an excellent correlation with metabolic demand. In a rate-adaptive pacing system, minute volume is determined by emission of a small charge of known current (1 mA every 15 msec) from the pacemaker and measurement of the resulting voltage at the lead tip.[40] When both current and voltage are known, transthoracic impedance can be measured between the ring electrode and the pacemaker. Because transthoracic impedance varies with respiration and its amplitude varies with tidal volume, the impedance measurement can be used to determine respiratory rate and tidal volume. A pacing algorithm uses the minute volume measurements to alter pacing rate.[41] Long-term reliability of the minute volume sensor has been excellent.

TABLE 24-7 -- CLASSIFICATION OF SENSORS BY RESPONSE TO PHYSIOLOGIC VARIABLES

ORDER	DESCRIPTION	PHYSIOLOGIC VARIABLE
First	A sensor that directly measures oxygen consumption or energy expenditure	Oxygen uptake
Second	A sensor with a linear relationship to sensors of the first order	Cardiac output, minute ventilation,* atrio-ventricular oxygen difference
Third	A sensor with a linear relationship to sensors of the second order	Heart rate,* stroke volume, mixed oxygen saturation, respiratory rate,* tidal volume
Fourth	A sensor that relies on changes in sympathetic activity and circulating catecholamines	QT interval,* right ventricular dP/dt, preejection interval, ventricular depolarization gradient
Fifth	A sensor that responds to physiological feedback mechanisms in terms of metabolic activity or receptor reflexes	Central venous pH, central venous temperature,* right atrial pressure, mixed venous lactate and bicarbonate levels

Data from Rossi P: Rate-responsive pacing: Biosensor reliability and physiological sensitivity. Pacing Clin Electrophysiol 10:454, 1987.

*Available clinically in the United States or Europe.

Under investigation.

Figure 24-9 Physiologic responses that have been investigated or clinically used for rate adaptation of permanent pacemakers. The "boxed" terms are the endpoints used for rate adaptation. ANS = autonomic nervous system; PDI = paced depolarization integral; PEI = preejection interval; SV = stroke volume.

STIMULUS-T OR QT SENSING PACEMAKER.

The interval from the onset of a paced QRS complex to the end of the T wave has been used for rate adaptation for many years.[42] Autonomic activity and heart rate affect the stimulus-T interval, and the relationship allows measurement of the stimulus-T interval to be used for rate adaptation. The QT-sensing rate-adaptive pacing system has been very successful clinically.

OTHER SENSORS.

Several other sensors have been used clinically for rate-adaptive pacing (Table 24-8) . Although some have shown significant clinical potential, none has achieved widespread clinical use.

DUAL-SENSOR COMBINATIONS.

The overall performance of market-approved single-sensor rate-adaptive systems has been excellent. However, the perfect sensor would mimic the response of the normal sinus node at all levels of activity and during emotional stress.

Clinical problems with available rate-adaptive pacing systems have been minimal. Both activity-sensing and minute-ventilation devices may respond to nonphysiological stimuli. For example, with activity-sensing systems, rate acceleration may occur when the pacemaker is tapped or the patient rolls over on the pacemaker. A paradoxical rate response to stair ascent has been shown with activity-sensing pacemakers that incorporate a piezoelectric crystal, that is, the sensor-driven rate response is often faster during descent of stairs than during ascent.[37] Although response to nonphysiological stimuli represents less-than-perfect specificity of the sensor response, both activity sensing and minute ventilation have served patients well. The perfect sensor would be resistant to these nonphysiological stimuli. A multisensor rate-adaptive pacing system could improve specificity by having one sensor verify or cross-check the other. For example, if one sensor indicated a rate increase and the other did not, a rate increase would not occur. Both sensors would have to indicate a rate increase before it would be allowed.

Potential concerns with dual-sensor pacing systems include more complex programming and greater battery consumption because two or more sensors are monitored and activated.[43] To date, the overall experience with multisensor rate-adaptive pacemakers is positive, and information is emerging to suggest that they may have a hemodynamic benefit over single-sensor devices.[44]

TABLE 24-8 -- OTHER SENSORS FOR RATE-ADAPTIVE PACING

SENSOR	SPEED OF RESPONSE	SPECIFICITY	COMMENTS
Temperature	Slow onset	Relatively specific	Special lead required
Preejective interval, stroke volume	Relatively rapid	Relatively specific	Special lead required; partially closed-loop system
dP/dt	Relatively rapid	High specificity	Special lead required; partially closed-loop system
Mixed V_{O_2}	Rapid	High specificity	Special lead required; some concern about long-term performance
Paced depolarization interval	Relatively rapid	Relatively specific	Standard lead; closed-loop characteristics

Figure 24-10 Hemodynamic tracing demonstrating left ventricular outflow gradient reduction during a temporary pacing study. During normal sinus rhythm (NSR), the patient exhibits marked left ventricular outflow obstruction with gradient of 70 to 90 mm Hg. With initiation of P-synchronous pacing at an atrioventricular interval of 120 milliseconds, the gradient is reduced to 10 to 25 mm Hg. *(From Symanski JD, Nishimura RA: The use of pacemakers in the treatment of cardiomyopathies. Curr Prob Cardiol 21:385, 1996. By permission of CV Mosby.)*

PACING FOR HEMODYNAMIC IMPROVEMENT

Whenever a patient receives a pacemaker for bradycardia-related symptoms for any of the pacemaker indications already discussed, resolution of the bradyarrhythmia results in hemodynamic improvement. In the past decade, however, several nonbradyarrhythmic indications for permanent pacing for hemodynamic improvement have emerged.

Hypertrophic Obstructive Cardiomyopathy (See Chap. 48.)

Dual-chamber pacing is useful as a therapeutic modality for some patients with severe, symptomatic hypertrophic obstructive cardiomyopathy (HCM).[45] [45A] [45B] Multiple investigators have reported a significant reduction in the left ventricular outflow tract gradient and symptomatic improvement in patients with HCM in whom dual-chamber pacemakers have been implanted (Fig. 24-10) .

Fananapazir and colleagues[45] reported on 84 patients with HCM and drug-resistant symptoms who were treated with dual-chamber pacemakers programmed to the DDD mode with AV intervals short enough to fully activate the ventricle from the pacing site at the right ventricular apex (according to ECG criteria). After a mean of 2.3 years, symptoms resolved (28 patients) or decreased (47 patients) in 89 percent of cases. These results were associated with a significant improvement in mean New York Heart Association (NYHA) functional class from 3.2 to 1.6 and a reduction in the left ventricular outflow tract gradient from 96 to 27 mm Hg in patients with significant outflow obstruction. These benefits persisted after cessation of pacing during normal sinus rhythm, as did some changes on the surface ECG (T wave morphology) and the signal-averaged ECG.

MECHANISMS OF BENEFIT.

The most widely accepted hypothesis to explain the improvement in hemodynamics that may occur with pacing in patients who have HCM is that the altered septal activation caused by right ventricular apical pacing may result in less narrowing of the left ventricular outflow tract and a subsequent decrease in the Venturi effect, responsible for systolic anterior motion of the mitral valve.[46] However, the persistence of improvement after cessation of pacing in some series and the observation that subjective and objective improvement may also be seen in some patients with left bundle branch block suggest that the effect of long-term pacing cannot be attributed solely to alteration of the septal activation sequence by ventricular pacing. There are hypotheses that permanent pacing in patients with hypertrophic cardiomyopathy may result in long-term remodeling of the left ventricle.[47]

CLINICAL TRIALS.

Pacing in HCM has been the subject of several randomized single-center and multicenter trials (Table 24-9) . A single-center randomized crossover trial demonstrated symptomatic improvement in 63 percent of patients with pacing in the DDD mode.[48] However, 42 percent of patients had improvement when the pacemaker was programmed to a low pacing rate in the AAI mode, that is, effectively no pacing, suggesting a significant placebo effect.

In the Pacing in Cardiomyopathy (PIC) study, a multicenter randomized crossover study,[49] dual-chamber pacing resulted in a 50 percent reduction of the left ventricular outflow tract gradient, a 21 percent increase in exercise duration, and improvement in NYHA functional class compared with baseline status. When clinical parameters, including chest pain, dyspnea, and subjective health status, were compared between DDD and backup AAI pacing, there was no significant difference, again suggesting a significant placebo effect.

In another randomized, double-blind crossover study, the Multicenter Study of Pacing Therapy for Hypertrophic Cardiomyopathy (M-PATHY) trial, no significant differences were evident with randomization between pacing and no pacing, either subjectively or objectively, when exercise capacity, quality of life score, treadmill exercise time, and peak oxygen consumption were compared.[50] The investigators

TABLE 24-9 -- CLINICAL TRIALS IN PACING FOR HYPERTROPHIC OBSTRUCTIVE CARDIOMYOPATHY (HCM)

STUDY	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
Mayo: Pacing in HCM[48]	Symptomatic HCM despite maximal medical regimen	LVOT gradient	Blinded crossover of DDD pacing	Subjective improvement in ~60% of patients
		Quality of life	*vs.*	Significant placebo effect from pacing
		Exercise duration	No pacing (AAI)	LVOT gradient of ~40%
		Oxygen consumption		

Pacing in Cardiomyopathy (PIC)[49]	Refractory symptoms from HCM despite stable drug regimen	Exercise tolerance	Blinded crossover of DDD pacing	50% reduction in LVOT gradient
		Dyspnea-angina symptom score	*vs.*	21% in exercise duration
	NYHA Class II or III	NYHA Class	No pacing (AAI)	0.7 in NYHA Class
	Angina or dyspnea	Quality of life		
	LVOT >30 mm Hg			
Multicenter Study of Pacing Therapy for Hypertrophic Cardiomyopathy (M-PATHY)[50]	Symptomatic HCM despite maximal medical regimen	Quality of life	Blinded crossover of DDD pacing	No significant subjective or objective improvement with randomization
	LVOT 50 mm Hg	Treadmill exercise duration	*vs.*	Significant placebo effect
		Peak O_2 consumption	No pacing (AAI at 30 beats/min)	LVOT gradient of 40%
		Delta LVOT gradient		
		Delta LV wall thickness		

LV = left ventricular; LVOT = left ventricular outflow tract; NYHA = New York Heart Association.

Data from Maron BJ, Nishimura RA, McKenna WJ, et al: Assessment of permanent dual-chamber pacing as a treatment for drug-refractory symptomatic patients with obstructive hypertrophic cardiomyopathy: A randomized, double-blind, crossover study (M-PATHY). Circulation 99:2927, 1999.

Figure 24-11 Pressure tracings at different atrioventricular (AV) intervals in a patient with hypertrophic obstructive cardiomyopathy. In this example, the outflow gradient was minimized at an AV interval of 120 milliseconds.

concluded that pacing should not be regarded as a primary treatment for HCM and that subjective benefit without objective evidence of improvement should be interpreted cautiously.

Pacing for the treatment of medically refractory HCM is currently a Class IIb indication for pacing by the ACC/AHA guidelines.[2]

When pacing is applied in the patient with HCM, AVI programming is crucial to achieve optimal hemodynamic improvement. Ventricular depolarization must occur as a result of pacing. Therefore, the AVI must be short enough to result in depolarization by the paced event (Fig. 24-11) . However, the shortest AVI is not necessarily the best.[48] Some experts have advocated AV nodal ablation to ensure paced ventricular depolarization if rapid intrinsic AV nodal conduction prevents total ventricular depolarization by means of the pacing stimulus.[46]

Dilated Cardiomyopathy (See Chap. 48.)

Treatment of idiopathic dilated cardiomyopathy with short AVI DDD pacing was first reported by Hochleitner and coworkers.[51] They treated 16 critically ill patients with idiopathic dilated cardiomyopathy refractory to pharmacological therapy who were in NYHA functional Class III or IV (see Chap. 18). They reported dramatic improvement in NYHA functional class and a reduction in mortality from that expected at 1 year. (Hochleitner and coworkers[52] subsequently published 5-year follow-up results for their original patient cohort. No deaths occurred from continued deterioration in ventricular function, and no patient needed rehospitalization because of worsening heart failure after pacemaker implantation.)

Subsequent investigators have shown markedly discrepant responses to standard dual-chamber pacing, with great interindividual variability and no consistent benefit from dual-chamber pacing.[53] [54] [55] [56] Although the finding is not consistent, some patients receive hemodynamic benefit from standard dual-chamber pacing by optimization of AV timing.[57] Pacing for the treatment of medically refractory dilated cardiomyopathy has been designated a Class IIb indication for pacing by the ACC/AHA guidelines.[2]

It was subsequently hypothesized that in addition to the need for optimization of AV synchrony, correction of intraventricular conduction disturbances might result in clinical improvement. Although estimates from limited studies vary on the proportion of patients with heart failure who also have ventricular dyssynchrony--usually left bundle branch--it appears to be fairly significant and certainly is in excess of the rate in the general population.[58] [59] Ventricular dyssynchrony has been associated with paradoxical septal wall motion, reduced left ventricular pressure, prolonged duration of mitral regurgitation, and reduced diastolic filling times in patients with left bundle branch block.

BIVENTRICULAR PACING.

Biventricular or left ventricular pacing may counter the decreased septal contribution to stroke volume caused by late left ventricular activation occurring as the septum has begun repolarizing and help to increase ejection fraction[59A] (Fig. 24-12) .

One of the earliest studies of biventricular pacing prospectively assessed six patients with end-stage congestive heart failure, dilated cardiomyopathy, sinus rhythm, and left bundle branch block (LBBB).[60] In this study, biventricular pacing was accomplished with a transvenous right ventricular lead and an epicardial left ventricular lead. After 3 months of biventricular pacing, median NYHA class had significantly improved from 4.0 to 2.5 ($p = 0.03$).

In a study of 47 patients with advanced heart failure (32 percent Class III, 68 percent Class IV), biventricular pacing resulted in improved quality of life, increased exercise tolerance, and improvement in NYHA functional class.[61]

Auricchio and associates[62] studied pacing with transvenous right atrial and right ventricular leads and a left ventricular epicardial lead in 27 patients with severe left ventricular systolic dysfunction. Overall, they found that biventricular and left ventricular pacing increased maximum left ventricular pressure derivative and aortic pulse pressure more than right ventricular pacing. They concluded that patients with congestive heart failure who have sufficiently wide QRS on surface ECGs derive maximum short-term benefit from left ventricular stimulation at an optimized AVI.

Although the data to date are promising, randomized prospective trials are necessary to prove the efficacy and safety of cardiac resynchronization. Trials currently under way are Multicenter InSync Randomized Clinical Evaluation (MIRACLE), Multisite Stimulation in Cardiomyopathy (MUSTIC), [63] Pacing Therapy in Congestive Heart Failure (PATH-CHF),[64] Right Ventricular Outflow Versus Apical Pacing (ROVA), and Vigor-Congestive Heart Failure (Vigor-CHF)[65] (Table 24-10) .

Pacing to Prevent Atrial Fibrillation (See Chaps. 23 and 25.)

Dual-site atrial pacing has been used to prevent recurrent atrial tachyarrhythmias, presumably by decreasing the dispersion of refractoriness in the atrium.[65A] Daubert and colleagues[66] used biatrial synchronous pacing with leads in the right atrial appendage and coronary sinus. Sensing from the lead in the right atrial appendage led to immediate pacing at the coronary sinus site. In a trial of biatrial synchronous pacing (SYNBIAPACE),[67] there was a trend toward a decreased incidence of atrial arrhythmias but no real benefit was shown. Saksena and associates[68] used one lead in a standard right atrial position and the other lead in the coronary sinus or near the coronary sinus ostium (Fig. 24-13) . Both leads were connected to the same port, resulting in simultaneous pacing at both sites. Dual-site pacing has been shown to reduce the number of episodes of paroxysmal atrial fibrillation and flutter and to increase the interval to recurrent atrial arrhythmias.[68] [69] When "no pacing" was compared with dual-site or single-site atrial pacing,

Figure 24-12 Posteroanterior *(A)* and lateral *(B)* chest radiographs demonstrating a ventricular lead that courses posteriorly in the coronary sinus and into a cardiac vein, probably a tributary of the posterior cardiac vein. From the posteroanterior view alone, this determination cannot be made.

TABLE 24-10 -- CLINICAL TRIALS IN PACING FOR CONGESTIVE HEART FAILURE (CHF)

STUDY	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
InSync[61]	NYHA Class III or IV on stable drug regimen	Quality of life	Nonrandomized	In a nonrandomized trial, biventricular pacing resulted in sustained improvement in all three endpoints
	LVEDD >60 mm, LVEF 0.35	NYHA Class		
	QRS width 150 msec	6-minute hall walk		
MIRACLE	NYHA Class III or IV on stable drug regimen	Quality of life	Randomized to pacing or no pacing for 6 mo and then to pacing	In progress
	LVEDD 55 mm, LVEF 0.35	NYHA Class		
	QRS width 130 msec	6-minute hall walk		
Vigor-CHF[65]	Symptomatic CHF on stable drugs	Oxygen consumption	One arm, VDD pacing	In progress
	QRS <120 msec	Peak exercise capacity	Other arm, no pacing for 6 wk and then reprogrammed to VDD	
	PR >160 msec	Quality of life		
	No bradycardia indication for pacing	Cost-effectiveness		
		NYHA Class		
PATH-CHF[64]	DCM of any cause	Maximum LV pressure derivative	Acute hemodynamic assessment of RV pacing	Biventricular and LV: LV pressure derivative and aortic pulse pressure more than RV pacing
	NYHA Class III or IV on stable drug regimen	Aortic pulse pressure	*vs.*	LV pacing: LV pressure derivative more than biventricular pacing
	QRS 120 msec		LV pacing	
	PR 150 msec		*vs.*	
			Biventricular pacing	
ROVA	Standard indication for PPM	Quality of life	Blinded crossover from RV apical to RV outflow tract pacing	In progress
	Chronic AF	VVIR pacing from RV apex vs. RV outflow tract		
	NYHA Class II or III			
	LVEF 0.40			
MUSTIC[63]	NYHA Class III	Functional capacity	Biventricular pacing	In progress
	Refractory symptoms on stable drug therapy	Quality of life	*vs.*	
	LVEF <0.35	Metabolic exercise performance	No pacing with crossover	
	LVEDD >60 mm	Mortality or need for transplant or LVAD		
	<450 m in 6-minute walk	Hospital admission for CHF		
	NSR with QRS >150 msec or AF with paced QRS >200 msec

dual-site pacing was better, but single-site atrial pacing also resulted in a significant improvement over "no pacing." Single-site atrial septal pacing[70] and Bachmann's bundle pacing[71] have also been tested. In the Atrial Pacing Periablation for Prevention of Paroxysmal Atrial Fibrillation (PA3) study, atrial rate-adaptive pacing did not prevent paroxysmal atrial fibrillation during short-term follow-up in patients with drug-resistant paroxysmal atrial fibrillation.[72] The best pacing approach will be determined by multiple trials already under way, including Dual-Site Atrial Pacing to Prevent Atrial Fibrillation (DPPAF),[73] Systematic Trial of Pacing for Atrial Fibrillation (STOP-AF),[74] Pacing in Prevention of Atrial Fibrillation (PIPAF), and Atrial Fibrillation Therapeutics Trial (AFT)[75] (Table 24-11) .

Pacing in Long QT Syndrome (See Chaps. 23 and 25.)

The long QT syndrome is characterized by abnormally prolonged ventricular repolarization and a risk of development of life-threatening ventricular tachyarrhythmias. Therapy must be individualized depending on the clinical situation. Therapeutic options include beta-blocker therapy, permanent pacing, and the ICD (see later and Chap. 25).[76]

PULSE GENERATOR IMPLANTATION

Only qualified physicians should undertake pacemaker or cardioverter-defibrillator implantation. The recommended training requirements for pacemaker implantation[77]

[78] are as follows: a base of core knowledge for pacemaker follow-up, participation in at least 100 pacemaker follow-up visits, participation in at least 50 initial transvenous pacemaker implantations as the primary operator (recommended that at least one half of these be dual-chamber), participation in at least 20 revisions of pacing systems, exposure to lead extraction techniques (suggested), and thorough knowledge of recognition and treatment of pacemaker and surgical complications and emergencies. A detailed description of pacemaker and cardioverter-defibrillator implantation technique can be found in texts devoted to these disciplines.[79] However, certain information related to the implantation technique is important for the referring physician to know.

Almost all pacemakers and defibrillators are now implanted transvenously, with the pulse generator placed in the upper anterior portion of the chest, just anterior to the pectoralis major muscle. Epicardial pacing is considered only in persons without reasonable venous access, that is, no access to the right ventricle because of an associated

TABLE 24-11 -- CLINICAL TRIALS IN PACING FOR THE PREVENTION OF ATRIAL FIBRILLATION (AF)

STUDY	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
SYNBIAPACE[67]	1 yr history of recurrent and drug-refractory AA P wave duration 120 msec and IACT 100 msec	Time to first AA recurrence	BASP at 70 beats/min *vs.* Single-site HRA at 70 beats/min *or* Single-site HRA at 40 beats/min	Trend to a in incidence of AA with BASP, but no real benefit of BASP
DAPPAF[73]	Bradycardia requiring pacing Two documented episodes of AF in prior 3 mo	Time to first recurrence of symptoms of AF Quality of life Safety of DAP	Dual-site right atrial pacing *or* Single-site atrial pacing *vs.* Support pacing mode (control arm)	Results pending
STOP-AF[74]		Time to recurrence of PAF	Physiological pacing *vs.* VVI pacing	In progress
PA3[72]	History of PAF with three episodes within year before Most recent PAF within 3 mo of entry At least one episode of PAF documented by ECG	Time to recurrence of PAF 5 min occurring 2 wk after entry Intervals between successive episodes of PAF Frequency of PAF Proportion of patients who chose to defer ablation	DDDR pacemaker implanted and randomized to atrial pacing or no pacing	Atrial RAP did not prevent PAF over short term in patients with drug-resistant PAF
PIPAF	Indication for pacing Documented paroxysmal AAs for at least 1 yr, three episodes Stable drug therapy < Two cardioversions in past year	Time to first recurrence of AA Cumulative arrhythmia duration	Comparison of six different lead and algorithm combinations	In progress
AFT[75]	Paroxysmal AF	Frequency of AF recurrences	DDD pacing at 40 beats/min (backup pacing) *vs.* DDD pacing at 70 beats/min with specific AF prevention algorithm	In progress

Figure 24-13 Posteroanterior *(A)* and lateral *(B)* chest radiographs in a patient with a dual-site atrial pacing system for the prevention of paroxysmal atrial fibrillation. Leads are positioned in the right atrium, near the coronary sinus ostium, and in the right ventricular apex.

congenital anomaly, a prosthetic tricuspid valve, or an intracardiac right-to-left shunt.

Although multiple venous routes have been used for lead placement, the subclavian and cephalic veins are most commonly used. The subclavian approach involves a subclavian puncture and the use of one or more peel-away introducers. A lateral approach to the subclavian vein, often lateral enough to be the axillary vein, is preferred to minimize the risk of pneumothorax and to avoid subclavian crush injury to the lead, which is more common when a medial approach is used. The cephalic vein is often large enough to accept one or two pacing leads, and this approach avoids the risks associated with blind subclavian puncture. Potential complications of subclavian puncture include pneumothorax, hemopneumothorax, subclavian artery puncture, brachial nerve plexus injury, and thoracic duct injury.

Specific measurements must be accomplished at the time of pacemaker or cardioverter-defibrillator implantation (Table 24-12) .

After placement of the pulse generator, posteroanterior and lateral chest radiographs must be obtained to exclude pneumothorax and also to ensure adequate lead positioning. Before hospital dismissal, the pulse generator should be programmed to determine pacing and sensing thresholds for final programming with adequate safety margins. If the pulse generator is being programmed to a rate-adaptive pacing mode, adequate rate response should be assessed by formal or informal stress testing.

*Necessary only when an atrial lead is being placed.

Necessary only when an atrial lead or a single-pass VDD lead is used.

Considered optional by many, and these measurements may be accomplished noninvasively with many devices.
§Necessary only when an AAI/R implant is considered.

For ICD implantation only.

PACEMAKER PROGRAMMING

Almost all pacemakers are capable of programming rate, pulse width, voltage amplitude, sensitivity, refractory period, and polarity (Table 24-13) . Many clinicians fail to take advantage of optimizing pacemaker function with programmable options, with estimates that up to 50 percent of all pacemakers implanted are never changed from nominal parameters. A few features deserve additional discussion.

Programming Pulse Width and Voltage Amplitude

Output programming is probably the most important aspect of programming that should be performed routinely. The output must be high enough to allow an adequate pacing margin of safety but should also be programmed with the intent of maximizing pacemaker longevity. A strength-duration curve plots voltage and pulse width thresholds and

Figure 24-14 Programmer-generated strength-duration threshold curve. "X" notes the output parameter settings calculated by the programmer that would allow an adequate safety margin and maximize pacemaker longevity.

TABLE 24-13 -- PROGRAMMABLE OPTIONS FOR PACEMAKERS

PARAMETER	DESCRIPTION	TYPICAL VARIABLES
Mode	Preset or programmed response from a pacemaker with or without intrinsic cardiac events	VOO, AOO, VVI, AAI, VDD, DVI, DDD, DDI, DOO, VVT, AAT (all but AAT, VVT could also have "R," or rate-adaptive, capability)
Lower rate limit	Preset or programmed rate at which a pacemaker emits an output pulse without intrinsic cardiac activity	30 to 150 beats/min (options faster than 150 beats/min available in some pulse generators)
Ventricular refractory period	An interval of the pacemaker timing cycle following a sensed or paced ventricular event during which the ventricular sensing channel is totally or partially unresponsive to incoming signals	150 to 500 msec
Pulse width	Duration, in milliseconds, over which the output is delivered	0.05 to 1.9 msec
Pulse amplitude	Magnitude of the voltage level reached during a pacemaker output pulse, usually expressed in volts	0.5 to 8.1 V
Sensitivity	Ability to sense an intrinsic electrical signal, which depends on the amplitude, slew rate, and frequency of the signal	Atrial: 0.18 to 8 mV Ventricular: 1.0 to 14 mV
Polarity	Stimulating electrode typically is the cathode, which has negative polarity relative to the indifferent electrode (anode)	Device may be programmable to only bipolar or unipolar; others may have more control by programming unipolar-bipolar pace-sense on either lead
Hysteresis	Extension of the escape interval after a sensed intrinsic event	In single-chamber modes, commonly 40, 50, or 60 beats/min or off
Circadian lower rate limit	Reduces the lower rate limit during sleeping hours	Lower rates during sleep, programmable from 30 beats/min as the slowest rate usually offered
Mode switch	Capability of a dual-chamber pacemaker to automatically switch from an atrial tracking (P-synchronous) mode to a non-atrial-tracking mode when an atrial rhythm occurs that the pacemaker determines to be pathologic. When the atrial rhythm meets the criteria for a physiologic rhythm, the mode switches back to an atrial-tracking mode.	On or off; if on, the detection rates are often programmable for rates 120 to 190 beats/min
Fallback	An upper rate response in which the ventricular paced rate decelerates to, and is maintained at, a programmable fallback rate that is lower than the original programmed maximum tracking rate. Fallback mechanisms vary among pacemakers.	May be programmable on or off; if on, the rate to which the fallback occurs may be fixed or programmable (i.e., 50 to 80 beats/min)
Rate smoothing	Prevents atrial or ventricular paced rate from changing by more than a programmed percentage from one cardiac cycle to the next. This prevents large cycle-to-cycle intervals that can be seen at the upper rate limit or during rapid acceleration of atrial rate.	On or off; may then have options of % smoothing (i.e., 9% to 25% change per cycle length allowed); may also have option of being on or off for rate increments or decrements, or both
Atrioventricular interval (AVI)	Period between the initiation of the paced or sensed atrial event and the delivery of a consecutive ventricular output pulse.	30 to 350 msec
Differential AVI	Feature that permits a longer AVI after a paced atrial event than after a sensed AVI. In some pacemakers, this differential is fixed; in others, it is programmable.	Offset from 0 to 200 msec
Rate-adaptive AVI	Shortens the AVI as the heart rate increases	On or off only in some devices; in others, able to set the minimum atrioventricular delay to as short as 30 msec

Postventricular atrial refractory period (PVARP)	Period after a paced or sensed ventricular event during which the atrial channel is refractory	150 to 500 msec; in some devices, auto-PVARP adjusts with cycle length
PVARP extension	Lengthening of the PVARP after a sensed premature ventricular contraction to prevent sensing of a retrograde P wave	On or off in some; others may program length of extension to as long as ~500 msec
Pacemaker-mediated tachycardia (PMT) algorithms	Manufacturer-specific algorithms to terminate PMT	On or off; in others, can choose how long the maximum tracking rate must persist before detection criteria are met
Blanking period	Temporary disabling of pacemaker-sensing amplifiers after an output pulse	Ventricular blanking: 20 to 50 msec Postventricular atrial blanking: 100 to 350 msec
Ventricular safety pacing	Delivery of a ventricular output pulse after atrial pacing if a signal is sensed by the ventricular channel during the crosstalk sensing portion of the AVI	On or off
Maximum tracking rate	The sum of the AVI and the PVARP	80 to 180 beats/min

Figure 24-15 *A*, The paced atrioventricular interval (AVI) corresponds to the programmed value, that is, the interval allowed after a paced atrial beat before a ventricular pacing artifact is delivered. *B*, The initial portion of the AVI in most dual-chamber pacemakers is designated the blanking period, during which sensing is suspended. The blanking period is intended to prevent ventricular sensing of the atrial pacing artifact. Any event that occurs during the blanking period, even if it is an intrinsic ventricular event, as shown in this illustration, is not sensed and is followed by a ventricular pacing artifact delivered at the programmed AVI. *C*, If the ventricular sensing circuit senses activity during the crosstalk sensing window, a ventricular pacing artifact is delivered early, usually at 100 to 110 milliseconds after the atrial event, that is, "ventricular safety pacing." PVC = premature ventricular contraction. *(From Hayes DL, Levine PA: Pacemaker timing cycles. In Ellenbogen KA [ed]: Cardiac Pacing, Boston, Blackwell Scientific Publications, 1992, p 263.)*

allows determination of appropriate values to ensure an adequate safety margin. There is no consensus of the best way to program output parameters, but options[80] include doubling the voltage amplitude at threshold; tripling the pulse width at threshold; determining the threshold, obtaining a telemetered reading of threshold energy in microjoules, and programming output parameters to achieve a triple microjoule threshold; basing programmer-determined output parameters on autothreshold testing; and applying autocapture technology.

At least one manufacturer has pacemakers capable of calculating and graphically displaying a strength-duration curve as well as suggesting optimal output parameters (Fig. 24-14) . Automatic programming of output functions, "autocapture," has been actively investigated for over a decade, but only recently have manufacturers developed this as a reliable option. It is too early to determine how widely this feature will be embraced by clinicians.[80A]

Atrioventricular Interval

Several components of the AVI must be understood to optimally program the pacemaker (Fig. 24-15 *A*). The initial portion of the AVI is the blanking period, during which all sensing is suspended. This period is necessary to prevent sensing of the atrial output pulse on the ventricular sensing circuit, that is, crosstalk. This interval is commonly in the range of 12 to 50 msec, depending on the pacemaker, and is programmable in many pacemakers. If the blanking period is too long, a spontaneous R wave, occurring soon after the atrial stimulus, is not sensed and a competitive ventricular stimulus is emitted (see Fig. 24-15 *B*). The period after the blanking period is the crosstalk-sensing window. After the relatively short blanking period, if an event is sensed on the ventricular sensing circuit, the pacemaker is unable to distinguish with certainty the source of the sensed event. Given the possibility of sensing the decay of the atrial pacing output, sensing in the crosstalk-sensing window forces ventricular safety pacing or the "nonphysiological AV delay" (see Fig. 24-15 *C*). Because the "safety" stimulus occurs at a fixed delay after the beginning of the "safety pacing" interval, the total AVI is likely to be abbreviated. Because several early pacemakers had a ventricular safety pacing interval of 110 milliseconds, the designation "110-msec phenomenon" has also been used.

DIFFERENTIAL AVI.

Because the interatrial contraction after a sensed atrial event is shorter than that after a paced atrial event, an option exists for a differential AVI in an attempt to provide a PR interval of equal duration whether the atrial contraction is paced or sensed[81] (Fig. 24-16) . In some pacemakers, the differential is programmable, and in others, a preset differential is used when this feature is programmed "on."

RATE-VARIABLE OR RATE-ADAPTIVE AVI.

DDDR pacemakers can shorten the AVI during AV sequential sensor-driven pacing. Rate-adaptive or rate-variable AVI is intended to optimize cardiac output by mimicking the normal physiological decrease in the PR interval that occurs in the normal heart as the atrial rate increases during exercise.[82]

Mode Switching

Mode switching is the ability of the pacemaker to automatically change from one mode to another in response to an inappropriately rapid atrial rhythm[83] [83A] (Fig. 24-17) . Mode switching is particularly useful for patients with paroxysmal supraventricular rhythm disturbances.[83B] In the DDD or

Figure 24-16 Differential atrioventricular interval (AVI) is demonstrated by a paced atrial event initiating an AVI of approximately 150 milliseconds and a sensed atrial event initiating an AVI of approximately 125 milliseconds. The measured AVI is numerically noted between the A and V markers. The numbers following the V marker reflect the measured VA interval (top) and VV interval (bottom).

DDDR pacing modes, if a supraventricular rhythm disturbance occurs and the pacemaker senses the pathological atrial rhythm, rapid ventricular pacing can occur. Any pacing mode that eliminates tracking of the pathological rhythm, that is, DDI, DDIR, DVI, or DVIR, also eliminates the ability to track normal sinus rhythm, which is usually the predominant rhythm. Mode switching avoids this limitation by switching from DDD or DDDR during sinus rhythm to a nontracking mode, such as DDIR, during the pathological atrial rhythm.

Rate-Adaptive Parameters

The goal of programming rate-adaptive pacemakers is to optimize the patient's chronotropic response.[83C] It is inappropriate to implant a rate-modulating pacemaker and program the sensor "on" without assessing rate response. Pacemakers capable of rate modulation are packaged with the sensor "off"; and to effect rate modulation, the sensor must be programmed "on." Although the manufacturer usually states "nominal" values for rate response parameters, the nominal values are not appropriate for all patients. Some form of exercise is necessary to optimize rate-adaptive parameters. For patients who are limited to "activities of daily living," informal exercise testing, such as walking at casual and brisk paces in the hospital corridor or in the outpatient facility, is often adequate. In determining the appropriate heart rate response, the patient's age and "usual activities" must be taken into consideration.[84]

If formal exercise testing is performed, the chronotropic exercise assessment protocol[85] or a low-intensity exercise protocol may be preferable to a standard Bruce protocol. The chronotropic exercise assessment protocol allows for a gradual increase in speed and grade and thus mimics levels of exercise that are likely to occur during activities of daily living.

Alternatively, rate adaptation can be assessed and enhanced

Figure 24-17 Electrocardiographic tracing from a patient with a DDD pacemaker. In the initial portion of the tracing, the pacing is in sinus rhythm. This is followed by the onset of an atrial tachyarrhythmia with initial tracking, but mode switching causes reversion to a VVIR pacing mode. (The top tracing is the surface electrocardiogram, the middle tracing represents the atrial electrogram, and the lower tracing represents the ventricular electrogram.)

by diagnostic tools incorporated within the pacemaker. There are many variations, including histograms of rate response and ambulatory monitoring capabilities. If the pacemaker is capable of automatically optimizing rate response parameters, the patient must still be assessed to see if the automatically programmed parameters result in the appropriate rate response.

PACEMAKER COMPLICATIONS

Complications can be divided into those related to implantation and those related to failure of a component of the pacing system.[86] There are also problems encountered during follow-up that are actually pseudoabnormalities, that is, a normal response that appears abnormal because of unusual timing or because of idiosyncrasies of the device. Many complications are directly related to the experience of the implanter. One study demonstrated a significantly higher incidence of complications when implanters performed fewer than 12 implantations per year.[87]

Implant-Related Complications

Most patients undergoing pacemaker implantation have some discomfort at the site of the incision in the early postoperative period. Mild analgesics may be required. Mild ecchymoses around the incision are not uncommon. As previously noted, if subclavian puncture is used for lead placement, several potential complications of this "blind" technique can occur, including the possibility of traumatic pneumothorax and hemopneumothorax, inadvertent arterial puncture, air embolism, arteriovenous fistula, thoracic duct injury, subcutaneous emphysema, and brachial plexus injury.[88]

Hematoma formation at the pulse generator site most commonly occurs when anticoagulant therapy is initiated or reinstituted prematurely. A hematoma must be dealt with on the basis of its secondary consequences. Evacuation of the hematoma should be considered only if there is continued bleeding, potential compromise of the suture line or skin integrity, or pain from the hematoma that cannot be managed with analgesics. Aspiration is generally not advised.

Introduction of the lead or leads into the subclavian artery, the aorta, and the left ventricle usually is readily recognized because of the pulsatile flow of saturated blood. A pacing lead may also be placed in the left ventricle by passing it across an unsuspected atrial or ventricular septal defect (Fig. 24-18) . Once the lead is within the subclavian artery, passage into the left ventricle is as easy as passage into the right ventricle via the venous system. Left ventricular lead placement should be recognized if lateral fluoroscopy is used or a lateral chest radiograph is obtained, because the lead is in the posterior aspect of the heart. The ECG during right ventricular pacing usually has an LBBB pattern and during left ventricular pacing most commonly an RBBB pattern.

Although thresholds may be adequate, lead placement in the arterial circulation is associated with thrombus formation, embolization, and, consequently, stroke. Reports of long-term uncomplicated left ventricular endocardial pacing exist, but the risk of embolization continues. Removal of the left ventricular lead should be undertaken if this position is recognized early after implantation. If it is recognized years after uncomplicated pacing, the best approach may be to administer anticoagulants and leave the lead in place. Management must be individualized.

Patients undergoing device implantation should be made aware of the potential for lead perforation. Although cardiac tamponade is the most dramatic outcome from perforation, lack of symptoms after ventricular perforation by a lead is not uncommon. The only sign may be a rising stimulation threshold. In other patients, the signs may include RBBB pattern from a lead placed in the right ventricle, intercostal muscle, or diaphragmatic contraction; friction rub after implantation; and pericarditis, pericardial effusion, or cardiac tamponade. (Depending on lead position, an RBBB pattern is also possible when the lead is within the right ventricular cavity.)

Ventricular perforation may be suggested by radiography, electrocardiography, and echocardiography. Once perforation is identified, lead withdrawal and repositioning are usually uncomplicated, although pericardial bleeding or tamponade results rarely.

Partial or silent inconsequential venous thrombosis of the subclavian vein is not uncommon after transvenous lead placement and is usually clinically insignificant. Such partial or silent thrombosis may limit venous access at the time of pacing system revision.[89] Symptomatic thrombosis can be the result of occlusion of the superior vena cava, with superior vena cava syndrome; thrombosis of the superior vena cava, right atrium, or right ventricle, with hemodynamic compromise or pulmonary embolism; or symptomatic thrombosis of the subclavian vein, with an edematous, painful upper extremity.

Lead-Related Complications

Several lead-related complications deserve attention, including lead dislodgment (Fig. 24-19) , loose connector pin

Figure 24-18 Posteroanterior chest radiographs of a dual-chamber pacemaker. *A*, Ventricular lead is passing through an atrial septal defect into the left ventricle. *B*, Lead is repositioned in the right ventricular apex.

Figure 24-19 Posteroanterior chest radiographs of a dual-chamber pacemaker. *A*, Underpenetrated film makes it difficult to identify lead position. *B*, Lateral view demonstrates definite dislodgment of the atrial lead into the superior vena cava.

(Fig. 24-20) , conductor coil fracture, insulation break, and exit block.

Active and passive fixation mechanisms common to current pacing leads have significantly reduced the incidence of lead dislodgment. Acceptable dislodgment rates should probably be less than 1 percent for ventricular leads and no more than 2 to 3 percent for atrial leads. Dislodgment has been classified as "macrodislodgment" and "micro-dislodgment." Macrodislodgment is radiographically evident (see Fig. 24-19), microdislodgment is not. Adequate lead position is assessed by posteroanterior and lateral chest radiographs and comparison with any previous chest radiographs.

Intermittent or complete failure of output can occur because of a loose connection at the interface of the lead and connector block (see Fig. 24-20), usually because the lead was inadequately secured at

Figure 24-20 *A*, Posteroanterior chest radiograph in a patient with a VVI pacemaker and a bifurcated bipolar ventricular lead. The patient presented with recurrent near-syncope and intermittent failure to output. (Arrowhead notes inadequate atrial lead positioning; that is, the J portion of the lead is too shallow.) *B*, Close-up of the pacemaker reveals that the lower connector pin is not securely in the connector block (arrow). (For comparison, the arrowhead notes an appropriately engaged connector pin.) *(From Hayes DL: Pacemaker radiography. In Furman S, Hayes DL, Holmes DR Jr [eds]: A Practice of Cardiac Pacing. 3rd ed. Mount Kisco, NY, Futura Publishing Company, 1993, p 361. By permission of Mayo Foundation.)*

Figure 24-21 Posteroanterior chest radiographs in a patient with a dual-chamber pacemaker. *A*, Fracture of one lead (upper arrow) has occurred where the lead passes below the clavicle. Positioning of the atrial lead is shallow and suboptimal (lower arrow). *B*, Enlarged view of fracture (arrow). *(From Hayes DL: Pacemaker complications. Cardiac Pacing. 3rd ed. Mount Kisco, NY, Futura Publishing Company, 1993, p 537. By permission of Mayo Foundation.)

the time of pacemaker implantation. When a connection is loose, manipulating the pulse generator or pocket may reproduce the problem. The poor connection may be evident radiographically.

Lead fractures most often occur adjacent to the pacemaker or near the site of venous access, that is, at a stress point (Fig. 24-21) . Although uncommon, direct trauma may result in damage to the pacing lead. If a fracture of a bipolar lead occurs and the pacemaker is polarity programmable, it may be possible to restore pacing by reprogramming to the unipolar configuration. This is a short-term solution and should not be a substitute for replacing the lead.

Loss of integrity of the insulating material has occurred because of flaws in the design or manufacturing process of the lead, "wear and tear," and crush injury. Insulation defects and conductor fractures may both be caused by crush injury, specifically at the costoclavicular space when placement is by the subclavian puncture technique.[90]

Thresholds, lead impedance, and electrograms are helpful in differentiating an insulation defect from a conductor fracture. This information may be obtained by measurements made during implantation or by telemetric capabilities of many pacemakers (Table 24-14) .

Failure to capture due to exit block is uncommon. Exit block appears to be an abnormality at the myocardial tissue-electrode interface, resulting in a progressive rise in thresholds with normal radiographic appearance. Steroid-eluting leads are often effective in preventing exit block.

Supraventricular and ventricular arrhythmias, often encountered during pacemaker implantation, are usually inconsequential.

"Tip extrasystoles" can be seen in the early postimplantation period. These are ventricular complexes morphologically similar to the paced beats because they originate at the same site as the paced beats, but they are not preceded by a pacemaker stimulus. Tip extrasystoles most often occur during the first 24 to 48 hours after implantation and usually resolve spontaneously. Pharmacological suppression of tip extrasystoles is rarely necessary.

"Runaway pacemaker" describes a sudden increase in pacing rate caused by circuit malfunction. This phenomenon is rare with current pacemakers. In recent years, the rare reports of runaway have usually described a complication of pacemaker exposure to therapeutic radiation, with subsequent damage to the circuit.[91]

Endless-loop tachycardia, already described, is another well-recognized pacemaker-related rhythm disturbance.

Extracardiac stimulation usually involves the diaphragm or pectoral muscle. Diaphragmatic stimulation may be due to direct stimulation of the diaphragm (usually stimulation of the left hemidiaphragm) or stimulation of the phrenic nerve (usually stimulation of the right hemidiaphragm). Diaphragmatic stimulation occurring during the early postimplantation period may be due to either microdislodgment or macrodislodgment of the pacing lead. Stimulation can be minimized or alleviated by decreasing the voltage output or pulse width (or both), but an adequate pacing margin of safety must be maintained after the output parameters are decreased.

Local muscle stimulation occurs much more commonly with unipolar than with bipolar pacemakers and is usually noted in the early postimplantation period. Pectoral muscle stimulation can also be due to an insulation defect of the pacing lead, current leakage from the connector or sealing plugs, or erosion of the pacemaker's protective coating. If the problem is due to an insulation defect on either a unipolar pacemaker or the pacemaker lead, decreasing the voltage output or the pulse width (or both) may minimize the stimulation, but the defective portion of the system may have to be replaced. If pectoral muscle stimulation occurs in a polarity-programmable pacemaker that is programmed unipolar, reprogramming to the bipolar configuration may alleviate the problem.

Pacemaker System Infection

Erosion is an uncommon complication that most commonly occurs because of an indolent infection, although it may also be the result of a pacemaker pocket that is too "tight."

If the patient seeks medical attention before the pacemaker has eroded through the skin, it may be possible to revise the pocket and reimplant the pacemaker. Impending erosion should be dealt with as an emergency, because once any portion of the pacemaker has eroded through the skin, the only choice is removal of the pacemaker system and placement of a new system in another site.

Infection may be present even without purulent material; therefore, a specimen for culture should be obtained and proven negative before pocket revision. Adherence of the

TABLE 24-14 -- INTRAOPERATIVE EVALUATION OF PACING SYSTEM

DEFECT	VOLTAGE THRESHOLD	CURRENT THRESHOLD	LEAD IMPEDANCE
Wire fracture	High	High, normal, or low	High
Insulation break	Low	High	Low
Lead dislodgment	High	High	Normal
Exit block	High	High	Normal

Modified from Hayes DL, Osborn MJ: Pacing: A. Antibradycardia devices. In Giuliani ER, Gersh BJ, McGoon MD, et al (eds): Mayo Clinic Practice of Cardiology, 3rd ed. St. Louis, CV Mosby, 1996, p 961. By permission of Mayo Foundation.

pacemaker to the skin strongly suggests an infection, and salvage of the site may not be possible.

The incidence of infection after pacemaker implantation should certainly be less than 2 percent and in most series has been less than 1 percent.[92] Careful attention to surgical details and sterile procedures is of paramount importance in avoiding pacemaker site infection. Prophylactic use of antibiotics before implantation and in the immediate postoperative period remains controversial.[93] Most studies do not show any significant difference in the rate of infection between patients who have had prophylactic administration of antibiotics and those who have not. Irrigation of the pacemaker pocket with an antibiotic solution at the time of pacemaker implantation is probably more important in the prevention of infection.

Pacemaker infection may appear as local inflammation or abscess formation in the pacemaker pocket, erosion of part of the pacing system with secondary infection, or sepsis with positive blood culture findings with or without a focus of infection elsewhere.

The most common clinical presentation is localized pocket infection; septicemia is uncommon. Many infectious agents can be responsible, but early infections are most commonly caused by *Staphylococcus aureus*, are aggressive, and are often associated with fever and systemic symptoms. Late infections commonly are caused by *Staphylococcus epidermidis* and are more indolent--usually without fever or systemic manifestation. Treatment for both organisms requires removal of the entire infected pacing system, pacemaker, and leads.

A detailed description of lead extraction techniques is beyond the scope of this text.[94] [94A] The various approaches include simple traction, locking stylet and telescoping sheaths with countertraction,[95] laser-assisted extraction,[96] and open surgical techniques.

Laser-assisted lead extraction has been the subject of a multicenter study, the Pacing Lead Extraction with Excimer Laser System (PLEXES) trial. Randomization of patients to laser-assisted extraction technique or to standard extraction techniques demonstrated efficacy of laser-assisted lead extraction.[96]

When to extract leads is at times controversial. A question that arises frequently is how many noninfected leads can be abandoned and left in place. Multiple leads can usually safely be left in place as long as no one of them has been part of an infected system.[97]

TROUBLESHOOTING ELECTROCARDIOGRAPHIC ABNORMALITIES

Electrocardiographic (ECG) abnormalities in the paced patient can be broadly grouped into failure to capture, failure to output, sensing abnormalities (undersensing or oversensing), and inappropriate rate change.[98] [99]

FAILURE TO CAPTURE.

Failure to capture indicates that a pacing artifact is present without subsequent cardiac depolarization (Fig. 24-22) . The possible causes of failure to capture are high thresholds with an inadequately programmed output, partial conductor coil fracture, insulation defect, lead dislodgment or perforation, impending total battery depletion, functional noncapture, poor or incompatible connection at the connector block, circuit failure, air in the pulse generator pocket (unipolar pacemaker), and elevated thresholds due to drugs or metabolic abnormality.

FAILURE TO PACE.

Failure to pace, or failure to output, that is, failure to deliver an appropriate pacing stimulus, is often due to oversensing and inhibition of output but could also be due to true failure to output from the pacemaker or circuit interruption that prevents the electrical signal from reaching the heart (Fig. 24-23) . The reasons for failure to output are circuit failure, complete or intermittent conductor coil fracture, intermittent or permanently loose set screw, incompatible lead or header, total battery depletion, internal insulation failure (bipolar lead), oversensing of any noncardiac activity, crosstalk, and lack of anodal connector contact (e.g., unipolar lead in bipolar generator, bipolar lead in pacemaker programmed in unipolar mode, air in the pocket of a unipolar device, and unipolar pacemaker not in the pocket).

The differential diagnoses of failure to capture and failure to pace obviously overlap somewhat. For example, ECG manifestations of a conductor coil fracture may include failure to capture due to significant leakage of current at the incomplete fracture site, with not enough current remaining to result in stimulation. Nonetheless, the pacemaker stimuli can appear. Alternatively, escaping current can be sensed by the pacemaker and inhibit pacemaker output. If the conductor coil is completely fractured, rendering the circuit incomplete, no pacemaker output will be detected on the ECG. Insulation defects can also be signaled by oversensing and failure to pace or by failure to capture, although the most common consequences of insulation failure are sensing abnormalities.

As the pacemaker battery reaches end stages of depletion, either failure to capture due to decreasing voltage output or failure to pace due to total battery depletion can occur. This degree of battery depletion should be avoided by appropriate pacemaker follow-up.

Apparent failure to capture is noted if a pacemaker stimulus occurs during the refractory period of a spontaneous beat. This is referred to as "functional noncapture."

FAILURE TO SENSE.

Sensing abnormalities can be divided into true abnormalities, including undersensing, a failure to recognize normal intrinsic cardiac activity (Fig. 24-24) , and oversensing (see Fig. 24-23), unexpected sensing of an intrinsic or extrinsic electrical signal, and functional sensing abnormalities. The possible causes of sensing abnormalities are lead dislodgment or poor lead positioning, lead insulation failure, circuit failure, magnet application, malfunction of reed switch, electromagnetic interference, and battery depletion. The morphology of the intrinsic event is different from that measured at implantation.

True undersensing is most commonly due to lead dislodgment or inadequate initial lead placement. Sensing abnormalities commonly can be seen secondary to insulation defects and to intermittent, "make or break" conductor fracture. A normally functioning pacing system at times fails to detect atrial or ventricular extrasystoles. The intrinsic events measured at the time of implantation generate an electrogram at the electrode tip. If an extrasystole is occurring elsewhere in the heart, the sensing vector is different from that of the normal intrinsic beat, and the resulting voltage generated may not be great enough to be sensed by the pacemaker. This anomaly cannot be anticipated unless extrasystoles of the same morphology occur during implantation and can be measured. It is reasonable to attempt reprogramming the sensitivity to allow the extrasystoles to be sensed, but if this is unsuccessful, it is rarely, if ever, necessary to reposition the lead for this abnormality.

Functional undersensing is present when an intrinsic cardiac event is not sensed because it falls within a programmed refractory period.[100] For example, if an intrinsic atrial event occurs within the PVARP, the event is not, and should not be, sensed. However, without a thorough understanding of the timing cycle, it may appear as though there is true undersensing.

Fusion and pseudofusion beats occur as a result of superimposition of an ineffective pacemaker stimulus on a spontaneously occurring P wave or QRS complex (Fig. 24-25) . (Fusion is present when the

Figure 24-22 Electrocardiographic tracing from a patient with a VVIR pacemaker programmed to a lower rate of 60 beats/min (1000 milliseconds). The second ventricular pacing artifact fails to result in ventricular depolarization, failure to capture. This is followed by a pause longer than the programmed lower rate of 1000 milliseconds. This pause most likely is explained by oversensing of some event on the ventricular sensing circuit. Ventricular pacing then resumes at the programmed rate of 60 beats/min.

Figure 24-23 Electrocardiographic tracings. *A*, Patient with a VVIR pacemaker with a lower rate of 70 beats/min. After an initial paced ventricular beat, there is a pause of approximately 2.8 seconds with significant baseline artifact. After two additional paced beats, another pause of approximately 2.8 seconds occurs. This patient had a pacemaker programmed to a unipolar sensing configuration. Sensing of myopotentials led to symptomatic pauses, and reprogramming the pacemaker to a bipolar sensing configuration prevented subsequent myopotential oversensing. *B*, Patient with a DDD pacemaker. After the third atrial pacing artifact, there is evidence of atrial depolarization, but there is no ventricular pacing output. Failure to deliver the ventricular pacing artifact is due to crosstalk; that is, the atrial pacing output is sensed by the ventricular sensing circuit, with subsequent inhibition.

morphology of the cardiac event is a hybrid of the intrinsic morphology and the paced morphology. Pseudofusion is present when the pacemaker artifact occurs late enough that the intrinsic morphology is not deformed, but it may appear so because of distortion on the ECG by the superimposed pacing artifact.) Pseudofusion is usually the consequence of pacemaker discharge during the refractory period of intrinsic P or QRS before sufficient intracardiac voltage is generated to activate the sensing circuit. This is most likely to occur when the pacing rate and the intrinsic rate are similar. Pseudofusion beats also can be the result of a delayed activation due to intraventricular conduction abnormalities.

INAPPROPRIATE PACING MODE.

Every pacing mode has a defined lower rate, and dual-chamber pacemakers and rate-adaptive pacemakers also require a defined upper rate. It is necessary to be familiar with the timing cycle of a particular pacing mode and any idiosyncrasies of the specific pacemaker to be able to determine whether the paced rate is appropriate. The possible causes of a paced rate that appears to be different from that programmed are circuit failure, battery failure, magnet application, hysteresis (Fig. 24-26) , crosstalk, undocumented reprogramming of the pacemaker, oversensing, runaway pacemaker, and malfunction of the ECG recording equipment, such as alteration in the paper speed.

Drugs can affect sensing thresholds, pacing thresholds, and defibrillation thresholds and result in ECG abnormalities.[98] [101] Although many drugs have been reported to affect pacing thresholds, the Class 1C agents are the only drugs that commonly cause a problem. Encainide, flecainide, propafenone, and moricizine have the potential to increase pacing thresholds and sensing thresholds. If these drugs are administered to the patient with a pacemaker, especially a pacemaker-dependent patient, thresholds should be monitored for change.

Electrolyte and metabolic abnormalities can also affect pacing and sensing thresholds. Hyperkalemia is the most common electrolyte abnormality to cause clinically significant problems, but severe acidosis or alkalosis, hypercapnia, severe hyperglycemia, hypoxemia, and myxedema may also result in threshold alteration.[98]

ELECTROMAGNETIC INTERFERENCE

Electromagnetic interference (EMI) is defined as any signal, biological or nonbiological, that is within a frequency spectrum that can be detected by the sensing circuitry

of the pacemaker or ICD. EMI can result in rate alteration, sensing abnormalities, asynchronous pacing, noise reversion (Fig. 24-27) , or reprogramming. [101A] EMI can also result in failure to deliver antibradycardia pacing, inappropriate delivery of antitachycardia therapy, resetting of programmed parameters, and damage to the pulse generator or myocardial interface.

Other cardiac and extracardiac signals that may be falsely interpreted as a P or QRS and result in oversensing include T waves (Fig. 24-28) , myopotential interference, afterpotential delay, and P waves.

Nonbiological sources of EMI are best divided into sources of EMI within the hospital and outside the hospital. Although multiple sources of EMI in the nonhospital environment can potentially result in single-beat inhibition, few, if any, of these are clinically significant and truly represent a threat to the paced patient.

Several potential sources of EMI require specific mention either because of their real potential for causing significant EMI or because of confusion or controversy that exists in or out of the medical community. Industrial-strength welding equipment, that is, more than 500 A, certain degaussing equipment, and induction ovens are identified sources of EMI that can cause significant pacemaker or ICD interference.[101] Most welding equipment used for "hobby" welding should

Figure 24-24 Electrocardiographic tracing from a patient with a VVI pacemaker with a programmed rate of 70 beats/min. After two paced ventricular complexes, a premature ventricular complex occurs. In approximately 260 milliseconds, a ventricular pacing artifact occurs. This is followed by a P wave with intrinsic atrioventricular nodal conduction and native QRS complex. A pacemaker artifact follows in approximately 220 milliseconds. This represents ventricular undersensing. In this patient, the abnormality occurred because of an insulation failure of the ventricular pacing lead.

Figure 24-25 Electrocardiographic tracing from a patient with a VVI pacemaker. The first two complexes represent fully paced ventricular depolarizations. The third ventricular event is an intrinsic QRS complex, and the fourth event represents a fusion beat. This is followed by two paced ventricular complexes.

Figure 24-26 Electrocardiographic tracing from a patient with a VVI pacemaker programmed to a lower rate of 60 beats/min and a hysteresis rate of 40 beats/min. The longer cycle follows an intrinsic ventricular beat.

Figure 24-27 Electrocardiographic tracing from a patient with a DDD pacemaker during exposure to electromagnetic interference. This pacemaker responds with asynchronous pacing as the noise reversion mode.

not cause any significant problems. In the pacemaker-dependent patient who does hobby welding or any other activity that raises the clinician's concerns about EMI, attempts should be made to be certain that the environment is safe for the patient.

Currently, there is much interest in the potential EMI that may emanate from cellular telephones[102] [103] and antitheft devices.[104] [105] [106] Available information suggests that analog cellular phones are safe for the paced patient. Digital cellular phones have greater potential for EMI, and some caution remains for the pacemaker-dependent patient using a telephone with digital technology. If the patient avoids having the cellular phone over the pacemaker, either from random motion of the phone or by carrying the activated phone in a breast pocket over the pacemaker, any adverse clinical event is unlikely.

Antitheft devices also have potential for pacemaker interference.[104] [105] [106] Practical suggestions are for patients with pacemakers or ICDs to be aware of electronic equipment for surveillance of articles and to avoid leaning on or lingering near such devices. If the patient passes through the equipment at a normal pace, adverse effects are unlikely. Any patient who feels unusual in any way when near electronic surveillance equipment should move away.

Hospital sources of potentially significant EMI are electrocautery, cardioversion, defibrillation, magnetic resonance imaging, lithotripsy, radiofrequency ablation, electroshock therapy, and diathermy. The most important aspect of pacemaker or ICD care after exposure to any of these sources of EMI is to reassess the device to be certain that programmed parameters have not been changed.

One of the most frequent questions asked is how to manage the patient with a pacemaker or ICD during an operative procedure, given the potential effects of electrocautery and guidelines for cardioversion and defibrillation. Routine interrogation of the device and deactivation of ICD therapy should be accomplished before the operation. After the procedure, the device should be reinterrogated and ICD therapy reinitiated. (During the time ICD therapy is "off," the patient must be monitored.) For pacemaker-dependent patients, it is reasonable to program the pacemaker to an asynchronous pacing mode, VOO or DOO, or to achieve the same effect by placing a magnet over the pacemaker throughout the procedure. The potential effects of electrocautery are reprogramming; permanent damage to the pulse generator; pacemaker inhibition; reversion to a fall-back mode, noise reversion mode, or electrical reset; and myocardial thermal damage. The guidelines for cardioversion and defibrillation in the patient with a pacemaker or ICD are as follows: Ideally, place paddles in the anterior-posterior position, try to keep the paddles at least 4 inches from the pulse generator, have the appropriate pacemaker programmer available, and interrogate the pacemaker after the procedure.

DEVICE FOLLOW-UP

Pacemakers and ICDs must be followed up on a regular schedule. There are different follow-up methods depending on clinician preference. Pacemaker and ICD follow-up schedules should be discussed separately because of the significant effect that transtelephonic monitoring has on pacemaker follow-up as opposed to essentially no use in ICD follow-up at this time. For pacemaker follow-up, some prefer regular office assessment, others predominantly transtelephonic follow-up, and still others a combination of the two techniques. Table 24-15 details the Medicare-approved follow-up schedule for reimbursement for transtelephonic monitoring.[106]

Figure 24-28 Electrocardiographic tracing from a patient with a VVI pacemaker programmed to a rate of 70 beats/min (857 milliseconds). The third and fourth VV cycles are longer than the programmed lower rate. Measuring 857 milliseconds backward from the ventricular pacing artifact at the end of the longer cycles locates the point at which there was oversensing. In this case, probably the T wave is sensed. Definite retrograde P waves can be recognized by deformation of the T wave. Although it is possible that the retrograde P wave is being oversensed, the relationship of the P waves does not appear to consistently coincide with the point of oversensing.

TABLE 24-15 -- FOLLOW-UP SCHEDULE FOR TRANSTELEPHONIC MONITORING OF PACEMAKERS*

Single-chamber pacemakers	
1st month	Every 2 weeks
2nd through 36th month	Every 8 weeks
37th month to battery depletion	Every 4 weeks
Dual-chamber pacemakers	
1st month	Every 2 weeks
2nd through 6th month	Every 4 weeks

7th through 72nd month	Every 8 weeks
73rd month to battery depletion	Every 4 weeks

*This guideline is in effect for most pacemakers currently in use. A separate set of guidelines is available for specific pacing systems with sufficient long-term clinical information to meet certain standards for longevity and battery depletion characteristics.

Transtelephonic assessment should include collection of a nonmagnet ECG strip, an ECG strip with magnet applied to the pacemaker, and measurement of magnet rate and pulse duration (pulse duration on both atrial and ventricular channels should be measured for a dual-chamber pacemaker). During an office visit, the same information should be collected. In addition, on some periodic basis, for example, once a year, patients programmed to a rate-adaptive pacing mode should be assessed to determine whether rate-response is appropriate.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR THERAPY

Indications

The ACC/AHA Joint Committee has established indications for implantation of an ICD and for pacing.[2] The indications for ICD therapy continue to evolve on the basis of results of clinical trials.

Clinical trials have been designed to determine the effect of ICD therapy in secondary prevention of sudden cardiac death (Table 24-16) , that is, in patients who have already experienced a life-threatening ventricular rhythm disturbance, or in primary prevention (Table 24-17) , that is, in patients who are at high risk for sudden cardiac death.[119] The Antiarrhythmics Versus Implantable Defibrillators (AVID)[107] trial (secondary prevention), Multicenter Automatic Defibrillator Implantation Trial (MADIT)[111] [112] (primary prevention), Cardiac Arrest Study-Hamburg (CASH)[108] (secondary prevention), and Multicenter Unsustained Tachycardia Trial (MUSTT)[114] (primary prevention) have all demonstrated significant improvement in overall survival with ICD therapy compared with conventional or drug treatment. No significant difference in overall survival was seen with ICD therapy in the Canadian Implantable Defibrillator Study (CIDS) trial (secondary prevention, probably underpowered) or the Coronary Artery Bypass Graft-Implantable Cardioverter-Defibrillator (CABG-PATCH)[113] study

TABLE 24-16 -- CLINICAL TRIALS OF PACING FOR THE SECONDARY PREVENTION OF SUDDEN CARDIAC DEATH

STUDY	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
AVID[107]	Survivor of cardiac arrest	Total mortality	Amiodarone or sotalol	Significant improvement in overall survival with ICD
	VT with syncope	Mode of death		
	Symptomatic sustained VT with LVEF 0.40	Quality of life		
		Cost benefit		
CASH[108]	Survivor of cardiac arrest	Total mortality	ICD	Significant improvement in overall survival with ICD
		Recurrences of arrhythmias requiring CPR	Amiodarone, propafenone, or metoprolol	
		Recurrence of unstable VT		
CIDS	Survivor of cardiac arrest	Total mortality	Amiodarone	No significant improvement in survival with ICD
	Syncope with symptomatic sustained VT with LVEF 0.35 or syncope with inducible VT			
MAVERIC[109]	Resuscitated VT/VF, SCD	All-cause mortality	Empirical amiodarone	In progress
	Sustained nonsyncopal VT	Event-free survival	EP-guided therapy (drug or nondrug)	
	Dilated nonischemic cardiomyopathy with EF 0.35, syncope, and NSVT or positive SAECG	Costs		Immediate ICD implantation
		Quality of life		
		Cost-effectiveness		
ASTRID[110]	Patients with Ventak AV1810 implanted for current indication	Time to first occurrence of inappropriate therapy	Standard-features programming	Completed; results not published
	DFT <600 V and minimum 1 mV atrial, 5 mV ventricular EGM amplitudes at implantation	Health care utilization	Enhanced-features programming	
		Quality of life		
VT-MASS	ICD indication	Combined endpoint of symptomatic arrhythmia, appropriate ICD therapy, or death	ICD and metoprolol	In progress
	EF >20%		ICD and sotalol	
			ICD without AAD or BB	

AAD = antiarrhythmia drugs; ASTRID = Atrial Sensing to Reduce Inappropriate Defibrillation; AVID = Antiarrhythmics Versus Implantable Defibrillators; BB = beta blockers; CASH = Cardiac Arrest Study-Hamburg; CIDS = Canadian Implantable Defibrillator Study; CPR = cardiopulmonary resuscitation; DFT = defibrillation threshold; EF = ejection fraction; EGM = electrogram; EP = electrophysiologic; ICD = implantable cardioverter-defibrillator; LVEF = left ventricular ejection fraction; MAVERIC = Midlands Trial of Empirical Amiodarone Versus Electrophysiologically Guided Intervention and Cardioverter Implant in Ventricular Arrhythmias; NSVT = nonsustained ventricular tachycardia; SAECG = signal-averaged electrocardiography; SCD = sudden cardiac death; VT = ventricular tachycardia; VT-MASS = Metoprolol and Sotalol for Sustained Ventricular Tachycardia.

TABLE 24-17 -- CLINICAL TRIALS OF PACING FOR THE PRIMARY PREVENTION OF SUDDEN CARDIAC DEATH

STUDY	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
MADIT[111] [112]	Q wave MI 3 weeks	Overall mortality	ICD (n = 95)	ICDs reduced overall mortality by 54%
	Asymptomatic NSVT	Costs and cost-effectiveness	Conventional therapy (n = 101)	ICDs cost $16,900 per life-year saved
	LVEF 0.35			*vs.*
	Inducible and nonsuppressible VT on EPS with procainamide			Conventional therapy

	NYHA Class I-III			
CABG-PATCH[113]	Scheduled for elective CABG surgery	Overall mortality	ICD (n = 446)Standard treatment (n = 454)	Survival not improved by prophylactic implantation of ICD at time of elective CABG
	LVEF <0.36			
	Abnormal SAECG			
MUSTT[114]	CAD	Sudden arrhythmic death or spontaneous sustained VT	ICD in nonsuppressible group	In progress
	EF 0.40		Antiarrhythmic drug therapy in suppressible group	
	NSVT		No therapy	
	Inducible VT or VF			
CardioMyopathy study[115]	Nonischemic DCM	Total mortality	ICD	In progress
	LVEF 0.30	Sudden death	Standard treatment	
	NYHA Class II or III	Serious arrhythmia		
Defibrillat	Patient with CHF awaiting heart transplant	Total mortality	ICD	In progress
		Serious arrhythmias	Standard treatment	
BEST[116]	Acute MI	All-cause mortality	Conventional + beta-blocker therapy	In progress
	EF 0.40	Cost-effectiveness	EPS: if inducible, ICD and beta blocker; if noninducible, beta blocker	
	SDRR <70 msec or 109 VPCs/hr or abnormal SAECG			
DINAMIT	Acute MI (6-21 days)	All-cause mortality	Conventional therapy	In progress
	LVEF 0.35	Quality of life	ICD	
	HR 80 beats/min or SDRR <70 msec	Cost-effectiveness		
MADIT-II[117]	Prior MI	All-cause mortality	Conventional therapy	In progress
	EF 0.30	Cost-effectiveness	ICD	
SCD-HeFT*[118]	Ischemic or nonischemic cardiomyopathy	All-cause mortality	Placebo and standard therapy	
	EF 0.35	Quality of life	*vs.*	
	NYHA Class II or III	Cost-effectiveness	Amiodarone and standard therapy	
	Appropriate ACE inhibitor	Morbidity	*vs.*	
	No history of sustained VT/VF	Incidence of arrhythmias	ICD and standard therapy	
DEFINITE*	Symptomatic nonischemic cardiomyopathy	All-cause mortality	ICD, standard drug therapy	In progress
	NSVT	Quality of life		
	Low EF (35%)	Cost-effectiveness	*vs.*	
			Standard drug therapy and beta blocker only	
DEBUT (SUDS)	Survivor of sudden cardiac arrest from resuscitated VT/VF	All-cause mortality	ICD	In progress
	Probable sudden cardiac arrest with RBBB and ST segment elevation	Rhythms from stored EGMs that triggered ICD shocks	*vs.*	
			Beta blocker	
VENTAK-CHF/CONTAK CD[65]	Indication for ICD	Functional capacity	Biventricular pacing or no pacing and then crossover	In progress
	Symptomatic CHF on stable drugs, including ACE	Quality of life		
	EF 0.35	NYHA Class		
	QRS >120 msec			
PRIDE	VT, VF, or cardiomyopathy with syncope, NSVT	All-cause mortality	ICD	In progress
		Cost-effectiveness	*vs.*	
			EPS and randomization to ICD	
			vs.

*Primary prevention in patients with heart failure.

(primary prevention). CABG-PATCH should probably be considered separately, because this study randomized patients who were to undergo coronary artery bypass grafting to either ICD implantation at the time of bypass surgery or postoperative antiarrhythmic treatment. The study was terminated prematurely when the interim analysis failed to show a survival difference between the two study groups. The deaths in both groups were perioperative and therefore could not have been prevented by antiarrhythmic therapy. Analysis of subgroups showed the benefits of the ICD in patients at risk of life-threatening ventricular tachyarrhythmia.[120] The role of ICD therapy for patients with asymptomatic sustained monomorphic ventricular tachycardia and structural heart disease but with an ejection fraction greater than 40 percent is less clear.[121] [122]

The underlying disease state may affect the decision to implant an ICD. In patients with coronary artery disease, active ischemia is the cause of significant ventricular tachyarrhythmias and should be assessed and treated before implantation. Patients with coronary artery disease and reduced left ventricular dysfunction appear to experience greater benefit with ICD therapy than with drug therapy.[112] [123] In the AVID trial, patients with an ejection fraction greater than 35 percent who received an ICD did not have a significant mortality benefit over those who received amiodarone. Clinical trials are under way to more specifically assess the benefit of primary prevention of sudden cardiac death after myocardial infarction (Table 24-18) .

In patients with idiopathic dilated cardiomyopathy (see Chap. 48), the combination of poor left ventricular function and nonsustained ventricular tachycardia is associated with an increased risk of sudden death[107] (see Chap. 26). Trials of primary prevention in patients with dilated cardiomyopathy are under way.

ICD therapy is recommended in patients with congenital long-QT syndrome who experience recurrent syncope, sustained ventricular arrhythmias, or sudden cardiac arrest despite drug therapy[124] (see Chaps. 23 and 25).

Patients with HCM who have experienced sudden cardiac arrest should receive an ICD[125] [125A] (see Chap. 48). Medications may still be necessary to control other symptoms secondary to HCM as well as for antiarrhythmic therapy, but ICD therapy affords better protection for the prevention of recurrent syncope. The asymptomatic patient with HCM and a family history of sudden death, syncope, or nonsustained ventricular tachycardia should also be considered for ICD implantation[126] (see Chap. 48).

The patient with idiopathic ventricular fibrillation should receive an ICD.[127] However, patients with idiopathic ventricular tachycardia and no structural heart disease should probably be considered for catheter ablation before consideration of ICD therapy.[128] Although several treatment

TABLE 24-18 -- CLINICAL TRIALS OF PACING FOR PRIMARY PREVENTION AFTER MYOCARDIAL INFARCTION

STUDY	PATIENT INCLUSION CRITERIA	ENDPOINT(S)	TREATMENT ARMS	KEY RESULTS
SEDET	Acute MI (1 to 3 weeks) Ineligible for thrombolysis EF 0.15 to 0.40 Nonsustained VT or 10 PVCs/hr between 6 and 21 days after MI	All-cause mortality Quality of life Incidence of VT Sudden and nonsudden death Cardiac death Predictive value of BRS and HRV	ICD *vs.* Conventional therapy	In progress
IRIS	Acute MI Fast NSVT >150 beats/min HR >100 beats/min at admission	All-cause mortality Resource utilization Quality of life	ICD *vs.* Conventional therapy	In progress

BRS = baroreceptor sensitivity; EF = ejection fraction; HR = heart rate; HRV = heart rate variability; ICD = implantable cardioverter-defibrillator; IRIS = Immediate Risk Stratification Improves Survival; MI = myocardial infarction; NSVT = nonsustained ventricular tachycardia; PVC = premature ventricular contraction; SEDET = South European Defibrillator Trial; VT = ventricular tachycardia.

strategies may be necessary for the patient with arrhythmogenic right ventricular dysplasia, ICD therapy should be considered for prophylaxis against syncope due to hemodynamically unstable ventricular tachycardia and sudden cardiac death (see Chap. 25).

Basics of Design and Selection

The basic components of the ICD are electronic circuitry, power source, and memory, with a microprocessor coordinating the various parts of the system.[119] [129] High-voltage capacitors transform the battery-provided voltage into discharges ranging from less than 1 V for pacing to 750 V for defibrillation. ICDs incorporate a different sensing circuit

TABLE 24-19 -- IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR THERAPY

ZONE	TACHYCARDIA RATE (beats/min)	THERAPY DELIVERED
1	126-160	ATP-1, ATP-2, 1 J, 5 J, 34 J
2	161-200	ATP, 10 J, 34 J
3	>200	34 J

ATP = antitachycardia pacing therapy; ATP-1 = first ATP; ATP-2 = second (and different) ATP.

Figure 24-29 Posteroanterior *(A)* and lateral *(B)* chest radiographs of an implantable cardioverter-defibrillator (ICD) system in the left prepectoral position. The ICD is connected to a single-coil ventricular lead and a lead positioned in the superior vena cava (SVC). In this patient, adequate defibrillation thresholds (DFTs) could not be obtained with the single-coil ventricular lead. With the additional lead positioned high in the SVC, excellent DFTs were achieved.

than most pacemakers. Because of the need to reliably sense low-amplitude signals during ventricular fibrillation and to avoid sensing extracardiac noise and cardiac signals other than ventricular tachycardia or fibrillation, the sensing circuit is designed to automatically adjust either the gain or the sensing threshold.[119] [130]

ICD systems have evolved rapidly from thoracotomy to nonthoracotomy, that is, transvenous pectorally placed systems, and from ventricular bradycardia pacing to dual-chamber pacing with rate-adaptive options.[130A] In addition, atrial defibrillation capabilities are available in some devices. Longevity of ICDs depends on the frequency of shock

Figure 24-30 Posteroanterior *(A)* and lateral *(B)* chest radiographs from a patient with an implantable cardioverter-defibrillator. Unacceptable defibrillation thresholds necessitated placement of a

subcutaneous array.

delivery, the degree of pacemaker dependency, and other programmable options, but most are expected to last from 5 to 9 years.

It is important to have an understanding of "shock waveforms." Biphasic waveforms are more efficient, that is, require lower energies, than monophasic shocks. All currently available ICDs use biphasic shock waveforms, but the specifics of the waveform differ among various manufacturers.

The ICD functions by continuously monitoring the patient's cardiac rate and delivering therapy when the rate exceeds the programmed rate "cutoff." For example, if the ICD is programmed to deliver shocks for the treatment of tachyarrhythmias at a rate cutoff of 175 beats/min, once the patient's heart rate exceeds 175 beats/min and this event is detected by the ICD, the device delivers antitachycardia pacing (ATP) or charges and delivers a shock, depending on the programmed therapy.

ATP has the advantage of terminating a rhythm disturbance without delivery of a shock. ICDs capable of ATP have significant programming flexibility to adjust many aspects of tachycardia detection and therapy and thereby customize therapy for the individual patient. Different "zones" or "tiers" of therapy can be programmed to detect ventricular tachyarrhythmias to allow slower arrhythmias to be treated with ATP before a shock is delivered but to still allow faster tachycardias to be treated more aggressively. Table 24-19 outlines programming for a hypothetical patient. In this patient, slower ventricular tachycardia in the range of 126 to 190 beats/min is treated with ATP therapies in zone 1. If initial ATP therapy (ATP-1) is unsuccessful, a second and different ATP therapy (ATP-2) is automatically delivered. If this is unsuccessful, lower energy shocks are attempted before high-energy (34 J) shocks are delivered. Shocks are synchronized during ventricular tachycardia (cardioversion) or are asynchronous

Figure 24-31 *A* and *B,* Printouts from an implantable cardioverterdefibrillator (ICD) programmer of a specific episode detected by the ICD. The text includes 29 VV interval lengths before therapy for ventricular fibrillation and 20 VV cycle lengths after therapy, documenting return to a nonpathologic ventricular rhythm. FD = fibrillation detected; FS = fibrillation sensed; TS = tachycardia sensed; VS = ventricular sensed event.

during ventricular fibrillation (defibrillation). A second zone of therapy is determined for a faster ventricular tachycardia, and still faster ventricular tachycardia or ventricular fibrillation is treated aggressively with a high-energy shock. In addition, current ICDs provide bradycardia support, as single- or dual-chamber devices.

The zones, detection rates of the different zones, specifics of the different therapies, and bradycardia pacing options are all programmable, and programming flexibility varies significantly from device to device.

Implant Procedure

When the ICD is placed transvenously with the pulse generator in the prepectoral position, the implantation technique and related complications are the same as those for pacemaker implantation, with the exception that complications can arise as a result of determining the defibrillation threshold (DFT). (DFT can be defined as the minimal energy that terminates ventricular fibrillation.[119]) Risks associated with both procedures include lead dislodgment, pneumothorax and other potential complications of subclavian puncture if this venous approach is used, infection, and perforation.

Most ICD implantations are now performed with conscious sedation and local anesthesia. During DFT testing, the patient is placed under deep anesthesia with mask-supported ventilation. When DFT determination is completed, the patient can be allowed to recover from deeper anesthesia as the pocket is closed.

An acceptable DFT is a value that ensures an adequate safety margin for defibrillation, usually at least 10 J less than the maximum output of the ICD. The maximum output of current ICDs is in the range of 26 to 38 J. It is difficult to state an "ideal" DFT because it is ideally the lowest achievable DFT with an adequate safety margin.

It is generally best to implant the ICD in the left pectoral region because of a more favorable vector for delivery of the shock. Although successful defibrillation can usually be accomplished with a right-sided implant, the shocking vector is less optimal and may have an effect on achievable DFT.[131] Regardless of whether the ICD is placed on the right or the left, in a small percentage of patients adequate DFT cannot be achieved with standard lead placement. In this situation, options include

1. Repositioning the ventricular lead. If the lead was not initially placed in a right ventricular apical position, such a position should be sought. If the right ventricular apical position resulted in unacceptable DFT, repositioning the lead slightly superior to the apex or in a septal position may be successful.
2. Adding a second lead in the superior vena cava (Fig. 24-29) .
3. Adding a subcutaneous array (Fig. 24-30) .

Follow-Up

Follow-up of the patient with an ICD must include periodic visits at which specific information is collected and assessed. In addition, patients may require interim assessment if there are concerns about the appropriateness of delivered therapy or other changes in the patient's medical status or drug regimen that could affect ICD therapy.

The electrophysiologist or an allied professional with ICD expertise and immediate access to the electrophysiologist should perform follow-up procedures. Aspects of follow-up are history with specific emphasis on awareness of delivered therapy and any tachyarrhythmic events, device interrogation, assessment of battery status and charge time, retrieval and assessment of stored diagnostic data, periodic radiographic assessment, and periodic arrhythmic induction in the electrophysiology laboratory to assess defibrillation thresholds and efficacy.

Diagnostic information that can be retrieved varies with different ICDs. All ICDs provide information about the cycle length, or rate, of the detected tachyarrhythmias (Fig. 24-31) , and most current devices provide stored electrograms of detected arrhythmias (Fig. 24-32) .

Follow-up protocols for patients with ICDs vary. Some manufacturers have recommended follow-up every 3 months, but some institutions are comfortable with follow-up every 6 months for the first 3 to 4 years, after which the follow-up frequency increases.

Complications

Exposure of the patient with an ICD to sources of EMI can result in the concerns expressed for pacemaker recipients.[119] EMI can interfere with bradycardia support and with detection of or response to tachyarrhythmias. Possible adverse effects of EMI are inappropriate delivery of anti-tachycardia therapy, reprogramming of the ICD parameters, and failure to deliver antibradycardia pacing. After any known or potential EMI exposure, the ICD, like a permanent pacemaker, should be reinterrogated, and programmed parameters should be compared with records obtained before the EMI exposure to be certain that EMI has not inappropriately reprogrammed the device.

Figure 24-32 Stored electrogram from a patient with an episode of ventricular fibrillation and a dual-chamber pacemaker and implantable cardioverter-defibrillator. The upper tracing is the atrial electrogram, the middle tracing is the ventricular electrogram, and the bottom tracing is the surface electrocardiogram.

TABLE 24-20 -- DIFFERENTIAL DIAGNOSIS AND MANAGEMENT OF MULTIPLE IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR (ICD) SHOCKS

CLINICAL FINDING	MANAGEMENT
Frequent ventricular tachycardia or ventricular fibrillation (electrical storm)	Reassess antiarrhythmic therapy and programmed ICD therapy
Unsuccessful ICD therapy due to inappropriately low output shock or elevation of defibrillation threshold	Reprogram ICD
	Assess potential causes of defibrillation threshold increase (e.g., drugs)
Lead fracture	Replace fractured lead
Lead dislodgement	Reposition lead
Sensing supraventricular rhythms	Reassess antiarrhythmic therapy
	Reprogram ICD parameters
	Ablate supraventricular arrhythmic focus
Oversensing separate pacing system	Reprogram pacemaker or ICD (or both)
	Reposition pacemaker or ICD leads (or both)
	Remove pacemaker and replace ICD with another ICD with more sophisticated bradycardia support
Oversensing electromagnetic interference	Avoid source
	Reprogram ICD
Oversensing intracardiac signals	Reprogram ICD
	Reposition sensing lead

Modified from Pinsky SL, Fahy GJ: Implantable cardioverter-defibrillators. Am J Med 106:446, 1999. By permission of Excerpta Medica.

Specific EMI sources and their potential effect on ICDs should be mentioned. In the hospital, magnetic resonance imaging is still considered contraindicated in the patient with an ICD, although there are scattered case reports of it being successfully done. Lithotripsy is contraindicated if the ICD is in the lithotripsy field.[132] Concerns have also been raised about transcutaneous nerve stimulation when an ICD is present.[133] Outside the hospital, welding has generally been considered a contraindication. However, some data suggest that some patients can be allowed to carry out this activity if they are evaluated in their work environment.

It appears that cellular phones can be used safely by the patient with an ICD so long as the same guidelines noted for pacemaker patients are followed.[134] When using a cellular phone, the patient should avoid having the phone in close contact with the ICD and should not carry an activated phone in a pocket that is near the device. Theft detector devices are not a problem unless there is prolonged exposure.[135]

Changes in drug therapy must be monitored closely in the patient with an ICD.[136] Certain drugs have the potential for interaction by altering the detection of ventricular tachycardia, altering the pacing threshold (as previously discussed), increasing defibrillation thresholds, and producing proarrhythmic effects.

Drug alteration of the rate of ventricular tachycardia may result in inadequate detection of the arrhythmia. Elevation of the DFT may occur as the result of amiodarone administration.[137] Other drugs can theoretically increase the DFT or have been reported to do so in single-case reports, but a clinically significant change does not often result.[136]

Frequent ICD discharges may represent a clinical emergency. These discharges may be appropriate or inappropriate (Table 24-20) . Appropriate discharges represent frequently occurring ventricular tachycardia or fibrillation or electrical storm. If the device is discharging frequently because the defibrillation is unsuccessful, the device may be programmed to an inappropriately low shock output or an alteration in the DFT may have occurred that resulted in inadequate programmed therapy.

Inappropriate discharges are usually the result of inappropriate detection of a supraventricular tachyarrhythmia, most commonly atrial fibrillation (see Table 24-20). Inappropriate discharge can also be the result of device failure, for example, lead fracture.

Before the incorporation of sophisticated bradycardia support within the ICD, many patients had separate pacing and ICD systems. Numerous types of interactions between pacemakers and ICDs have been described.[138] Pacemaker output preventing proper detection of ventricular tachycardia or ventricular fibrillation by the ICD is one of the more serious. Asynchronous pacemaker activity during ventricular arrhythmias may be caused by either undersensing of the arrhythmia or noise reversion. Conditions favoring noise reversion are specific pacemaker models, arrhythmia cycle lengths in the range causing noise reversion of the individual pacemaker model, long noise sampling periods, and the VVI pacing mode. Noise reversion can be diagnosed by telemetering the pacemaker marker channel during ventricular arrhythmias as a part of routine evaluation of pacemaker-ICD interaction.

GUIDELINES USE OF CARDIAC PACEMAKERS AND ANTIARRHYTHMIA DEVICES

Thomas H. Lee

An American College of Cardiology/American Heart Association (ACC/AHA) task force updated guidelines for the implantation of cardiac pacemakers and antiarrhythmia devices in 1998.[1] These guidelines evaluate potential indications for the implantation of pacemakers and antiarrhythmic devices. The guidelines use the same system as other guidelines from these organizations; i.e., they divide them into classes according to their appropriateness. Class I signifies general agreement that the device or therapy is indicated. Class II indicates a divergence of opinion with respect to their usefulness, with Class IIa favoring and Class IIb not favoring usefulness. The level of evidence to support each position is rated on a scale from A to C (see Guidelines to Chap. 5), in which "A" indicates that data were derived from multiple randomized trials involving a large number of individuals, "B" indicates that data were derived from a limited number of trials involving a relatively small number of patients or from well-designed observational studies, and "C" indicates that expert consensus was the primary source of the recommendation.

Indications for Permanent Pacing (Table 24-G-1)

ACQUIRED ATRIOVENTRICULAR BLOCK.

For patients with acquired atrioventricular (AV) block, bifascicular or trifascicular block, or sinus node dysfunction, permanent pacing was considered appropriate when the abnormality caused complications and was not precipitated by a drug that could be discontinued. Examples of complications include symptomatic bradycardia, congestive heart failure, and confusional states. Permanent pacing was also deemed appropriate for asymptomatic patients with a high risk for the subsequent development of complications, such as patients with complete heart block and periods of asystole of 3 seconds or more or a slow escape rate or patients with bifascicular or trifascicular block with intermittent third-degree AV block.

For patients with first-degree AV block who have symptoms suggestive of pacemaker syndrome, these guidelines include a new indication for permanent pacing that is considered equivocal but supported by some data (Class IIa). Patients with pacemaker syndrome need a dual-chamber pacemaker to restore normal AV synchrony. A Class IIb indication for permanent pacing was described for patients with a prolonged PR interval and drug-refractory dilated cardiomyopathy if acute hemodynamic studies demonstrate the benefit of pacing.

Indications for permanent pacing for patients who do not have symptoms or complications are less certain. In asymptomatic patients, complete heart block with a ventricular escape rate of 40 or more beats/min or type II second-degree AV block was considered an equivocal (Class IIa) indication for permanent pacing. Bifascicular or trifascicular block in patients with syncope was also not a clear indication for permanent pacing but was regarded as acceptable if other possible causes of syncope cannot be identified. Pacemakers were explicitly discouraged for patients with mild asymptomatic conduction abnormalities, such as type I second-degree AV block at the supra-His level, fascicular block with no or only a first-degree AV block, and sinus node dysfunction.

Symptoms do not play as important a role in determination of the appropriateness of permanent pacing in patients with acute myocardial infarction because of the poor prognosis and high incidence of sudden death in postinfarction patients with conduction system disturbances. The ACC/AHA task force emphasized that the requirement for temporary pacing after acute myocardial infarction is not in itself an indication for permanent pacing (see Guidelines to Chap. 35 for guidelines on temporary pacing in acute myocardial infarction). However, permanent pacemakers were considered appropriate for patients with persistent advanced-degree AV block or transient infranodal AV block and associated bundle branch block. The usefulness of electrophysiology study to determine the site of block was acknowledged. The usefulness of permanent pacemakers for patients with advanced

TABLE 24--G-1 -- ACC/AHA GUIDELINES FOR PERMANENT PACING*

Issue	Class	Recommendation	Level of Evidence

Permanent pacing in acquired AV block	I	Third-degree AV block at any anatomical level associated with any one of the following conditions:	
		Bradycardia with symptoms presumed to be due to AV block	C
		Arrhythmias and other medical conditions that require drugs that result in symptomatic bradycardia	C
		Documented periods of asystole of 3.0 sec or any escape rate of < 40 beats/min in awake, symptom-free patients	B, C
		After catheter ablation of the AV junction	B, C
		Postoperative AV block that is not expected to resolve	C
		Neuromuscular diseases with AV block such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb's dystrophy (limb-girdle), and peroneal muscular atrophy	B
		Second-degree AV block, regardless of the type or site of block, with associated symptomatic bradycardia	B
	IIa	Asymptomatic third-degree AV block at any anatomical site with average awake ventricular rates of 40 beats/min or faster	B, C
		Asymptomatic type II second-degree AV block	B
		Asymptomatic type I second-degree AV block at the intra- or infra-His levels found incidentally at electrophysiological study performed for other indications	B
		First-degree AV block with symptoms suggestive of pacemaker syndrome and documented alleviation of symptoms with temporary AV pacing	B
	IIb	Marked first-degree AV block (> 0.30 sec) in patients with LV dysfunction and symptoms of congestive heart failure in whom a shorter AV interval results in hemodynamic improvement, presumably by decreasing left atrial filling pressure	C
	III	Asymptomatic first-degree AV block	B
		Asymptomatic type 1 second-degree AV block at the supra-His (AV node) level or not known to be intra- or infra-Hisian	B, C
		AV block expected to resolve and unlikely to recur (e.g., drug toxicity, Lyme disease)	B
Permanent pacing in chronic bifascicular and trifascicular block	I	Intermittent third-degree AV block	B
		Type II second-degree AV block	B
	IIa	Syncope not proved to be due to AV block when other likely causes have been excluded, specifically VT	B
		Incidental finding at electrophysiological study of markedly prolonged H-V interval (> 100 msec) in asymptomatic patients	B
		Incidental finding at electrophysiological study of a pacing-induced infra-His block that is not physiological	B
	III	Fascicular block without AV block or symptoms	B
		Fascicular block with first-degree AV block without symptoms	B
Permanent pacing after the acute phase of myocardial infarction	I	Persistent second-degree AV block in the His-Purkinje system with a bilateral bundle branch block or third-degree AV block within or below the His-Purkinje system after acute MI	B
		Transient advanced (second- or third-degree) infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiological study may be necessary	B
		Persistent and symptomatic second- or third-degree AV block	C
	IIb	Persistent second- or third-degree AV block at the AV node level	B
	III	Transient AV block in the absence of intraventricular conduction defects	B
		Transient AV block in the presence of isolated left anterior fascicular block	B
		Acquired left anterior block in the absence of AV block	B
		Persistent first-degree AV block in the presence of a bundle branch block that is old or age indeterminate	B
Permanent pacing in sinus node dysfunction	I	Sinus node dysfunction with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms	C
		Symptomatic chronotropic incompetence	C
	IIa	Sinus node dysfunction occurring spontaneously or as a result of necessary drug therapy, with a heart rate of <40 beats/min when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented	C
	IIb	In minimally symptomatic patients, chronic heart rate of less than 30 beats/min while awake	C
	III	Sinus node dysfunction in asymptomatic patients, including those in whom substantial sinus bradycardia (heart rate of <40 beats/min) is a consequence of long-term drug treatment	
		Sinus node dysfunction in patients with symptoms suggestive of bradycardia that are clearly documented as not associated with a slow heart rate	
		Sinus node dysfunction with symptomatic bradycardia from nonessential drug therapy	
Permanent pacemakers that automatically detect and pace to terminate tachycardias	I	Symptomatic recurrent supraventricular tachycardia that is reproducibly terminated by pacing after drugs and catheter ablation fail to control the arrhythmia or produce intolerable side effects	C
		Symptomatic recurrent sustained VT as part of an automatic defibrillator system	B
	IIb	Recurrent supraventricular tachycardia or atrial flutter that is reproducibly terminated by pacing as an alternative to drug therapy or ablation	C
	III	Tachycardias frequently accelerated or converted to fibrillation by pacing	
		The presence of accessory pathways with the capacity for rapid anterograde conduction regardless of whether the pathways participate in the mechanism of the tachycardia	
Pacing indications to prevent tachycardia	I	Sustained pause-dependent VT, with or without a prolonged QT, in which the efficacy of pacing is thoroughly documented	C
	IIa	High-risk patients with congenital long QT syndrome	C
	IIb	AV reentrant or AV node reentrant supraventricular tachycardia not responsive to medical or ablative therapy	C
		Prevention of symptomatic, drug-refractory, recurrent atrial fibrillation	C
	III	Frequent or complex ventricular ectopic activity without sustained VT in the absence of long QT syndrome	
		Long QT syndrome from reversible causes	

Permanent pacing in hypersensitive carotid sinus syndrome and neurally mediated syncope	I	Recurrent syncope caused by carotid sinus stimulation; minimal carotid sinus pressure induces ventricular asystole of >3-sec duration in the absence of any medication that depresses the sinus node or AV conduction	C
	IIa	Recurrent syncope without clear, provocative events and with a hypersensitive cardioinhibitory response	C
		Syncope of unexplained origin when major abnormalities of sinus node function or AV conduction are discovered or provoked in electrophysiological studies	C
	IIb	Neurally mediated syncope with significant bradycardia reproduced by a head-up tilt with or without isoproterenol or other provocative maneuvers	B
	III	A hyperactive cardioinhibitory response to carotid sinus stimulation in the absence of symptoms	
		A hyperactive cardioinhibitory response to carotid sinus stimulation in the presence of vague symptoms such as dizziness, lightheadedness, or both	
		Recurrent syncope, lightheadedness, or dizziness in the absence of a hyperactive cardioinhibitory response	
		Situational vasovagal syncope in which avoidance behavior is effective	
Hypertrophic cardiomyopathy	I	Class I indications for sinus node dysfunction or AV block as previously described	C
	IIb	Medically refractory, symptomatic hypertrophic cardiomyopathy with significant resting or provoked LV outflow obstruction	C
	III	Patients who are asymptomatic or medically controlled	
		Symptomatic patients without evidence of LV outflow obstruction	
Dilated cardiomyopathy	I	Class I indications for sinus node dysfunction or AV block as previously described	C
	IIb	Symptomatic, drug-refractory dilated cardiomyopathy with a prolonged PR interval when acute hemodynamic studies have demonstrated a hemodynamic benefit of pacing	C
	III	Asymptomatic dilated cardiomyopathy	
		Symptomatic dilated cardiomyopathy when patients are rendered asymptomatic by drug therapy	
		Symptomatic ischemic cardiomyopathy	
Cardiac transplantation	I	Symptomatic bradyarrhythmias/chronotropic incompetence not expected to resolve and other Class I indications for permanent pacing	C

AV = atrioventricular; LV = left ventricular; MI = myocardial infarction; VF = ventricular fibrillation; VT = ventricular tachycardia.

*For definition of classes and levels of evidence, see guidelines AHA/ACC guidelines for Electrocardiography.

block at the AV node was less clear (Class II), but permanent pacing was discouraged if the sole indication was transient AV conduction disturbances or left anterior hemiblock.

The ACC/AHA guidelines also defined explicit criteria for the appropriateness of permanent pacing in patients with hypersensitive carotid sinus and neurovascular syndromes. The only Class I indication was recurrent syncope[2] associated with clear, spontaneous events provoked by carotid sinus stimulation. In such patients, minimal carotid sinus pressure should induce asystole of 3 seconds or more in the absence of medications that depress the sinus node.

Recommendations were also included for the use of permanent pacemakers for termination of tachyarrhythmias. Antitachycardia devices include permanent pacemakers that can be programmed to interrupt reentrant arrhythmias or prevent their occurrence, as well as automatic defibrillator devices. The ACC/AHA guidelines stressed that these devices should be implanted only after careful evaluation by experienced electrophysiologists.

Permanent pacemakers were considered appropriate for use for recurrent supraventricular tachycardias in patients who were symptomatic and whose arrhythmias could not be controlled with drug therapy or catheter ablation. For patients with symptomatic ventricular tachycardia, permanent pacemakers were considered appropriate as part of an automatic defibrillator system.

For patients with hypertrophic cardiomyopathy or dilated cardiomyopathy, clearly appropriate indications for permanent pacemakers were similar to those for patients without these conditions. The task force thought there was some evidence to support the use of dual-chamber or right ventricular pacemakers in some patients with medically refractory, symptomatic hypertrophic cardiomyopathy and significant resting or provoked left ventricular outflow obstruction (Class IIb). Similarly, permanent pacemakers for patients with symptomatic, drug-refractory dilated cardiomyopathy with a prolonged PR interval were considered to be possibly appropriate when acute hemodynamic studies demonstrated hemodynamic benefit from pacing. For patients who have undergone cardiac transplantation, permanent pacemakers were considered appropriate when the patients had symptomatic bradyarrhythmias that were not expected to resolve.

The guidelines offer general recommendations on the type of permanent pacemaker most appropriate for specific patient subsets but noted that technologies are evolving quickly and prospective randomized data are few.

Implantable Cardioverter-Defibrillator Therapy

The enthusiasm for implanting cardioverter-defibrillator devices has been increasing because of disappointing data on the lack of impact of antiarrhythmic medications on survival and data showing low rates of sudden cardiac death and improved quality of life after device implantation. Implantable cardioverter-defibrillators (ICDs) can be combined with drug therapy or ablation techniques applied at surgery or percutaneously via catheter techniques. Ablation techniques are in particularly rapid evolution, which hinders the ability to develop formal guidelines for their appropriateness and relative merits in comparison to alternative strategies.

ICDs are now regarded as clearly appropriate therapy for patients who have had cardiac arrest as a result of ventricular fibrillation or ventricular tachycardia without a transient or reversible cause, as well as for patients with spontaneous sustained ventricular tachycardia (Table 24-G-2) . The ACC/AHA guidelines consider ICDs appropriate for patients who have electrophysiological studies that suggest arrhythmia as a likely cause of syncope and other patients with high-risk electrophysiology tests.

ICDs are not recommended by the ACC/AHA task force for several groups, including the following:

Patients for whom a reversible triggering factor for arrhythmia can be identified, such as evolving myocardial infarction or electrolyte abnormalities.

Patients with coronary disease without inducible or spontaneous ventricular tachycardia who are undergoing routine coronary artery bypass graft surgery.

Patients with Wolff-Parkinson-White syndrome and ventricular fibrillation secondary to atrial fibrillation. (These patients should undergo catheter or surgical ablation if their accessory pathways are amenable to such treatment.)

Patients with frequent tachyarrhythmias that may trigger shock therapy.

TABLE 24--G-2 -- ACC/AHA GUIDELINES FOR IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR THERAPY*

Class	Recommendation	Level of Evidence
I	Cardiac arrest due to VF or VT not due to a transient or reversible cause	A
	Spontaneous sustained VT	B
	Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiological study when drug therapy is ineffective, not tolerated, or not preferred	B
	Nonsustained VT with coronary disease, prior MI, LV dysfunction, and inducible VF or sustained VT at electrophysiological study that is not suppressible by a class I antiarrhythmic drug	B
IIb	Cardiac arrest presumed to be due to VF when electrophysiological testing is precluded by other medical conditions	C
	Severe symptoms attributable to sustained ventricular tachyarrhythmias while awaiting cardiac transplantation	C
	Familial or inherited conditions with a high risk for life-threatening ventricular tachyarrhythmias such as long QT syndrome or hypertrophic cardiomyopathy	B
	Nonsustained VT with coronary artery disease, prior MI, and LV dysfunction and inducible sustained VT or VF at electrophysiological study	B
	Recurrent syncope of undetermined etiology in the presence of ventricular dysfunction and inducible ventricular arrhythmias at electrophysiological study when other causes of syncope have been excluded	C
III	Syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias	C
	Incessant VT or VF	C

LV = left ventricular; MI = myocardial infarction; VF = ventricular fibrillation; VT = ventricular tachycardia.

Chapter 25 - Specific Arrhythmias: Diagnosis and Treatment

JEFFREY E. OLGIN
DOUGLAS P. ZIPES

DIAGNOSTIC AND THERAPEUTIC CONSIDERATIONS

History

The initial evaluation of a patient suspected of having a cardiac arrhythmia begins with a careful history addressing specific questions regarding the presence of palpitations, syncope, spells of lightheadedness, chest pain, or symptoms of congestive heart failure. Palpitations,[1] an awareness of one's heartbeat (see Chap. 3), may result from irregularities in cardiac rate or rhythm or a change in contractility of the heart. Some patients are able to reproduce this sensation by tapping their hand on their chest, knee, or a table top in a fashion similar to the perceived palpitation or may recognize a cadence tapped out by a physician. Such a maneuver can help establish the rate and rhythm of the arrhythmia by narrowing it to a particular rate range, a regular or irregular arrhythmia, or one in which a regular rhythm is interrupted by premature beats. The latter are often perceived only upon the contraction that ends the pause following the premature beat. The patient may feel as though the heart has stopped for a moment. Rapid, irregular tapping can suggest the ventricular response to atrial fibrillation, whereas rapid, regular tapping can suggest an atrioventricular (AV) nodal reentrant supraventricular tachycardia, particularly in a young person, or ventricular tachycardia (VT) in an older person. Information regarding the nature of the onset and termination of the rhythm disturbance is particularly important. Knowing the rate of the arrhythmia is crucial, and a brief demonstration by the physician of how to determine the heart rate can yield important dividends. The patient, and sometimes a close relative, should be instructed in how to count the pulse.

Answers by the patient to key questions can provide clues to the type of rhythm disturbance, particularly if the physician has additional information, such as physical findings and a 12-lead electrocardiogram (ECG). For example, a young adult with presyncope, normal physical findings, and ECG changes indicating Wolff-Parkinson-White (WPW) syndrome should be asked whether the palpitations are regular or irregular, how fast they are, and how they start and stop. If the tachycardia is regular, with a rate of approximately 200 beats/min, and of sudden onset and termination, it is likely that the patient is experiencing an AV reciprocating tachycardia; on the other hand, if the rhythm is irregular, the patient may have atrial fibrillation, a potentially more serious arrhythmia in the presence of WPW syndrome. In an older patient with presyncope, especially with a history of myocardial infarction, the physician should suspect VT if the ventricular rate is rapid and suspect AV heart block or sinus nodal disease if the rate is slow. The ventricular rhythm can be regular or irregular. Premature atrial or ventricular beats, perceived as dropped or skipped beats by the patient, are probably the most common cause of palpitations.

The physician should inquire about circumstances that can trigger the arrhythmia, such as emotionally upsetting events, ingestion of caffeine-containing beverages, cigarette smoking, exercise, excessive alcohol intake, or gastrointestinal problems (Fig. 25-1) . A careful diet and drug history can be useful, for example, in revealing that palpitations develop only after the use of a nasal decongestant that contains a sympathomimetic vasoconstrictor or in revealing that the patient has been exposed to "street" drugs such as cocaine. States conducive to the genesis of arrhythmias should be considered, such as thyrotoxicosis, pericarditis, mitral valve prolapse, hypokalemia secondary to diuretics, and so forth. The family history can be helpful. In addition to the congenital long QT syndrome, a variety of other familial disorders can result in arrhythmias, including myotonic dystrophy, Duchenne muscular dystrophy (see Chap. 71), and dilated cardiomyopathy (see Chap. 48). Congenital conduction system disorders can result in sudden death.

Physical Examination

In addition to recording the cardiac rate and rhythm, a number of physical findings can be helpful. For example, findings accompanying AV dissociation include variable peak systolic blood pressure as the atria alter their contribution

TABLE 25-1 -- ARRHYTHMIA CHARACTERISTICS*

TYPE OF ARRHYTHMIA	P WAVES			QRS COMPLEXES			VENTRICULAR RESPONSE TO CAROTID SINUS MASSAGE	P WAVES	QRS COMPLEXES		
								Physical Examination			
	Rate (bpm)	*Rhythm*	*Contour*	*Rate*	*Rhythm*	*Contour*		*Intensity of S_1*	*Splitting of S_2*	*a Waves*	*Treatment*
Sinus rhythm	60-100	Regular	Normal	60-100	Regular	Normal	Gradual slowing and return to former rate	Constant	Normal	Normal	None
Sinus bradycardia	<60	Regular	Normal	<60	Regular	Normal	Gradual slowing and return to former rate	Constant	Normal	Normal	None, unless symptomatic; atropine
Sinus tachycardia	100-180	Regular	May be peaked	100-180	Regular	Normal	Gradual slowing and return to former rate	Constant	Normal	Normal	None, unless symptomatic; treat underlying disease

AV nodal reentry	150-250	Very regular except at onset and termination	Retrograde; difficult to see; lost in QRS complex	150-250	Very regular except at onset and termination	Normal	Abrupt slowing caused by termination of tachycardia, or no effect	Constant	Normal	Constant cannon *a* waves	Vagal stimulation, adenosine, verapamil, digitalis, propranolol, DC shock, pacing
Atrial flutter	250-350	Regular	Sawtooth	75-175	Generally regular in absence of drugs or disease	Normal	Abrupt slowing and return to former rate; flutter remains	Constant; variable if AV block changing	Normal	Flutter waves	DC shock, digitalis, quinidine, propranolol, verapamil, adenosine
Atrial fibrillation	400-600	Grossly irregular	Baseline undulation, no P waves	100-160	Grossly irregular	Normal	Slowing; gross irregularity remains	Variable	Normal	No *a* waves	Digitalis, quinidine, DC shock, verapamil, adenosine
Atrial tachycardia with block	150-250	Regular; may be irregular	Abnormal	75-200	Generally regular in absence of drugs or disease	Normal	Abrupt slowing and return to normal rate; tachycardia remains	Constant; variable if AV block changing	Normal	More *a* waves than *c-v* waves	Stop digitalis if toxic; digitalis if not toxic; possibly verapamil
AV junctional rhythm	40-100§	Regular	Normal	40-60	Fairly regular	Normal	None; may be slight slowing	Variables¶	Normal	Intermittent cannon waves	None, unless symptomatic; atropine
Reciprocating tachycardias using an accessory (WPW) pathway	150-250	Very regular except at onset and termination	Retrograde; difficult to see; monitor the QRS complex	150-250	Very regular except at onset and termination	Normal	Abrupt slowing caused by termination of tachycardia, or no effect	Constant but decreased	Normal	Constant cannon waves	See AV nodal reentry above
Nonparoxysmal AV junctional tachycardia	60-100¶	Regular	Normal	70-130	Fairly regular	Normal	None, may be slight slowing	Variable¶	Normal	Intermittent cannon waves¶	None, unless symptomatic; stop digitalis if toxic
Ventricular tachycardia	60-100¶	Regular	Normal	110-250	Fairly regular; may be irregular	Abnormal, >0.12 sec	None	Variable¶	Abnormal	Intermittent cannon waves¶	Lidocaine, procainamide, DC shock, quinidine, amiodarone
Accelerated idioventricular rhythm	60-100¶	Regular	Normal	50-110	Fairly regular; may be irregular	Abnormal, >0.12 sec	None	Variable¶	Abnormal	Intermittent cannon waves¶	None, unless symptomatic; lidocaine, atropine
Ventricular flutter	60-100¶	Regular	Normal; difficult to see	150-300	Regular	Sine wave	None	Soft or absent	Soft or absent	Cannon waves	DC shock
Ventricular fibrillation	60-100¶	Regular	Normal; difficult to see	400-600	Grossly irregular	Baseline undulations; no QRS complexes	None	None	None	Cannon waves	DC shock
First-degree AV block	60-100**	Regular	Normal	60-100	Regular	Normal	Gradual slowing caused by sinus	Constant, diminished	Normal	Normal	None
Type I second-degree AV block	60-100**	Regular	Normal	30-100	Irregular	Normal	Slowing caused by sinus slowing and an increase in AV block	Cyclic decrease, then increase after pause	Normal	Normal; increasing *a-c* interval; *a* waves without *c* waves	None, unless symptomatic; atropine
Type II second-degree AV block	60-100**	Regular	Normal	30-100	Irregular	Abnormal, >0.12 sec	Gradual slowing caused by sinus slowing	Constant	Abnormal	Normal; constant *a-c* interval; *a* waves without *c* waves	Pacemaker
Complete AV block	60-100¶	Regular	Normal	<40	Fairly regular	Abnormal, 0.12 sec	None	Variable**	Abnormal	Intermittent cannon waves**	Pacemaker
Right bundle branch block	60-100	Regular	Normal	60-100	Regular	Abnormal, 0.12 sec	Gradual slowing and return to former rate	Constant	Wide	Normal	None
Left bundle branch block	60-100	Regular	Normal	60-100	Regular	Abnormal, >0.12 sec	Gradual slowing and return to former rate	Constant	Paradoxical	Normal	None

AV = atrioventricular; WPW = Wolff-Parkinson-White.

Modified from Zipes DP: Arrhythmias. In Andreoli K, Zipes DP, Wallace AG, et al (eds): Comprehensive Cardiac Care. 6th ed. St Louis, CV Mosby, 1987.

*In an effort to summarize these arrhythmias in tabular form, generalizations have to be made. For example, the response to carotid sinus massage may be slightly different from what is listed. Acute therapy to terminate a tachycardia may be different from chronic therapy to prevent recurrence. Some of the exceptions are indicated in the footnotes; the reader is referred to the text for a complete discussion.

P waves initiated by sinus node discharge may not be precisely regular because of sinus arrhythmia.

Often, carotid sinus massage fails to slow a sinus tachycardia.
§Any independent atrial arrhythmia may exist or the atria may be captured retrogradely.
¶Constant if the atria are captured retrogradely.
**Atrial rhythm and rate may vary, depending on whether sinus bradycardia, sinus tachycardia, or another abnormality is the atrial mechanism.

Regular or constant if block is unchanging.

Figure 25-1 Transient atrioventricular (AV) block. This monitor lead recording demonstrates a transient AV block during a period of nausea and vomiting that was most probably caused by excessive vagal stimulation.

to ventricular filling, variable intensity of the first heart sound as the PR interval changes despite a regular ventricular rhythm, intermittent cannon *a* waves in the jugular venous pulse as atrial contraction occurs against closed AV valves, and apparent "intermittent" gallop sounds when atrial systole occurs at various times of the cardiac cycle. The *venous pulse* provides a window through which to judge atrial and ventricular rates and relative timing relationships. It is of interest that Wenckebach first noted the two types of second-degree AV block that bear his name by recording the jugular phlebogram before the ECG was available.

Examining the *second heart sound* can be helpful (see Chap. 4). A paradoxically split second heart sound can occur during a QRS complex with a left bundle branch block contour that results from VT or supraventricular tachycardia with aberration. A widely split second heart sound that does not become single during expiration can accompany a right bundle branch block. Unfortunately, similar physical findings occur with different cardiac arrhythmias. For example, progressive diminution of the intensity of the first heart sound results as the PR interval lengthens, which can occur during AV dissociation when the atrial rate exceeds the ventricular rate or during a Wenckebach second-degree AV block. Similarly, constant cannon *a* waves can occur with 1:1 AV relationships during ventricular or supraventricular tachycardia. Since AV dissociation can occur (uncommonly) during supraventricular tachycardia and VA association can occur during VT, the clues provided by physical findings can be only suggestive.

Carotid Sinus Massage

The response to carotid sinus massage or the Valsalva maneuver provides important diagnostic information by increasing vagal tone and primarily slowing the rate of sinus nodal discharge and prolonging AV nodal conduction time and refractoriness. Sinus tachycardia slows gradually during carotid massage and then returns to the previous rate when the massage is discontinued; AV nodal reentry and AV reciprocating tachycardias that involve the AV node in one of its pathways can slow slightly, terminate abruptly, or not change, and the ventricular response to atrial flutter, atrial fibrillation, and some atrial tachycardias usually decreases (Table 25-1) . Rarely, carotid sinus massage terminates a VT.

To perform carotid massage, the patient is placed in a supine position with the neck hyperextended and the head turned away from the side being tested, the sternocleidomastoid muscles relaxed or gently pushed out of the way, and the carotid impulse felt at the angle of the jaw. The carotid bifurcation is touched gently initially with the palmar portion of the fingertips to detect hypersensitive responses. Then, if no change in cardiac rhythm occurs, pressure is applied more firmly for approximately 5 seconds, first on one side and then on the other (*never* on both sides simultaneously) with a gentle rotating massaging motion. External pressure stimulates baroreceptors in the carotid sinus to trigger a reflex increase in vagal activity and sympathetic withdrawal. Responses can occur with right-sided massage and not left, or vice versa, so each side should be tested separately. Generally, the maximal response occurs with the first massage if repeated attempts are performed at short intervals. Some risk is associated with carotid sinus massage, particularly in older patients, and cerebral emboli can occur.[2] Before massage, the carotid artery should be auscultated so that massage is not performed in patients who have carotid bruits indicative of carotid arterial disease.

Electrocardiography

The ECG remains the most important and definitive single noninvasive diagnostic test. Figure 25-2 depicts an algorithm for diagnosing specific tachyarrhythmias from the 12-lead ECG. Initially, a 12-lead ECG is recorded, and a long recording using the lead that shows distinct P waves is obtained for proper analysis. If P waves are not clearly visible, atrial activity can be recorded by placing the right and left arm leads in various chest positions to discern P waves (so-called Lewis leads) and applying esophageal electrodes or by using intracavitary right atrial leads. An echocardiogram showing atrial contraction can be helpful.

Each arrhythmia must be approached in a systematic manner to answer the following questions: Are P waves present? What are the atrial and ventricular rates? Are they identical? Are the P-P and R-R intervals regular or irregular? If irregular, is it a consistent, repeating irregularity? Is there a P wave related to each ventricular complex? Does the P wave precede or follow the QRS complex? Is the resultant PR or RP interval constant? Is the RP interval long and the PR interval short, or vice versa? Are all P waves and QRS complexes identical and normal in contour? To determine the significance of changes in P wave or QRS contour or amplitude, one must know the lead being recorded. Are P, PR, QRS, and QT durations normal? In view of the clinical setting, what is the significance of the arrhythmia? Should it be treated and, if so, how? For supraventricular tachycardias with a normal QRS complex, a branching decision tree may be useful.

The Ladder Diagram

The ladder diagram is used to depict depolarization and conduction schematically. Straight or slightly slanting lines drawn on a tiered framework beneath an ECG trace represent electrical events occurring in the various cardiac structures (Fig. 25-3 *A* and *B*). Since the ECG and therefore the ladder diagram represent electrical activity against a time base, conduction is indicated by the lines of the ladder diagram sloping in a left-to-right direction. A less steep line depicts slower conduction. A short bar drawn perpendicular to a sloping line represents blocked conduction (Fig. 25-3 *C*). Activity originating in an ectopic site such as the ventricle is indicated in another tier drawn beneath the ventricular tier. In general, atrial, AV junctional, or ventricular activity is diagrammed to begin in that particular tier. It is important to remember that sinus nodal discharge and conduction and, under certain circumstances, AV junctional discharge and conduction can only be assumed; their activity is not recorded on scalar ECG.

Figure 25-2 Stepwise approach to diagnose tachycardias from the 12-lead electrocardiogram (ECG). The first step is to determine whether the tachycardia is a narrow- or wide-complex tachycardia. For wide-complex tachycardias, refer to Table 25-4 . The remainder of the algorithm is useful in diagnosing types of supraventricular tachycardias from the 12-lead ECG.

Electrophysiological Study

When an electrophysiological study is indicated, it is performed by introducing multipolar catheter electrodes into the vascular system and positioning them in various parts of the heart. The catheters are used to record local electrical activity and to stimulate the heart. Multiple leads are recorded simultaneously, usually at a paper speed of 50 to 200 mm/sec. (Standard ECGs are generally recorded at a paper speed of 25 mm/sec.) Because of the rapid recording speed, intervals or complexes of normal duration may appear prolonged. An electrode positioned across the septal leaflet of the tricuspid valve records His bundle activity, as well as low right atrial activity and high ventricular septal depolarization. Occasionally, a right bundle branch deflection

---

Figure 25-3 *A,* Ladder diagram. Straight or slightly sloping lines beginning with the P wave and QRS complex indicate atrial and ventricular depolarization. The instants at which the sinus node discharges and the duration of sinoatrial conduction cannot be measured in the surface electrocardiogram and are therefore assumed. The sloping line connecting A and V, delimited by the interrupted lines, represents atrioventricular (AV) conduction. *B,* Normal and ectopic beats; a = normal sinus rhythm; b = ectopic atrial beat; c = AV junctional beat; d = ventricular ectopic beats. All are drawn with appropriate ladder diagrams beneath (T waves omitted). Retrograde atrial conduction is inscribed for the latter two beats. As with the sinus node, the exact discharge time of the AV junctional focus and the conduction time from that point to the ventricles and atria are assumed. *C,* Second-degree Wenckebach type I AV block. The PR interval lengthens progressively until finally the fourth P wave fails to reach the ventricles. As the PR interval is prolonged, note the decreasing slope of the line representing AV conduction and the small line perpendicular to the fourth sloping line indicating that the P wave is blocked. *(A to C from Zipes DP, Fisch C: ECG analysis: 1. Introduction. Premature ventricular complexes. Arch Intern Med 128:140, Copyright 1971, American Medical Association.) D,* A single cardiac cycle showing the intervals measured during an electrophysiological study. In this and in similar subsequent figures, A-H = interval representing AV nodal conduction time; BAE = bipolar atrial electrogram recording high right atrial activity; BHE = bipolar His electrogram recording low right atrial activity (A), His bundle activity (H), and ventricular septal activity (V); CS = bipolar electrogram recording of left atrial activity in the coronary sinus lead; H-V = interval representing His-Purkinje conduction time; I = lead I; II = lead II; III = lead III; PA = interval representing intraatrial conduction time; RV = right ventricular electrogram recording right ventricular activity; V_1 = lead V_1 . All values are in milliseconds. Normal values for the PA, A-H, and H-V intervals are given at the upper right. Paper speed = 100 mm/sec unless otherwise stated. Interrupted lines demarcate the various intervals. Note the normal sequence of atrial activation recorded with this technique: High right atrial activity (BAE) precedes low right atrial activity recorded in the BHE lead, which precedes left atrial activity recorded in the CS lead. Large time lines = 50 milliseconds. Small time lines = 10 milliseconds.

can also be recorded. Three basic measurements are made by using the ECG and the His bundle catheter recording: the PA, A-H, and H-V intervals (Fig. 25-3 *D*). The PA interval is the time between the onset of the P wave in the surface tracing (which generally slightly precedes the onset of the high right atrial recording) and the low right atrial deflection and is recorded in the His lead. This interval reflects intraatrial conduction and has not proved to be of much clinical value.

THE A-H INTERVAL.

The A-H interval is timed from the onset of the first rapid deflection recorded in the atrial electrogram (A) in the His bundle lead to the beginning of the His (H) deflection. Since the low right part of the atrium and the His bundle anatomically delineate the boundaries of the AV node, the A-H interval closely approximates AV nodal conduction time. The A-H interval is affected by various interventions: Atropine and isoproterenol shorten the A-H interval, whereas vagal maneuvers, digitalis, propranolol, verapamil, adenosine, and rapid or premature atrial pacing lengthen it. The normal range for the A-H interval is 55 to 130 milliseconds, depending on the heart rate, autonomic tone, and other factors.

THE H-V INTERVAL.

The H-V interval is the time from the beginning of the H deflection to the earliest onset of ventricular depolarization recorded in *any* lead. This interval represents conduction from the His bundle through the bundle branch-Purkinje system to the point of ventricular muscle activation and is usually constant--between 30 and 55 milliseconds--regardless of the heart rate or autonomic tone. Other intervals are discussed under the individual tachycardias.

Consequences of Arrhythmias

The ventricular rate and duration of an arrhythmia, its site of origin, and the cardiovascular status of the patient primarily determine the electrophysiological and hemodynamic consequences of a particular rhythm disturbance. Electrophysiological consequences, often influenced by the presence of underlying heart disease such as acute myocardial infarction, include the development of serious arrhythmias as a result of rapid or slow rates, initiation of sustained arrhythmias by premature systoles, or the progression of rhythms such as VT to ventricular fibrillation. Extremes of heart rate or loss of the atrial contribution to ventricular filling can alter circulatory dynamics. Rapid rates greatly shorten the diastolic filling time, and particularly in diseased hearts, the increased heart rate can fail to compensate for the reduced stroke output; as a consequence, arterial pressure, cardiac output, and coronary blood flow decline. Arrhythmias that prevent sequential AV contraction mitigate the hemodynamic benefits of the atrial booster pump, whereas atrial fibrillation causes complete loss of atrial contraction and can reduce cardiac output. Chronic tachycardias can cause cardiac dilation and heart failure from tachycardia-induced cardiomyopathy.[3]

Management

The therapeutic approach to a patient with a cardiac arrhythmia begins with an accurate ECG *interpretation* of the arrhythmia and continues with determination of the *cause* of the arrhythmia (if possible), the nature of the underlying *heart disease* (if any), and the *consequences* of the arrhythmias in the individual patient. Thus, one does not treat arrhythmias as isolated events without having knowledge of the entire clinical situation. *Patients* who have arrhythmias are treated rather than the arrhythmias themselves.

When a tachyarrhythmia develops, slowing the ventricular rate is the initial and often the most important therapeutic maneuver. Therapy can differ radically for the same arrhythmia in two different patients because the consequences of tachycardia in individual patients differ. For example, a supraventricular tachycardia at a rate of 200 beats/min can produce few or no symptoms in a healthy young adult and therefore requires little or no therapy because it is usually self-limited. The same arrhythmia can precipitate pulmonary edema in a patient with mitral stenosis, syncope in a patient with aortic stenosis, shock in a patient with acute myocardial infarction, or hemiparesis in a patient with cerebrovascular disease. In these situations, the tachycardia requires prompt electrical conversion.

The *cause* of the arrhythmia can influence therapy greatly. Electrolyte imbalance (potassium, magnesium, calcium), acidosis or alkalosis, hypoxemia, and many drugs can produce rhythm disturbances, and their identification and treatment can abolish or prevent these arrhythmias. Because heart failure can cause arrhythmias, treatment of this condition with digitalis, diuretics, or vasodilators can suppress some of the arrhythmias that accompany cardiac decompensation. Similarly, arrhythmias secondary to hypotension may respond to leg elevation or vasopressor therapy. Mild sedation or reassurance can be successful in treating some arrhythmias related to emotional stress. Precipitating or contributing disease states such as myocarditis, infection, hypokalemia, anemia, and thyroid disorders should be sought and treated when possible. Since therapy always involves some risk, one must be sure--particularly as the therapeutic regimen escalates--that the risks of *not* treating the arrhythmia continue to outweigh the risks of therapy with potentially hazardous antiarrhythmic measures.

Individual Cardiac Arrhythmias

SINUS NODAL DISTURBANCES

Normal Sinus Rhythm

Normal sinus rhythm is arbitrarily limited to impulse formation beginning in the sinus node at frequencies between 60 and 100 beats/min. A range of 50 to 90 beats/min has been suggested.[4] Infants and children generally have faster heart rates than adults do, both at rest and during exercise. The P wave is upright in leads I, II, and aV_f and negative in lead aV_r , with a vector in the frontal plane between 0 and +90 degrees. In the horizontal plane, the P vector is directed anteriorly and slightly leftward and can therefore be negative in leads V_1 and V_2 but positive in V_3 to V_6 . The PR interval exceeds 120 milliseconds and can vary slightly with the rate. If the pacemaker site shifts, a change in morphology of the P wave can occur. The rate of sinus rhythm varies significantly and depends on many factors, including age, sex, and physical activity.

The sinus nodal discharge rate responds readily to autonomic stimuli and depends on the effect of the two opposing autonomic influences. Steady vagal stimulation decreases the spontaneous sinus nodal discharge rate and predominates over steady sympathetic stimulation, which increases the spontaneous sinus nodal discharge rate. Single or brief bursts of vagal stimulation can speed, slow, or entrain sinus nodal discharge. A given vagal stimulus produces a greater absolute reduction in heart rate when the basal heart rate has been increased by sympathetic stimulation, a phenomenon known as *accentuated antagonism.*

Sinus Tachycardia

ELECTROCARDIOGRAPHIC RECOGNITION(Fig. 25-4 *A*).

Tachycardia in an adult is defined as a rate exceeding 100 beats/min. During sinus tachycardia, the sinus node exhibits a discharge frequency between 100 and 180 beats/min, but it may be higher with extreme exertion. The maximum heart rate achieved during strenuous physical activity decreases with age from near 200 beats/min to less than 140 beats/min. Sinus tachycardia generally has a gradual onset and termination. The P-P interval can vary slightly from cycle to cycle. P waves have a normal contour, but a larger amplitude can develop and the wave can

Figure 25-4 *A,* Sinus tachycardia (150 beats/min) in a patient during acute myocardial ischemia; note the ST segment depression. P waves are indicated by arrows. *B,* Sinus bradycardia at a rate of 40 to 48 beats/min. The second and third QRS complexes (arrows) represent junctional escape beats. Note the P waves at the onset of the QRS complex. *C,* Nonrespiratory sinus arrhythmia occurring as a consequence of digitalis toxicity. Monitor leads.

become peaked. They appear before each QRS complex with a stable PR interval unless concomitant AV block ensues.

Accelerated phase 4 diastolic depolarization of sinus nodal cells is generally responsible for sinus tachycardia. Rate changes can result from a shift in pacemaker cells to a different locus within the sinus node. Carotid sinus massage and the Valsalva or other vagal maneuvers gradually slow a sinus tachycardia, which then accelerates to its previous rate upon cessation of enhanced vagal tone. More rapid sinus rates can fail to slow in response to a vagal maneuver.

CLINICAL FEATURES.

Sinus tachycardia is common in infancy and early childhood and is the normal reaction to a variety of physiological or pathophysiological stresses such as fever, hypotension, thyrotoxicosis, anemia, anxiety, exertion, hypovolemia, pulmonary emboli, myocardial ischemia, congestive heart failure, or shock. It can occur during rapid eye movement sleep[5] and can be an adverse prognostic sign after heart transplantation.[6] Drugs such as atropine, catecholamines,[7] and thyroid medications, [8] as well as alcohol, nicotine, caffeine, and inflammation, can produce sinus tachycardia. Persistent sinus tachycardia can be a manifestation of heart failure.

In patients with mitral stenosis or severe ischemic heart disease, sinus tachycardia can result in reduced cardiac output or angina or can precipitate another arrhythmia, in part related to the abbreviated ventricular filling time and compromised coronary blood flow. Sinus tachycardia can be a cause of inappropriate defibrillator discharge in patients with an implantable automatic defibrillator.[9] *Chronic inappropriate sinus tachycardia* has been described in otherwise healthy persons, possibly secondary to increased automaticity of the sinus node or an automatic atrial focus located near the sinus node.[10] [11] [12] The abnormality can result from a defect in either sympathetic or vagal nerve control of sinoatrial (SA) automaticity, or an abnormality of the intrinsic heart rate can be present.[13] It has been noted after radiofrequency catheter ablation of AV nodal tachycardia.[14] [15] [16]

MANAGEMENT.

Management should focus on the *cause* of the sinus tachycardia. Elimination of tobacco, alcohol, coffee, tea, or other stimulants, such as the sympathomimetic agents in nose drops, may be helpful. Drugs such as propranolol or verapamil or fluid replacement in a hypovolemic patient or fever reduction in a febrile patient can be used to help slow the sinus nodal discharge rate. Treatment of inappropriate sinus tachycardia requires beta blockers, calcium channel blockers, or digitalis, alone or in combination. In severe cases, sinus node radiofrequency[11] [17] or surgical[18] ablation may be indicated.

Sinus Bradycardia

ELECTROCARDIOGRAPHIC RECOGNITION (Fig. 25-4 *B*).

Sinus bradycardia exists in an adult when the sinus node discharges at a rate less than 60 beats/min. P waves have a normal contour and occur before each QRS complex with a constant PR interval exceeding 120 milliseconds unless a concomitant AV block is present. Sinus arrhythmia often coexists.

CLINICAL FEATURES.

Sinus bradycardia can result from excessive vagal or decreased sympathetic tone, as an effect of medications, or from anatomical changes in the sinus node. Sinus bradycardia frequently occurs in healthy young adults, particularly well-trained athletes (who can also have tachyarrhythmias), and decreases in prevalence with advancing age. It may be present in patients with anorexia nervosa[19] and following cardiac transplantation.[20] During sleep, the normal heart rate can fall to 35 to 40 beats/min, especially in adolescents and young adults, with marked sinus arrhythmia sometimes producing pauses of 2 seconds or longer. Eye surgery, coronary arteriography, meningitis, intracranial tumors, increased intracranial pressure, cervical and mediastinal tumors, and certain disease states such as severe hypoxia, Chagas disease,[21] myxedema, hypothermia, fibrodegenerative changes, convalescence from some infections, gram-negative sepsis, and mental depression can produce sinus bradycardia. Obstructive jaundice is thought to cause sinus bradycardia, but the evidence is not clear. Sinus bradycardia also occurs during vomiting or vasovagal syncope (see Chap. 27) and can be produced by carotid sinus stimulation or by the administration of parasympathomimetic drugs, lithium, amiodarone, beta-adrenoceptor blocking drugs, clonidine, propafenone, or calcium antagonists. Conjunctival instillation of beta blockers for glaucoma can produce sinus or AV nodal abnormalities, especially in the elderly.

In most instances, sinus bradycardia is a benign arrhythmia and can actually be beneficial by producing a longer period of diastole and increasing the ventricular filling time. It can be associated with syncope caused by an abnormal reflex.[22] Sinus bradycardia occurs in 10 to 15 percent of patients with acute myocardial infarction and may be even more prevalent when patients are seen in the early hours of infarction. Unless accompanied by hemodynamic decompensation or arrhythmias, sinus bradycardia is generally associated with a more favorable outcome following myocardial infarction than is the presence of sinus tachycardia. It is usually transient and occurs more commonly during inferior than anterior myocardial infarction; it has also been noted during reperfusion with thrombolytic agents. Bradycardia following resuscitation from cardiac arrest is associated with a poor prognosis.

MANAGEMENT.

Treatment of sinus bradycardia per se is not usually necessary. For example, if a patient with acute myocardial infarction is asymptomatic, it is probably best to not speed up the sinus rate. If cardiac output is inadequate or if arrhythmias are associated with the slow rate, atropine (0.5 mg intravenously [IV] as an initial dose, repeated if necessary) is usually effective. Lower doses of atropine, particularly when given subcutaneously or intramuscularly, can exert an initial parasympathomimetic effect, possibly via a central action. Ephedrine, hydralazine, or theophylline can be useful in managing some patients with symptomatic sinus bradycardia. These drugs should be given with caution so as to not "overshoot" and produce too rapid a rate. In some patients who experience congestive heart failure or symptoms of low cardiac output as a result of chronic sinus bradycardia, electrical pacing may be needed. Atrial pacing is usually preferable to ventricular pacing to preserve sequential AV contraction and is preferable to drug therapy for long-term management of sinus bradycardia. As a general rule, no available drugs increase the heart rate reliably and safely over long periods without important side effects.

Sinus Arrhythmia

Sinus arrhythmia (see Fig. 25-4 *C*) is characterized by a phasic variation in sinus cycle length during which the maximum sinus cycle length minus the minimum sinus cycle length exceeds 120 milliseconds or the maximum sinus cycle length minus the minimum sinus cycle length divided by the minimum sinus cycle length exceeds 10 percent. It is the most frequent form of arrhythmia and is considered to be a normal event. P wave morphology does not usually vary, and the PR interval exceeds 120 milliseconds and remains unchanged since the focus of discharge remains relatively fixed within the sinus node. Occasionally, the pacemaker focus can wander within the sinus node, or its exit to the atrium may change and produce P waves of slightly different contour (but not retrograde) and a slightly changing PR interval that exceeds 120 milliseconds.

Sinus arrhythmia commonly occurs in the young, especially those with slower heart rates or following enhanced vagal tone, such as after the administration of digitalis or morphine, and decreases with age or with autonomic dysfunction, such as diabetic neuropathy. Sinus arrhythmia appears in two basic forms. In the *respiratory* form, the P-P interval cyclically shortens during inspiration, primarily as a result of reflex inhibition of vagal tone, and slows during expiration; breath-holding eliminates the cycle length variation. Efferent vagal effects alone have been suggested as being responsible for respiratory sinus arrhythmias. *Nonrespiratory* sinus arrhythmia is characterized by a phasic variation in the P-P interval unrelated to the respiratory cycle and may be the result of digitalis intoxication. Loss of sinus rhythm variability is a risk factor for sudden cardiac death (see Chap. 26). Loss of sinus arrhythmia can occur in patients with acute intracranial lesions.[23]

Symptoms produced by sinus arrhythmia are uncommon, but on occasion, if the pauses between beats are excessively long, palpitations or dizziness may result. Marked sinus arrhythmia can produce a sinus pause sufficiently long to produce syncope if not accompanied by an escape rhythm.

Treatment is usually unnecessary. Increasing the heart rate by exercise or drugs generally abolishes sinus arrhythmia. Symptomatic individuals may experience relief from palpitations with sedatives, tranquilizers, atropine, ephedrine, or isoproterenol administration, as in the treatment of sinus bradycardia.

VENTRICULOPHASIC SINUS ARRHYTHMIA.

This arrhythmia occurs when the ventricular rate is slow. The most common example occurs during complete AV block, when P-P cycles that contain a QRS complex are shorter than P-P cycles without a QRS complex. Similar lengthening can be present in the P-P cycle that follows a premature ventricular complex with a compensatory pause. Alterations in the P-P interval are probably due to the influence of the autonomic nervous system responding to changes in ventricular stroke

volume.

Sinus Pause or Sinus Arrest

Sinus pause or sinus arrest (Fig. 25-5) is recognized by a pause in the sinus rhythm. The P-P interval delimiting the pause does not equal a multiple of the basic P-P interval. Differentiation of sinus arrest, which is thought to be due to slowing or cessation of spontaneous sinus nodal automaticity and therefore a disorder of impulse formation, from sinoatrial (SA) exit block (see below) in patients with sinus arrhythmia can be quite difficult without direct recordings of sinus node discharge.[24] [25]

Failure of sinus nodal discharge results in the absence of atrial depolarization and in periods of ventricular asystole if escape beats initiated by latent pacemakers do not occur (see Fig. 25-5). Involvement of the sinus node by acute myocardial infarction,[26] degenerative fibrotic changes, effects of digitalis toxicity, stroke, or excessive vagal tone can all produce sinus arrest. Transient sinus arrest may have no clinical significance by itself if latent pacemakers promptly escape to prevent ventricular asystole or the genesis of other arrhythmias precipitated by the slow rates. Sinus arrest and AV block have been demonstrated in as many as 30 percent of patients with sleep apnea.[27]

Treatment is as outlined above for sinus bradycardia. In patients who have a chronic form of sinus node disease characterized by marked sinus bradycardia or sinus arrest, permanent pacing is often necessary. However, as a general rule, chronic pacing for sinus bradycardia is indicated only in symptomatic patients or those with a sinus pause exceeding 3 seconds.[28]

Sinoatrial Exit Block

This arrhythmia is recognized electrocardiographically by a pause resulting from absence of the normally expected P wave[25] [29] (Fig. 25-6) . The duration of the pause is a multiple of the basic P-P interval. SA exit block is due to a conduction disturbance during which an impulse formed within the sinus node fails to depolarize the atria or does so with delay[30] (Fig. 25-7) . An interval without P waves that equals approximately two, three, or four times the normal P-P cycle characterizes type II second-degree SA exit block. During type I (Wenckebach) second-degree SA exit block, the P-P interval progressively shortens prior to the pause, and the duration of the pause is less than two P-P cycles. (See Chap. 23 for further discussion of Wenckebach intervals.) First-degree SA exit block cannot be recognized by ECG because SA nodal discharge is not recorded. Third-degree SA exit block can be manifested as a complete absence of P waves and is difficult to diagnose with certainty without sinus node electrograms.

Excessive vagal stimulation, acute myocarditis, infarction, or fibrosis involving the atrium, as well as drugs such as quinidine, procainamide, or digitalis, can produce SA exit block. SA exit block is usually transient. It may be of no clinical importance except to prompt a

Figure 25-5 Sinus arrest. The patient had a long-term electrocardiographic (ECG) recorder connected when he died suddenly of cardiac standstill. The rhythms demonstrate progressive sinus bradycardia and sinus arrest at 8:41 A.M. The rhythm then becomes a ventricular escape rhythm, which progressively slows and finally ceases at 8:47 A.M. Monitor lead. The double ECG strips are continuous recordings.

Figure 25-6 Sinus nodal exit block. *A,* A type I sinoatrial (SA) nodal exit block has the following features: The P-P interval shortens from the first to the second cycle in each grouping, followed by a pause. The duration of the pause is less than twice the shortest cycle length, and the cycle after the pause exceeds the cycle before the pause. The PR interval is normal and constant. Lead V_1 . *B,* The P-P interval varies slightly because of sinus arrhythmia. The two pauses in sinus nodal activity equal twice the basic P-P interval and are consistent with a type II 2:1 SA nodal exit block. The PR interval is normal and constant. Lead III.

search for the underlying cause. Occasionally, syncope can result if the SA block is prolonged and unaccompanied by an escape rhythm. SA exit block can occur in well-trained athletes[31] and can be a factor in sick sinus syndrome.[30]

Therapy for patients who have symptomatic SA exit block is as outlined for sinus bradycardia.

Wandering Pacemaker

This variant of sinus arrhythmia involves passive transfer of the dominant pacemaker focus from the sinus node to latent pacemakers that have the next highest degree of automaticity located in other atrial sites (usually lower in the crista terminalis) or in AV junctional tissue. Thus, only one pacemaker at a time controls the rhythm, in sharp contrast to AV dissociation. As with other forms of sinus arrhythmia, the change occurs in a gradual fashion over the duration of several beats. The ECG (Fig. 25-8) displays a cyclical increase in the R-R interval, a PR interval that gradually shortens and can become less than 120 milliseconds, and a change in the P wave contour, which becomes negative in lead I or II (depending on the site of discharge) or is lost within the QRS complex. Generally, these changes occur in reverse as the pacemaker shifts back to the sinus node. Rarely, the rate may remain unchanged during these P wave transitions.

Wandering pacemaker is a normal phenomenon that often occurs in the very young and particularly in athletes, presumably because of augmented vagal tone. Persistence of an AV junctional rhythm for long periods, however, may indicate underlying heart disease. *Treatment* is not usually indicated but, if necessary, is the same as that for sinus bradycardia (see above).

Figure 25-7 Sinus node exit block. After a period of atrial pacing (only the last paced cycle is shown), sinus node exit block developed. The tracing demonstrates sinus node potentials (arrowheads), recorded with a catheter electrode, not conducting to the atrium until the last complex. Recordings are leads I, II, III, and V_1 , right atrial recording, sinus node recording, and right ventricular apical recording. The bottom tracing is femoral artery blood pressure.

Hypersensitive Carotid Sinus Syndrome (see also Chap. 27)

ELECTROCARDIOGRAPHIC RECOGNITION (Fig. 25-9) .

Hypersensitive carotid sinus syndrome is characterized most frequently by ventricular asystole caused by cessation of atrial activity from sinus arrest or SA exit block. AV block is observed less frequently, probably in part because the absence of atrial activity from sinus arrest precludes the manifestations of AV block. However, if an atrial pacemaker maintained an atrial rhythm during the episodes, a higher prevalence of AV block would probably be noted. In symptomatic patients, AV junctional or ventricular escapes generally do not occur or are present at very slow rates, thus suggesting that heightened vagal tone and sympathetic withdrawal can suppress subsidiary pacemakers located in the ventricles, as well as supraventricular structures.

CLINICAL FEATURES.

Two types of hypersensitive carotid sinus responses are noted. *Cardioinhibitory* carotid sinus hypersensitivity is generally defined as ventricular asystole exceeding 3 seconds during carotid sinus stimulation, although normal limits have not been carefully established. In fact, asystole exceeding 3 seconds during carotid sinus massage is not common but can occur in asymptomatic subjects (see Fig. 25-9). *Vasodepressor* carotid sinus hypersensitivity is generally defined as a decrease in systolic blood pressure of 50 mm Hg or more without associated cardiac slowing or a decrease in systolic blood pressure exceeding 30 mm Hg when the patient's symptoms are reproduced.

Even if a hyperactive carotid sinus reflex is elicited in patients, particularly in older patients who complain of syncope or presyncope, the hyperactive reflex elicited with carotid sinus massage may not necessarily be responsible for these symptoms. Direct pressure or extension on the carotid sinus from head turning, neck tension, and tight collars can also be a source of syncope by reducing blood flow through the cerebral arteries.

Hypersensitive carotid sinus reflex is most commonly associated with coronary artery disease. The mechanism responsible for hypersensitive carotid sinus reflex is not known, but possibilities include a high level of resting vagal tone, hyperresponsiveness to acetylcholine, excessive release of acetylcholine, baroreflex hypersensitivity,

inadequate cholinesterase activity to metabolize the acetylcholine released, and concomitant sympathetic abnormality. Carotid sinus receptors, autonomic centers of the brain stem, and the afferent limb of the reflex have all been incriminated.

Figure 25-8 Wandering atrial pacemaker. As the heart rate slows, the P waves become inverted and then gradually revert toward normal when the heart rate speeds up again. The PR interval shortens to 0.14 second with the inverted P wave and is 0.16 second with the upright P wave. This phasic variation in cycle length with varying P wave contour suggests a shift in pacemaker site and is characteristic of wandering atrial pacemaker.

MANAGEMENT.

Atropine abolishes cardioinhibitory carotid sinus hypersensitivity. However, most symptomatic patients require pacemaker implantation. It must be stressed that because AV block can occur during periods of hypersensitive carotid reflex, some form of *ventricular* pacing, with or without atrial pacing, is generally required. Atropine and pacing do not prevent the decrease in systemic blood pressure in the vasodepressor form of carotid sinus hypersensitivity,[32] which may result from inhibition of sympathetic vasoconstrictor nerves and possibly from activation of cholinergic sympathetic vasodilator fibers. Combinations of vasodepressor and cardioinhibitory types can occur, and vasodepression can account for continued syncope after pacemaker implantation in some patients. Patients who have a hyperactive carotid sinus reflex that does not cause symptoms require no treatment. Drugs such as digitalis, alpha-methyldopa, clonidine, and propranolol can enhance the response to carotid sinus massage and be responsible for symptoms in some patients. Severe vasodepressor or mixed vasodepressor and cardioinhibitory responses may require treatment with either radiation therapy or surgical denervation of the carotid sinus. Elastic support hose and sodium-retaining drugs may be helpful in patients with vasodepressor responses.

Figure 25-9 *A,* Right carotid sinus massage (RCSM, arrow) results in sinus arrest and a ventricular escape beat (probably fascicular) 5.4 seconds later. Sinus discharge then resumes. *B,* Carotid sinus massage (CSM, see arrow; monitor lead) results in slight sinus slowing but, more importantly, advanced atrioventricular block. Obviously, an atrial pacemaker without ventricular pacing would be inappropriate for this patient.

Figure 25-10 Sick sinus syndrome with bradycardia-tachycardia. Intermittent sinus arrest is apparent with junctional escape beats at irregular intervals (filled circles, top). In the *bottom* panel of this continuous monitor lead recording, a short episode of atrial flutter is followed by almost 5 seconds of asystole before a junctional escape rhythm resumes. The patient became presyncopal at this point.

Sick Sinus Syndrome

This term is applied to a syndrome encompassing a number of sinus nodal abnormalities[25] that include (1) persistent spontaneous sinus bradycardia not caused by drugs and inappropriate for the physiological circumstance, (2) sinus arrest or exit block,[29] [30] [33] (3) combinations of SA and AV conduction disturbances, or (4) alternation of paroxysms of rapid regular or irregular atrial tachyarrhythmias and periods of slow atrial and ventricular rates (bradycardia-tachycardia syndrome, Fig. 25-10). More than one of these conditions can be recorded in the same patient on different occasions, and often their mechanisms can be shown to be causally interrelated and combined with an abnormal state of AV conduction or automaticity. Animal data suggest that rapid atrial rates can "remodel" the sinus node and depress its automaticity, so the sinus tachycardia may be functional and, in part, reversible.[34]

More than one pathophysiological mechanism can produce the clinical manifestations of sick sinus syndrome. The spontaneous clinical arrhythmia and the response to electrophysiological testing (see Chap. 23) depend on the underlying mechanism of sinus nodal dysfunction. Patients who have sinus node disease can be categorized as having intrinsic sinus node disease unrelated to autonomic abnormalities or combinations of intrinsic and autonomic abnormalities. Symptomatic patients with sinus pauses and/or SA exit block frequently show abnormal responses on electrophysiological testing and can have a relatively high incidence of atrial fibrillation[35] and/or embolic episodes.[36] In children, sinus node dysfunction most commonly occurs in those with congenital or acquired heart disease, particularly following corrective cardiac surgery.[37] [38] [39] A familial disorder has also been suggested. Sick sinus syndrome can, however, occur in the absence of other cardiac abnormalities. The course of the disease is frequently intermittent and unpredictable because it is influenced by the severity of the underlying heart disease. Excessive physical training can heighten vagal tone and produce syncope related to sinus bradycardia or AV conduction abnormalities in otherwise normal individuals.

The anatomical basis of sick sinus syndrome can involve total or subtotal destruction of the sinus node, areas of nodal-atrial discontinuity, inflammatory or degenerative changes in the nerves and ganglia surrounding the node, and pathological changes in the atrial wall. Fibrosis and fatty infiltration occur, and the sclerodegenerative processes generally involve the sinus node and the AV node or the bundle of His and its branches or distal subdivisions.[40] Occlusion of the sinus node artery may be important.[41]

MANAGEMENT.

For patients with sick sinus syndrome, treatment depends on the basic rhythm problem but generally involves permanent pacemaker implantation when symptoms are manifested[42] (see Chap. 24). DDD pacing may be preferable. [43] Although medical therapy is usually ineffective in the long term, theophylline has been used.[44] Pacing for the bradycardia combined with drug therapy to treat the tachycardia is required in those with the bradycardia-tachycardia syndrome. In these patients, drug therapy without pacing can aggravate the bradycardia. Digitalis and other drugs that can affect sinus discharge should be used cautiously in patients with sick sinus syndrome without a pacemaker. Beta blockers with intrinsic sympathetic activity may help prevent bradycardia.[45] A prolonged SA conduction time or sinus nodal recovery time at electrophysiological study in the absence of symptoms is not an indication for prophylactic pacing since therapy is directed toward control of symptoms. Adenosine has been suggested as a noninvasive test of sinus node function.[46] [47]

Figure 25-11 Sinus node reentry. After three spontaneous sinus-initiated beats, premature stimulation of the high right atrium (S_2 , S_3) initiates a sustained tachycardia at a cycle length of 450 milliseconds that has the identical high-low atrial activation sequence characteristic of sinus node discharge. This is sinus node reentry. Leads I, II, III, and V_1 are scalar leads. A = atrial electrogram; H = His electrogram; HBE = His bundle electrogram; HRA = high right atrial electrogram; RV = right ventricular electrogram; V = ventricular electrogram. Numbers are milliseconds.

Figure 25-12 Diagrammatic representation of various tachycardias. In the top portion of each example, a schematic of the presumed anatomical pathways is drawn; in the bottom half, the electrocardiographic appearance and the explanatory ladder diagram are depicted. *A,* Atrioventricular (AV) nodal reentry. In the left example, reentrant excitation is drawn with retrograde atrial activity occurring simultaneously with ventricular activity as a result of anterograde conduction over the slow AV nodal pathway (SP) and retrograde conduction over the fast AV nodal pathway (FP). In the right example, atrial activity occurs slightly later than ventricular activity because of retrograde conduction delay. *B,* Atypical AV nodal reentry caused by anterograde conduction over a fast AV nodal pathway and retrograde conduction over a slow AV nodal pathway. *C,* Concealed accessory pathway. Reciprocating tachycardia is due to anterograde conduction over the AV node and retrograde conduction over the accessory pathway. Retrograde P waves occur after the QRS complex. *D,* Sinus nodal reentry. The tachycardia is due to reentry within the sinus node, which then conducts the impulse to the rest of the heart. *E,* Atrial reentry. Tachycardia is due to reentry within the atrium, which then conducts the impulse to the rest of the heart. *F,* Automatic atrial tachycardia. Tachycardia is due to automatic discharge in the atrium, which then conducts the impulse to the rest of the heart; it is difficult to distinguish from atrial reentry. *G,* Nonparoxysmal AV junctional tachycardia. Various manifestations of this tachycardia are depicted with retrograde atrial capture, AV dissociation with the sinus node in control of the atria, and AV dissociation with atrial fibrillation.

SINUS NODAL REENTRY TACHYCARDIA

The rate of sinus nodal reentrant tachycardia varies from 80 to 200 beats/min but is generally slower than the other forms of supraventricular tachycardia, with an average rate of 130 to 140 beats/min[48] (Fig. 25-11) . Electrocardiographically, P waves are identical or very similar to the sinus P wave morphologically; the PR interval

is related to the tachycardia rate, but generally the RP interval is long, with a shorter PR interval (Fig. 25-12 *D*). AV block can occur without affecting the tachycardia, and vagal maneuvers can slow and then abruptly terminate the tachycardia. Electrophysiologically, the tachycardia can be initiated and terminated by premature atrial and, uncommonly, premature ventricular stimulation (see Fig. 25-11). Initiation of sinus nodal reentry does not depend on a critical degree of intraatrial or AV nodal conduction delay, and the atrial activation sequence is the same as during sinus rhythm. An AV nodal Wenckebach block during the tachycardia is common. The development of a bundle branch block does not affect the cycle length or PR interval during tachycardia. Prolongation of AV nodal conduction time or development of an AV nodal block can occur prior to termination of the tachycardia but does not affect sinus nodal reentry.

Sinus nodal reentry may account for 5 to 10 percent of cases of supraventricular tachycardia. It occurs in all age groups without sex predilection. Patients may be slightly older and have a higher incidence of heart disease than do patients with supraventricular tachycardia resulting from other mechanisms. Many may not seek medical attention because the relatively slow rate of the tachycardia does not result in serious symptoms. On the other hand, sinus nodal reentry may be responsible for apparent "anxiety-related sinus tachycardia" in some patients. Drugs such as beta blockers, calcium channel blockers, and digitalis may be effective in terminating and preventing recurrences of sinus node reentrant tachycardia. Catheter ablation is very effective in treating this arrhythmia when drugs fail or are not tolerated.

DISTURBANCES OF ATRIAL RHYTHM

Premature Atrial Complexes

Premature complexes are among the most common causes of an irregular pulse. They can originate from any area in the heart--most frequently from the ventricles, less often from the atria and the AV junctional area, and rarely from the sinus node. Although premature complexes arise commonly in normal hearts, they are more often associated with structural heart disease and increase in frequency with age.

ELECTROCARDIOGRAPHIC RECOGNITION (Fig. 25-13) .

The diagnosis of premature atrial complexes is indicated on

Figure 25-13 *A,* Premature atrial complexes (PACs) that block conduction entirely or conduct with a functional right or functional left bundle branch block. Depending on the preceding cycle length and coupling interval of the PAC, the latter blocks conduction entirely in the atrioventricular (AV) node (
) or conducts with a functional left bundle branch block (
) or functional right bundle branch block (
). *B,* A PAC on the left (arrow) initiates AV nodal reentry that is due to reentry anterogradely and retrogradely over two slow AV nodal pathways, with a retrograde P wave produced midway in the cardiac cycle. On the right, a PAC (arrow) initiates AV nodal reentry as a result of anterograde conduction over the slow pathway and retrograde conduction over the fast pathway (see Fig. 25-12 *A*), which produces a retrograde P wave in the terminal portion of the QRS complex that simulates an r
wave. *C* and *D,* A PAC (
) initiating a short run of atrial flutter *(C)* and a PAC (
) depressing return of the next sinus nodal discharge *(D)*. A slightly later PAC (
) in *D* does not depress sinus nodal automaticity. *B* to *D*, Monitor leads. *E,* Diagrammatic example of the effects of a PAC. The sinus interval (A_1 -A_1) equals X. The third P wave represents a PAC (A_2) that reaches and discharges the sinoatrial (SA) node, which causes the next sinus cycle to begin at that time. Therefore, the P-P (A_2 -A_3) interval equals X+2Y milliseconds, assuming no depression of SA nodal automaticity. *(Modified from Zipes DP, Fisch C: Premature atrial contraction. Arch Intern Med 128:453, 1971.) F,* Diagram of interactions of a PAC (QRS complexes omitted) with the sinus node depending on the degree of prematurity. The top represents spontaneous sinus rhythm. The bottom is a late coupled PAC that collides with the exiting sinus impulse and therefore does not affect (or reset) the sinus pacemaker. The next sinus impulse (S3) occurs at exactly twice the sinus interval. An early coupled PAC in the next diagram is able to penetrate the sinus node and thus resets the pacemaker, thereby resulting in resetting of the sinus node (as depicted in *E*). An even earlier coupled PAC in the lower figure reaches refractory tissue around the sinus node and is thus unable to penetrate the sinus node (SN entrance block); therefore, it does not affect sinus node discharge. The next spontaneous sinus beat (S3) arrives exactly at the sinus interval.

the ECG by a premature P wave with a PR interval exceeding 120 milliseconds (except in WPW syndrome, in which case the PR interval is usually less than 120 milliseconds). Although the contour of a premature P wave can resemble that of a normal sinus P wave, it generally differs. While variations in the basic sinus rate can at times make the diagnosis of prematurity difficult, differences in the contour of the P waves are usually apparent and indicate a different focus of origin. When a premature atrial complex occurs early in diastole, conduction may not be completely normal. The AV junction may still be refractory from the preceding beat and prevent propagation of the impulse (blocked or nonconducted premature atrial complex, Fig. 25-13 *A*) or cause conduction to be slowed (premature atrial complex with a prolonged PR interval). As a general rule, the RP interval is inversely related to the PR interval; thus, a short RP interval produced by an early premature atrial complex occurring close to the preceding QRS complex is followed by a long PR interval. When premature atrial complexes occur early in the cardiac cycle, the premature P waves can be difficult to discern because they are superimposed on T waves. Careful examination of tracings from several leads may be necessary before the premature atrial complex is recognized as a slight deformity of the T wave. Often, such premature atrial complexes are blocked before reaching the ventricle and can be misinterpreted as a sinus pause or sinus exit block (Fig. 25-13 *A*).

The length of the pause following any premature complex or series of premature complexes is determined by the interaction of several factors. If the premature atrial complex occurs when the sinus node and perinodal tissue are not refractory, the impulse can be conducted into the sinus node, discharge it prematurely, and cause the next sinus cycle to begin from that time. The interval between the two normal P waves flanking a premature atrial complex that has reset the timing of the basic sinus rhythm is less than twice the normal P-P interval, and the pause after the premature atrial complex is said to be "noncompensatory." Referring to Figure 25-13 *E* and *F,* reset (noncompensatory pause) occurs when the A_1 -A_2 interval plus the A_2 -A_3 interval is less than two times the A_1 -A_1 interval and the A_2 -A_3 interval is greater than the A_1 -A_1 interval. The interval between the premature atrial complex (A_2) and the following sinus-initiated P wave (A_3) exceeds one sinus cycle but is less than "fully compensatory" (see below) because the A_2 -A_3 interval is lengthened by the time that it takes the ectopic atrial impulse to conduct to the sinus node and depolarize it and then for the sinus impulse to return to the atrium. These factors lengthen the return cycle, i.e., the interval between the premature atrial complex (A_2) and the following sinus-initiated P wave (A_3) (Fig. 25-13 *E* and *F*). Premature discharge of the sinus node by an early premature atrial complex can temporarily depress sinus nodal automatic activity and cause the sinus node to beat more slowly initially (Fig. 25-13 *D*). Often when this happens, the interval between the A_3 and the next sinus-initiated P wave exceeds the A_1 -A_1 interval.

Less commonly, the premature atrial complex encounters a refractory sinus node or perinodal tissue (Fig. 25-13F), in which case the timing of the basic sinus rhythm is not altered since the sinus node is not reset by the premature atrial complex, and the interval between the two normal, sinus-initiated P waves flanking the premature atrial complex is twice the normal P-P interval. The interval following this premature atrial discharge is said to be a "full compensatory pause," i.e., of sufficient duration so that the P-P interval bounding the premature atrial complex is twice the normal P-P interval. However, sinus arrhythmia can lengthen or shorten this pause. Rarely, an *interpolated premature atrial* complex may occur. In this case, the pause after the premature atrial complex is very short, and the interval bounded by the normal sinus-initiated P waves on each side of the premature atrial complex is only slightly longer than or equals one normal P-P cycle length. The interpolated premature atrial complex fails to affect the sinus nodal pacemaker, and the sinus impulse following the premature atrial complex is conducted to the ventricles, often with a slightly lengthened PR interval. An interpolated premature complex of any type represents the only type of premature systole that does not actually replace the normally conducted beat. Premature atrial complexes can originate in the sinus node and are identified by premature P waves that have a contour identical to that of the normal sinus P wave. The cycle after the premature sinus complex equals or is slightly shorter than the basic sinus cycle. Premature sinus complexes are not commonly recognized.

On occasion, when the AV node has had sufficient time to repolarize and conduct without delay, the supraventricular QRS complex initiated by the premature atrial complex can be aberrant in configuration because the His-Purkinje system or ventricular muscle has *not* completely repolarized and conducts with a functional delay or block (Fig. 25-13 *A*). It is important to remember that the refractory period of cardiac fibers is directly related to cycle length. (In an adult, the AV nodal effective refractory period is prolonged at shorter cycle lengths.) A slow heart rate (long cycle length) produces a longer His-Purkinje refractory period than does a faster heart rate. As a consequence, a premature atrial complex that follows a long R-R interval (long refractory period) can result in a functional bundle branch block (aberrant ventricular conduction). Since the right bundle branch at long cycles has a longer refractory period than the left bundle branch does, aberration with a right bundle branch block pattern at slow rates occurs more commonly than aberration with a left bundle branch block pattern. At shorter cycles, the refractory period of the left bundle branch exceeds that of the right bundle branch, and a left bundle branch block pattern may be more likely to occur.

CLINICAL FEATURES.

Premature atrial complexes can occur in a variety of situations, e.g., during infection, inflammation, or myocardial ischemia, or they can be provoked by a variety of medications, by tension states, or by tobacco, alcohol, or caffeine. Premature atrial complexes can precipitate or presage the occurrence of sustained supraventricular (see Fig. 25-13 *B* and *C*) and, rarely, ventricular tachyarrhythmias.

MANAGEMENT.

Premature atrial complexes generally do not require therapy.[49] In symptomatic patients or when the premature atrial complexes precipitate tachycardias, treatment with digitalis, a beta blocker, or a calcium antagonist can be tried.

Atrial Flutter (see also Chap. 23)

Atrial flutter is now recognized as a macro-reentrant atrial rhythm. Typical atrial flutter (sometimes called *type I*) is a reentrant rhythm in the right atrium constrained anteriorly by the tricuspid annulus[50] and posteriorly by the crista terminalis and eustachian ridge.[51] The flutter can circulate in a counterclockwise direction around the tricuspid annulus in the frontal plane (typical flutter, counterclockwise flutter) or in a clockwise direction (atypical, clockwise, or reverse flutter).[52] [53] Since both of these forms of atrial flutter are constrained by anatomical structures, their rates and flutter wave morphology on surface ECG are consistent and predictable (see below).[52] Other forms of atrial flutter are now

Figure 25-14 Various manifestations of atrial flutter. *A,* Atrial flutter at a rate of 300 beats/min conducting impulses to ventricles with a 2:1 block. In the midportion of the tracing, carotid sinus massage converts the block to 4:1, and the ventricular rate slows to 75 beats/min. *B,* Carotid sinus massage produces a transient period of atrioventricular (AV) block clearly revealing the flutter waves. *C,* Quinidine has slowed the atrial flutter rate to approximately 188 beats/min. The block is variable. *D,* Wide QRS complexes with an rSR' configuration in V_1 begin after a short cycle that follows a long cycle in the midportion of the electrocardiogram strip. This pattern represents a functional right bundle branch block. Arrows indicate flutter waves. *E,* The QRS complexes are 0.12 second in duration and have a regular interval at a rate of 200 beats/min. Atrial activity is also regular at a rate of 300 beats/min and independent of ventricular activity (arrows). Thus, atrial flutter is present with a probable ventricular tachycardia, an example of complete AV dissociation. *F*, Adenosine injection given to a patient with an supraventricular tachycardia (SVT) at a rate of 150 beats/min reveals underlying atrial flutter, thus diagnosing the SVT as atrial flutter with 2:1 AV conduction and the flutter waves obscured within the T waves. Monitor leads in *A, B, C, E*, and *F*.

recognized as distinct types and include atrial macro-reentry caused by incisional scars from prior atrial surgery,[54] idiopathic fibrosis in areas of the atrium, or other anatomical or functional conduction barriers in the atria.[52] [53] [55] [56] Because the barriers that constrain these atrial flutters are variable, the ECG pattern of these so-called atypical atrial flutters can be varied. Oftentimes, flutter wave morphology changes during the same episode of flutter, which indicates multiple circuits and/or nonfixed conduction barriers.

ELECTROCARDIOGRAPHIC RECOGNITION.

The atrial rate during typical atrial flutter is usually 250 to 350 beats/min, although it is occasionally slower, particularly when the patient is treated with antiarrhythmic drugs, which can reduce the rate to the range of 200 beats/min. If such slowing occurs, the ventricles can respond in a 1:1 fashion to the slower atrial rate. Ordinarily, the atrial rate is about 300 beats/min, and in untreated patients the ventricular rate is half the atrial rate, i.e., 150 beats/min (Fig. 25-14 *A* and *F*). A significantly slower ventricular rate (in the absence of drugs) suggests abnormal AV conduction. In children, in patients with the preexcitation syndrome (see also Chap. 23), occasionally in patients with hyperthyroidism, and in those whose AV nodes conduct rapidly, atrial flutter can conduct to the ventricle in a 1:1 fashion and produce a ventricular rate of 300 beats/min.

In typical atrial flutter, the ECG reveals identically recurring regular sawtooth flutter waves (see Figs. 25-13 *C* and 25-14 *B* and *F*) and evidence of continual electrical activity (lack of an isoelectric interval between flutter waves), often best visualized in leads II, III, aV_f , or V_1 (Fig. 25-15) . In some instances, transient slowing of the ventricular response, either with carotid sinus massage (see Fig. 25-14 *B*) or with adenosine (see Fig. 25-14 *F*), is necessary to visualize the flutter waves. The flutter waves for (type I) typical atrial flutter are inverted (negative) in these leads because of a counterclockwise reentrant pathway, and sometimes they are upright (positive) when the reentrant loop is clockwise (see Fig 25-15). When the flutter waves are upright from clockwise rotation, they are often notched. If the AV conduction ratio remains constant, the ventricular rhythm will be regular; if the ratio of conducted beats varies (usually the result of a Wenckebach AV block), the ventricular rhythm will be irregular. Alternation between 2:1 and 4:1 AV conduction often occurs and may be due to two levels of block--2:1 high in the AV node and 3:2 lower down. The irregular ventricular response is frequently due to Wenckebach periodicity. Recurrent alternation of short and long ventricular intervals can be due to concealed conduction. Various degrees of penetration into the AV junction by flutter impulses can also influence AV conduction. The ratio of flutter waves to conducted ventricular complexes is most often an even number (e.g., 2:1, 4:1, and so on).

CLINICAL FEATURES.

Atrial flutter is less common than atrial fibrillation. Paroxysmal atrial flutter can occur in patients without structural heart disease, whereas chronic (persistent) atrial flutter is usually associated with underlying heart disease such as rheumatic or ischemic heart disease or cardiomyopathy. It can occur as a result of atrial dilation from septal defects, pulmonary emboli, mitral or tricuspid valve stenosis or regurgitation, or chronic ventricular failure. Toxic and metabolic conditions that affect the heart, such as thyrotoxicosis, alcoholism, and pericarditis, can cause atrial flutter. Occasionally, it can be congenital, follow surgery for congenital heart disease,[57] or even occur in utero.[58] [59] In children, continued episodes of atrial flutter are associated with an increased possibility of sudden death.

Figure 25-15 Twelve-lead electrocardiogram of counterclockwise and clockwise atrial flutter. In counterclockwise atrial flutter, the flutter waves are negative in leads II, III, aV_f , and V_6 and upright in V_1 . In counterclockwise atrial flutter, the flutter waves are upright in leads II, III, and aV_f and often notched.

Atrial flutter usually responds to carotid sinus massage with a decrease in the ventricular rate in stepwise multiples and returns in reverse manner to the former ventricular rate at the termination of carotid massage (see Fig. 25-14 *A*). Very rarely, sinus rhythm follows carotid sinus massage. Exercise, by enhancing sympathetic or lessening parasympathetic tone, can reduce the AV conduction delay and produce a doubling of the ventricular rate.

Physical examination may reveal rapid flutter waves in the jugular venous pulse. If the relationship of flutter waves to conducted QRS complexes remains constant, the first heart sound will have a constant intensity. Occasionally, sounds caused by atrial contraction can be auscultated.

MANAGEMENT.

Cardioversion (see Chap. 23) is commonly the initial treatment of choice for atrial flutter since it promptly and effectively restores sinus rhythm. Cardioversion can be accomplished with synchronous direct current (DC), which often requires relatively low energies (<50 J). If the electrical shock results in atrial fibrillation, a second shock at a higher energy level is used to restore sinus rhythm, or depending on clinical circumstances, the atrial fibrillation can be left untreated. The latter can revert to atrial flutter or sinus rhythm. The short-acting antiarrhythmic medication ibutilide can also be given IV to convert atrial flutter. Ibutilide appears to successfully cardiovert about 60 to 90 percent of episodes of atrial flutter.[60] [61] [62] [63] However, because this medication prolongs the QT interval, torsades de pointes is a potential complication during and shortly after the infusion. Other medications such as procainamide can be given to chemically convert atrial flutter. *Rapid atrial pacing* with a catheter in the esophagus[64] or the right atrium can effectively terminate type I (counterclockwise and clockwise) and some forms of atypical atrial flutter in most patients and produce sinus rhythm or atrial fibrillation with a slowing of the ventricular rate and concomitant clinical improvement.[65] [66] [67] Although the risk of

thromboembolism is lower than that for atrial fibrillation, patients with atrial flutter do appear to have a risk of thromboembolism immediately after conversion to sinus rhythm.[68] [69] [70]

Verapamil (see Chap. 23) given as an initial bolus of 5 to 10 mg IV, followed by a constant infusion at a rate of 5 mg/kg/min, or *diltiazem* 0.25 mg/kg to slow the ventricular response can be tried. *Adenosine* produces a transient AV block and can be used to reveal flutter waves if diagnosis of the arrhythmias is in doubt. It will not generally terminate the atrial flutter and can provoke atrial fibrillation.[71] Esmolol, a beta-adrenergic blocker with a 9-minute elimination half-life, can be used in doses of 200 mg/kg/min to slow the ventricular rate.[72]

If the flutter cannot be electrically cardioverted, terminated by pacing, or slowed by the aforementioned drugs, a *short-acting digitalis preparation* (such as digoxin or deslanoside) can be tried alone or with a calcium antagonist or beta blocker. The dose of digitalis necessary to slow the ventricular response varies and at times can result in toxic levels because it is often difficult to slow the ventricular rate during atrial flutter. Frequently, atrial fibrillation develops after digitalis administration and can revert to normal sinus rhythm upon withdrawal of digitalis treatment; occasionally, normal sinus rhythm may occur without intervening atrial fibrillation. IV amiodarone has been shown to slow the ventricular rate as effectively as digoxin.[73]

If the atrial flutter persists, class IA or IC drugs (see Chap. 23) can be tried in an attempt to restore sinus rhythm and prevent recurrence of atrial flutter.[74] Amiodarone, especially in low doses of 200 mg/day, can also prevent recurrences. Side effects of these drugs, especially proarrhythmic responses, must be carefully considered and are dealt with at length in Chapter 23 . Sometimes, treatment of the underlying disorder, such as thyrotoxicosis, is

Figure 25-16 Atrial flutter with 1:1 conduction caused by flecainide. *Top,* Atrial flutter occurs with 2:1 conduction. *Middle,* 2:1 conduction alternates with 3:2 conduction. *Bottom*, Flecainide administration has been started, and the atrial flutter rate slows, with subsequent 1:1 conduction.

necessary to effect conversion to sinus rhythm. In certain instances, atrial flutter can continue, and if the ventricular rate can be controlled with drugs, conversion to sinus rhythm may not be indicated. Therapy with class I and III drugs should be discontinued if flutter remains.

It is important to reemphasize that class I or III drugs should *not* be used unless the ventricular rate during atrial flutter has been *slowed* with digitalis or with a calcium antagonist or beta-blocking drug.[75] Because of the vagolytic action of quinidine, procainamide, and disopyramide (see Chap. 23) , but primarily because of the ability of class I drugs to slow the flutter rate, AV conduction can be *facilitated* sufficiently to result in a 1:1 ventricular response to the atrial flutter (Fig. 25-16) .

Prevention of recurrent atrial flutter is often difficult to achieve medically but should be approached as outlined for the prevention of paroxysmal supraventricular tachycardia resulting from AV nodal reentry (see also Chap. 23). If recurrences cannot be prevented, therapy is directed toward controlling the ventricular rate when the flutter does recur with digitalis alone or combined with beta blockers or calcium antagonists. Mounting evidence indicates that the risk of emboli in atrial flutter may be more significant[68] [69] [70] than once thought.[76] Since many patients with atrial flutter also have atrial fibrillation, anticoagulation is usually warranted. However, carefully controlled studies to determine the degree of embolic risk in patients with only atrial flutter are lacking. Long-term anticoagulation, as in atrial fibrillation, should probably be considered until more definitive data are available. Radiofrequency catheter ablation of typical flutter (counterclockwise and clockwise) is highly effective at curing atrial fibrillation and has a long-term success rate of 90 to 100 percent.[77] [78] [79] Because ablation of atrial flutter is highly effective with little risk, it can be offered as an alternative to drug therapy. Ablation of other forms of atrial flutter is also effective, although success rates are somewhat lower and more variable.[54] [56] [80]

Atrial Fibrillation (see also Chap. 22)

ELECTROCARDIOGRAPHIC RECOGNITION (Fig. 25-17) .

This arrhythmia is characterized by wavelets propagating in different directions[81] and causing disorganized atrial depolarizations without effective atrial contraction.[82] [83] [84] Electrical activity of the atrium can be detected on ECG as small irregular baseline undulations of variable amplitude and morphology, called f waves, at a rate of 350 to 600 beats/min. At times, small, fine, rapid f waves can occur and are detectable only by right atrial leads or by intracavitary or esophageal electrodes. The ventricular response is grossly irregular ("irregularly irregular") and, in an untreated patient with normal AV conduction, is usually between 100 and 160 beats/min. In patients with WPW syndrome, the ventricular rate during atrial fibrillation can at times exceed 300 beats/min and lead to ventricular fibrillation. Atrial fibrillation should be suspected when the ECG shows supraventricular complexes at an irregular rhythm and no obvious P waves. The recognizable f waves probably do not represent total atrial activity but depict only the larger vectors generated by the multiple wavelets of depolarization that occur at any given moment.

Each recorded f wave is not conducted through the AV junction, so a rapid ventricular response comparable to the atrial rate does not occur. Many atrial impulses are concealed because of a collision of wavefronts, or they are blocked in the AV junction without reaching the ventricles (i.e., concealed conduction, which accounts for the irregular ventricular rhythm). The refractory period and conductivity of the AV node are determinants of the ventricular rate. When the ventricular rate is very rapid or very slow, it may appear to be more regular. Even though conversion of atrial fibrillation to atrial flutter is accompanied by slowing of the atrial rate, an increase in the ventricular response can result since more atrial impulses are transmitted to the ventricle because of less concealed conduction. Also, it is easier to slow the ventricular rate during atrial fibrillation than during atrial flutter with drugs such as digitalis, calcium antagonists, and beta blockers because the increased concealed conduction makes it easier to produce an AV block.

CLINICAL FEATURES.

Atrial fibrillation is a common arrhythmia that is found in 1 percent of persons older than 60 years to more than 5 percent of patients older than 69 years.[85] The overall chance of atrial fibrillation developing over a period of two decades in patients older than 30 years, according to Framingham data, is 2 percent. Estimates are that 1 to 2 million Americans have atrial fibrillation, which occurs more commonly in men than in women.[86] In one study of men and women 65 years or older, atrial fibrillation had a prevalence of 9.1 percent in those with clinical cardiovascular disease, 4.6 percent in those with subclinical cardiovascular disease, and 1.6 percent in those without cardiovascular disease.[87] A history of congestive heart failure, valvular heart disease and stroke, left atrial enlargement, abnormal mitral or aortic valve function, treated systemic hypertension, and advanced age was independently associated with the prevalence of atrial fibrillation. Four important aspects of atrial fibrillation are etiology, control of the ventricular rate, prevention of recurrences, and prevention of thromboembolic episodes. Occult or manifested thyrotoxicosis should be considered in patients with recent-onset atrial fibrillation.[88] [89] Atrial fibrillation can be intermittent or chronic and may be influenced by autonomic activity.[90] Atrial fibrillation, whether it is persistent or intermittent, is a predictor of stroke. Symptoms as a result of atrial fibrillation are determined by multiple factors, including the underlying cardiac status, the rapid ventricular rate, and loss of atrial contraction.

Physical findings include a slight variation in intensity of the first heart sound, absence of *a* waves in the jugular venous pulse, and an irregularly irregular ventricular rhythm. Often, with fast ventricular rates a significant pulse deficit appears, during which the auscultated or palpated apical rate is faster than the rate palpated at the wrist (pulse deficit) because each contraction is not sufficiently strong to open the aortic valve or transmit an arterial pressure

Figure 25-17 Atrial fibrillation produced by "focal" mechanisms. *A*, A rapid, regular atrial tachycardia (left side of figure) at a cycle length of 200 milliseconds degenerates into atrial fibrillation (right side of figure) characterized by rapid, irregular atrial depolarizations. *B*, A premature atrial complex (marked by the asterisk) induces atrial fibrillation (right side of figure). Elimination of these focal triggers for atrial fibrillation can eliminate the atrial fibrillation.

wave through the peripheral artery. If the ventricular rhythm becomes regular in patients with atrial fibrillation, conversion to sinus rhythm, atrial tachycardia, or atrial flutter with a constant ratio of conducted beats or the development of junctional tachycardia or VT should be suspected.

EMBOLIZATION AND ANTICOAGULATION (see also Chap. 62) .

In addition to hemodynamic alterations, the risk of systemic emboli, probably arising in the left atrial cavity or appendage as a result of circulatory stasis, is an important consideration. Nonvalvular atrial fibrillation is the most common cardiac disease associated with cerebral embolism. In fact, almost half of cardiogenic emboli in the

United States occur in patients with nonvalvular atrial fibrillation. The risk of stroke in patients with nonvalvular atrial fibrillation is five to seven times greater than that in controls without atrial fibrillation. Overall, 20 to 25 percent of ischemic strokes are due to cardiogenic emboli.

Many studies have evaluated the risk of stroke in patients with nonvalvular atrial fibrillation and the benefits of anticoagulation and antiplatelet therapy.[91] [92] [93] [94] [95] [96] [97] [98] [99] [100] Certain patients with atrial fibrillation appear to have a higher risk of emboli.[101] For example, patients with mitral stenosis and atrial fibrillation have a 4 to 6 percent incidence of embolism per year. Risk factors that predict stroke in patients with nonvalvular atrial fibrillation include a history of previous stroke or transient ischemic attack (relative risk 22.5), diabetes (relative risk 1.7), history of hypertension (relative risk 1.6), and increasing age (relative risk 1.4 for each decade). Patients with any of these risk factors have an annual stroke risk of at least 4 percent if untreated. Patients whose only stroke risk factor is congestive heart failure or coronary artery disease have stroke rates approximately three times higher than do patients without any risk factors.[102] Left ventricular (LV) dysfunction and a left atrial size greater than 2.5 cm/m^2 on echocardiographic examination are associated with thromboembolism.

Patients younger than 60 to 65 years who have a normal echocardiogram and no risk factors have an extremely low risk for stroke (1 percent per year).[103] Therefore, the risk of stroke in patients with *lone atrial fibrillation,* i.e., idiopathic atrial fibrillation in the absence of any structural heart disease or any of the above risk factors, is quite low.

The annual rate of stroke for the unanticoagulated control group in five large anticoagulation trials[104] was 4.5 percent but was reduced to 1.4 percent (68 percent risk reduction) for the warfarin-treated group (60 percent risk reduction in men; 84 percent risk reduction in women). Aspirin 325 mg/d produced a risk reduction of 44 percent. The annual rate of major hemorrhage was 1 percent for the control group, 1 percent for the aspirin group, and 1.3 percent for the warfarin group. No difference was noted in stroke risk when patients with paroxysmal (intermittent) atrial fibrillation were compared with those with constant (chronic) atrial fibrillation. Anticoagulation therapy was approximately 50 percent more effective than aspirin therapy for the prevention of ischemic stroke in patients with atrial fibrillation. Risk factors for anticoagulant-associated intracranial hemorrhage included excessive anticoagulation and poorly controlled hypertension. Elderly individuals were at increased risk for anticoagulant-associated brain hemorrhage, especially if overanticoagulated.[104]

From these and other data, it appears that individuals younger than 60 years without any clinical risk factors or structural heart disease (lone atrial fibrillation) do not require antithrombotic therapy for stroke prevention because of their low risk. The stroke rate is also low (about 2 percent per year) in patients between the ages of 60 and 75 years with lone atrial fibrillation. These patients may be adequately protected from stroke by aspirin therapy. In very elderly (older than 75 years) patients with atrial fibrillation, anticoagulation should be used with caution and carefully monitored because of the potential increased risk of intracranial hemorrhage. Nevertheless, elderly patients with atrial fibrillation are still likely to benefit from anticoagulation because they are at particularly high stroke risk.[105] Food[106] and drugs such as antibiotics and antiarrhythmics (e.g., amiodarone) can influence the effects of warfarin (see Chap. 62).

The following recommendations for antithrombotic therapy can be made[102] [105] : Any patient with atrial fibrillation who has risk factors for stroke (prior stroke or transient ischemic attack, significant valvular heart disease, hypertension, diabetes, age older than 65 years, left atrial enlargement, coronary artery disease, or congestive heart failure) should be treated with warfarin anticoagulation to achieve an international normalized ratio (INR) of 2.0 to 3.0 for stroke prevention if the individual is a good candidate for oral anticoagulation. Patients with contraindications to anticoagulation and unreliable individuals should be considered for aspirin treatment. Patients with atrial fibrillation who do not have any of the preceding risk factors have a low stroke risk (2 percent per year or less) and can be protected from stroke with aspirin. In patients older than 75 years, anticoagulation should be used with caution and monitored carefully to keep the INR less than 3.0 because of the risk of intracranial hemorrhage.[107] [108] [109] [110] [111] [112]

The risk of embolism following cardioversion to sinus rhythm in patients with atrial fibrillation varies from 0 to 7 percent, depending on the underlying risk factors. Importantly, this risk is independent of the mode of cardioversion, either by chemical (drug) or DC shock. Patients at high risk are those with prior embolism, a mechanical valve prosthesis, or mitral stenosis. Low-risk patients are those younger than 60 years without underlying heart disease. The high-risk group should receive chronic anticoagulation (see below), regardless of whether they will undergo cardioversion, and anticoagulation may not be necessary in the low-risk group. Patients not in the low-risk group who have atrial fibrillation longer in duration than 2 days should receive warfarin to achieve an INR of 2.0 to 3.0 for 3 weeks before elective cardioversion and for 3 to 4 weeks after reversion to sinus rhythm.[113] [114] An alternative strategy is to obtain a transesophageal echocardiogram to exclude the presence of an atrial thrombus. It appears that this technique predicts a group at low risk for the development of thromboembolism following cardioversion, provided that the patients are immediately treated with heparin followed by therapeutic doses of warfarin.[115] [116] [117] [118] Anticoagulation with heparin has been recommended for emergency cardioversion when 3 weeks of anticoagulation or a transesophageal echocardiogram cannot be obtained. It is important to emphasize that no matter which strategy is used, anticoagulation should be continued for at least 4 weeks following cardioversion since atrial contractile function may not fully return until then.[119] [120] [121] [122] [123]

It is important to emphasize that these suggestions must be individualized for a given patient. For example, patients at risk of trauma by virtue of occupation, participation in sports, and episodes of dizziness or syncope are at increased risk of bleeding if given anticoagulants and should probably not receive warfarin. Patients should be warned about taking any new drugs, e.g., nonsteroidal antiinflammatory agents, if they are receiving warfarin.

For patients with intermittent atrial fibrillation, guidelines are unclear. A reasonable approach would be to treat them according to the recommendations noted above, particularly if recurrences are frequent.

MANAGEMENT.

The atria are often abnormal in patients with atrial fibrillation in that they show an increased conduction time or enlargement. Maintenance of sinus rhythm after cardioversion is influenced by the duration of atrial fibrillation and, in some adults, atrial dilatation. Animal studies[83] [124] [125] [126] [127] indicate that atrial fibrillation begets atrial fibrillation; the longer the patient has atrial fibrillation, the

greater the likelihood that it will remain because of a process called electrophysiological remodeling. While similar electrophysiological abnormalities can be demonstrated in patients following short episodes of atrial fibrillation, the mechanism(s) and clinical significance are currently unknown.[128] [129] [130] [131] Nonetheless, the overall management strategies in patients with atrial fibrillation are to prevent thromboembolism (see above) and reduce symptoms. The latter is accomplished by controlling the ventricular rate during atrial fibrillation and/or restoring and maintaining sinus rhythm. Currently, no clear benefit has been ascribed to one treatment strategy over the other (rate control vs. rhythm control), particularly since antiarrhythmic drugs are not 100 percent effective and carry risks of proarrhythmia (see below). Data from large clinical studies (such as Atrial Fibrillation Follow Up Investigation of Rhythm Management [AFFIRM], Pharmacologic Intervention in Atrial Fibrillation [PIAF], and Rate Control versus Electrical Cardioversion [RACE]) will address this issue, at least in part.[132] The overall treatment strategy (i.e., ventricular rate control or restoration and maintenance of sinus rhythm) should be individualized for each patient and based on symptomatology and risk for side effects from drugs.

A patient with atrial fibrillation discovered for the first time should be evaluated for a precipitating cause, such as thyrotoxicosis, mitral stenosis, pulmonary emboli, or pericarditis. The patient's clinical status determines initial therapy, the objectives being to slow the ventricular rate and restore atrial systole. If sudden onset of atrial fibrillation with a rapid ventricular rate results in acute cardiovascular decompensation, electrical cardioversion is the initial treatment of choice. For other patients, the decision to cardiovert is largely based on the individual clinical situation. The need for restoration of sinus rhythm must be weighed against the likelihood of successful cardioversion and long-term maintenance of sinus rhythm. While parameters such as atrial size and duration of atrial fibrillation predict the success of cardioversion in population studies, enlarged atria and atrial fibrillation of long duration are not absolute contraindications to attempted cardioversion. Internal cardioversion via intracavitary catheters can be effective when transthoracic shocks fail, particularly in obese patients or those with significant pulmonary disease.[133] [134] Alternatively, antiarrhythmic drugs that lower defibrillation thresholds such as ibutilide can be used to pretreat the patient and increase the success of DC cardioversion.[135] Recently, a biphasic waveform has been adapted to external cardioversion, which in early studies appears to require less energy than traditional external cardioversion (damped sine wave waveform) and may be more efficacious in the difficult-to-cardiovert patient.[135A] Atrial contraction may not return immediately after restoration of electrical systole, and clinical improvement may be delayed.[119] [120] DC cardioversion establishes normal sinus rhythm in over 90 percent of patients, but sinus rhythm remains for 12 months in only 30 to 50 percent. Patients with atrial fibrillation of less than 12 months' duration have a greater chance of maintaining sinus rhythm after cardioversion. For patients who do not require emergent cardioversion, chemical cardioversion with IV antiarrhythmics is effective in 35 to 75 percent of patients, depending on the population studied.[60] [61] [62] [136] Although procainamide has been used extensively for years, no well-controlled studies have been performed to determine its efficacy. Outside the United States, IV flecainide has been used with good results.[136] IV amiodarone appears to be less effective, with no difference in conversion rates from placebo. IV ibulitide is also effective in about 35 to 75 percent of patients, depending on the population studied.[60] [62] [63] [137] In the absence of decompensation, the patient can be treated with drugs such as digitalis, beta blockers, or calcium antagonists to maintain a resting apical rate of 60 to 80 beats/min that does not exceed 100 beats/min after slight exercise.[138] The combined use of digitalis and a beta blocker[72] or calcium antagonist can be helpful in slowing the ventricular rate. Digitalis may be more effective if associated LV dysfunction is present; without such dysfunction, a beta blocker may be preferable to control the ventricular rate.[139] Clonidine has been used to slow the rate.[140]

Class IA, IC,[141] and III (amiodarone, sotalol[142]) agents can be used to terminate acute-onset atrial fibrillation and prevent recurrences of atrial fibrillation.[74] No one drug, with the possible exception of amiodarone,[108] appears clearly superior, and selection is often based on the side effect profile and risk of proarrhythmia.[136] [143] [144] [145] [146] This appears to be true for newer drugs, such as azimilide and dofetilide, as well, although comparative trials have not yet been done.[146A] [146B] Most antiarrhythmic drugs increase the likelihood of maintaining sinus rhythm from about 30 to 50 percent to 50 to 70 percent of patients per year after cardioversion. However, whether it is preferable to allow atrial fibrillation to continue with just rate control is being evaluated by a multicenter trial (AFFIRM). Before electrical cardioversion, an antiarrhythmic agent is often administered for a few days to help prevent relapse of atrial fibrillation, as well as to convert some patients to sinus rhythm.[147] Rapid atrial pacing will not terminate atrial fibrillation.[124] [148] In some patients with frequent recurrence and rapid ventricular rates not controlled by drugs, AV node modification[149] or interruption by radiofrequency catheter ablation and implantation of a rate-adaptive VVI (VVIR) pacemaker can be acceptable therapy[150] [151] (see Chap. 24). Whenever possible, atrial or dual-chamber pacing is preferable since the incidence of atrial fibrillation and stroke appears to be reduced in comparison to VVI pacing. Surgical application of the Maze procedure,[152] the atrial compartment operation,[153] and new catheter ablation approaches have been used to eliminate atrial fibrillation.[154] [155] [156] Identification of triggers (either premature atrial complexes or atrial tachycardias, see Fig. 25-17) for atrial fibrillation at electrophysiology study and ablation of these foci have been demonstrated to prevent recurrence of atrial fibrillation in some patients[157] [158] [159] (see Chap. 23). Although most of these patients have had paroxysmal atrial fibrillation and frequent premature atrial complexes without structural heart disease, the role of these triggers and the efficacy of ablation in patients with significant structural heart disease remain to be determined. There are, however, some data to suggest that even chronic atrial fibrillation is initiated by these triggers, which can potentially be ablated.[159A] An atrial defibrillator has also been designed and implanted in patients in several early studies[160] [161] [161A] (see Chap. 24). Further studies will be needed to determine its tolerability and which patients are most appropriate for this form of therapy. Atrial or dual-chamber pacing may reduce recurrences of atrial fibrillation in some patients who have intermittent episodes.[162] [163] [164] [165]

Many elderly patients tolerate atrial fibrillation well without therapy because the ventricular rate is slow as a result of concomitant AV nodal disease. These patients often have associated sick sinus syndrome, and the development of atrial fibrillation represents a cure of sorts. Such patients may demonstrate serious supraventricular and ventricular arrhythmias or asystole after cardioversion, so the likelihood of establishing and maintaining sinus rhythm should be weighed against the risks of cardioversion or other forms of therapy.

Atrial Tachycardias

ELECTROCARDIOGRAPHIC RECOGNITION (Fig. 25-18) .

Atrial tachycardia has an atrial rate of generally 150 to 200 beats/min with a P wave contour different from that of the sinus P wave. P waves are usually found in the second half of the tachycardia cycle[48] (long RP/short PR tachycardia).

Figure 25-18 Atrial tachycardia. This 12-lead electrocardiogram and rhythm strip (bottom) demonstrate an atrial tachycardia at a cycle length of approximately 520 milliseconds. Conduction varies between 3:2 and 2:1. Note the negative P waves in leads II, III, and aV_f and, when consecutive P waves are conducted, that the RP interval exceeds the PR interval. Note also that the tachycardia persists despite the development of atrioventricular (AV) block, an important finding that excludes the participation of an AV accessory pathway and sharply differentiates this tachycardia from the one shown in Figure 25-36 .

When the tachycardia is due to digitalis excess, the atrial rate can increase gradually as digitalis therapy is continued (a similar response can occur in nonparoxysmal AV junctional tachycardia); this increase may be associated with gradual prolongation of the PR interval. If the atrial rate is not excessive and AV conduction is not significantly depressed by the digitalis, each P wave may conduct to the ventricles. As the atrial rate increases and AV conduction becomes impaired, a Wenckebach (Mobitz type I) second-degree AV block can ensue. This aberration is sometimes called *atrial tachycardia with block.* Frequently, other manifestations of digitalis excess are present, such as premature ventricular complexes. In nearly half the cases of atrial tachycardia with block, the atrial rate is irregular. Characteristic isoelectric intervals between P waves, in contrast to atrial flutter, are usually present in all leads. However, at rapid atrial rates, the distinction between atrial tachycardia with block and atrial flutter can be difficult. Analysis of P wave configuration during tachycardia indicates that a positive or biphasic P wave in aV_f predicts a right atrial focus whereas a positive P wave in V_1 predicts a left atrial focus.

CLINICAL FEATURES.

While atrial tachycardia occurs most commonly in patients with significant structural heart disease such as coronary artery disease, with or without myocardial infarction, cor pulmonale, or digitalis intoxication, it is also seen in patients without structural heart disease. Potassium depletion can precipitate the arrhythmia in patients taking digitalis. The signs, symptoms, and prognosis are usually related to the underlying cardiovascular status and the rate of the tachycardia.

Physical findings include a variable rhythm and intensity of the first heart sound as a result of the varying AV block and PR interval. An excessive number of *a* waves may be seen in the jugular venous pulse. Carotid sinus massage increases the degree of AV block by slowing the ventricular rate in stepwise fashion without terminating the tachycardia, as in atrial flutter. It should be performed cautiously in patients with digitalis toxicity because serious ventricular arrhythmias can result.

MANAGEMENT.

Atrial tachycardia with block in a patient not receiving digitalis is treated in a manner similar to the treatment of other atrial tachyarrhythmias. Depending on the clinical situation, digitalis, a beta blocker, or a calcium channel blocker can be administered to slow the ventricular rate, and then if atrial tachycardia remains, class IA, IC, or III drugs can be added. Catheter ablation procedures are usually effective at eliminating the atrial tachycardia, depending on the mechanism and underlying heart disease[54] [80] [166] [167] [168] (see Chap. 23). However, tachycardias can occasionally recur at a different site following a successful ablation attempt. If atrial tachycardia appears in a patient receiving digitalis, the drug should initially be assumed to be responsible for the arrthythmia. Therapy includes cessation of digitalis and administration of potassium chloride orally or IV if serum [K^+] is not abnormally elevated or administration of a drug such as lidocaine, propranolol, and phenytoin while cardiac rhythm is monitored. Often, the ventricular response is not excessively fast, and simply withholding digitalis is all that is necessary.

Mechanisms: Automatic Atrial Tachycardia

Three types of atrial tachycardia have been distinguished experimentally: automatic, triggered, and reentrant atrial tachycardia. The characteristics of automatic and reentrant tachycardias will be discussed separately. Entrainment,[169] [170] resetting of curve patterns in response to overdrive pacing,[171] the patient's response to adenosine,[172] and recording of monophasic action potentials can be used to help distinguish one mechanism from the other.[173] [174] However, no clear clinical distinctions can be made between tachycardias with different mechanisms.

ELECTROCARDIOGRAPHIC FEATURES(see Fig. 25-12 *F*).

Automatic atrial tachycardia is characterized electrocardiographically by a supraventricular tachycardia that generally accelerates after its initiation, with heart rates less than 200 beats/min. The P wave contour differs from the sinus P wave, the PR interval is influenced directly by the tachycardia rate, and AV block can exist without affecting the tachycardia; i.e., it continues uninterrupted. Vagal maneuvers do not generally terminate the tachycardia, even though they can produce AV nodal block. Thus, pharmacological or physiological maneuvers that selectively result in AV block do not affect the automatic focus, nor does the development of bundle branch block alter the PR or RP interval unless it is associated with prolongation of the H-V interval.

Initiation of tachycardia with premature atrial stimulation is not generally possible but is independent of intraatrial or AV nodal conduction delay when it occurs. The atrial activation sequence usually differs from a sinus-initiated P wave, and the A-H interval is related to the tachycardia rate. The first P wave of the tachycardia is the same as the subsequent P waves of the tachycardia, in contrast to most forms of reentrant supraventricular tachycardia, in which the initial and subsequent P waves differ.[175] Usually,

Figure 25-19 Macro-reentrant atrial tachycardia in a patient who underwent atrial septal defect repair 10 years earlier. This tachycardia uses a reentrant circuit established by the atriotomy on the lateral atrial wall. Ablation to extend the scar to the tricuspid annulus eliminated this tachycardia.

the tachycardia cannot be terminated by pacing, although it can exhibit overdrive suppression. The introduction of premature atrial complexes during tachycardia merely resets the timing of the tachycardia. It is very difficult to differentiate this mechanism from micro-reentry by the leading-circle concept (see Chap. 22).

CLINICAL FEATURES.

Many supraventricular tachycardias associated with AV block are probably due to automatic atrial tachycardia,[175] including atrial tachycardia from digitalis intoxication (see Fig. 25-18). Automatic atrial tachycardia occurs in all age groups and is seen in settings of myocardial infarction, chronic lung disease (especially with acute infection), acute alcohol ingestion, and a variety of metabolic derangements. Abnormal histology can be present.[175] Differentiation from other tachycardias such as sinus nodal reentry (if the P waves of the automatic atrial tachycardia resemble the sinus-initiated P waves), atrial reentry (particularly if caused by micro-reentry), and some other mechanisms can be difficult.

Management is as discussed under atrial tachycardia from digitalis.

Mechanisms: Atrial Tachycardia Caused by Reentry

ELECTROCARDIOGRAPHIC RECOGNITION(Figs. 25-12 *E* and 25-19).

This arrhythmia is electrocardiographically manifested by a P wave that has a contour different from that of the sinus P wave, a PR interval directly influenced by the tachycardia rate, and the capability of development of an AV block without interrupting the tachycardia. Reentry can exist around a surgical scar, anatomical structure, or atriotomy incision.[54] [166] Electrophysiologically, initiation of the tachycardia occurs with premature stimulation during the atrial relative refractory period, which results in a critical degree of intraatrial conduction delay, an atrial activation sequence different from what occurs during sinus rhythm, and an AV nodal conduction time related to the tachycardia rate. Vagal maneuvers generally do not terminate the tachycardia and can produce AV block.

CLINICAL FEATURES.

Forms of atrial reentry producing atrial tachycardias include those that occur with atrial fibrosis (with pulmonary disease) or surgical atriotomy scars (see Fig. 25-19). The tachycardia can be started and stopped by an atrial extrastimulus. Spontaneous termination can be either sudden, with progressive slowing, or with alternating long-short cycle lengths.

Chaotic Atrial Tachycardia

Chaotic (sometimes called *multifocal*) atrial tachycardia is characterized by atrial rates between 100 and 130 beats/min, with marked variation in P wave morphology and totally irregular P-P intervals (Fig. 25-20) . Generally, at least three P wave contours are noted, with most P waves conducted to the ventricles. This tachycardia occurs commonly in older patients with chronic obstructive pulmonary disease and congestive heart failure and may eventually develop into atrial fibrillation. Digitalis appears to be an unusual cause, and theophylline administration has been implicated. Chaotic atrial tachycardia can occur in childhood.

Figure 25-20 Chaotic (multifocal) atrial tachycardia. Premature atrial complexes occur at varying cycle lengths and with differing contours.

MANAGEMENT.

Management is primarily directed toward the underlying disease. Antiarrhythmic agents are often ineffective in slowing either the rate of the atrial tachycardia or the ventricular response. Beta-adrenoreceptor blockers should be avoided in patients with bronchospastic pulmonary disease but can be effective if tolerated. Verapamil and amiodarone have been useful. Potassium and magnesium replacement may suppress the tachycardia.

AV JUNCTIONAL RHYTHM DISTURBANCES

AV Junctional Escape Beats

MECHANISM.

Automatic fibers that are prevented from initiating depolarization by a pacemaker such as the sinus node, which possesses a more rapid rate of firing, are called *latent pacemakers.* Such latent pacemakers are found in some parts of the atrium, in the AV node-His bundle area, in the right and left bundle branches, and in the Purkinje system. Under usual conditions, automatic fibers are *not* found in atrial or ventricular myocardium. It is possible that the N region of the AV node is automatic, at least in some species, but is kept suppressed by neighboring atrial tissue. A latent pacemaker can become the dominant pacemaker by default or usurpation, i.e., by passive or active mechanisms. A decrease in the number of impulses arriving at a latent pacemaker site, the result of slowing of the sinus node or interruption of propagation of the normal impulse anywhere along its course, allows the latent pacemaker to escape and initiate depolarization passively, by default. An increase in the discharge rate of a latent pacemaker can capture pacemaker control actively, by usurpation. As will be seen, the implication of the two different mechanisms of ectopic impulse formation is important therapeutically.

ELECTROCARDIOGRAPHIC RECOGNITION.

An AV junctional escape beat occurs when the rate of impulse formation of the primary pacemaker, generally the sinus node, becomes less than that of the AV junctional region or when impulses from the primary pacemaker do not penetrate to the region of the escape focus and allow the AV junctional focus to reach threshold and discharge. The interval from the last normally conducted beat to the AV junctional escape beat is a measure of the initial discharge rate of the AV junctional focus and generally corresponds to a rate of 35 to 60 beats/min (see Fig. 25-4 *B*). Although an AV junctional escape rhythm is usually fairly regular, intervals between subsequent escape beats after the initial escape beat can gradually shorten as the rate of discharge of the escape focus increases, the so-called *rhythm of development* or *warm-up phenomenon.*

The ECG displays pauses longer than the normal P-P interval, interrupted by a QRS complex of supraventricular configuration with absent, retrograde, fusion, or sinus P waves that do not conduct to the ventricle. If P waves precede the QRS, they have a PR interval generally less than 0.12 second. The exact site of impulse formation (i.e., AN, N, or NH regions; low atrium; or His bundle) is not known and may differ from patient to patient and be influenced by the cause of the arrhythmia.

Treatment, if any, lies in increasing the discharge rate of the higher pacemakers and improving AV conduction and can require pacing. Frequently, no treatment is necessary.

Premature AV Junctional Complexes

Premature AV junctional complexes are characterized by an impulse that arises prematurely in the AV junction (the exact site--i.e., AN, N, or NH regions; low atrium; or His bundle--is not known and may vary from patient to patient) and that attempts conduction in anterograde and retrograde directions. If unimpeded in its course, the impulse discharges the atrium to produce a premature retrograde P wave and a premature QRS complex with a supraventricular contour. The retrograde P wave can occur before, during, or after the QRS complex. Alterations in conduction time can influence the PR or RP relationships without a change in the site of origin of the impulse. Premature AV junctional complexes that conduct aberrantly are difficult to distinguish from premature ventricular complexes observed on scalar ECG.

Treatment of premature AV junctional complexes is not generally necessary. However, since they may arise distal to the AV node, they can occur early in the cardiac cycle and can initiate a ventricular tachyarrhythmia in some instances. Under these circumstances, therapy is approached as for premature ventricular complexes (see

Chap. 23).

AV Junctional Rhythm

If the AV junctional escape beats continue for a period of time, the rhythm is called an *AV junctional rhythm* (Fig. 25-21) . Since the inherent rate of the AV junctional tissue is 35 to 60 beats/min, the AV junctional tissue can assume the role of the dominant pacemaker at this rate only by passive default of the sinus pacemaker. The ECG displays a normally conducted QRS complex, which can conduct retrogradely to the atrium or can occur independently of atrial discharge and produce AV dissociation.

An AV junctional escape rhythm can be a normal phenomenon in response to the effects of vagal tone, or it can occur during pathological sinus bradycardia or heart block. The escape beat or rhythm serves as a safety mechanism to prevent the occurrence of ventricular asystole. *Physical findings* vary depending on the P-QRS relationship. Large *a* waves in the jugular venous pulse and a loud, soft, or changing intensity of the first heart sound may be present if atrial contraction occurs when the tricuspid valve is shut.

Therapy is discussed under AV junctional escape beats (see above).

Nonparoxysmal AV Junctional Tachycardia

ELECTROCARDIOGRAPHIC RECOGNITION (Figs. 25-22 and 25-23) .

To usurp dominant pacemaker status, AV junctional tissue must exhibit an enhanced discharge rate such as during nonparoxysmal AV junctional tachycardia. The tachycardia is usually of gradual onset and termination,

Figure 25-21 Atrioventricular (AV) junctional rhythm. *Top,* AV junctional discharge occurs fairly regularly at a rate of approximately 50 beats/min. Retrograde atrial activity follows each junctional discharge. *Bottom,* Recording made on a different day in the same patient. The AV junctional rate is slightly more variable, and retrograde P waves precede onset of the QRS complex. The positive terminal portion of the P wave gives the appearance of AV dissociation, which was not present.

Figure 25-22 Nonparoxysmal atrioventricular (AV) junctional tachycardia. *A,* Control; *B,* response to carotid sinus massage; *C,* response to atropine 1 mg intravenously. Note that His bundle depolarization is the earliest recordable electrical activity in each cycle. The atria are depolarized retrogradely (low right atrial activity recorded in the BHE precedes high right atrial activity recorded in the BAE). Note also that carotid sinus massage slows the junctional discharge rate while atropine speeds it up. From these tracings alone one could not distinguish the rhythm from some other types of supraventricular tachycardia. However, the onset and termination of this tachycardia were typical of nonparoxysmal AV junctional tachycardia.

hence the modifier *nonparoxysmal.* On occasion, nonparoxysmal AV junctional tachycardia can become manifested abruptly because slowing of the dominant pacemaker may then allow sudden capture and control of the rhythm by the AV junctional focus.

Nonparoxysmal AV junctional tachycardia is recognized by a QRS of supraventricular configuration at a fairly regular rate of 70 to 130 beats/min, but it can be faster. Accepted terminology assigns the label of tachycardia to rates exceeding 100 beats/min. The term *nonparoxysmal AV junctional tachycardia,* although not entirely correct when the rate is 70 to 100 beats/min, has generally been accepted since rates exceeding 60 beats/min in effect represent tachycardia for the AV junctional tissue. Enhanced vagal tone can slow while vagolytic agents can speed up the discharge rate. Although retrograde activation of the atria can occur, the atria are commonly controlled by an independent sinus, atrial, or on occasion, a second AV junctional focus resulting in AV dissociation (see Fig. 25-12 *G*). The ECG diagnosis can be complicated by the presence of entrance and exit blocks at the AV junctional tissue level and incomplete forms of AV dissociation.

The cause of this arrhythmia is probably *accelerated automatic discharge* in or near the His bundle. It is possible that nonparoxysmal AV junctional tachycardia originates in atrial fibers without recognition of the latter's role from analysis of the scalar ECG or on intracardiac electrograms unless a careful search is made. Wenckebach periods can occur, but the presence of exit block has not yet been demonstrated by His bundle recording in humans, and the block can be in the AV node with the origin of the nonparoxysmal AV junctional tachycardia proximal to the site of the His bundle recording.

CLINICAL FEATURES.

Nonparoxysmal AV junctional tachycardia occurs most commonly in patients with underlying heart disease, such as inferior infarction or myocarditis (often the result of acute rheumatic fever), or after open-heart surgery.[176] [177] [178] An important cause is excessive digitalis, which can also produce the ECG manifestations of varying degrees of exit block (usually the Wenckebach type) from the accelerated AV junctional focus. Junctional tachycardia occurs commonly during radiofrequency catheter ablation of the slow pathway[179] (see Chap. 23). Nonparoxysmal AV junctional tachycardia can occur in otherwise healthy individuals without symptoms (Fig. 25-23) or can be a serious and difficult-to-control tachycardia, occasionally chronic, rapid, and long lasting. It can occur congenitally in infants or children and is associated with relatively high mortality.[173] [180]

The clinical features vary depending on the rate of the arrhythmia and the underlying etiology and severity of heart disease. As in most arrhythmias, the physical signs are determined by the relationship of the P wave to the QRS complex and the rate of atrial and ventricular discharge. The first heart sound can therefore be constant or varying, and cannon *a* waves may or may not occur in the jugular venous pulse.

The ventricular rhythm can be regular or irregular, often in a constant fashion. It is especially important to recognize slowing and regularization of the ventricular rhythm in a patient with atrial fibrillation as being caused by nonparoxysmal AV junctional tachycardia and as a possible early sign of *digitalis intoxication* (see Chap. 23). Initially, during atrial fibrillation the regular ventricular rhythm can result from an AV junctional escape rhythm because the depressed AV conduction caused by digitalis blocks the passage of impulses from the fibrillating atria (see Fig. 25-12 *G*). As digitalis administration is continued, the ventricular rate can then accelerate because of increased discharge of the AV junctional pacemaker but can still be regular. Further digitalis administration can produce a rate that is slow and irregular because of varying degrees of AV junctional exit block. The rhythm can be misdiagnosed as resumption of conduction from the fibrillating atria. The rate can then increase further because of development of VT.

MANAGEMENT.

Therapy is directed toward the underlying etiological factor and functional support of the cardiovascular system. If the rhythm is regular, cardiovascular status is not compromised, and the patient is not taking digitalis, digitalis administration could be considered. Electrical cardioversion can be tried if necessary and if digitalis toxicity is excluded; theoretically, however, if the nonparoxysmal AV junctional tachycardia is due to enhanced automaticity, cardioversion may be ineffective. If the patient tolerates the arrhythmia well, careful monitoring and attention to the underlying heart disease are usually all that are required in an adult. The arrhythmia will generally abate spontaneously. If digitalis toxicity is the cause, treatment with the drug must be stopped and potassium, lidocaine, phenytoin, or propranolol administered. Drug therapy includes agents from classes IA, IC, and III.[173] [176] [180] [181] Catheter ablation of the junctional site can be effective.[182] [183] [184] [185]

Figure 25-23 Nonparoxysmal atrioventricular junctional tachycardia in a healthy young adult. This tachycardia occurs at a fairly regular interval ("W-shaped" complexes) and is interrupted intermittently with sinus captures that produce functional right and left bundle branch blocks. Two P waves are indicated by arrows. The junctional discharge rate is approximately 120 beats/min (cycle length = 500 milliseconds) and the rhythm irregular, sometimes shortened by sinus captures or delayed by concealed conduction that resets and displaces the junctional focus. In the bottom panel, carotid sinus massage slows the junctional as well as the sinus discharge rate.

TACHYCARDIAS INVOLVING THE AV JUNCTION

Much confusion exists regarding the nomenclature of tachycardias characterized by a supraventricular QRS complex, a regular R-R interval, and no evidence of ventricular preexcitation. Because it is now apparent that a variety of electrophysiological mechanisms can account for these tachycardias (see Fig. 25-12), the nonspecific term *paroxysmal supraventricular tachycardia* has been proposed to encompass the entire group. This term may be inappropriate because some tachycardias in patients with accessory pathways (see below) are no more supraventricular than they are ventricular in origin in that they may require participation of both the atria and the ventricles in the reentrant pathway and they exhibit a QRS complex of normal contour and duration only because anterograde conduction occurs over the normal AV node-His bundle pathways (see Fig. 25-12 *C*). If conduction over the reentrant pathway reverses direction and travels in an "antidromic" direction--i.e., to the ventricles over the accessory pathway and to the atria over the AV node-His bundle--the QRS complex exhibits a prolonged duration, although the tachycardia is basically the same. The term *reciprocating tachycardia* has been offered as a substitute for paroxysmal supraventricular tachycardia, but use of such a term presumes the mechanism of the tachycardia to be reentrant (which is probably the case for many supraventricular tachycardias). Reciprocating tachycardia is probably the mechanism of many VTs as well. Thus, no universally acceptable nomenclature exists for these tachycardias. In this chapter, descriptive titles, although cumbersome, will be used for the sake of clarity. In addition, the mechanism of reentry will be assumed to be operative when the weight of evidence supports its presence even though unequivocal proof is not always available.

AV Nodal Reentrant Tachycardia

ELECTROCARDIOGRAPHIC RECOGNITION.

Reentrant tachycardia in the AV node is characterized by a tachycardia with a QRS complex of supraventricular origin, with sudden onset and termination generally at rates between 150 and 250 beats/min (commonly 180 to 200 beats/min in adults) and with a regular rhythm. Uncommonly, the rate may be as low as 110 beats/min and occasionally, especially in children, may exceed 250. Unless functional aberrant ventricular conduction or a previous conduction defect exists, the QRS complex is normal in contour and duration. P waves are generally buried in the QRS complex. Often, the P wave is seen just prior to or just after the end of the QRS and causes a subtle alteration in the QRS complex that results in a pseudo-S or pseudo-r
, which may be recognized only on comparison to the QRS complex in normal sinus rhythm (Fig. 25-24) . AV nodal reentry recorded at the onset begins abruptly, usually following a premature atrial complex that conducts with a prolonged PR interval (see Figs. 25-12 *A* and 25-13 *B*). The abrupt termination, usually with a retrograde P wave, is sometimes followed by a brief period of asystole or bradycardia. The R-R interval can shorten over the course of the first few beats at the onset or lengthen during the last few beats preceding termination of the tachycardia. Variation in cycle length is usually caused by variation in anterograde AV nodal conduction time. Cycle length and/or QRS alternans can occur, usually when the rate is very fast. Carotid sinus massage can slow the tachycardia slightly prior to its termination or, if termination does not occur, can produce only slight slowing of the tachycardia.

ELECTROPHYSIOLOGICAL FEATURES.

An atrial complex that conducts with a critical prolongation of AV nodal conduction time generally precipitates AV nodal reentry (Figs. 25-25 , 25-26 , and 25-27) . Premature ventricular stimulation can also induce AV nodal reentry in about one third of patients. Data from radiofrequency catheter ablation results[186] [187] and mapping[188] [189] [190] [191] support the presence of separate atrial inputs into the AV node, the fast and slow pathways,[192] [193] to explain this tachycardia (see Chap. 22). In Figure 22-31 , and Figure 25-12 *A* and *B*, the atria are shown as a necessary link between the fast and slow pathways. In most examples, the retrograde P wave occurs at the onset of the QRS complex, clearly excluding the possibility of an accessory pathway. If an accessory pathway in the ventricle were part of the tachycardia circuit, the ventricles would have to be activated anterogradely before the accessory pathway could be activated retrogradely

Figure 25-24 Twelve-lead electrocardiogram of atrioventricular nodal reentrant tachycardia. *A*, During tachycardia a pseudo-r
is seen in lead V_1 (arrow) and pseudo-S waves (arrow) are seen in leads II, III, and aV_f . These waves become more obvious when compared with the QRS complexes during sinus rhythm *(B)*.

Figure 25-25 *A,* Initiation of atrioventricular (AV) nodal reentrant tachycardia in a patient with dual AV nodal pathways. *Upper* and *lower* panels show the last two paced beats of a train of stimuli delivered to the coronary sinus at a pacing cycle length of 500 milliseconds. The results of premature atrial stimulation at an S_1 -S_2 interval of 250 milliseconds on two occasions are shown. In the *upper* panel, S_2 was conducted to the ventricle with an A-H interval of 170 milliseconds and was then followed by a sinus beat. In the *lower* panel, S_2 was conducted with an A-H interval of 300 milliseconds and initiated AV nodal reentry. Note that the retrograde atrial activity occurs (arrow) prior to the onset of ventricular septal depolarization and is superimposed on the QRS complex. Retrograde atrial activity begins first in the low right atrium (HBE lead) and then progresses to the high right atrium (RA) and coronary sinus (CS) recordings. *B,* Two QRS complexes in response to a single atrial premature complex. After a basic train of S_1 stimuli at 600 milliseconds, an S_2 at 440 milliseconds is introduced. The first QRS complex in response to S_2 occurs after a short (95 milliseconds) A-H interval caused by anterograde conduction over the fast AV nodal pathway. The first QRS complex is labeled number 1 (in lead V_1). The second QRS complex in response to the S_2 stimulus (labeled number 2) follows a long A-H interval (430 milliseconds) caused by anterograde conduction over the slow AV nodal pathway.

Figure 25-26 H_1 -H_2 intervals *(left)* and A_2 -H_2 intervals *(right)* at various A_1 -A_2 intervals with a discontinuous atrioventricular (AV) nodal curve. At a critical A_1 -A_2 interval the H_1 -H_2 and the A_1 -H_2 intervals increase markedly. At the break in the curves, AV nodal reentrant tachycardia is initiated.

and depolarize the atria, thus placing the retrograde P wave no earlier than during the ST segment (see Preexcitation Syndrome, Chap. 23).

In approximately 30 percent of instances, atrial activation begins at the end of or just after the QRS complex and gives rise to a discrete P wave on the surface ECG (often appearing as a nubbin of an R in V_1) (see Fig. 25-12 *A*), whereas in the majority of patients, P waves are not seen since they are buried within the inscription of the QRS complex. In the most common variety of AV nodal reentrant tachycardia, the VA interval (i.e., the interval between the onset of QRS and the onset of atrial activity) is less than 50 percent of the R-R interval, and the ratio of the AV to the VA interval exceeds 1.0. Most

Figure 25-27 Atrial preexcitation during atrioventricular (AV) reciprocating tachycardia in a patient with a concealed accessory pathway. No evidence of accessory pathway conduction is present in the two sinus-initiated beats shown in *A*. A premature stimulus in the coronary sinus (S) precipitates a supraventricular tachycardia at a cycle length of approximately 330 milliseconds. The retrograde atrial activation sequence begins first in the distal coronary sinus (A
, DCS), followed by activation recorded in the proximal coronary sinus (PCS), low right atrium (HBE), and then the high right atrium (not shown). The QRS complex is normal and identical to the sinus-initiated QRS complex. (The terminal portion is slightly deformed by superimposition of the retrograde atrial recording.) Note that the RP interval is short and the PR interval is long. The shortest VA interval exceeds 65 milliseconds, consistent with conduction over a retrogradely conducting AV pathway. *B,* Premature ventricular stimulation at a time when the His bundle is still refractory from anterograde activation during tachycardia shortens the A-A interval from 330 to 305 milliseconds without a change in the retrograde atrial activation sequence. (Note that no change occurs in the H-H interval when the right ventricular stimulus, S, is delivered. H-H intervals are in milliseconds in the HBE lead.) Thus the ventricular stimulus, despite His bundle refractoriness, still reaches the atrium and produces an identical retrograde atrial activation sequence. The only way that this finding can be explained is via conduction over a retrogradely conducting accessory pathway. Therefore, the patient has a concealed accessory pathway with the Wolff-Parkinson-White syndrome.

of these patients during tachycardia have a VA minimum value of 61 milliseconds measured to the earliest recorded atrial activity and 95 milliseconds measured to atrial activity recorded in the high right atrial electrogram. These VA intervals are longer in patients with tachycardia related to accessory pathways, as well as in atypical forms of AV nodal reentry (see Fig. 25-12 *B*).

SLOW AND FAST PATHWAYS.

In the majority of patients, anterograde conduction to the ventricle occurs over the slow (alpha) pathway and retrograde conduction occurs over the fast (beta) pathway (see Chap. 22 and Fig. 25-12 *A* and *B*). To initiate tachycardia, an atrial complex blocks conduction in the fast pathway anterogradely, travels to the ventricle over the slow pathway, and returns to the atrium over the previously blocked fast pathway. The proximal and distal final pathways for this circus movement appear to be located within the AV node, so as currently conceived, the circus movement occurs over the two atrial approaches and the AV node (see Fig. 25-12 *A* and *B*). The reentrant loop for typical AV nodal reentry is the anterograde slow AV nodal pathway to the final distal common pathway (probably the distal AV node), to the retrograde fast AV nodal pathway, and then to atrial myocardium. In atypical AV node reentry, the reentry occurs in the opposite direction.[194] In some patients, the His bundle may be incorporated in the reentrant circuit. Less commonly, the reentry pathway can be over two slow pathways, so-called slow-slow AV node reentry (see Fig. 25-13 *B*). Some data are consistent with intranodal activity.[195]

The cycle length of the tachycardia generally depends on how well the slow pathway conducts because the fast pathway usually exhibits excellent capability for retrograde conduction and has the shorter refractory period in the retrograde direction. Therefore, conduction time in the anterograde slow pathway is a major determinant of the cycle length of the tachycardia.

THE DUAL-PATHWAY CONCEPT.

Evidence supporting the dual-pathway concept derives from several observations, the most compelling of which is that radiofrequency catheter ablation of *either* the slow pathway or the fast pathway eliminates AV nodal reentry without eliminating AV nodal conduction. Other observations provide supporting proof. For example, in these patients a plot of the A_1 -A_2 versus the A_2 -H_2 or the A_1 -A_2 versus the H_1 -H_2 interval shows a discontinuous curve (see Fig. 25-26). The explanation is that at a crucial A_1 -A_2 interval the impulse is suddenly blocked in the fast pathway and is conducted with delay over the slow pathway, with sudden prolongation of the A_2 -H_2 (or H_1 -H_2) interval. Generally, the A-H interval increases at least 50 milliseconds, with only a 10- to 20-millisecond decrease in the coupling interval of the premature atrial complex. Less commonly, dual pathways may be manifested by different PR or A-H intervals during sinus rhythm or at identical paced rates or by a sudden jump in the A-H interval during atrial pacing at a constant cycle length. Two QRS complexes in response to one P wave provide additional evidence[196] (see Fig. 25-25 *B*).

Some patients with AV nodal reentry may not have discontinuous refractory period curves, and some patients who do not have AV nodal reentry can exhibit discontinuous refractory curves. In the latter patients, dual AV nodal pathways can be a benign finding. Many of these patients also exhibit discontinuous curves retrogradely. Similar mechanisms of tachycardia can occur in children. Triple AV nodal pathways can be demonstrated in occasional patients. Virtually irrefutable proof of dual AV nodal pathways is the simultaneous propagation in opposite directions of two AV nodal wavefronts without collision (see Chap. 22) or the production of two QRS complexes from one P wave (Fig. 25-25 *B*) or two P waves from one QRS complex.[197]

In less than 5 to 10 percent of patients with AV nodal reentry, anterograde conduction proceeds over the fast pathway and retrograde conduction over the slow pathway (termed the *unusual form* of AV nodal reentry or atypical AV node reentry), with production of a long VA interval and a relatively short AV interval[186] [187] [188] [189] [190] [191] [193] [194] (generally AV/VA<0.75; see Fig. 25-12 *B*). Finally, it is possible to have tachycardias that use either the anterograde slow or fast pathways and conduct retrogradely over an accessory pathway (see below).

The ventricles are not needed to maintain AV nodal reentry in humans, and spontaneous AV block has been noted on occasion, particularly at the onset of the arrhythmia. Such block can take place in the AV node distal to the reentry circuit, between the AV node and bundle of His, within the bundle of His, or distal to it[198] (see Chap. 22). Rarely, the block can be located between the reentry circuit in the AV node and the atrium. Most commonly, when block appears, it is below the bundle of His. Termination of the tachycardia generally results from a block in the anterogradely conducting slow pathway ("weak link"), so a retrograde atrial response is not followed by a His or ventricular response.

RETROGRADE ATRIAL ACTIVATION.

The sequence of retrograde atrial activation is normal during AV nodal reentrant supraventricular tachycardia, which means that the earliest site of atrial activation during retrograde conduction over the fast pathway is recorded in the His bundle electrogram, followed by electrograms recorded from the os of the coronary sinus and then spreading to depolarize the rest of the right and left atria. During retrograde conduction over the slow pathway in the atypical type of AV nodal reentry, atrial activation recorded in the proximal coronary sinus precedes atrial activation recorded in the low right atrium, which suggests that the slow and fast pathways can enter the atria at slightly different positions. Mapping at the time of surgery confirms this conclusion. Functional bundle branch block during AV nodal reentrant tachycardia does not modify the tachycardia significantly.

CLINICAL FEATURES.

AV nodal reentry commonly occurs in patients who have no structural heart disease. Symptoms frequently accompany the tachycardia and range from feelings of palpitations,[199] nervousness, and anxiety to angina, heart failure, syncope, or shock, depending on the duration and rate of the tachycardia and the presence of structural heart disease. Tachycardia can cause syncope because of the rapid ventricular rate, reduced cardiac output, and cerebral circulation or because of asystole when the tachycardia terminates as a result of tachycardia-induced depression of sinus node automaticity. The prognosis for patients without heart disease is usually good.

The hemodynamic consequences of supraventricular tachyarrhythmias in patients with normal ventricular function are due primarily to a marked decrease in LV end-diastolic and stroke volumes along with an increase in the ejection rate and cardiac output but without a significant change in the ejection fraction (EF) as the heart rate is increased and the atrial contribution to ventricular filling is lost. Heart disease or tachycardia can reduce the EF. Initial hypotension during tachycardia can evoke a sympathetic response that increases blood pressure and in turn causes a rise in vagal tone that can terminate the tachycardia.

MANAGEMENT

The Acute Attack (Table 25-2) .

Management depends on the underlying heart disease, how well the tachycardia is tolerated, and the natural history of previous attacks in the individual patient. For some patients, rest, reassurance, and sedation may be all that are required to abort an attack. Vagal maneuvers, including carotid sinus massage, the Valsalva and Mueller maneuvers, gagging, and occasionally exposure of the face to ice water, serve as the first line of therapy. These maneuvers may slightly slow the tachycardia rate, which may then speed up to the original rate following cessation of the attempt or may terminate it. Vagal maneuvers should be tried *again* after each pharmacological approach. Digitalis, calcium antagonists, beta-adrenoceptor blockers, and adenosine normally depress conduction in the anterogradely conducting slow AV nodal pathway, whereas class IA and IC drugs depress conduction in the retrogradely conducting fast pathway.

Adenosine(see Chap. 23).

Adenosine 6 to 12 mg given rapidly IV is the initial drug of choice.[200] *Verapamil* (Chap. 23) 5 to 10 mg IV or diltiazem 0.25 to 0.35 mg/kg IV terminates AV nodal reentry successfully in about 2 minutes in approximately 90 percent of instances and is given when simple vagal manuevers and adenosine fail.

Cholinergic Drugs.

Cholinergic drugs such as *edrophonium chloride* (Tensilon), a short-acting cholinesterase inhibitor, can terminate AV nodal reentry when administered initially at a trial dose of 3 to 5 mg IV. If unsuccessful, a dose of 10 mg IV may be given. Edrophonium is infrequently needed. Similarly, *intravenous digitalis* administration is not usually necessary to terminate AV nodal reentry. If digitalis is used, digoxin can be given, 0.5 to 1.0 mg IV over a period of 10 to 15 minutes, followed by 0.25 mg every 2 to 4 hours, with a total dose less than 1.5 mg within any 24-hour period. *Oral digitalis* administration to terminate an acute attack is not generally indicated. Vagal

TABLE 25-2 -- DRUGS THAT SLOW CONDUCTION IN AND PROLONG REFRACTORINESS OF THE ACCESSORY PATHWAY AND AV NODE

AFFECTED TISSUE	DRUGS
Accessory pathway	Class IA
AV node	Class II

maneuvers that were previously ineffective can terminate the tachycardia following digitalis administration and should therefore be repeated.

Beta-adrenoceptor blockers must be used cautiously, if at all in patients with heart failure, chronic lung disease, or a history of asthma because its beta-adrenoceptor blocking action depresses myocardial contractility and can produce bronchospasm. Digitalis, calcium antagonists, beta blockers, and adenosine normally depress conduction in the anterogradely conducting slow pathway, whereas class IA and IC drugs depress conduction in the retrogradely conducting fast pathway.

DC Cardioversion.

Before digitalis or a beta blocker is administered, it is advisable to reassess the clinical status of the patient and consider whether DC cardioversion may be advisable. DC shock administered to patients who have received excessive amounts of digitalis can be dangerous and result in serious postshock ventricular arrhythmias (see Chap. 23). Particularly if signs or symptoms of cardiac decompensation occur, DC electrical shock should be considered early. DC shock, synchronized to the QRS complex to avoid precipitating ventricular fibrillation, successfully terminates AV nodal reentry with energies in the range of 10 to 50 J; higher energies may be required in some instances.

In the event that digitalis has been given in large doses and DC shock is contraindicated, competitive *atrial* or *ventricular pacing* can restore sinus rhythm. In some instances, esophageal pacing can be useful (see Chap. 24).

Class IA, IC, and III drugs are not usually required to terminate AV nodal reentry. Unless contraindicated, DC cardioversion should generally be attempted before using these agents, which are more often administered to prevent recurrence.

Pressor drugs can terminate AV nodal reentry by inducing reflex vagal stimulation mediated by baroreceptors in the carotid sinus and aorta when systolic blood pressure is acutely elevated to levels of about 180 mm Hg. One of the following drugs, diluted in 5 to 10 ml of 5 percent dextrose and water, can be given over a 1- to 3-minute period: phenylephrine (Neo-Synephrine) 0.5 to 1.0 mg, methoxamine (Vasoxyl) 3 to 5 mg, or metaraminol (Aramine) 0.5 to 2.0 mg. Pressor drugs should be used cautiously or not at all in the elderly and in patients who have structural heart disease, significant hypertension, hyperthyroidism, or acute myocardial infarction. This potentially dangerous and almost always uncomfortable mode of therapy is rarely needed unless the patient is also hypotensive.

Prevention of Recurrences.

Initially, one must decide whether the frequency and severity of the attacks warrant long-term therapy. If the attacks of paroxysmal tachycardia are infrequent, well tolerated, and short lasting and either terminate spontaneously or are easily terminated by the patient, no prophylactic therapy may be necessary. If the attacks are sufficiently frequent and/or long lasting to necessitate therapy, the patient can be treated with drugs empirically or on the basis of serial electrophysiological testing. If empirical testing is desirable, digitalis, a long-acting calcium antagonist, or a long-acting beta-adrenoceptor blocker is a reasonable initial choice. The clinical situation and potential contraindications, e.g., beta blockers in an asthmatic, usually dictate the selection. If digitalis is used, rapid oral digitalization can be accomplished in 24 to 36 hours with digoxin at an initial dose of 1.0 to 1.5 mg, followed by 0.25 to 0.5 mg every 6 hours for a total dose of 2.0 to 3.0 mg. A less rapid oral regimen induces digitalization in 2 to 3 days with an initial dose of 0.75 to 1.0 mg, followed by 0.25 to 0.5 mg every 12 hours for a total dose of 2.0 to 3.0 mg. Alternatively, digoxin administered as a maintenance dose of 0.125 to 0.500 mg achieves digitalization in about 1 week. If any of these drugs are ineffective when taken singly, combinations can be tested.

Because it is preferable to *cure* the patient of the tachycardia rather than use potentially toxic drugs to suppress it or to implant an antitachycardia device that terminates the tachycardia only after its onset (see Chap. 23), radiofrequency catheter ablation should be considered early in the management of patients with symptomatic recurrent episodes of AV node reentry. For patients who do not wish to take drugs, patients who are drug intolerant, or those in whom drugs are ineffective, radiofrequency catheter ablation is the treatment of choice.[201] [202] It should be considered before long-term therapy with class IA, IC, or III antiarrhythmic drugs. Ablation has replaced surgery[191] [203] [204] in virtually all instances and may be considered the initial treatment of choice in many symptomatic patients.[205] [206] [207] [208] [209] [210] [211] [212] [213] [214] [215]

Reentry over a Concealed (Retrograde Only) Accessory Pathway

ELECTROCARDIOGRAPHIC RECOGNITION(seeFig. 25-27).

The presence of an accessory pathway that conducts unidirectionally from the ventricle to the atrium but not in the reverse direction is not apparent by analysis of the scalar ECG during sinus rhythm because the ventricle is not preexcited.[216] [217] Therefore, ECG manifestations of WPW syndrome are absent, and the accessory pathway is said to be "concealed." Since the mechanism responsible for most tachycardias in patients who have WPW syndrome is macro-reentry caused by anterograde conduction over the AV node-His bundle pathway and retrograde conduction over an accessory pathway, the latter, even if it only conducts retrogradely, can still participate in the reentrant circuit to cause an *AV reciprocating* tachycardia. Electrocardiographically, a tachycardia resulting from this mechanism can be *suspected* when the QRS complex is normal and the retrograde P wave occurs *after* completion of the QRS complex, in the ST segment, or early in the T wave (see Fig. 25-12 *C*).

MECHANISMS.

The cause of unidirectional propagation is not clear and can relate to multiple factors. During sinus rhythm, the atrial impulse probably enters the accessory pathway but is blocked near the ventricular insertion site with both right- and left-sided concealed accessory pathways. During functional block in patients with anterograde conduction over accessory pathways, block occurs near the ventricular insertion site most commonly with left-sided pathways but more often near the atrial insertion site with right-sided accessory pathways.

The P wave follows the QRS complex during tachycardia because the ventricle must be activated before the propagating impulse can enter the accessory pathway and excite the atria retrogradely. Therefore, the retrograde P wave must occur after ventricular excitation, in contrast to AV nodal reentry, in which the atria are usually excited during ventricular activation (see Fig. 25-12 *A*). Also, the contour of the retrograde P wave can differ from that of the usual retrograde P wave since the atria may be activated eccentrically, i.e., in a manner other than the normal retrograde activation sequence, which starts at the low right atrial septum as in AV nodal reentry. This eccentric activation occurs because the concealed accessory pathway in most instances is left sided, i.e., inserts into the left atrium, which makes the left atrium the first site of retrograde atrial activation and causes the retrograde P wave to be negative in lead I (see Fig. 25-27).

Finally, since the tachycardia circuit involves the ventricles, if a functional bundle branch block occurs in the same ventricle in which the accessory pathway is located, the VA interval and cycle length of the tachycardia can become longer (see Fig. 25-32). This important change ensues because the bundle branch block lengthens the reentrant circuit (see Preexcitation Syndrome). For example, the normal activation sequence for a reciprocating tachycardia circuit with a left-sided accessory pathway but without a functional bundle branch block progresses from the atrium to the AV node-His bundle, to the right and left ventricles, to the accessory pathway, and then to the atrium. However, during a functional left bundle branch block, for example, the tachycardia circuit travels from the atrium to the AV node-His bundle, to the right ventricle, to the septum, to the left ventricle, to the accessory pathway, and then back to the atrium. This increase in the VA interval provides definitive proof that the ventricle and accessory pathway are part of the reentry circuit. The additional time required for the impulse to travel across the septum from the right to the left ventricle before reaching the accessory pathway and atrium lengthens the VA interval, which lengthens the cycle length of the tachycardia by an equal amount, assuming that no other changes

in conduction times occur within the circuit. Thus, lengthening of the tachycardia cycle length by more than 35 milliseconds during an ipsilateral functional bundle branch block is diagnostic of a free wall accessory pathway if the lengthening can be shown to be due to VA prolongation only and not to prolongation of the H-V interval (which can develop with the appearance of a bundle branch block). In an occasional patient, the increase in cycle length because of prolongation of VA conduction can be nullified by a simultaneous decrease in the PR (A-H) interval.

The presence of an ipsilateral bundle branch block can facilitate reentry and cause an incessant AV reentrant tachycardia.[218] A functional bundle branch block in the ventricle contralateral to the accessory pathway does not lengthen the tachycardia cycle if the H-V interval does not lengthen.

Septal Accessory Pathway.

An exception to these observations occurs in a patient with a concealed septal accessory pathway. First, retrograde atrial activation is normal because it occurs retrogradely up the septum. Second, the VA interval and the cycle length of the tachycardia increase 25 milliseconds or less with the development of an ipsilateral functional bundle branch block.

Vagal maneuvers, by acting predominantly on the AV node, produce a response on AV reentry similar to AV nodal reentry, and the tachycardia can transiently slow and sometimes terminate. Generally, termination occurs in the anterograde direction, so the last retrograde P wave fails to conduct to the ventricle.

ELECTROPHYSIOLOGICAL FEATURES.

Electrophysiological criteria supporting the diagnosis of tachycardia involving reentry over a concealed accessory pathway include the fact that initiation of tachycardia depends on a critical degree of atrioventricular delay (necessary to allow time for the accessory pathway to recover excitability so that it can conduct retrogradely), but the delay can be in the AV node or His-Purkinje system; i.e., a critical degree of A-H delay is not necessary. Occasionally, a tachycardia can start with little or no measurable lengthening of AV nodal or His-Purkinje conduction time. The AV nodal refractory period curve is smooth, in contrast to the discontinuous curve found in many patients with AV nodal reentry. Dual AV nodal pathways can occasionally be noted as a concomitant, but unrelated finding.

Diagnosis of Accessory Pathways.

Diagnosis can be accomplished by demonstrating that during ventricular pacing, premature ventricular stimulation activates the atria before retrograde depolarization of the His bundle, thus indicating that the impulse reached the atria before it depolarized the His bundle and must have traveled a different pathway to do so. Also, if the ventricles can be stimulated prematurely during tachycardia at a time when the His bundle is refractory and the impulse still conducts to the atrium, retrograde propagation traveled to the atrium over a pathway other than the bundle of His (see Fig. 25-27 *B*). If the premature ventricular complex depolarizes the atria without lengthening of the VA interval and with the same retrograde atrial activation sequence, one assumes that the stimulation site (i.e., ventricle) is within the reentrant circuit without intervening His-Purkinje or AV nodal tissue that might increase the VA interval and therefore the A-A interval. In addition, if a premature ventricular complex delivered at a time when the His bundle is refractory terminates the tachycardia without activating the atria retrogradely, it most likely invaded and blocked conduction in an accessory pathway.

The VA interval (a measurement of conduction over the accessory pathway) is generally constant over a wide range of ventricular paced rates and coupling intervals of premature ventricular complexes, as well as during the tachycardia in the absence of aberration. Similar short VA intervals can be observed in some patients during AV nodal reentry, but if the VA conduction time or RP interval is the same during tachycardia *and* ventricular pacing at comparable rates, an accessory pathway is almost certainly present. The VA interval is usually less than 50 percent of the R-R interval. The tachycardia can be easily initiated following premature ventricular stimulation that conducts retrogradely in the accessory pathway but blocks conduction in the AV node or His bundle. Atria and ventricles are required components of the macro-reentrant circuit, and therefore, continuation of the tachycardia in the presence of AV or VA block excludes an accessory AV pathway as part of the reentrant circuit.

CLINICAL FEATURES.

The presence of concealed accessory pathways is estimated to account for about 30 percent of patients with apparent supraventricular tachycardia referred for electrophysiological evaluation. The great majority of these accessory pathways are located between the left ventricle and left atrium and in the posteroseptal area, less commonly between the right ventricle and right atrium. It is important to be aware of a concealed accessory pathway as a possible cause of apparently "routine" supraventricular tachycardia since the therapeutic response may at times not follow the usual guidelines. Tachycardia rates tend to be somewhat faster than those occurring in AV nodal reentry (200 beats/min), but a great deal of overlap exists between the two groups.

Syncope can occur because the rapid ventricular rate fails to provide adequate cerebral circulation or because the tachyarrhythmia depresses the sinus pacemaker and causes a period of asystole when the tachyarrhythmia terminates. Physical examination reveals an unvarying, regular ventricular rhythm with constant intensity of the first heart sound. Jugular venous pressure can be elevated, but the waveform generally remains constant.

MANAGEMENT.

The therapeutic approach to terminate this form of tachycardia acutely is as outlined for AV nodal reentry. It is necessary to achieve block of a single impulse from atrium to ventricle or ventricle to atrium. Generally, the most successful method is to produce a transient AV nodal block; therefore, vagal maneuvers, IV adenosine, verapamil or diltiazem, digitalis, and beta blockers are acceptable choices. Radiofrequency catheter ablation and conventional antiarrhythmic agents that prolong the activation time or refractory period in the accessory pathway need to be considered for chronic prophylactic therapy, similar to that discussed for reciprocating tachycardias associated with the preexcitation syndrome. Radiofrequency catheter ablation is curative, has low risk, and should be considered early for symptomatic patients[215] [216] [217] [219] [220] [221] (see Chap. 23). The presence of atrial fibrillation in patients with a *concealed accessory pathway* should not be a greater therapeutic challenge than in patients who do not have such a pathway because anterograde AV conduction occurs only over the AV node and not over an accessory pathway. Intravenous verapamil and digitalis are not contraindicated. However, it must be remembered that under some circumstances, such as catecholamine stimulation, anterograde conduction can occur in the apparently concealed accessory pathway.

Preexcitation Syndrome

ELECTROCARDIOGRAPHIC RECOGNITION (Fig. 25-28) .

Preexcitation, or the WPW ECG abnormality, occurs when the atrial impulse activates the whole or some part of the ventricle or the ventricular impulse activates the whole or some part of the atrium earlier than would be expected if the impulse traveled by way of the normal specialized conduction system only.[216] [217] This premature activation is caused by muscular connections composed of working myocardial fibers that exist outside the specialized conducting tissue and connect the atrium and ventricle while bypassing AV nodal conduction delay. They are named *accessory AV pathways* or connections and are responsible for the most common variety of preexcitation (incidentally noted in other species such as monkeys, dogs, and cats). The term *syndrome* is attached to this disorder when tachyarrhythmias occur as a result of the accessory pathway. Three basic features typify the ECG abnormalities of patients with the usual form of WPW conduction caused by an AV connection: (1) PR interval less than 120 milliseconds during sinus rhythm; (2) QRS complex duration exceeding 120 milliseconds with a slurred, slowly rising onset of the QRS in some leads (delta wave) and usually a normal terminal QRS portion; and (3) secondary ST-T wave changes that are generally directed in an opposite direction to the major delta and QRS vectors. Analysis of the scalar ECG can be used to localize the accessory pathway[222] [223] [224] [225] (Fig. 25-28 *D*). Body surface mapping can be useful.[226]

In the *WPW syndrome,* the most common tachycardia is characterized by a normal QRS, a regular rhythm, ventricular rates of 150 to 250 beats/min (generally faster than AV nodal reentry), and sudden onset and termination, in most respects behaving like the tachycardia described for conduction over a concealed pathway (see Chap. 22). The major difference between the two is the capacity for anterograde conduction over the accessory pathway during atrial flutter or atrial fibrillation (see below).

Figure 25-28 *A,* Right anteroseptal accessory pathway. The 12-lead electrocardiogram characteristically exhibits a normal to inferior axis. The delta wave is negative in V_1 and V_2 , upright in leads I, II, aVL, and aVF, isoelectric in lead III, and negative in aVR. Location was verified at surgery. The arrow indicates a delta wave (lead I). *B,* Right posteroseptal accessory pathway. Negative delta waves in leads II, III, and aVF, upright in I and aVL, localize this pathway to the posteroseptal region. The negative delta wave in V_1 with sharp transition to an upright delta wave in V_2 pinpoints it to the right posteroseptal area. Atrial fibrillation is present. Location was verified at surgery. *C,* Left lateral accessory pathway. A positive delta wave in the anterior precordial leads and in leads II, III, and aVF, positive or isoelectric in leads I and aVL, and isoelectric or negative in V_5 and V_6 is typical of a left lateral accessory pathway. Rapid coronary sinus pacing (450-millisecond cycle length) was used to enhance preexcitation (negative P wave in leads I, II, III, aVF, and V_3 through V_6). Location was verified at surgery. *D,* Right free wall accessory pathway. The predominantly negative delta wave in V_1 and the axis more leftward than in *A* indicate the presence of a right free wall accessory pathway. *E,* Logic diagram to determine the location of accessory pathways. Begin with analysis of V_1 to determine whether the delta wave and the QRS complex are negative or positive. That establishes the ventricle in which the accessory pathway is located. Next, determine whether the delta wave and QRS complex are negative in leads II, III, and aVF. If so, the accessory pathway is located in a posteroseptal position. If the accessory pathway is located in the right ventricle, an inferior axis indicates an anteroseptal location whereas a left axis indicates a right free wall location. If the accessory pathway is located in the left ventricle, an isoelectric or negative delta wave and QRS complex in leads I, aVL, V_5 , and V_6 indicate a left lateral (free wall) location.

VARIANTS

A variety of other anatomical substrates exist and provide the basis for different ECG manifestations of several variations of the preexcitation syndrome[216] (Fig. 25-29 . Fibers from the atrium to the His bundle bypassing the physiological delay of the AV node are called *atriohisian tracts* (Fig. 25-29 *B*) and are associated with a short PR interval and a normal QRS complex. Although demonstrated anatomically (see below), the electrophysiological significance of these tracts in the genesis of tachycardias with a short PR interval and a normal QRS complex (Lown-Ganong-Levine [LGL] syndrome) remains to be established. Indeed, evidence does *not* support the presence of a specific LGL syndrome consisting of a short PR interval, normal QRS complex, and tachycardias related to an atriohisian bypass tract.

Another variant of accessory pathway conduction is that due to *atriofascicular or nodofascicular* accessory pathways. These fibers result in a unique AV conduction pattern (sometimes referred to as Mahaim conduction) characterized by the development of ventricular

preexcitation (widened QRS and short H-V interval) with a progressive increase in the AV interval in response to atrial overdrive pacing, as opposed to the behavior of the usual accessory pathway in which preexcitation occurs with short AV intervals (Fig. 25-30) . Because the accessory pathways responsible for this conduction pattern usually insert into the right bundle branch, preexcitation generally results in a left bunch branch block pattern. This phenomenon can be due to fibers passing from the AV node to the ventricle, called *nodoventricular fibers* (or nodofascicular if the insertion is into the right bundle branch rather than ventricular muscle) (see Fig. 25-29 *C*). For nodoventricular connections, the PR interval may be normal or short, and the QRS complex is a fusion beat. This pattern of preexcitation can also result from *atriofascicular* accessory pathways. These fibers almost always represent a duplication of the AV node and the distal conducting system and are located in the right ventricular free wall. The apical end lies close to the lateral tricuspid annulus and conducts slowly, with AV node-like properties. After a long course, the distal portion of these fibers, which conducts rapidly, inserts into the distal right bundle branch or the apical region of the right ventricle.[216] [227] [228] [229] No preexcitation is generally apparent during sinus rhythm but can be exposed by premature right atrial stimulation. The absence of retrograde conduction in these pathways produces only an antidromic AV reentry tachycardia ("preexcited" tachycardia) characterized by anterograde conduction over the accessory pathway and retrograde conduction over the right bundle branch-His bundle-AV node, thus making the atrium a necessary part of the circuit. The preexcited tachycardia has a left bundle branch block pattern, long AV interval (because of the long conduction time over the accessory pathway), and short VA interval. A right bundle branch block can be proarrhythmic by increasing the length of the tachycardia circuit (the VA interval is prolonged because of a delay in retrograde activation of the His bundle), and the tachycardia can become incessant.[216] [227]

In patients who have an atriohisian tract, theoretically, the QRS complex would remain normal and the short A-H interval fixed or show very little increase during atrial pacing at more rapid rates. This response is very uncommon. Rapid atrial pacing in patients who have

nodoventricular or nodofascicular connections shortens the H-V interval and widens the QRS complex, with production of a left bundle branch block contour, but in contrast to the situation in patients who have an AV connection (Fig. 25-31) , the AV interval also lengthens. In patients who have fasciculoventricular connections, the H-V interval remains short and the QRS complex unchanged and anomalous during rapid atrial pacing.

ELECTROPHYSIOLOGICAL FEATURES OF PREEXCITATION(see Figs. 25-29 to 25-38).

If the accessory pathway is capable of anterograde conduction, two parallel routes of AV conduction are possible, one subject to physiological delay over the AV node and the other passing directly without delay from the atrium to the ventricle. This direct route of conduction produces the typical QRS complex that is a fusion beat as a result of depolarization of the ventricle in part by the wavefront traveling over the accessory pathway and in part by the wavefront traveling over the normal AV node-His bundle route. The delta wave represents ventricular activation from input over the accessory pathway. The extent of the contribution to ventricular deplorization by the wavefront over each route depends on their relative activation times. If AV nodal conduction delay occurs because of a rapid atrial pacing rate or premature atrial complex, e.g., more of the ventricle becomes activated over the accessory pathway, and the QRS complex becomes more anomalous in contour. Total activation of the ventricle over the accessory pathway can occur if the AV nodal conduction delay is sufficiently long. In contrast, if the accessory pathway is relatively far from the sinus node, e.g., a left lateral accessory pathway, or if the AV nodal conduction time is relatively short, more of the ventricle may be activated by conduction over the normal pathway (see Fig. 25-31). The normal fusion beat during sinus rhythm has a short H-V interval, or His bundle activation actually begins after the onset of ventricular depolarization because part of the atrial impulse bypasses the AV node and activates the ventricle

Figure 25-29 Schematic representation of accessory pathways. *A,* The "usual" atrioventricular (AV) accessory pathway giving rise to most clinical manifestations of tachycardia associated with Wolff-Parkinson-White (WPW) syndrome. *B,* The very uncommon atriohisian accessory pathway. If the Lown-Ganong-Levine syndrome exists, it would have this type of anatomy, which has been demonstrated on occasion histopathologically. *C,* Nodoventricular pathways, original concept, in which anterograde conduction travels down the accessory pathway with retrograde conduction in the bundle branch-His bundle-AV node (see below). *D,* Fasciculoventricular connections, which are not thought to play an important role in the genesis of tachycardias. *E,* The current concept of nodofascicular accessory pathway in which the accessory pathway is an AV communication with AV nodal-like properties. Sinus rhythm results in a fusion QRS complex, as in the usual form of WPW syndrome shown in *A*. Maximum preexcitation results in ventricular activation over the accessory pathway, and the His bundle is activated retrogradely. During reciprocating tachycardia, anterograde conduction occurs over the accessory pathway with retrograde conduction over the normal pathway. (*E* from Benditt DG, Milstein S: Nodoventricular accessory connection: A misnomer or a structural/functional spectrum. J Cardiovasc Electrophysiol 1:231, 1990.)

Figure 25-30 Development of preexcitation over an atriofascicular accessory pathway. During atrial pacing (S), on the left side of the figure, conduction occurs down the atrioventricular node as evidenced by a normal-appearing QRS complex and a normal H-V interval. The stimulus marked by the arrow conducts the impulse down an atriofascicular fiber, which results in a preexcited QRS, as evidenced by a widened QRS and short H-V interval.

Figure 25-31 Atrial pacing at different atrial sites illustrating different conduction over the accessory pathway. *A,* High right atrial pacing at a cycle length of 500 milliseconds produces anomalous activation of the ventricle (note the upright QRS complex in V_1) and a stimulus-delta interval of 155 milliseconds. This interval indicates that the time from the onset of the stimulus to the beginning of the QRS complex is relatively long because the stimulus is delivered at a fairly large distance from the accessory pathway. Note that His bundle activation (H) occurs at about the onset of the QRS complex. *B,* Atrial pacing occurs through the distal coronary sinus electrode (DCS). At the same pacing cycle length, DCS pacing results in more anomalous ventricular activation and a shorter

stimulus-delta interval (80 milliseconds). His bundle activation is now buried within the inscription of the ventricular electrogram in the HBE lead. *C,* Pacing from the proximal coronary sinus electrode (PCS) results in the shortest stimulus-delta interval (45 milliseconds); such an interval indicates that the pacing stimulus is being delivered very close to the atrial insertion of the accessory pathway, which is located in the left posteroseptal region of the atrioventricular groove.

Figure 25-32 *A,* Recording of depolarization of an accessory pathway (AP) with a catheter electrode. The first QRS complex illustrates conduction over the AP. In the scalar ECG, a short P-R interval and delta wave (best seen in leads I and V_1) are apparent. His bundle activation is buried within the ventricular complex. In the following complex, conduction has blocked over the AP and a normal QRS complex results. His bundle activation clearly precedes the onset of ventricular depolarization by 45 milliseconds. The A-H interval for this complex is 90 milliseconds. *(From Prystowsky EN, Browne KF, Zipes DP: Intracardiac recording by catheter electrode of accessory pathway depolarization. J Am Coll Cardiol 1:468, 1983. Reprinted with permission from the American College of Cardiology.) B,* Influence of functional ipsilateral bundle branch block on the VA interval during an atrioventricular reciprocating tachycardia. Partial preexcitation can be noted in the sinus-initiated complex (first complex). Two premature ventricular stimuli (S_1 , S_2) initiate a sustained supraventricular tachycardia that persists with a left bundle branch block for several complexes before finally reverting to normal. The retrograde atrial activation sequence is recorded first in the proximal coronary sinus lead (arrow, PCS), then in the distal coronary sinus lead (DCS) and low right atrium (HBE), and then high in the right atrium (HRA). During the functional bundle branch block, the VA interval in the PCS lead is 140 milliseconds, which shortens to 110 milliseconds when the QRS complex reverts to normal. Such behavior is characteristic of a left-sided accessory pathway with prolongation of the reentrant pathway by the functional left bundle branch block.

early, at a time when the atrial impulse traveling the normal route just reaches the His bundle. This finding of a short or negative H-V interval occurs *only* during conduction over an accessory pathway or from retrograde His activation during a complex originating in the ventricle, such as a VT.

Pacing the atrium at rapid rates, at premature intervals, or from a site close to the atrial insertion of the accessory pathway accentuates the anomalous activation of the ventricles and shortens the H-V interval even more (His activation may become buried in the ventricular electrogram, as in Fig. 25-31 *B*). The position of the accessory pathway can be determined by careful analysis of the spatial direction of the delta wave in the 12-lead ECG in maximally preexcited beats[222] [223] [224] [225] (see Fig. 25-28). T wave abnormalities can occur after the disappearance of preexcitation with orientation of the T wave according to the site of preexcitation (T wave memory). A variety of electrical, radionuclide, and echocardiographic techniques can be used to localize the insertion site of the accessory pathway (see Chap. 23).

ACCESSORY PATHWAY CONDUCTION.

Even though the accessory pathway conducts more rapidly than the AV node (conduction velocity is faster in the accessory pathway), the accessory pathway usually has a longer refractory period during long cycle lengths (e.g., sinus rhythm)--i.e., it takes longer for the accessory pathway to recover excitability than it does for the AV node. Consequently, a premature atrial complex can occur sufficiently early to block conduction anterogradely in the accessory pathway and conduct to the ventricle only over the normal AV node-His bundle (Fig. 25-33 *A* and *B*). The resultant H-V interval and the QRS complex become normal. Such an event can initiate the most common type of reciprocating tachycardia, one characterized by anterograde conduction over the normal pathway and retrograde conduction over the accessory pathway *(orthodromic AV reciprocating tachycardia*) (Fig. 25-33) . The accessory pathway, which blocks conduction in an anterograde direction, recovers excitability in time to be activated after the QRS complex in a retrograde direction, thereby completing the reentrant loop.

Much less commonly, patients can have tachycardias called *antidromic* tachycardias during which anterograde conduction occurs over the accessory pathway and retrograde conduction over the AV node. The resultant QRS complex is abnormal because of total ventricular activation over the accessory pathway (Figs. 25-33 *C* and 25-34). In both tachycardias, the accessory pathway is an obligatory part of the reentrant circuit. In patients with bidirectional conduction over the accessory pathway, different fibers can be used anterogradely and retrogradely.

A small percentage of patients have multiple accessory pathways often suggested by various ECG clues, and on occasion, tachycardia can be due to a reentrant loop conducting anterogradely over one accessory pathway and retrogradely over the other. Interestingly, 15 to 20 percent of patients may exhibit AV nodal echoes or AV nodal reentry after interruption of the accessory pathway.

Figure 25-33 Schematic diagram of tachycardias associated with accessory pathways. *A,* Orthodromic tachycardia with anterograde conduction over the atrioventricular (AV) node-His bundle route and retrograde conduction over the accessory pathway (left sided for this example as depicted by left atrial activation preceding right atrial activation). *B,* Orthodromic tachycardia and ipsilateral functional bundle branch block. *C,* Antidromic tachycardia with anterograde conduction over the accessory pathway and retrograde conduction over the AV node-His bundle. *D,* Orthodromic tachycardia with a slowly conducting accessory pathway. *E,* Atrial fibrillation with the accessory pathway as a bystander. *F,* Anterograde conduction over a portion of the AV node and a nodoventricular pathway and retrograde conduction over the AV node.

Figure 25-34 Antidromic atrioventricular (AV) reciprocating tachycardia. Tachycardia in this example is due to anterograde conduction over the accessory pathway (note the abnormal QRS complex of a left posterior accessory pathway) and a normal retrograde atrial activation sequence (beginning first in the HBED lead), which is due to retrograde conduction over the AV node. Tachycardia cycle length is 390 milliseconds, with a VA interval of 300 milliseconds measured in the high right atrial lead, 260 milliseconds in the distal His lead, and 280 milliseconds in the proximal coronary sinus lead. I, II, III, and V_1 are scalar leads. DCS = distal coronary sinus lead; HBEP and HBED leads = His bundle electrogram, proximal and distal; HRA = high right atrial electrogram; MCS1-3 = midcoronary sinus leads; PCS = proximal coronary sinus; RV = right ventricular electrogram.

PERMANENT FORM OF AV JUNCTIONAL RECIPROCATING TACHYCARDIA.

An incessant form of supraventricular tachycardia has been recognized that generally occurs with a long RP interval that exceeds the PR interval (Figs. 25-35 and 25-36). Usually, a posteroseptal accessory pathway (most often the right ventricular but other locations as well[230]) that conducts very slowly, possibly because of a long and tortuous route, appears responsible. Tachycardia is maintained by anterograde AV nodal conduction and retrograde conduction over the accessory pathway (see Fig. 25-33 *D*). While anterograde conduction over this pathway has been demonstrated, the long anterograde conduction time over the accessory pathway ordinarily prevents ECG manifestations of accessory pathway conduction during sinus rhythm. Therefore, during sinus rhythm, the QRS is prolonged from conduction over this accessory pathway only when conduction times through the AV node-His bundle exceed those in the accessory pathway.[216] [217]

RECOGNITION OF ACCESSORY PATHWAYS.

When retrograde atrial activation during tachycardia occurs over an accessory pathway that connects the left atrium to the left ventricle, the earliest retrograde activity is recorded from a left atrial electrode usually positioned in the coronary sinus (see Fig. 25-27). When retrograde atrial activation during tachycardia occurs over an accessory pathway that connects the right ventricle to the right atrium, the earliest retrograde atrial activity is generally recorded from a lateral right atrial electrode. Participation of a septal accessory pathway creates the earliest retrograde atrial activation in the low right portion of the atrium situated near the septum, anterior or posterior, depending on the insertion site. These mapping techniques with catheter electrodes and at the time of surgery (see Chap. 23) provide an accurate assessment of the position of the accessory pathway, which can be anywhere in the AV groove except in the intervalvular trigone between the mitral valve and the aortic valve annuli. Recording electrical activity directly from the accessory pathway obviously provides precise localization.

It may be difficult to distinguish AV nodal reentry from participation of a septal accessory connection using the retrograde sequence of atrial activation because activation sequences during both tachycardias are similar. Other approaches to demonstrate retrograde atrial activation over the accessory pathway must be tried and can be accomplished by inducing premature ventricular complexes during tachycardia to determine whether retrograde atrial excitation can occur from the ventricle at a time when the His bundle is refractory (see Fig. 25-27 *B*). Since VA conduction cannot occur over the normal conduction system because the His bundle is refractory, an accessory pathway must be present for the atria to become excited. No patient with a reciprocating tachycardia from an accessory AV pathway has a VA interval of less than 70 milliseconds measured from the onset of ventricular depolarization to the onset of the earliest atrial activity recorded on an esophageal lead or a VA interval of less than 95 milliseconds when measured to the high right part of the atrium. In contrast, in the majority of patients with reentry in the AV node, intervals from the onset of ventricular activity to the earliest onset of atrial activity recorded in the esophageal lead are less than 70 milliseconds.

Other Forms of Tachycardia in Patients with Wolff-Parkinson-White Syndrome

Patients can have other types of tachycardia during which the accessory pathway is a "bystander," i.e., uninvolved in the mechanism responsible for the tachycardia,

such as AV nodal reentry or an atrial tachycardia that conducts to the ventricle over the accessory pathway. In patients with atrial flutter or atrial fibrillation, the accessory pathway is not a requisite part of the mechanism responsible for tachycardia, and the flutter or fibrillation occurs in the atrium unrelated to the accessory pathway (see Fig. 25-33 *E*). Propagation to the ventricle during atrial flutter or atrial fibrillation can therefore occur over the normal AV node-His bundle or accessory pathway. Patients with WPW syndrome who have atrial fibrillation almost always have inducible reciprocating tachycardias as well, which can develop into atrial fibrillation (Fig. 25-37) . In fact, interruption of the accessory pathway and elimination of AV reciprocating tachycardia usually prevent recurrence of the atrial fibrillation. Atrial fibrillation presents a potentially serious risk because of the possibility for very rapid conduction over the accessory pathway. At more rapid rates, the refractory period of the accessory pathway can shorten significantly and

Figure 25-35 Termination of the permanent form of atrioventricular (AV) junctional reciprocating tachycardia (PJRT). In the left portion of this example, PJRT is present. The atrial activation sequence is indistinguishable from atypical AV nodal reentry and atrial tachycardia originating in the low right atrium. The response to premature stimulation(s) identifies the tachycardia as PJRT. Premature ventricular stimulation (arrowhead) occurs at a time when the His bundle is refractory from depolarization during the tachycardia (second labeled H). Therefore, premature ventricular stimulation cannot enter the AV node. Furthermore, premature ventricular stimulation does not reach the atrium. Yet premature ventricular stimulation terminates the tachycardia. This detail can only be explained by the premature ventricular complex invading and blocking in a retrogradely conducting accessory pathway. I, II, III, and V_1 are scalar electrocardiographic leads. DCS = distal coronary sinus electrograms; HBEP, HBED = His bundle electrogram, proximal and distal; HRA = high right atrial electrogram; MCS1, MCS2 = midcoronary sinus electrograms; PCS = proximal coronary sinus electrogram; RV = right ventricular electrogram.

permit an extremely rapid ventricular response during atrial flutter or atrial fibrillation (see Fig. 25-28 *B*). The rapid ventricular response can exceed the ability of the ventricle to follow in an organized manner; it can result in fragmented, disorganized ventricular activation and hypotension and lead to ventricular fibrillation (Fig. 25-38) . Alternatively, a supraventricular discharge bypassing AV nodal delay can activate the ventricle during the vulnerable period of the antecedent T wave and precipitate ventricular fibrillation. Patients who have had ventricular fibrillation have ventricular cycle lengths during atrial fibrillation in the range of 200 milliseconds or less.

Patients with preexcitation syndrome can have other causes of tachycardia such as AV nodal reentry, sometimes with dual AV nodal curves, sinus nodal reentry, or even VT unrelated to the accessory pathway. Some accessory pathways can conduct anterogradely only; more commonly, pathways conduct retrogradely only. If the pathway conducts only anterogradely, it cannot participate in the usual form of reciprocating tachycardia (see Fig. 25-33 *A*). It can, however, participate in antidromic tachycardia (Fig. 25-33 *C*), as well as conduct to the ventricle during atrial flutter or atrial fibrillation (Fig. 25-33 *E*). Some data suggest that the accessory pathway demonstrates automatic activity, which could conceivably be responsible for some instances of tachycardia.

"WIDE QRS TACHYCARDIAS."

In patients with the preexcitation syndrome, so-called wide QRS tachycardias can be due to multiple mechanisms, including sinus or atrial tachycardias, AV nodal reentry, and atrial flutter or fibrillation with anterograde conduction over the accessory pathway; orthodromic reciprocating tachycardia with functional or preexisting bundle branch block; antidromic reciprocating tachycardia; reciprocating tachycardia with anterograde conduction over one accessory pathway and retrograde conduction over a second one; tachycardias using nodofascicular or atriofascicular fibers; or VT.[231]

CLINICAL FEATURES.

The reported incidence of preexcitation syndrome depends in large measure on the population studied and varies from 0.1 to 3.0 per thousand in apparently healthy subjects, with an average of about 1.5 per thousand. The incidence of the ECG pattern of WPW conduction in 22,500 healthy aviation personnel was 0.25 percent with a prevalence of documented tachyarrhythmias of 1.8 percent. Left free wall accessory pathways are most common, followed in frequency by posteroseptal, right free wall, and anteroseptal locations. WPW syndrome is found in all age groups from the fetal and neonatal periods to the elderly, as well as in identical twins. The prevalence is higher in males and decreases with age, apparently because of loss of preexcitation. The majority of adults with preexcitation syndrome have normal hearts, although a variety of acquired and congenital cardiac defects have been reported, including Ebstein anomaly,[232] mitral valve prolapse,[233] and cardiomyopathies. Patients with Ebstein anomaly (see Chaps. 43 and 44) often have multiple accessory pathways, right sided either in the posterior septum or in the posterolateral wall, with preexcitation localized to the atrialized ventricle. They often have reciprocating tachycardia with a long VA interval and a right bundle branch block morphology.

The frequency of paroxysmal tachycardia apparently increases with age, from 10 per 100 patients with WPW syndrome in a 20- to 39-year-old age group to 36 per 100 in

Figure 25-36 Permanent form of junctional reciprocating tachycardia (PJRT) in a patient with a left-sided accessory pathway. The 12-lead electrocardiogram demonstrates a long RP interval-short PR interval tachycardia, which in contrast to the usual form of PJRT, exhibits negative P waves in leads I and aV_l . The rhythm strips below (lead I) indicate that whenever a nonconducted P wave occurs, the tachycardia always terminates, only to begin again after several sinus beats. This pattern is in marked contrast to that in Figure 25-14 , in which the tachycardia continues despite nonconducted P waves.

patients older than 60 years. Approximately 80 percent of patients with tachycardia have a reciprocating tachycardia, 15 to 30 percent have atrial fibrillation, and 5 percent have atrial flutter. VT occurs uncommonly. The anomalous complexes can mask or mimic myocardial infarction (see Chap. 35), bundle branch block, or ventricular hypertrophy, and the presence of the preexcitation syndrome can call attention to an associated cardiac defect. The prognosis is excellent in patients without tachycardia or an associated cardiac anomaly. For most patients with recurrent tachycardia the prognosis is good, but sudden death occurs rarely,[234] with an estimated frequency of 0.1 percent.[235]

Figure 25-37 Atrioventricular (AV) reciprocating tachycardia disorganizing into atrial fibrillation. During sustained AV reciprocating tachycardia at a cycle length of approximately 265 milliseconds, the retrograde atrial activation sequence began first in the right paraseptal region (not shown in this example; location proved at surgery) and was then recorded in the proximal coronary sinus electrogram, followed by atrial activity in the distal coronary sinus, in the low right atrium recorded in the His bundle lead, and then in the high right atrium. Spontaneously, the atrial activation sequence becomes irregular (after the last A
) and atrial fibrillation begins. Note that the last QRS complex reflects conduction over the accessory pathway. Such a transformation occurred repeatedly in this patient and was associated with quickening of the ventricular rate. Atrial fibrillation did not recur following surgical interruption of the accessory pathway.

Figure 25-38 Atrial fibrillation (AF) becoming ventricular fibrillation (VF). In the left portion of this panel, the electrocardiogram (ECG) demonstrates AF with conduction over an accessory pathway producing a rapid ventricular response, at times in excess of 350 beats/min. In the midportion of the tracing VF can be seen to develop. I, II, III, and V_1 are scalar ECG leads. HRA = high right atrial electrogram; RVA = right ventricular apex electrogram.

It is very likely that an accessory pathway is congenital, although its manifestations can be detected in later years and appear to be "acquired." Relatives of patients with preexcitation, particularly those with multiple pathways, have an increased prevalence of preexcitation, thus suggesting a hereditary mode of acquisition. Some children and adults can lose their tendency for the development of tachyarrhythmias as they grow older, possibly as a result of fibrotic or other changes at the site of the accessory pathway insertion. Pathways can lose their ability to conduct anterogradely. Tachycardia beginning in infancy can disappear but frequently recurs. Tachycardia still present after 5 years of age persists in 75 percent of patients regardless of accessory pathway location. Intermittent preexcitation during sinus rhythm and abrupt loss of conduction over the accessory pathway after intravenous ajmaline or procainamide and with exercise suggest that the refractory period of the accessory pathway is long and that the patient is not at risk for a rapid ventricular rate should atrial flutter or fibrillation develop. These approaches are relatively specific, but not very sensitive, with a low positive predictive accuracy. Exceptions to these safeguards can occur.

TREATMENT.

Patients with ventricular preexcitation who have only the ECG abnormality, without tachyarrhythmias, do not require electrophysiological evaluation or therapy. However, for patients with frequent episodes of symptomatic tachyarrhythmia, therapy should be initiated.

Three therapeutic options exist: electrical or surgical (see Chap. 23) ablation and pharmacological therapy. Drugs are chosen to prolong conduction time and/or refractoriness in the AV node, the accessory pathway, or both to prevent rapid rates from occurring. If successful, this therapy prevents maintenance of an AV reciprocating tachycardia or a rapid ventricular response to atrial flutter or atrial fibrillation. Some drugs can suppress premature complexes that precipitate the arrhythmias.

Adenosine, verapamil, propranolol, and digitalis all prolong conduction time and refractoriness in the AV node. Verapamil and propranolol do not directly affect conduction in the accessory pathway, and digitalis has had variable effects. Because digitalis has been reported to shorten refractoriness in the accessory pathway and speed the ventricular response in some patients with atrial fibrillation, it is advisable to *not* use digitalis as a single drug in patients with WPW syndrome who have or may undergo atrial flutter or atrial fibrillation. Since atrial fibrillation can develop *during* the reciprocating tachycardia in many patients (see Fig. 25-37) , this caveat probably applies to *all* patients who have tachycardia and WPW syndrome. Rather, drugs that prolong the refractory period in the accessory pathway should be used, such as class IA and IC drugs (see Chap. 23).

Class IC drugs,[236] [237] amiodarone,[238] and sotalol can affect both the AV node and the accessory pathway. Lidocaine does not generally prolong refractoriness of the accessory pathway. Verapamil and IV lidocaine can *increase* the ventricular rate during atrial fibrillation in patients with WPW syndrome. IV verapamil can precipitate *ventricular fibrillation* when given to a patient with WPW syndrome who has a rapid ventricular rate during atrial fibrillation. This effect does not appear to happen with *oral* verapamil. Catecholamines can expose WPW syndromes, shorten the refractory period of the accessory pathway, and reverse the effects of some antiarrhythmic drugs.[239]

Termination of an Acute Episode.

Termination of an acute episode of reciprocating tachycardia, suspected electrocardiographically from a normal QRS complex, regular R-R intervals, a rate of about 200 beats/min, and a retrograde P wave in the ST segment, should be approached similar to AV nodal reentry. After vagal maneuvers, adenosine followed by IV verapamil or diltiazem is the initial treatment of choice. It is important to note that atrial fibrillation can occur after drug administration, particularly adenosine, with a rapid ventricular response. An external cardioverter-defibrillator should be immediately available if necessary. For atrial flutter or fibrillation, the latter suspected from an anomalous QRS complex and grossly irregular R-R intervals (see Figs. 25-28 *B* and 25-37), drugs must be used that prolong refractoriness in the accessory pathway, often coupled with drugs that prolong AV nodal

refractoriness (e.g., procainamide and propranolol). In many patients, particularly those with a very rapid ventricular response and any signs of hemodynamic impairment, electrical cardioversion is the *initial* treatment of choice.

Prevention.

For long-term therapy to prevent recurrence, it is not always possible to predict which drugs may be most effective for an individual patient. Some drugs can actually increase the frequency of episodes of reciprocating tachycardia by prolonging the duration of anterograde and not retrograde refractory periods of the accessory pathway, thereby making it easier for a premature atrial complex to block conduction anterogradely in the accessory pathway and initiate tachycardia. Oral administration of two drugs, such as quinidine and propranolol or procainamide and verapamil, to decrease conduction capability in both limbs of the reentrant circuit can be beneficial. Class IC drugs, amiodarone, or sotalol, which prolong refractoriness in both the accessory pathway and the AV node, can be effective.[240] [241] Depending on the clinical situation, empirical drug trials or serial electrophysiological drug testing can be used to determine optimal drug therapy for patients with reciprocating tachycardia. For patients who have atrial fibrillation with a rapid ventricular response, induction of atrial fibrillation while the patient is receiving therapy is essential to be certain that the ventricular rate is controlled. Patients who have accessory pathways with very short refractory periods may be poor candidates for drug therapy since the refractory periods may be insignificantly prolonged in response to the standard agents.

Electrical or Surgical Ablation(see Chap. 23).

Radiofrequency catheter ablation of the accessory pathway is advisable for patients with frequent symptomatic arrhythmias that are not fully controlled by drugs, in patients who are drug intolerant, or in those who do not wish to take drugs. This option should be considered early in the course of treatment of a symptomatic patient because of its high success rate, low frequency of complications, and potential cost-effectiveness.[215] [242] [243] [244] [245] [246] [247] [248] Rarely, surgical interruption of the accessory pathway may be necessary.[249] [250]

Summary of Electrocardiographic Diagnosis of Supraventricular Tachycardias

ECG clues that permit differentiation among the various supraventricular tachycardias are often present. P waves during tachycardia that are identical to sinus P waves and occur with a long RP interval and a short PR interval are most likely due to sinus nodal reentry. Retrograde (inverted in leads II, III, and aV_f) P waves generally represent reentry involving the AV junction, either AV nodal reentry or reciprocating tachycardia using a paraseptal accessory pathway. Tachycardia without manifested P waves is probably due to AV nodal reentry (P waves buried in QRS), while a tachycardia with an RP interval exceeding 90 milliseconds may be due to an accessory pathway. AV dissociation or AV block during tachycardia excludes the participation of an AV accessory pathway and makes AV nodal reentry less likely. Multiple tachycardias can occur at different times in the same patient. QRS alternans, thought to be a feature of AV reciprocating tachycardia, is more likely a rapid rate-related phenomenon independent of the tachycardia mechanism. RP-PR relationships (Table 25-3) help differentiate supraventricular tachycardias.

TABLE 25-3 -- SUPRAVENTRICULAR TACHYCARDIAS

SHORT RP/LONG PR	LONG RP/SHORT PR
AV node reentry	Atrial tachycardia
AV reentry	Sinus node reentry
	Atypical AV node reentry
	AVRT with a slowly conducting accessory pathway (e.g., PJRT)

AVRT = atrioventricular reciprocating tachycardia; PJRT = paroxysmal junctional reciprocating tachycardia.

VENTRICULAR RHYTHM DISTURBANCES

Premature Ventricular Complexes

ELECTROCARDIOGRAPHIC RECOGNITION.

A premature ventricular complex is characterized by the premature occurrence of a QRS complex that is abnormal in shape and has a duration usually exceeding the dominant QRS complex, generally greater than 120 milliseconds. The T wave is commonly large and opposite in direction to the major deflection of the QRS. The QRS complex is not preceded by a premature P wave but can be preceded by a nonconducted sinus P wave occurring at its expected time. The diagnosis of a premature ventricular complex can never be made with unequivocal certainty from the scalar ECG since a supraventricular beat or rhythm can mimic the manifestations of ventricular arrhythmia (Fig. 25-39) . Retrograde transmission to the atria from the premature ventricular complex occurs fairly frequently but is often obscured by the distorted QRS complex and T wave. If the retrograde impulse discharges and resets the sinus node prematurely, it produces a pause that is not fully compensatory. More commonly, the sinus node and atria are not discharged prematurely by the retrograde impulse since interference of impulses frequently occurs at the AV junction in the form of collision between the anterograde impulse conducted from the sinus node and the retrograde impulse conducted from the premature ventricular complex.

Therefore, a fully compensatory pause usually follows a premature ventricular complex: The R-R interval produced by the two sinus-initiated QRS complexes on either side of the premature complex equals twice the normally conducted R-R interval. The premature ventricular complex may not produce any pause and may therefore be interpolated (Fig. 25-39 *E*), or it may produce a postponed compensatory pause when an interpolated premature complex causes PR prolongation of the first postextrasystolic beat to such a degree that the P wave of the second postextrasystolic beat occurs at a very short RP interval and is therefore blocked.[251]

Interference within the ventricle can result in *ventricular fusion beats* caused by simultaneous activation of the ventricle by two foci, one from the supraventricular impulse and the other from the premature ventricular complex. On occasion, a fusion beat can be narrower than the dominant sinus beat. This abnormality occurs when a right bundle branch block pattern of a premature ventricular complex arising in the left ventricle fuses with the sinus-initiated complex conducting through the AV junction or when a ventricle with a left bundle branch block pattern is paced artificially and a narrow ventricular fusion beat is produced between the paced and the sinus-conducted beats. Narrow premature ventricular complexes have also been explained as originating at a point equidistant from each ventricle in the ventricular septum and by arising high in the fascicular system. Whether a compensatory or noncompensatory pause, retrograde atrial excitation, or an interpolated complex, fusion complex, or echo beat occurs (see Fig. 25-39), it is merely a function of how the AV junction conducts and the timing of the events taking place.

The term *bigeminy* refers to pairs of complexes and indicates a normal and premature complex, *trigeminy* indicates a premature complex following two normal beats, a premature complex following three normal beats is called *quadrigeminy,* and so on. Two successive premature ventricular complexes are termed a *pair* or a *couplet,* while three successive premature ventricular complexes are termed a *triplet.*

Figure 25-39 Premature ventricular complexes. *A* to *D* were recorded in the same patient. *A,* A late premature ventricular complex results in a compensatory pause. *B,* A slower sinus rate and a slightly earlier premature complex result in retrograde atrial excitation (P). The sinus node is reset, followed by a noncompensatory pause. Before the sinus-initiated P wave that follows the retrograde P wave can conduct the impulse to the ventricle, ventricular escape (E) occurs. *C,* Events are similar to those in *B* except that a ventricular fusion beat (F) results after the premature ventricular complex because of a slightly faster sinus rate. *D,* The impulse propagating retrogradely to the atrium reverses its direction after a delay and returns to reexcite the ventricles (R) to produce a ventricular echo. *E,* An interpolated premature ventricular complex is followed by a slightly prolonged PR interval of the sinus-initiated beat. Lead II.

Arbitrarily, three or more successive premature ventricular complexes are termed *ventricular tachycardia.* Premature ventricular complexes can have different contours and are often called *multifocal* (Fig. 25-40) . More properly they should be called "multiform," "polymorphic," or "pleomorphic" since it is not known whether multiple foci are discharging or whether conduction of the impulse originating from one site is merely changing.

Premature ventricular complexes can exhibit fixed or variable coupling; i.e., the interval between the normal QRS complex and the premature ventricular complex can be relatively stable or variable. Fixed coupling can be due to reentry, triggered activity (see Chap. 22), or other mechanisms. Variable coupling can be due to parasystole, [252] to changing conduction in a reentrant circuit, or to changing discharge rates of triggered activity. Usually, it is difficult to determine the precise mechanism responsible for the premature ventricular complex based on either constant or variable coupling intervals. Focal mechanism can be important, without macro-reentry.[253]

CLINICAL FEATURES.

The prevalence of premature complexes increases with age, and they are associated with male sex and a reduced serum potassium concentration.[254] Premature ventricular complexes are more frequent in the morning in patients after myocardial infarction, but this circadian variation is absent in patients with severe LV

Figure 25-40 Multiform premature ventricular complexes. The normally conducted QRS complexes exhibit a left bundle branch block contour (arrow) and are followed by premature ventricular complexes with three different morphologies.

dysfunction. [255] Symptoms of palpitations or discomfort in the neck or chest can result because of the greater than normal contractile force of the postextrasystolic beat or the feeling that the heart has stopped during the long pause after the premature complex. Long runs of frequent premature ventricular complexes in patients with heart disease can produce angina, hypotension, or heart failure. Frequent interpolated premature ventricular complexes actually represent a doubling of the heart rate and can compromise the patient's hemodynamic status. Activity that increases the heart rate can decrease the patient's awareness of the premature systole or reduce their number. Exercise can increase the number of premature complexes in some patients. Premature systoles can be quite uncomfortable in patients who have aortic regurgitation because of the large stroke volume. Sleep is usually associated with a decrease in the frequency of ventricular arrhythmias, but some patients can experience an increase.

Premature ventricular complexes occur in association with a variety of stimuli and can be produced by direct mechanical, electrical, and chemical stimulation of the myocardium. Often they are noted in patients with LV false tendons, during infection, in ischemic or inflamed myocardium, and during hypoxia, anesthesia, or surgery. They can be provoked by a variety of medications, by electrolyte imbalance, by tension states, by myocardial stretch,[256] [257] and by excessive use of tobacco, caffeine, or alcohol. Both central and peripheral autonomic stimulation has profound effects on the heart rate and can produce or suppress premature complexes. Almost 20 percent of patients treated by fibrinolytic drugs who are recovering from acute myocardial infarction have more than 10 premature ventricular complexes per hour.[258] Increased premature ventricular complexes during antiarrhythmic drug titration in the Cardiac Arrhythmia Suppression Trial predicted patients at increased risk of arrhythmic death despite antiarrhythmic drug treatment.[259]

Physical examination reveals the presence of a premature beat followed by a pause that is longer than normal. A fully compensatory pause can be distinguished from one that is not fully compensatory in that the former does not change the timing of the basic rhythm. The premature beat is often accompanied by a decrease in intensity of the heart sounds, often with auscultation of just the first heart sound, which can be sharp and snapping, and a decreased or absent peripheral (e.g., radial) pulse. The relationship of atrial to ventricular systole determines the presence of normal *a* waves or giant *a* waves in the jugular venous pulse, and the length of the PR interval determines the intensity of the first heart sound. The second heart sound can be abnormally split, depending on the origin of the ventricular complex.

The importance of premature ventricular complexes depends on the clinical setting. In the absence of underlying heart disease, the presence of premature ventricular complexes usually has no impact on longevity or limitation of activity; antiarrhythmic drugs are not indicated.[260] [261] Patient should be reassured if they are symptomatic (see Chap. 23 , Exercise Testing and Long-Term ECG Recording). In men without apparent coronary disease, the incidental detection of ventricular arrhythmias is associated with a twofold increased risk for all-cause mortality and myocardial infarction or death from coronary disease.[262] However, it has not been demonstrated that premature ventricular systoles or complex ventricular arrhythmias play a *precipitating* role in the genesis of sudden death in these patients, and the arrhythmias may simply be a marker of heart disease. Results from electrophysiological testing suggest that patients with premature ventricular complexes who do not have VT induced at electrophysiological study have a low incidence of subsequent sudden death. Antiarrhythmic therapy given to suppress the premature ventricular systoles or complex ventricular arrhythmias has not been shown to reduce the incidence of sudden death in such apparently healthy men.

In patients suffering from acute myocardial infarction, premature ventricular complexes once considered to presage the onset of ventricular fibrillation, such as those occurring close to the preceding T wave, more than five or six per minute, bigeminal or multiform complexes, or those occurring in salvoes of two, three, or more, do not occur in about half the patients in whom ventricular fibrillation develops, and ventricular fibrillation does not develop in about half of the patients who have these premature ventricular complexes. Thus these premature ventricular complexes are not particularly helpful prognostically. The presence of 1 to more than 10 ventricular extrasystoles per hour[263] [264] can identify patients at increased risk for VT or sudden cardiac death after myocardial infarction.[265]

MANAGEMENT.

Both fast and slow heart rates can provoke the development of premature ventricular complexes. Premature ventricular complexes accompanying slow ventricular rates can be abolished by increasing the basic rate with atropine or isoproterenol or by pacing, whereas slowing the heart rate in some patients with sinus tachycardia can eradicate premature ventricular complexes. In hospitalized patients, IV lidocaine (see Chap. 23) is generally the initial treatment of choice to suppress premature ventricular complexes. If maximum dosages of lidocaine are unsuccessful, procainamide given IV can be tried. Quinidine can be given IV slowly and cautiously. Propranolol can be tried if the other drugs have been unsuccessful. IV magnesium can be useful.[266] For long-term oral maintenance, a variety of class I,[241] II,[267] and III[238] [268] drugs can be useful to prevent VT. Class IC drugs seem particularly successful in suppressing premature ventricular complexes, but flecainide and moricizine

have been shown to increase mortality in patients treated after myocardial infarction.[269] Amiodarone can be quite effective. [238] [270] [271] [272] [273] [274] Athletes with structural heart disease and ventricular extrasystoles who are in high-risk groups can participate in low-intensity sports only.[49] Thrombolysis therapy does not influence the frequency of ventricular extrasystoles,[275] which are related to residual LV pump performance after myocardial infarction.[276] Low levels of serum potassium and magnesium are associated with higher prevalence rates of ventricular arrhythmias.[277] Metroprolol and diltiazem but not enalapril or hydrochlorothiazide reduce premature ventricular complexes in patients with hypertension.[278]

Ventricular Tachycardia

ELECTROCARDIOGRAPHIC RECOGNITION.

VT arises distal to the bifurcation of the His bundle in the specialized

Figure 25-41 Fusion and capture beats during ventricular tachycardia. The QRS complex is prolonged, and the R-R interval is regular except for occasional capture beats (C) that have a normal contour and are slightly premature. Complexes intermediate in contour represent fusion beats (F). Thus, even though atrial activity is not clearly apparent, atrioventricular dissociation is present during ventricular tachycardia and produces intermittent capture and fusion beats.

conduction system, in ventricular muscle, or in combinations of both tissue types.[279] Mechanisms include disorders of impulse formation and conduction considered earlier (see Chap. 22). Autonomic modulation can be important. The ECG diagnosis of VT is suggested by the occurrence of a series of three or more consecutive, abnormally shaped premature ventricular complexes whose duration exceeds 120 milliseconds, with the ST-T vector pointing opposite the major QRS deflection. The R-R interval can be exceedingly regular or can vary. Patients can have VTs with multiple morphologies originating at the same or closely adjacent sites, probably with different exit paths. Others have multiple sites of origin. Atrial activity can be independent of ventricular activity, or the atria can be depolarized by the ventricles retrogradely (VA association). Depending on the particular type of VT, rates range from 70 to 250 beats/min, and the onset can be paroxysmal (sudden) or nonparoxysmal. QRS contours during the VT can be unchanging (uniform, monomorphic), can vary randomly (multiform, polymorphic, or pleomorphic), can vary in a more or less repetitive manner (torsades de pointes), can vary in alternate complexes (bidirectional ventricular tachycardia), or can vary in a stable but changing contour (i.e., right bundle branch contour changing to a left bundle branch contour). VT can be sustained, defined arbitrarily as lasting longer than 30 seconds or requiring termination because of hemodynamic collapse, or nonsustained, when it stops spontaneously in less than 30 seconds. Most commonly, very premature stimulation is required to initiate VT electrically, whereas late coupled ventricular complexes usually initiate its spontaneous onset[279] (Fig. 25-41) .

Making the ECG distinction between supraventricular tachycardia with aberration and VT can be difficult at times since features of both arrhythmias overlap and under certain circumstances a supraventricular tachycardia can mimic the criteria established for VT.[280] [281] [282] Ventricular complexes with an abnormal and prolonged configuration indicate only that conduction through the ventricle is abnormal, and such complexes can occur in supraventricular rhythms as a result of preexisting bundle branch block, aberrant conduction during incomplete recovery of repolarization, conduction over accessory pathways, and several other conditions. These complexes do not necessarily indicate the origin of impulse formation or the reason for the abnormal conduction. Conversely, ectopic beats originating in the ventricle can uncommonly have a fairly normal duration and shape. However, it is important to emphasize that VT is the most common cause of tachycardia with a wide QRS complex. A past history of myocardial infarction makes the diagnosis even more likely.

During the course of a tachycardia characterized by widespread, abnormal QRS complexes, the presence of fusion beats and capture beats provides maximum support for the diagnosis of VT (Table 25-4) . *Fusion beats* indicate activation of the ventricle from two different foci, with the implication that one of the foci had a ventricular origin. *Capture* of the ventricle by the supraventricular rhythm with a normal configuration of the captured QRS complex at an interval shorter than the tachycardia in question indicates that the impulse has a supraventricular origin (see Fig. 25-41). AV dissociation has long been considered a hallmark of VT. However, retrograde VA conduction to the atria from ventricular beats occurs in at least 25 percent of patients, and therefore, VT may not exhibit AV dissociation. AV dissociation can occur uncommonly during supraventricular tachycardias. Even if a P wave appears to be related to each QRS complex, it is at times difficult to determine whether the P wave is conducted anterogradely to the next QRS complex (i.e., supraventricular tachycardia with aberrancy and a long PR interval) or retrogradely from the preceding QRS complex (i.e., a VT). As a general rule, however, AV dissociation during tachycardia with a wide QRS is strong presumptive evidence that the tachycardia is of ventricular origin.

TABLE 25-4 -- MAJOR FEATURES IN THE DIFFERENTIAL DIAGNOSIS OF WIDE QRS BEATS VERSUS TACHYCARDIA

SUPPORTS SVT	SUPPORTS VT
Slowing or termination by vagal tone	Fusion beats
Onset with premature P wave	Capture beats
RP interval 100 msec	AV dissociation
P and QRS rate and rhythm linked to suggest that ventricular activation depends on atrial discharge, e.g., 2:1 AV block	P and QRS rate and rhythm linked to suggest that atrial activation depends on ventricular discharge, e.g., 2:1 VA block
rSR V_1	
Long-short cycle sequence	"Compensatory" pause
	Left axis deviation; QRS duration >140 msec
	Specific QRS contours (see text)

SVT = supraventricular tachycardia; VT = ventricular tachycardia.

Differentiation Between Ventricular and Supraventricular Tachycardia.

While fusion and capture beats and AV dissociation provide the strongest ECG evidence for differentiating VT from supraventricular tachycardia with aberrant conduction, these features are not always present. Therefore, other clues from the ECG may be required to help with this differentiation. Some ECG features characterizing supraventricular arrhythmia with aberrancy are (1) consistent onset of the tachycardia with a premature P wave, (2) a very short RP interval (0.1 second) often requiring an esophageal recording to visualize the P waves, (3) a QRS configuration the same as that occurring from known supraventricular conduction at similar rates, (4) P wave and QRS rate and rhythm linked to suggest that ventricular activation depends on atrial discharge (e.g., an AV Wenckebach block), and (5) slowing or termination of the tachycardia by vagal maneuvers.

Analysis of specific QRS contours can also be helpful in diagnosing VT and localizing its site of origin. For example, QRS contours suggesting VT include left-axis deviation in the frontal plane and a QRS duration exceeding 140 milliseconds with a QRS of normal duration during sinus rhythm. During VT with a right bundle branch block appearance, (1) the QRS complex is monophasic or biphasic in V_1 with an initial deflection different from that of the sinus-initiated QRS complex, (2) the amplitude of the R wave in V_1 exceeds the R
, and (3) a small R and large S wave or a QS pattern in V_6 may be present. With a VT having a left bundle branch block contour, (1) the axis can be rightward with negative deflections deeper in V_1 than in V_6 , (2) a broad prolonged (>40 milliseconds) R wave can be noted in V_1 , and (3) a small Q-large R wave or QS pattern in V_6 can exist. A QRS complex that is similar in V_1 through V_6 , either all negative or all positive, favors a ventricular origin, as does the presence of a 2:1 VA block. (An upright QRS complex in V_1 through V_6 can also occur from conduction over a left-sided accessory pathway.) Supraventricular beats with aberration often have a triphasic pattern in V_1 , an initial vector of the abnormal complex similar to that of the normally conducted beats, and a wide QRS complex that terminates a short cycle length following a long cycle (long-short cycle sequence). During atrial fibrillation, fixed coupling, short coupling intervals, a long pause after the abnormal beat, and runs of bigeminy rather than a consecutive series of abnormal complexes all favor a ventricular origin of the premature complex rather than a supraventricular origin

with aberration. A grossly irregular, wide QRS tachycardia with ventricular rates exceeding 200 beats/min should raise the question of atrial fibrillation with conduction over an accessory pathway (see Fig. 25-7 *B*). In the presence of a preexisting bundle branch block, a wide QRS tachycardia with a contour different from the contour during sinus rhythm is most likely a VT. Several algorithms, based on the above criteria, for distinguishing VT from supraventricular tachycardia with aberrancy have been suggested.[283] [284] [285] Exceptions exist to all the aforementioned criteria, especially in patients who have preexisting conduction disturbances or preexcitation syndrome; when in doubt, one must rely on sound clinical judgment and consider the ECG only one of several helpful ancillary tests.

Termination of a tachycardia by triggering vagal reflexes is considered diagnostic of supraventricular tachycardias. However, VT can rarely be stopped in a similar manner.

ELECTROPHYSIOLOGICAL FEATURES.

Electrophysiologically, VT can be distinguished by a short or negative H-V interval (i.e., H begins after the onset of ventricular depolarization) because of retrograde activation from the ventricles (see Chap. 23). His bundle deflections are not usually apparent during VT because they are obscured by simultaneous ventricular septal depolarization or inadequate catheter position. The latter must be determined during supraventricular rhythm before the onset or after the termination of VT (Fig. 25-42) . His bundle deflections dissociated from ventricular activation are diagnostic, with rare exception. VT can produce QRS complexes of narrow duration and short H-V interval, most likely when the site of origin is close to the His bundle in the fascicles.

Successful electrical induction of VT by premature stimulation of the ventricle (see Fig. 25-42) depends on the characteristics of the VT and the anatomical substrate. Patients with sustained, hemodynamically stable VT and VT secondary to chronic coronary artery disease have monomorphic VT induced (90 percent) more frequently than do patients with nonsustained VT, VT from non-coronary-related causes or acute ischemia, and cardiac arrest (40 to 75 percent).[286] In general, it is more difficult to induce VT with late premature ventricular stimuli than with early premature stimuli, during sinus rhythm than during ventricular pacing, and with one premature stimulus than with two or three.[287] The specificity of VT induction using more than two premature ventricular stimuli begins to decrease (while the sensitivity increases), and nonsustained polymorphic VT or ventricular fibrillation can be induced in patients who have no history of VT. Of patients with stable VT who have inducible sustained monomorphic VT, the latter is induced in about 25 percent with single extrastimuli, in 50 percent with double extrastimuli, and in 25 percent with triple extrastimuli.[288] A recent study suggests that using a single basic cycle length of 400 milliseconds and up to four extrastimuli can be an adequate induction technique.[289] Occasionally, VT can be initiated only from the left ventricle or from specific sites in the right ventricle. Multiple premature stimuli reduce the need for LV stimulation. Drugs such as isoproterenol, various antiarrhythmic agents, and alcohol can facilitate the induction of VT. Coughing during VT that causes hypotension can help maintain blood pressure.

Termination by pacing depends significantly on the rate

Figure 25-42 Initiation and termination of ventricular tachycardia by means of programmed ventricular stimulation. The last two ventricular-paced beats at a cycle length of 600 milliseconds are shown in *A*. A premature stimulus (S_2) at an S_1 -S_2 interval of 260 milliseconds and another premature stimulus (S_3) at a cycle length of 210 milliseconds initiate a sustained monomorphic ventricular tachycardia at a cycle length of 300 milliseconds. Two premature ventricular stimuli (S_1 -S_2) in *B* create an unstable ventricular tachycardia that persists for several beats at a shorter cycle length (230 milliseconds) and then terminates, followed by sinus rhythm.

TABLE 25-5 -- CLINICAL TRIALS IN THE TREATMENT OF VENTRICULAR TACHYCARDIA AND PREVENTION OF CARDIAC ARREST

STUDY	PATIENT INCLUSION	ENDPOINTS	TREATMENT ARMS	KEY RESULTS
Primary prevention studies				
BHAT[311]	*Post-MI*	Total mortality	Propranolol	Total mortality and sudden cardiac death reduced in treatment arm
		Sudden cardiac death	Placebo	
CAST[269] [312]	*Post-MI*	Arrhythmic death	Flecainide	Arrhythmic death increased with all treatment arms
	6 PVCs/hr		Encainide	
	LVEF 40%		Moricizine	
			Placebo	
SWORD[313]	*Post-MI*	Total mortality	*d*-Sotalol	Increased mortality in treatment arm
	LVEF <40%		Placebo	
	or			
	Remote MI			
	NYHA II-III			
EMIAT[314]	*Post-MI*	Total mortality	Amiodarone	Amiodarone reduced arrhythmic death but not total mortality
	LVEF <40%	Arrhythmic death	Placebo	
CAMIAT[315]	*Post-MI*	Arrhythmic death	Amiodarone	Amiodarone reduced arrhythmic death but not total mortality
		Total mortality	Placebo	
	10 PVCs/hr or NSVT			
GESICA[316]	*CHF*	Total mortality	Amiodarone	Amiodarone reduced mortality. Patients with NSVT had higher mortality
	LVEF 35%		Best therapy	
CHF-STAT[317]	*CHF*	Total mortality	Amiodarone	No effect in ischemic cardiomyopathy but trend toward reduced mortality in nonischemic cardiomyopathy
	LVEF 40%		Placebo	
	10 PVCs/hr (asymptomatic)			
SCD-HeFT[318]	*CHF*	Total mortality	ICD	Ongoing
	LVEF 35%	Arrhythmic mortality	Amiodarone	
	NYHA II-III	Cost	Placebo	
		Quality of life		

CABG Patch[319]	*CAD undergoing CABG*	Total mortality	CABG	No difference in total mortality
			CABG+ICD	
	LVEF <36%			
	Positive SAECG			
MADIT[320]	*Post-MI*	Total mortality	ICD	ICD reduced mortality
	NSVT sustained		Antiarrhythmic drug (80% amiodarone)	
	LVEF 35%			
	NYHA I-III			
	Inducible VT not suppressed by procainamide			
MADIT II[318]	*Post-MI*	Total mortality	ICD	Ongoing
	EF 30%		No ICD	
	>10 PVCs/hr or couplets			
MUSTT*	*Post-MI*	Arrhythmic death or cardiac arrest	ICD in nonsuppressible group	Ongoing
	LVEF <40%			
	NSVT sustained		Antiarrhytmic drug in suppressible group	
			No therapy	
Secondary prevention studies				
ESVEM[321] [322]	*Cardiac arrest, sustained VT or syncope*	Recurrence of arrhythmia	EP guided antiarrhythmics (imipramine, mexiletine, procainamide, quinidine, sotalol, pirmenol, propafenone)	No difference between Holter- and EP-guided groups. Sotalol group had lowest recurrence rate of VT, arrhythmic death, and total death
	10 PVCs/hr			
	Inducible VT			
			Holter-guided antiarrhythmics	
CASCADE[323]	Cardiac arrest	Cardiac mortality	EP- or Holter-guided conventional drug therapy	Amiodarone survival better than conventional guided drug therapy
	Not associated with acute MI	Aborted cardiac arrest		
			Empirical amiodarone	
CASH[324]	*Cardiac arrest*	Total mortality	Empirical amiodarone	Sudden cardiac death mortality lowest in ICD arm. Increased mortality in propafenone arm
	Not associated with acute MI			
			Metoprolol	
			Propafenone	
			ICD	
AVID[325]	*Cardiac arrest or sustained VT*	Total mortality	ICD	Survival better in ICD group, with most of benefit occurring in the first 9 months. Benefit most pronounced in patients with EF <35%
		Cost	Drug therapy (empirical amiodarone or EP/Holter-guided sotalol)	
			Quality of life	
CIDS[326] [327]	*Cardiac arrest or sustained VT*	Total mortality	ICD	Survival trended better in ICD group
			Amiodarone	

CABG = coronary artery bypass grafting; CAD = coronary artery disease; CHF = congestive heart failure; EF = ejection fraction; EP = electrophysiology; ICD = implanted cardioverter-defibrillator; LVEF = left ventricular ejection fraction; MI = myocardial infarction; NSVT = nonsustained ventricular tachycardia; NYHA = New York Heart Association; PVC = premature ventricular contraction; SAECG = signal-averaged electrocardiogram; VT = ventricular tachycardia.

*Buxton AE, Lee KL, Fisher JD, et al: A randomized study of the prevention of sudden death in patients with coronary artery disease. Multicenter Unsustained Tachycardia Trial Investigators. N Engl J Med 341:1882-1890, 1999.

of the VT and the site of pacing. [290] Slower VTs are terminated more easily and with fewer stimuli than are more rapid ones. An increasing number of stimuli are required to terminate more rapid VTs, which increases the risks of pacing-induced acceleration of the VT. Subthreshold stimulation and transthoracic stimulation can terminate VT. Atrial pacing, at times, can also induce and terminate VT (see Chap. 23).

CLINICAL FEATURES.

Symptoms occurring during VT depend on the ventricular rate, duration of tachycardia, and the presence and extent of the underlying heart disease and peripheral vascular disease. VT can be in the form of short, asymptomatic, nonsustained episodes[291] ; sustained, hemodynamically stable events, generally occurring at slower rates or in otherwise normal hearts; or unstable runs, often degenerating into ventricular fibrillation. In some patients who have nonsustained VTs initially, sustained episodes or ventricular fibrillation later develops.[288] The location of impulse formation and therefore the way in which the depolarization wave spreads across the myocardium can also be important. Physical findings depend in part on the P-to-QRS relationship. If atrial activity is dissociated from the ventricular contractions, the findings of AV dissociation are present. If the atria are captured retrogradely, regularly occurring cannon *a* waves appear when atrial and ventricular contractions occur simultaneously and signs of AV dissociation are absent.

More than half the patients treated for symptomatic recurrent VT have ischemic heart disease. The next biggest group has cardiomyopathy (both congestive[292] [293] [294] and hypertrophic[295] [296] [297]), with lesser percentages divided among those with primary electrical disease,[298] mitral valve prolapse,[299] valvular heart disease, congenital heart disease,[300] and miscellaneous causes. LV hypertrophy can lead to ventricular arrhythmias.[301] [302] Coronary artery spasm can cause transient myocardial ischemia with severe ventricular arrhythmias in some patients (during ischemia as well as during the apparent reperfusion period).[286] Complex ventricular arrhythmias can occur *after* coronary artery bypass grafting. In patients resuscitated from sudden cardiac death (see Chap. 26), the majority (75 percent) have severe coronary artery disease, and ventricular tachyarrhythmias can be induced by premature ventricular stimulation in approximately 75 percent. When VT occurs in an ambulatory patient, it is uncommonly induced by R-on-T premature ventricular complexes. Patients who have sustained VT are more likely to have a reduced EF, slowed ventricular conduction and electrogram abnormalities, LV aneurysm, abnormal signal-averaged ECGs, and previous myocardial infarction than are patients who

have ventricular fibrillation,

thus indicating different electrophysiological and anatomical substances. When sustained VT can be induced electrically, patients in cardiac arrest have faster rates than do patients with VT. The cycle length of induced VT correlates with whether the patient is in cardiac arrest or has sustained VT.[288] Young patients can also suffer cardiac arrest from VT or ventricular fibrillation, and persistent electrical inducibility of arrhythmias in these patients connotes a poor prognosis. In patients with coronary artery disease, sustained VT displays a circadian variation, with peak frequency in the morning.[303]

Many approaches have been used to assess prognosis in patients with ventricular arrhythmias. Reduced baroreceptor sensitivity and heart period variability apparently caused by reduced vagal activity may indicate an increased risk of VT or sudden cardiac death.[304] [305] The presence of nonsustained VT after myocardial infarction often presages sudden cardiac death. Findings of reduced LV function, spontaneous ventricular arrhythmias, late potentials on signal-averaged ECG,[306] QT interval dispersion,[307] [308] T wave alternans,[309] [310] and inducible sustained VTs at electrophysiological study all carry increased risk, further exaggerated when two or more of these features are present in the same patient. However, currently, no noninvasive technique reliably predicts outcome better than does assessment of LV function. LV function and inducibility of VT during electrophysiological study are the two strongest predictors of poor outcome. Also, clinical occurrence of cardiac arrest during the first spontaneous episode of ventricular arrhythmia identifies patients at increased risk. Ventricular fibrillation is more likely to occur earlier than sustained VT in patients after myocardial infarction. Electrophysiological testing can be used to stratify patients according to risk and to help guide therapy in cardiac arrest survivors and patients with sustained or nonsustained VT, unexplained syncope after myocardial infarction, and cardiomyopathy. In general, the prognosis for patients with idiopathic VT (see below), in the absence of structural heart disease or a prolonged QT interval, is good and warrants less aggressive treatment than in patients with structural heart disease.

MANAGEMENT.

The dramatic changes in the management of VT and aborted sudden death over the past several years have been fueled by several large clinical trials (Table 25-5) and development of the implantable cardioverter-defibrillator. Management decisions can be stratified into those involved in the acute management (or termination)

and those involved in long-term therapy (or prevention of recurrence or sudden death) (see Chap. 26).

Acute Management of Sustained Ventricular Tachycardia.

VT that does not cause hemodynamic decompensation can be treated medically to achieve acute termination by administering IV lidocaine or procainamide, followed by an infusion of the successful drug. Lidocaine is often ineffective[272] ; sotalol [328] [329] and procainamide appear to be superior. Although quinidine can be used IV, great caution is needed because of hypotension. In patients in whom procainamide is ineffective or in whom procainamide may be problematic (severe heart failure, renal failure), IV amiodarone is often effective.[330] [331] [332] [333] [334] [335] In general, an initial loading dose of 15 mg/min is given over a 10-minute period. This dose is followed by an infusion of 1 mg/min for 6 hours and then a maintenance dose of 0.5 mg/min for the remaining 18 hours and for the next several days, as necessary. If VT does not terminate or if it recurs, a repeat loading dose can be given. Rarely, sinus bradycardia or AV block can be seen with IV amiodarone. The hypotension associated with IV amiodarone, caused largely by the diluent used in earlier formulations, does not seem to be as frequent a problem and is usually related to the rate of infusion. Bretylium is rarely used in this setting because of the frequently associated hypotension and because amiodarone appears to be more effective.

If the arrhythmia does not respond to medical therapy, electrical DC cardioversion can be used. VT that precipitates hypotension, shock, angina, congestive heart failure, or symptoms of cerebral hypoperfusion should be treated *promptly* with DC cardioversion (see Chaps. 23 and 26). Very low energies can terminate VT, beginning with a synchronized shock of 10 to 50 J. Digitalis-induced VT is best treated pharmacologically. After conversion of the arrhythmia to a normal rhythm, it is essential to institute measures to prevent recurrence.

Striking the patient's chest, sometimes called "thumpversion," can terminate VT by mechanically inducing a premature ventricular complex that presumably interrupts the reentrant pathway necessary to support it. Chest stimulation at the time of the vulnerable period during the arrhythmia can accelerate the VT or possibly provoke ventricular fibrillation.

In some instances, such as VT associated with a remote myocardial infarction (which is due to reentry), ventricular pacing via a pacing catheter inserted into the right ventricle or transcutaneously at rates faster than the tachycardia can terminate the tachycardia. This procedure incurs the risk of accelerating the VT to ventricular flutter or ventricular fibrillation. In patients with recurrent VT, competitive ventricular pacing can be used to prevent recurrence. Intermittent VT, interrupted by several supraventricular beats, is generally best treated pharmacologically.

A search for reversible conditions contributing to the initiation and maintenance of VT should be made and the conditions corrected if possible. For example, VT related to ischemia, hypotension, or hypokalemia can at times be terminated by antianginal treatment, vasopressors, or potassium, respectively. Correction of heart failure can reduce the frequency of ventricular arrhythmias.[294] Slow ventricular rates that are caused by sinus bradycardia or AV block can permit the occurrence of premature ventricular complexes and ventricular tachyarrhythmias, which can be corrected by administering atropine, by temporary isoproterenol administration, or by transvenous pacing. Supraventricular tachycardia can initiate ventricular tachyarrhythmias and should be prevented if possible.

Long-Term Therapy for Prevention of Recurrences.

Long-term therapy for patients with VT or those who have been resucitated from cardiac arrest is based on the high risk of recurrent sudden cardiac death and ventricular arrhythmias in patients with structural heart disease. After myocardial infarction, the risk of death is 5 to 10 percent, with a large portion of these patients dying of an arrhythmia and the largest risk being in patients with poor LV function and spontaneous or induced ventricular arrhythmias. Patients with a prior myocardial infarction and nonsustained VT have a 2-year mortality of 30 percent.[336] Patients with inducible VT have a 50 percent 2-year mortality.[327] In patients with heart failure, up to 50 percent may die suddenly.[338] [339] In patients who survive a cardiac arrest, the mortality is 20 percent at 1 year.[340] [341] These data have spurred several clinical trials (see Table 25-5) that have had an impact on the long-term management of patients with VT or survivors of cardiac arrest.

Since the prognosis is related to whether the patient has structural heart disease, evaluation of LV function and determination of whether the patient has had a prior myocardial infarction are critical in determining whether to treat. In addition, the existence of symptoms and/or hemodynamic compromise during VT is useful clinical information to guide long-term therapy. The following discussion applies to patients with structural heart disease. Management of specific types of VT and clinical entities is discussed in the following sections.

The goal of long-term therapy is to prevent sudden cardiac death and recurrence of symptomatic VT. Asymptomatic nonsustained ventricular arrhythmias in low-risk populations (i.e., preserved LV function) most often need not be treated. In patients with symptomatic nonsustained tachycardia, beta blockers are frequently effective in preventing recurrences. In patients refractory to beta blockers, class IC agents, sotalol, or amiodarone is usually effective. However, class IC agents should be avoided in patients with structural heart disease, especially those with coronary artery disease because of the increased mortality associated with these drugs because of proarrhythmia. Sotalol should be used cautiously because of its potential for prolonging the QT interval and producing torsades des pointes. Patients with nonsustained VT after myocardial infarction and with poor LV function are at significant risk for sudden death. These patients should generally undergo electrophysiological study and, if they have inducible VT (that is, not suppressed with procainamide), should have an implanted defibrillator.[320]

For secondary prevention of sustained VT or cardiac arrest (see Table 25-5 , Chap. 26) in patients with structural heart disease, it is now clear from several clinical trials that (1) class I antiarrhythmic drugs produce a worse outcome than do class III antiarrhythmic drugs,[321] [322] [324] (2) empirical amiodarone results in better survival than does electrophysiology-guided antiarrhythmic drugs,[323] and (3) implantable defibrillators provide better survival than amiodarone does, particularly in patients with a left ventricular ejection fraction (LVEF) less than 35 percent.[324] [325] [326] Therefore, in patients who have survived a cardiac arrest or who have sustained VT resulting in hemodynamic compromise and poor LV function (EF<35%), an implantable cardioverter-defibrillator is the treatment of choice.[325] For those with higher EFs, amiodarone may produce outcomes similar to those of implanted defibrillators. In patients who refuse a cardioverter-defibrillator, empirical amiodarone is the next best therapy.[323] [324] The optimal therapy for patients with coronary disease who have preserved LV function with sustained VT is not currently known. Empirical amiodarone appears to be the safest therapy,[314] [315] [316] although Holter-guided sotalol has been advocated.[321] [322] Some patients who receive implanted cardioverter-defibrillators have frequent shocks because of recurrent VT. In these patients, concomitant therapy with amiodarone may be required to reduce the frequency of VT or slow the rate of the VT to allow it to be pace-terminated. Other drugs such as sotalol, procainamide, mexiletine, or flecainide may be required if amiodarone is not effective.

Occasionally, a combination of drugs may be effective when a single drug is not. While radiofrequency ablation of certain types of idiopathic VT (see below)

is very effective, ablation for postinfarct VT or that associated with dilated cardiomyopathy is somewhat less effective. In addition, because of the significant mortality associated with these arrhythmias in patients with structural heart disease and depressed LV function, ablation is generally used as an adjunct to implanted cardioverter-defibrillator placement to reduce the frequency of VT and cardioverter-defibrillator shocks.[342] [343] [344] [345] However, in patients with well-tolerated postinfarct VT and well-preserved LV function or in patients refractory to drugs, it may be used as first-line therapy.[342] [343] [345]

Because of the marked increase in sudden death after myocardial infarction and in patients with depressed LV function, numerous clinical trials have been performed to determine whether primary prevention of sudden death is achievable (see Table 25-5). Several conclusions can be drawn from the clinial trials to date: (1) Patient survival after myocardial infarction is dramatically improved with long-term beta blocker therapy.[311] (2) In the post-myocardial infarction population, class IC drugs result in increased mortality (especially in patients with a left ventricular ejection fraction [LVEF]<40%), presumably from proarrhythmia.[269] [312] (3) Amiodarone does not appear to increase mortality in patients after myocardial infarction and/or those with poor LV function. Amiodarone appears to reduce arrhythmic death, but not total mortality in patients after myocardial infarction who have poor LV function.[314] [315] Amiodarone may reduce mortality in patients with nonischemic cardiomyopathy and an EF less than 35 to 40 percent.[316] [317] [317A] Therefore, amiodarone may have a role in primary prevention in patients with nonischemic cardiomyopathy and nonsustained VT. (4) Implantable cardioverter-defibrillators reduce mortality in patients with poor LV function after myocardial infarction who have nonsustained VT that is inducible at electrophysiological study (and not suppressible with procainamide).[320] [320A]

It is still not entirely clear in what population primary prevention is effective and whether amiodarone or implantable cardioverter-defibrillators reduce overall mortality in this setting. Several ongoing studies (Multicenter Automatic Defibrillator Implantation Trial [MADIT] II, Sudden Cardiac Death Heart Failure Trial [SCD-HeFT]) will, it is hoped, refine the populations in which such therapy is effective and determine which of these therapies is more appropriate (see Chap. 26).

Specific Types of Ventricular Tachycardia

A number of fairly specific types of VT have been identified, and distinction is based on either a constellation of distinctive ECG and electrophysiological features or a specific set of clinical events. While our understanding of the electrophysiological mechanisms responsible for clinically occurring VTs is still naive, being able to identify different kinds of VTs is the first step toward understanding their mechanisms. These different kinds of VT often carry different prognoses and responses to different therapy. They are distinct from VTs associated with remote myocardial infarction or dilated cardiomyopathies.

Arrhythmogenic Right Ventricular Dysplasia

Patients with arrhythmogenic right ventricular dysplasia have VT that generally has a left bundle branch block contour (since the tachycardia arises in the right ventricle), often with right-axis deviation and T waves inverted over the right precordial leads[346] (Fig. 25-43 *A*). The VT may be due to reentry.[347] Supraventricular arrhythmias can also occur, and exercise can induce the VT in some patients.

Arrhythmogenic right ventricular dysplasia is due to a type of cardiomyopathy,[348] possibly familial in some patients,[349] with hypokinetic areas involving the wall of the right ventricle. In the familial form, the genetic abnormality has been mapped to chromosomes 1 and 14q23-q24[350] [351] and, most recently, chromosome 10.[351A] It can be an important cause of ventricular arrhythmia in children and young adults with apparently normal hearts, as well as in older patients. Initial findings can be subtle and often mimic those of out-flow tract VT (see below), i.e., manifested only by tachycardia and no symptoms of right-sided heart failure.[352] Right-sided heart failure or asymptomatic right ventricular enlargement can be present with normal pulmonary vasculature. Males predominate, and most patients usually show an abnormal right ventricle by echocardiography,[353] computed tomography,[354] right ventricular angiography, or magnetic resonance imaging,[355] [356] although this abnormality may not be apparent on initial evaluation.[355] [357] Two pathological patterns have been identified, fatty and fibrofatty infiltration. In the latter, myocardial atrophy appears to be the result of injury and myocyte death (perhaps from apoptosis) and culminates in fibrofatty replacement mediated by patchy myocarditis. The fatty degeneration preferentially occurs in the right ventricular in-flow and out-flow tracts and the apex. The left ventricle can be involved in advanced forms of the disease in up to 60 percent of patients.[350] Sympathetic innervation appears to be abnormal.[358] The ECG during sinus rhythm can exhibit complete or incomplete right bundle branch block and T wave inversions in V_1 to V_3 .[359] A terminal notch in the QRS (called an epsilon wave) may be present as a result of slowed intraventricular conduction.[350] The signal-averaged ECG can be abnormal.[360] [361] Although conventional pharmacological approaches to therapy may be appropriate, surgical manipulations have been successful in some of these patients,[362] [363] as has been implantable defibrillator therapy.[364] Radiofrequency catheter ablation can be tried but is often not successful because of the multiple morphologies of VT and the progressive nature of the disease.

Tetralogy of Fallot (see also Chap. 43)

Chronic serious ventricular arrhythmias can occur in patients some years after repair of the *tetralogy of Fallot.* [300] Sustained VT after repair can be caused by reentry at the site of previous surgery in the right ventricular out-flow tract and can be cured by resection[365] or catheter ablation[366] [367] of this area. The signal-averaged ECG can be abnormal.[368] Decreased cardiac output can occur during VT and residual right ventricular out-flow obstruction and lead to ventricular fibrillation.[369]

Cardiomyopathies (see also Chap. 48)

DILATED CARDIOMYOPATHY.

Both dilated and hypertrophic cardiomyopathies (see discussion above under management of VT) can be associated with VTs and an increased risk of sudden cardiac death. Use of the signal-averaged ECG in identifying patients with dilated cardiomyopathy at risk for sudden death is controversial, with positive[370] and negative [371] [372] results. Induction of VT by programed stimulation[373] does not appear to identify high-risk patients,[292] [374] whereas QT dispersion may.[307] Because it is difficult to predict patients at risk of sudden death or those who might respond favorably to an antiarrhythmic drug, implantable cardioverter-defibrillators have been advocated for patients with life-threatening ventricular arrhythmias and dilated cardiomyopathy.[375] [376] This recommendation has been supported by a large multicenter randomized trial (see Table 25-5) comparing amiodarone with implantable defibrillators in patients with poor ventricular function and symptomatic sustained VT; the study found improved survival in patients who received a defibrillator.[325] Bundle branch reentry may be the basis of some VTs in this population and can be treated by ablating the right bundle branch.[377] [378] [379] Asymptomatic ventricular arrhythmias are common.[380] The role of antiarrhythmic drugs and implantable

Figure 25-43 *A,* Normal sinus rhythm in a patient with arrhythmogenic right ventricular dysplasia. The arrowheads point to late right ventricular activation called an epsilon wave. *B,* Ventricular tachycardia in the same patient with right ventricular dysplasia.

defibrillators in the primary prevention of sudden cardiac death in patients with dilated cardiomyopathy may be warranted in certain high-risk patients, as discussed above. However, ongoing clinical trials will further clarify which patient population will benefit the most and which modality is most effective.

HYPERTROPHIC CARDIOMYOPATHY(see also Chap. 48).

The risk of sudden death in patients with hypertrophic cardiomyopathy is increased by the presence of syncope, a family history of sudden death in first-degree relatives, or the presence of nonsustained VT on 24-hour ECG recordings.[297] [381] Asymptomatic or mildly symptomatic patients with brief and infrequent episodes of nonsustained VT have a low mortality.[295] Results of electrophysiological testing can help identify patients at increased risk of ventricular arrhythmias and sudden death,[382] [383] although its use is controversial. A negative electrophysiological study may not necessarily indicate a good prognosis. Triggering events

such as supraventricular tachycardia and atrial fibrillation[384] and ischemia[296] may be important. Amiodarone has been useful in some patients with mildly symptomatic, nonsustained VT,[381] [385] but not in patients with nonarrhythmic problems. [386] QT dispersion is increased in those with ventricular arrhythmias and sudden death.[387]

DDD pacing has been useful in reducing the out-flow gradient, and its role in affecting ventricular arrhythmia is being evaluated. Currently, no totally acceptable way to risk-stratify patients with hypertrophic cardiomyopathy in terms of ventricular tachycardia has been identified. In patients believed to be at high risk of sudden death, those with sustained VT or frequent nonsustained VT, an implantable defibrillator may be indicated.[388] Since DDD pacing may also be useful in reducing out-flow gradients and since these patients are also at risk for atrial fibrillation, a dual-chamber defibrillator (a ventricular defibrillator with an integrated DDD pacemaker) is often the best choice of devices. Alcohol ablation of the septum via direct injection into the septal branches of the coronary circulation has been used to improve out-flow gradients.

Mitral Valve Prolapse (see also Chap. 46)

Patients with mitral valve prolapse[299] frequently have ventricular arrhythmias, although a causal relationship has not been clearly established between the arrhythmia and the mitral valve prolapse. The prognosis for most patients appears good, although sudden death can occur.[389]

Idiopathic Ventricular Tachyarrhythmias

Idiopathic ventricular fibrillation may occur in about 1 percent of cases of out-of-hospital ventricular fibrillation and affects mostly men and those in middle age.[390] Cardiovascular evaluation is normal except for the arrhythmia. Monomorphic VT is rarely induced at electrophysiological study. The natural history is incompletely known, but recurrences are not uncommon.[391] [392] It is important in this entity, as well as in patients with idiopathic VTs (see below), to remember that the arrhythmia may at times be an early manifestation of a developing cardiomyopathy, at least in some patients. Antiarrhythmic drugs and implantable defibrillators[393] are useful therapeutic choices.

Brugada syndrome is a distinct form of idiopathic ventricular fibrillation in which patients have right bundle branch block and ST segment elevation in the anterior precordial leads without evidence of structural heart disease[394] [395] [396] [397] [398] [399] (Fig. 25-44) . This syndrome[395] probably accounts for approximately 40 to 60 percent of all cases of idiopathic ventricular fibrillation.[400] Sudden unexplained nocturnal death syndrome occurring in apparently healthy young Southeast Asians, sometimes associated with nightmares, is thought to be due to Brugada syndrome. The precise mechanism of the ECG changes and the development of ventricular fibrillation is not known. It is thought that loss of the action potential dome in the right ventricular epicardium, but not in the endocardium, results in the persistent ST segment elevation.[396] Ventricular fibrillation is thought to result from the electrophysiological heterogeneity in the right ventricle that also produces ST elevation and can produce reentry.[396] Among several agents that can reproduce this ECG phenomenon are sodium channel blockers. They can expose latent ECG forms of the syndrome. Recently, mutations in a gene responsible for the sodium channel (*SCN5A*) has been identified in some families with Brugada syndrome.[400] While the mutations are on the same gene as that responsible for one form of the long QT syndrome (LQT3) (see below), the site of mutation is different and does not result in a prolonged QT interval.[400A] Mutations in the Brugada syndrome result either in acceleration of sodium channel recovery or in nonfunctional sodium channels. Mutations on other genes are likely to be found in

Figure 25-44 Twelve-lead electrocardiogram (ECG) of a patient with Brugada syndrome. The ECG is characterized by a right bundle branch block pattern and persistent ST elevation in V_1 through V_3 . *(From Brugada J, Brugada R, Brugada P: Right bundle-branch block and ST-segment elevation in leads V1 through V3: A marker for sudden death in patients without demonstrable structural heart disease. Circulation 97:457-60, 1998. By permission of the American Heart Association, Inc.)*

some patients with Brugada syndrome. Candidate genes include those affecting I_{to} , I_{Ca} , $I_{K\text{-}ATP}$, and autonomic receptors. Currently, no pharmacological treatment can reliably prevent ventricular fibrillation in these patients. Implanted cardioverter-defibrillators are the only effective treatment for preventing sudden death.

Idiopathic VTs with monomorphic contours can be divided into at least three types. Two types, paroxysmal VT and repetitive monomorphic VT,[401] appear to originate from the region of the right ventricular out-flow tract (Figs. 25-45 and 25-46). Right ventricular out-flow tract VTs have a characteristic ECG appearance of a left bundle branch block contour in V_1 and an inferior axis in the frontal plane. Vagal maneuvers, including adenosine,[402] terminate the VT, whereas exercise, stress, isoproterenol infusion, and rapid or premature stimulation can initiate or perpetuate the tachycardia. Beta blockers and verapamil[403] can suppress this tachycardia as well. The mechanism responsible may be cyclic adenosine monophosphate-triggered activity[404] [405] resulting from early[406] or delayed[407] afterdepolarizations. The paroxysmal form is exercise or stress induced, whereas the repetitive monomorphic type occurs at rest with sinus beats interposed between runs of nonsustained VT that may be precipitated by transient increases in sympathetic activity unrelated to exertion.[407] The prognosis for most patients is quite good. Radiofrequency catheter ablation effectively eliminates this focal tachycardia in symptomatic patients.[408] In others, antiarrhythmic drugs can be effective.[409] An anatomical abnormality in the out-flow tract of the right ventricle has been recognized in some patients.[404] [410] [411] In a small number of patients, the tachycardia seems to arise in the in-flow tract or apex of the right ventricle.[408] A similar

Figure 25-45 Ventricular tachycardia originating from the right ventricular out-flow tract. This tachycardia is characterized by a left bundle branch block contour in V_1 and an inferior axis.

tachycardia has been identified in the left ventricle and may mimic that of right ventricular out-flow tract tachycardia.[412]

A *left septal VT* has been described as arising in the left posterior septum, often preceded by a fascicular potential,[413] and is sometimes called a *fascicular tachycardia* (Fig. 25-47) . Entrainment has been demonstrated, which suggests reentry as a cause of some of the tachycardias.[414] Verapamil [415] [416] or dilitiazem[417] suppresses this tachycardia, while adenosine does so only rarely.[418] [419] [420] The response to verapamil suggests that the slow inward current may be important, possibly in a reentrant circuit or via delayed afterdepolarizations. Several mechanisms may be operative, and the group may not be homogeneous.[182] Oral verapamil is not as effective as IV verapamil. Once initiated, the tachycardia is paroxysmal and sustained. It can be started by rapid atrial or ventricular pacing and sometimes by exercise or isoproterenol. Generally, the prognosis is good.[415] [416] Radiofrequency catheter ablation is effective in symptomatic patients.[408] [413] [421] Late potentials have been reported in one third of patients.[422]

Sudden infant death syndrome is a syndrome of unexplained death that occurs in infancy. The precise cause is not known and is probably due to a variety of etiologies, both cardiac and noncardiac. It is not known what percentage, if any, are due to arrhythmias. Some have suggested that the long QT syndrome (see below) and Brugada syndrome may be responsible in some cases[423] [423A] (see also Chaps. 26 and 43).

Accelerated Idioventricular Rhythm

ELECTROCARDIOGRAPHIC RECOGNITION.

The ventricular rate, commonly between 60 and 110 beats/min, usually hovers within 10 beats of the sinus rate, so control of the cardiac rhythm shifts between these two competing pacemaker sites.[424] Consequently, fusion beats often occur at the onset and termination of the arrhythmia as the pacemakers vie for control of ventricular depolarization (Fig. 25-48) . Because of the slow rate, capture beats are common. The onset of this arrhythmia is generally gradual (nonparoxysmal) and occurs when the rate of the VT exceeds the sinus

Figure 25-46 *A,* Repetitive monomorphic ventricular tachycardia. Short episodes of a monomorphic ventricular tachycardia at a rate of 160 beats/min repeatedly interrupt the normal sinus rhythm. Retrograde atrial capture probably occurs (the arrow points to the deflection in the ST segment), and the retrograde P wave of the last complex of the repetitive monomorphic ventricular tachycardia conducts over the normal pathway to produce a QRS complex with a normal contour. *B,* Short runs of a very rapid (260 beats/min) ventricular tachycardia of uniform contour. They probably provoke a compensatory sympathetic response because each is followed by a brief period of sinus tachycardia. The sinus pacemaker appears unstable as changes in P wave morphology result.

Figure 25-47 Left septal ventricular tachycardia. This tachycardia is characterized by a right bundle branch block contour. In this instance, the axis was rightward. The site of the ventricular tachycardia

was established to be in the left posterior septum by electrophysiological mapping and ablation.

rate because of sinus slowing or SA or AV block. The ectopic mechanism can also begin after a premature ventricular complex, or the ectopic ventricular focus can simply accelerate sufficiently to overtake the sinus rhythm. The slow rate and nonparoxysmal onset avoid the problems initiated by excitation during the vulnerable period, and consequently, precipitation of more rapid ventricular arrhythmias is rarely seen. Termination of the rhythm generally occurs gradually as the dominant sinus rhythm accelerates or as the ectopic ventricular rhythm decelerates. The ventricular rhythm can be regular or irregular and can occasionally show sudden doubling, which suggests the presence of exit block. Many characteristics incriminate enhanced automaticity as the responsible mechanism.

The arrhythmia occurs as a rule in patients who have heart disease, e.g., those with acute myocardial infarction or with digitalis toxicity. It is transient and intermittent, with episodes lasting a few seconds to a minute, and does not appear to seriously affect the patient's clinical course or the prognosis. It commonly occurs at the moment of reperfusion of a previously occluded coronary artery,[425] and it can be found during resuscitation.[426]

MANAGEMENT.

Suppressive therapy is rarely necessary because the ventricular rate is generally less than 100 beats/min, but such therapy may be considered when AV dissociation results in loss of sequential AV contraction, when an accelerated idioventricular rhythm occurs together with a more rapid VT, when an accelerated idioventricular rhythm begins with a premature ventricular complex and causes discharges in the vulnerable period of the preceding T wave, when the ventricular rate is too rapid and produces symptoms, and if ventricular fibrillation develops as a result of the accelerated idioventricular rhythm. This last event appears to be fairly rare. Therapy, when indicated, should be as already noted for VT. Often, simply increasing the sinus rate with atropine or atrial pacing suppresses the accelerated idioventricular rhythm.

Torsades de Pointes

ELECTROCARDIOGRAPHIC RECOGNITION.

The term *torsades de pointes* refers to a VT characterized by QRS complexes of changing amplitude that appear to twist around the isoelectric line and occur at rates of 200 to 250/min[427] [428] [429]

Figure 25-48 Accelerated idioventricular rhythm. In this continuous monitor lead recording, an accelerated idioventricular rhythm competes with the sinus rhythm. Wide QRS complexes at a rate of 90 beats/min fuse (F) with the sinus rhythm, which takes control briefly, generates the narrow QRS complexes, and then yields once again to the accelerated idioventricular rhythm as the P waves move "in and out" of the QRS complex. This example of isorhythmic atrioventricular dissociation may be due to hemodynamic modulation of the sinus rate via the autonomic nervous system.

Figure 25-49 Torsades de pointes. *A,* Continuous monitor lead recording. A demand ventricular pacemaker (VVI) had been implanted because of type II second-degree atrioventricular block. After treatment with amiodarone for recurrent ventricular tachycardia, the QT interval became prolonged (about 640 milliseconds during paced beats), and episodes of torsades de pointes developed. In this recording, the tachycardia spontaneously terminates and a paced ventricular rhythm is restored. Motion artifact is noted at the end of the recording as the patient lost consciousness. *B,* Tracing from a young boy with congenital long QT syndrome. The QTU interval in the sinus beats is at least 600 milliseconds. Note TU wave alternans in the first and second complexes. A late premature complex occurring in the downslope of the TU wave initiates an episode of ventricular tachycardia.

(Fig. 25-49 *A*). Originally described in the setting of bradycardia caused by complete heart block,[430] the term *torsades de pointes* is usually used to connote a *syndrome,* not simply an ECG description of the QRS complex of the tachycardia, characterized by prolonged ventricular repolarization with QT intervals generally exceeding 500 milliseconds. The U wave can also become prominent and merge with the T wave, but its role in this syndrome and in the long QT syndrome is not clear. The abnormal repolarization need not be present or at least prominent on all beats but may be apparent only on the beat prior to the onset of torsades de pointes (i.e., following a premature ventricular contraction).[431] Long-short R-R cycle sequences commonly precede the onset of torsades de pointes from acquired causes.[432] Relatively late premature ventricular complexes can discharge during termination of the long T wave and precipitate successive bursts of VT during which the peaks of the QRS complexes appear successively on one side and then on the other side of the isoelectric baseline and give the typical twisting appearance with continuous and progressive changes in QRS contour and amplitude.[433] Torsades de pointes can terminate with progressive prolongation in cycle length and larger and more distinctly formed QRS complexes and culminate in a return to the basal rhythm, a period of ventricular standstill, and a new attack of torsades de pointes or ventricular fibrillation.

VT that is similar morphologically to torsades de pointes and occurs in patients *without* QT prolongation, whether spontaneous or electrically induced, should generally be classified as polymorphic VT, not as torsades de pointes. The distinction has important therapeutic implications (see below).

ELECTROPHYSIOLOGICAL FEATURES.

The electrophysiological mechanisms responsible for torsades de pointes are not completely understood.[434] [435] Most data suggest that early afterdepolarizations (see Chap. 22) are responsible for both the long QT and the torsades de pointes, or at least its initiation.[436] [437] [438] Perpetuation may be due to triggered activity, reentry resulting from dispersion of repolarization[439] produced by the early afterdepolarizations, or abnormal automaticity. Two out-of-phase discharging foci have been experimentally shown to produce a tachycardia similar to torsades de pointes, as have drifting rotors[440] (see Chap. 22). Dispersion of repolarization from endocardium to epicardium may also play a role. A distinct group of cells, called M cells, located in the subepicardium have prolonged repolarization and may play a role in the genesis of torsades de pointes.[441] [442] [443]

CLINICAL FEATURES.

While many predisposing factors have been cited, the most common causes are congenital severe bradycardia, potassium depletion, and use of class IA and some class IC drugs. Clinical features depend on whether the torsades de pointes is due to the acquired or congenital (idiopathic) long QT syndrome (see below). Symptoms from the tachycardia depend on its rate and duration, as with other VTs, and range from palpitations to syncope and death. Females, perhaps because of a longer QT interval, are at greater risk for torsades de pointes than are males.[444]

MANAGEMENT.

The approach to VT with a polymorphic pattern depends on whether it occurs in the setting of a prolonged QT interval. For this practical reason and because the mechanism of the tachycardia can differ depending on whether a long QT interval is present, it is important to restrict the definition of torsades de pointes to the typical polymorphic VT in the setting of a long QT and/or U wave in the basal complexes. In all patients with torsades de pointes, administration of class IA, possibly some class IC, and class III antiarrhythmic agents (amiodarone and sotalol) can increase the abnormal QT interval and worsen the arrhythmia. IV magnesium is the initial treatment of choice for torsades de pointes from an acquired cause,[445] [446] followed

by temporary ventricular or atrial pacing. Isoproterenol, given cautiously because it can exacerbate the arrhythmia, can be used to increase the rate until pacing is instituted. Lidocaine, mexiletine, or phenytoin can be tried. Potassium channel openers may be useful.[447] [448] [449] The cause of the long QT should be determined and corrected if possible. When the QT interval is normal, polymorphic VT *resembling* torsades de pointes is diagnosed, and standard antiarrhythmic drugs can be given. In borderline cases, the clinical context may help determine whether treatment should be initiated with antiarrhythmic drugs. Torsades de pointes resulting from congenital long QT syndrome is treated with beta blockade, surgical sympathetic interruption, pacing, and implantable defibrillators (see below). ECGs taken on close relatives can help secure the diagnosis of long QT syndrome in borderline cases.

Long QT Syndrome

ELECTROCARDIOGRAPHIC RECOGNITION(see Fig. 25-49 *B*).

The upper limit for duration of the normal QT interval *corrected* for heart rate (QTc) is often given as 0.44 seconds. However, the normal corrected QT interval may actually be longer, 0.46 for men and 0.47 for women, with a normal range of plus or minus 15 percent of the mean value.[450] The nature of the U wave abnormality and its relationship to the long QT syndrome are not clear. M cells may be responsible for the U wave[442] (see Chap. 22). The probable risk of life-threatening ventricular arrhythmias developing in patients with idiopathic long QT syndrome is exponentially related to the length of the QTc interval.[450] T wave "humps" in the ECG suggest the presence of long QT syndrome[451] and may be caused by early afterdepolarizations.[452] A point score system has been suggested to aid in the diagnosis.[453] Two-to-one AV block (because of the long repolarization time) and T wave alternans can occur.[454] [455] [456]

CLINICAL FEATURES.

Long QT syndrome can be divided into idiopathic (congenital) and acquired forms.[429] The idiopathic form is a familial disorder that can be associated with sensorineural deafness (Jervell and Lange-Nielsen syndromes, autosomal recessive) or normal hearing (Romano-Ward syndrome, autosomal dominant). A nonfamilial form with normal hearing has been called the sporadic form.

The hypothesis that the idiopathic long QT syndrome results from a preponderance of left sympathetic tone has been replaced by genetic information linking the disorder in different families to sites in several different chromosomes[457] [458] [459] [460] [461] [462] [463] (Table 25-6) . The gene products from several of these mutations have been identified as potassium and sodium channels[464] [465] [466] [467] [468] [469] [470] [471] (see Table 25-5). Clear evidence for genetic heterogeneity exists, and this heterogeneity can be responsible for different-shaped T waves.[471] The chromosome 3 abnormality (LQT3-SCN5A) is associated with the longest QTc durations and delay in onset of the T wave, while the chromosome 7 abnormality (LQT2-HERG) results in T waves of low amplitude and the chromosome 11 mutation (LQT1-KVLQT1) results in the broadest T waves.[471] [472] [473] Thus, the intrinsic cardiac repolarization abnormality probably gives rise to early afterdepolarizations that prolong the QT interval and produce torsades de pointes.

The acquired form has a long QT interval caused by various drugs such as quinidine, procainamide, *N*-acetylprocainamide, sotalol,[474] amiodarone, disopyramide,[475] phenothiazines, or tricyclic antidepressants; cisapride;[476] nonsedating antihistamines such as astemizole and terfenedine,[477] [478] [479] whose actions can be exacerbated by drugs affecting their metabolism such as ketoconazoles; drugs such as erythromycin,[480] [481] [482] pentamidine,[483] [484] and some antimalarials; electrolyte abnormalities such as hypokalemia and hypomagnesemia; the results of a liquid protein diet and starvation; central nervous system lesions; significant bradyarrhythmias; cardiac ganglionitis; mitral valve prolapse; and probucol.[485] The acquired long QT syndrome may be a *forme fruste* of the inherited form.[486]

Patients with congenital long QT syndrome can initially have syncope, at times misdiagnosed as epilepsy,[487] [488] [489] from VTs that are often caused by torsades de pointes. Sudden death can occur in this group of patients, and it occurs in about 10 percent of pediatric patients without preceding symptoms.[488] [490] It is obvious that in some patients the ventricular arrhythmia becomes sustained and probably results in ventricular fibrillation. Patients with idiopathic long QT syndrome who are at increased risk for sudden death include those with family members who died suddenly at an early age and those who have experienced syncope. It also appears that the specific mutations carry different risks, with LQT1 and LQT2 carrying the highest risk for arrhythmias. Although patients with the LQT3 mutation tend to have fewer cardiac events, they tend to be more lethal ones. Thus, the cumulutive mortality appears to be the same for LQT1, LQT2, and LQT3.[491] Ventricular tachyarrhythmias commonly develop during periods of adrenergic stimulation, such as fright or exertion. However, some phenotypic variation is noted, such that patients with LQT1 and LQT2 mutations tend be more sympathetically driven whereas LQT3 patients tend to have more events during sleep.[491] Syndactyly has recently been described in some patients with the idiopathic form.[492]

Stress testing can prolong the QT interval and produce T wave alternans, the latter indicative of electrical instability.[493] ECGs should be obtained for all family members when the propositus has symptoms. Patients should undergo prolonged ECG recording with various stresses designed to evoke ventricular arrhythmias, such as auditory stimuli, psychological stress, cold pressor stimulation, and exercise.[494] [495] The Valsalva maneuver can lengthen the QT interval and cause T wave alternans and VT in patients who have prolonged QT syndromes. Catecholamines can be infused in some patients,[496] [497] [498] but this challenge must be performed cautiously, with resuscitative equipment along with alpha and beta antagonists close at hand. Stellate ganglion stimulation and blockade have been useful to provoke or abolish arrhythmias. Premature ventricular stimulation electrically does not generally induce arrhythmias in this syndrome. Torsades de pointes commonly develops in patients with the acquired form during periods of bradycardia or after a long pause in the R-R interval, whereas those with the idiopathic form can have a sinus tachycardia preceding the ventricular arrhythmia. Competitive sports are contraindicated for patients with the congenital long QT syndrome.[49] An interesting contractile abnormality that is

TABLE 25-6 -- GENETIC BASIS OF THE LONG QT SYNDROME

abolished by verapamil has been described in patients with the idiopathic long QT syndrome.[499] Cardiac sympathetic innervation appears to be normal,[500] although this point is not completely resolved.[501]

MANAGEMENT.

For patients who have idiopathic long QT syndrome but do not have syncope, complex ventricular arrhythmias, or a family history of sudden cardiac death, generally no therapy is recommended. In asymptomatic patients with complex ventricular arrhythmias or a family history of early sudden cardiac death, beta-adrenoceptor blockers at maximally tolerated doses are recommended initially. Implantation of a permanent pacemaker to prevent the bradycardia and/or pauses that may predispose to the development of torsades de pointes may be indicated.[28] [502] [503] In patients with syncope, beta blockers at maximally tolerated doses, perhaps combined with a class IB antiarrhythmic drug, are suggested. For patients who continue to have syncope despite maximum drug therapy, left-sided cervicothoracic sympathetic ganglionectomy that interrupts the stellate ganglion and the first three or four thoracic ganglia may be helpful, and permanent pacing[504] has also been used. Implantation of a cardioverter-defibrillator seems advisable in patients who have syncope despite sympathetic interruption or in patients in whom aborted sudden death is the initial manifestation of long QT syndrome[28] [429] [505] (see Chap 24). For patients with the acquired form and torsades de pointes, IV magnesium and atrial or ventricular pacing are initial choices. Class IB antiarrhythmic drugs or isoproterenol (cautiously) to increase the heart rate can be tried. Avoidance of precipitating drugs is mandatory. Potassium channel-activating drugs such as pinacidil and cromakalim may be useful[447] [448] [449] in both forms of long QT syndrome. Interventions that reduce QT dispersion may be beneficial.[504]

Bidirectional Ventricular Tachycardia

This uncommon type of VT is characterized by QRS complexes with a right bundle branch block pattern, alternating polarity in the frontal plane from -60 to -90 degrees to +120 to +130 degrees, and a regular rhythm. The ventricular rate is between 140 and 200 beats/min. Although the mechanism and site of origin of this tachycardia have remained somewhat controversial, most evidence supports a ventricular origin.

Bidirectional VT is usually, but not exclusively a manifestation of digitalis excess, typically in older patients and in those with severe myocardial disease. When the tachycardia is due to digitalis, the extent of toxicity is often advanced, with a poor prognosis.

In addition to digoxin-binding antibodies (Digibind), drugs useful to treat digitalis toxicity such as lidocaine, potassium, phenytoin, and propranolol should be considered

if excessive digitalis administration is suspected. Otherwise, the usual therapeutic approach to VT is recommended.

Bundle Branch Reentrant Ventricular Tachycardia

VT secondary to bundle branch reentry is characterized by a QRS morphology determined by the circuit established over the bundle branches or fascicles. Retrograde conduction over the left bundle branch system and anterograde conduction over the right bundle branch create a QRS complex with a left bundle branch block contour and constitute the most common form. The frontal plane axis may be about +30 degrees. Conduction in the opposite direction produces a right bundle branch block contour. Reentry can also occur over the anterior and posterior fascicles. Electrophysiologically, bundle branch reentrant complexes are started after a critical S_2 -H_2 or S_3 -H_3 delay. The H-V interval of the bundle branch reentrant complex equals or exceeds the H-V interval of the spontaneous normally conducted QRS complex.

Bundle branch reentry is a form of monomorphic sustained VT that is usually seen in patients with structural heart disease such as dilated cardiomyopathy. During follow-up, congestive heart failure is the most common cause of death in this population.[506] [507] Myocardial VTs can also be present. Uncommonly, bundle branch reentry can occur in the absence of myocardial disease.[506] [507]

The therapeutic approach is as for other types of VT, except that creation of a bundle branch block by catheter ablation interrupts the reentry circuit and can eliminate the tachycardia.[508]

Ventricular Flutter and Fibrillation (See also Chap. 26)

ELECTROCARDIOGRAPHIC RECOGNITION.

These arrhythmias represent severe derangements of the heartbeat that usually terminate fatally within 3 to 5 minutes unless corrective measures are undertaken promptly. Ventricular flutter is manifested as a sine wave in appearance: regular large oscillations occurring at a rate of 150 to 300/min (usually about 200) (Fig. 25-50 *A*). The distinction between rapid VT and ventricular flutter can be difficult and is usually of academic interest only. Hemodynamic collapse is present with both. Ventricular fibrillation is recognized by the presence of irregular undulations of varying contour and amplitude (Fig. 25-50 *B*). Distinct QRS complexes, ST segments, and T waves are absent. Fine-amplitude fibrillatory waves (0.2 mV) are present with prolonged ventricular fibrillation. These fine waves identify patients with worse survival rates and are sometimes confused with asystole.[509]

MECHANISMS.

Ventricular fibrillation occurs in a variety of clinical situations but is most commonly associated with coronary artery disease and as a terminal event.[510] Intracellular calcium accumulation,[511] the action of free radicals, metabolic alterations, and autonomic modulation are some important influences on the development of ventricular fibrillation during ischemia. Thrombolytic agents reduce the incidence of ventricular arrhythmias[512] and inducible VT after myocardial infarction. Cardiovascular events, including sudden cardiac death from ventricular fibrillation, but not asystole,[513] occur most frequently in the morning and may be related to increased platelet aggregability. Aspirin reduces this mortality. An excess in sudden deaths appears to occur during the winter months.[514] Ventricular fibrillation can occur during antiarrhythmic drug administration, hypoxia, ischemia, atrial fibrillation, and very rapid ventricular rates in the preexcitation syndrome; after electrical shock administered during cardioversion (see Chaps. 23 and 24) or accidentally by improperly grounded equipment; and during competitive ventricular pacing to terminate VT.

Figure 25-50 Ventricular flutter and ventricular fibrillation. *A,* The sine wave appearance of the complexes occurring at a rate of 300 beats/min is characteristic of ventricular flutter. *B,* The irregular undulating baseline typifies ventricular fibrillation.

CLINICAL FEATURES.

Ventricular flutter or ventricular fibrillation results in faintness, followed by loss of consciousness, seizures, apnea, and eventually, if the rhythm continues untreated, death. The blood pressure is unobtainable, and heart sounds are usually absent. The atria can continue to beat at an independent rhythm for a time or in response to impulses from the fibrillating ventricles. Eventually, electrical activity of the heart ceases.

In patients resuscitated from out-of-hospital cardiac arrest, 75 percent have ventricular fibrillation. Bradycardia or asystole, which can occur in 15 to 25 percent of these patients, is associated with a worse prognosis than is ventricular fibrillation and is usually associated with more advanced LV dysfunction. VT commonly precedes the onset of ventricular fibrillation, although frequently no consistent premonitory patterns emerge. Heart rate variability may be decreased.[515] [516]

While 75 percent of resuscitated patients exhibit significant coronary artery disease, acute transmural myocardial infarction develops in only 20 to 30 percent. In one study, 73 percent had recent coronary artery thrombosis.[517] Those in whom myocardial infarction does *not* develop have an increased recurrence rate for sudden cardiac death or ventricular fibrillation. Patients who have ventricular fibrillation and acute myocardial infarction have a recurrence rate at 1 year of 2 percent. In the past 20 years, there appears to have been an overall decrease in the incidence of sudden cardiac death, parallel to the decrease in death from coronary heart disease. In some studies, patients at risk for sudden cardiac death have ischemia, reduced LV function, 10 or more premature ventricular complexes per hour, spontaneous and induced VT, hypertension and LV hypertrophy, obesity, and elevated cholesterol levels; smoking, male sex, increased age, and excess alcohol consumption also predispose to sudden cardiac death (see Chap. 26).

Predictors of death for resuscitated patients include a reduced EF,[518] [519] abnormal wall motion, history of congestive heart failure, history of myocardial infarction but no acute event, and the presence of ventricular arrhythmias. Patients discharged after an anterior myocardial infarction complicated by ventricular fibrillation appear to represent a subgroup at high risk of sudden death. Ventricular fibrillation can occur in infants, young people, athletes, and persons without known structural heart disease[520] [521] and in unexplained syndromes. Severe bradycardia or asystole bodes a reduced survival rate for most patients. Transcutaneous pacing for severe bradyarrhythmias does not seem to be helpful.[522] Persons in lower socioeconomic strata are at greater risk for cardiac mortality and are less likely to survive an episode of out-of-hospital cardiac arrest.[523]

MANAGEMENT(see Chap. 26).

Immediate nonsynchronized DC electrical shock using 200 to 400 J is mandatory therapy for ventricular fibrillation and for ventricular flutter that has caused loss of consciousness. Cardiopulmonary resuscitation is used only until the defibrillation equipment is readied. Time should not be wasted with cardiopulmonary resuscitation maneuvers if electrical defibrillation can be done promptly. Defibrillation requires fewer joules if done early. If the circulation is markedly inadequate despite return to sinus rhythm, closed-chest massage with artificial ventilation as needed should be instituted. The use of anesthesia during electrical shock is obviously dictated by the patient's condition and is not generally required. After conversion of the arrhythmia to a normal rhythm, it is essential to monitor the rhythm continuously and institute measures to prevent recurrence.

Metabolic acidosis quickly follows cardiovascular collapse. If the arrhythmia is terminated within 30 to 60 seconds, significant acidosis does not occur. Judicious use of sodium bicarbonate to reverse the acidosis may be necessary (see Chap 26). Intravenous calcium is generally recommended only for situations characterized by hypocalcemia, hyperkalemia, calcium antagonist overdose, and possibly electromechanical dissociation.

If the resuscitation time is short, artificial ventilation by means of a tightly fitting rubber face mask and an AMBU bag is quite satisfactory and eliminates the delay attending intubation by inexperienced personnel. If such a mask and bag are not available, mouth-to-mouth or mouth-to-nose resuscitation is indicated. It is important to reemphasize that there should be *no delay in instituting electrical shock.* If the patient is not monitored and it cannot be established whether asystole or ventricular fibrillation caused the cardiovascular collapse, the electrical shock should be administered *without* wasting precious seconds attempting to obtain an ECG. The DC shock may cause the asystolic heart to begin discharging and also terminate ventricular fibrillation, if the latter is present.

A search for conditions contributing to the initiation of ventricular flutter or fibrillation should be made and the conditions corrected, if possible. Initial medical approaches to prevent recurrence of ventricular fibrillation include IV administration of lidocaine, bretylium, procainamide, or amiodarone. Ventricular fibrillation rarely terminates spontaneously, and death results unless countermeasures are instituted immediately. Subsequent therapy is necessary to prevent recurrence. Antiischemic approaches are useful in selected patients.[524] Catheter ablation techniques are useful in only well-tolerated monomorphic ventricular arrhythmias.[525] Implantable

defibrillators have become the mainstay of chronic therapy in patients at continued risk for ventricular fibrillation or VT from nonreversible causes (see discussion above).

HEART BLOCK

Heart block is a disturbance of impulse conduction that can be permanent or transient depending on the anatomical or functional impairment. It must be distinguished from *interference,* a normal phenomenon that is a disturbance of impulse conduction caused by physiological refractoriness resulting from inexcitability from a preceding impulse. Either interference or block can occur at any site where impulses are conducted, but they are recognized most commonly between the sinus node and atrium (SA block), between the atria and ventricles (AV block), within the atria (intraatrial block), or within the ventricles (intraventricular block). During AV block, the block can occur in the AV node, His bundle, or bundle branches. In some instances of bundle branch block the impulse may only be delayed and not completely blocked in the bundle branch, yet the resulting QRS complex may be indistinguishable from a QRS complex generated by a complete bundle branch block.

The conduction disturbance is classified by severity into three categories. During *first-degree heart block,* conduction time is prolonged but all impulses are conducted. *Second-degree heart block* occurs in two forms: Mobitz type I (Wenckebach) and type II. Type I heart block is characterized by a progressive lengthening of the conduction time until an impulse is not conducted. Type II heart block denotes occasional or repetitive sudden block of conduction of an impulse without prior measurable lengthening of conduction time. When no impulses are conducted, *complete* or *third-degree block* is present. The degree of block may depend in part on the direction of impulse propagation. For unknown reasons, normal retrograde conduction can occur in the presence of advanced anterograde AV block. The reverse can also occur. Some electrocardiographers use the term *advanced heart block* to indicate blockage of two or more consecutive impulses.[526]

Certain features of type I second-degree block deserve special emphasis because when actual conduction times are

Figure 25-51 Typical 4:3 Wenckebach cycle. P waves ("A" tier) occur at a cycle length of 1000 milliseconds. The PR interval ("AV" tier) is 200 milliseconds for the first beat and generates a ventricular response ("V" tier). The PR interval increases by 100 milliseconds in the next complex, which results in an R-R interval of 1100 milliseconds (1000+100). The increment in the PR interval is only 50 milliseconds for the third cycle, and the PR interval becomes 350 milliseconds. The R-R interval shortens to 1050 milliseconds (1000+50). The next P wave is blocked, and an R-R interval is created that is less than twice the P-P interval by an amount equal to the increments in the PR interval. Thus, the Wenckebach features explained in the text can be found in this diagram. If the increment in the PR interval of the last conducted complex increased rather than decreased (e.g., 150 milliseconds rather than 50 milliseconds), the last R-R interval before the block would increase (1150 milliseconds) rather than decrease and thus become an example of an atypical Wenckebach cycle (see Fig. 25-45). If this were a Wenckebach exit block from the sinus node to the atrium, the sinus node cycle length (S) would be 1000 milliseconds, and the sinoatrial interval would increase from 200 to 300 to 350 milliseconds and culminate in a block. These events would be inapparent in the scalar electrocardiogram (ECG). However, the P-P interval in the ECG would shorten from 1100 to 1050 milliseconds, and finally, there would be a pause of 1850 milliseconds (A) (see Fig. 22-4). If this rhythm were a junctional rhythm arising from the His bundle and conducting to the ventricle, the junctional rhythm cycle length would be 1000 milliseconds (H), and the H-V interval would progressively lengthen from 200 to 300 to 350 milliseconds, whereas the R-R interval would decrease from 1100 to 1050 milliseconds and then increase to 1850 milliseconds (V). The only clue to the Wenckebach exit block would be the cycle length changes in the ventricular rhythm.

not apparent in the ECG, e.g., during SA, junctional, or ventricular exit block (Fig. 25-51) , a type I conduction disturbance can be difficult to recognize. During a typical type I block, the increment in conduction time is greatest in the second beat of the Wenckebach group, and the absolute *increase* in conduction time *decreases* progressively over subsequent beats. These two features serve to establish the characteristics of classic Wenckebach group beating: (1) The interval between successive beats progressively decreases, although the conduction time increases (but by a decreasing function); (2) the duration of the pause produced by the nonconducted impulse is less than twice the interval preceding the blocked impulse (which is usually the shortest interval); and (3) the cycle following the nonconducted beat (beginning the Wenckebach group) is longer than the cycle preceding the blocked impulse. Although much emphasis has been placed on this characteristic grouping of cycles, primarily to be able to diagnose a Wenckebach exit block, this typical grouping occurs in fewer than 50 percent of patients who have a type I Wenckebach AV nodal block.

Differences in these cycle length patterns can result from changes in pacemaker rate (e.g., sinus arrhythmia), in neurogenic control of conduction, and in the increment of conduction delay. For example, if the PR increment in the last cycle *increases,* the R-R cycle of the last conducted beat can lengthen rather than shorten. In addition, since the last conducted beat is often at a critical state of conduction, it can become blocked and produce a 5:3 or 3:1 conduction ratio instead of a 5:4 or 3:2 ratio. During a 3:2 Wenckebach structure, the duration of the cycle following the nonconducted beat will be the same as the duration of the cycle preceding the nonconducted beat.

AV Block

An AV block exists when the atrial impulse is conducted with delay or is not conducted at all to the ventricle at a time when the AV junction is not physiologically refractory.

FIRST-DEGREE AV BLOCK.

During first-degree AV block, every atrial impulse conducts to the ventricles and a regular ventricular rate is produced, but the PR interval exceeds 0.20 second in adults. PR intervals as long as 1.0 second have been noted and can at times exceed the P-P interval, a phenomenon known as "skipped" P waves. Clinically important PR interval prolongation can result from a conduction delay in the AV node (A-H interval), in the His-Purkinje system (H-V interval), or at both sites. Equally delayed conduction over both bundle branches can uncommonly produce PR prolongation without significant QRS complex aberration. Occasionally, an intraatrial conduction delay can result in PR prolongation. If the QRS complex in the scalar ECG is normal in contour and duration, the AV delay almost always resides in the AV node, rarely within the His bundle itself. If the QRS complex shows a bundle branch block pattern, the conduction delay may be within the AV node and/or His-Purkinje system (Fig. 25-52) . In this latter instance, His bundle ECG is necessary to localize the site of conduction delay. Acceleration of the atrial rate or enhancement of vagal tone by carotid massage can cause first-degree AV nodal block to progress to type I second-degree AV block. Conversely, type I second-degree AV nodal block can revert to first-degree block with deceleration of the sinus rate.

SECOND-DEGREE AV BLOCK (Figs. 25-51 , 25-53 , and 25-54).

Blocking of some atrial impulses conducted to the ventricle at a time when physiological interference is not

Figure 25-52 First-degree atrioventricular (AV) block. One complex during sinus rhythm is shown. The PR interval in the *left* panel measured 370 milliseconds (PA = 25 milliseconds; A-H = 310 milliseconds; H-V = 35 milliseconds) during a right bundle branch block. Conduction delay in the AV node causes the first-degree AV block. In the panel on the *right*, the PR interval is 230 milliseconds (PA = 35 milliseconds; A-H = 100 milliseconds; H-V = 95 milliseconds) during a left bundle branch block. The conduction delay in the His-Purkinje system causes the first-degree AV block.

Figure 25-53 Unidirectional block. *Top*, During spontaneous sinus rhythm at a rate of 68 beats/min, 2:1 anterograde atrioventricular conduction occurs. In the *bottom* electrocardiogram, 1:1 retrograde conduction is seen during ventricular pacing at a rate of 70 beats/min. P waves are indicated by arrows.

involved constitutes second-degree AV block. The nonconducted P wave can be intermittent or frequent, at regular or irregular intervals, and can be preceded by fixed or lengthening PR intervals. A distinguishing feature is that conducted P waves relate to the QRS complex with recurring PR intervals; i.e., the association of P with QRS is not random. Wenckebach and Hay, by analyzing the *a-c* and *v* waves in the jugular venous pulse, described two types of second-degree AV block. After introduction of the ECG, Mobitz classified them as type I and type II. Electrocardiographically, typical type I second-degree AV block is characterized by progressive PR prolongation culminating in a nonconducted P wave (see Fig. 25-53), whereas in type II second-degree AV block, the PR interval remains constant prior to the blocked P wave (Fig. 25-55 *A*). In both instances the AV block is intermittent and generally repetitive and can block several P waves in a row. Often, the eponyms *Mobitz type I* and *Mobitz type II* are applied to the two types of block, whereas the term *Wenckebach block* refers to type I block only. A Wenckebach block in the His-Purkinje system in a patient with a bundle branch block can resemble an AV nodal Wenckebach block very closely (Fig. 25-55 *B*).

Although it has been suggested that type I and type II AV blocks are different manifestations of the same electrophysiological mechanism that differ only quantitatively in the size of the increments, clinically separating second-degree AV block into type I and type II serves a useful function, and in most instances, the differentiation can be made easily and reliably from the surface ECG. Type II AV block often antedates the development of Adams-Stokes syncope and complete AV block, while type I AV block with a normal QRS complex is generally more benign and does not progress to more advanced forms of AV conduction disturbance. In older people, type I AV block with or without bundle branch block has been associated with a clinical picture similar to that in type II AV block.

In a patient with an acute myocardial infarction, type I AV block usually accompanies inferior infarction (perhaps more often if a right ventricular infarction also occurs), is transient, and does not require temporary pacing, whereas type II AV block occurs in the setting of an acute anterior myocardial infarction, can require temporary or permanent pacing, and is associated with a high rate of mortality, generally from pump failure.[527] A high degree of AV block can occur in patients with acute inferior myocardial infarction and is associated with more myocardial damage and a higher mortality rate than in those without AV block.

While type I conduction disturbance is ubiquitous and can occur in any cardiac tissue in vivo, as well as in vitro, the site of block for the usual forms of second-degree AV block can be judged from the surface ECG with sufficient reliability to permit clinical decisions without requiring invasive electrophysiological studies in most instances. Type I AV block with a normal QRS complex almost always takes place at the level of the AV node, proximal to the His bundle. An exception is the uncommon patient with type I intrahisian block. Type II AV block, particularly in association with a bundle branch block, is localized to the His-Purkinje system. Type I AV block in a patient with a bundle branch block can be due to block in the AV node or in the His-Purkinje system. Type II AV block in a patient with a normal QRS complex can be due to an intrahisian AV block, but the block is likely to be a type I AV nodal block, which exhibits small increments in AV conduction time.

Figure 25-54 Type I (Wenckebach) atrioventricular (AV) nodal block *(A)*. During spontaneous sinus rhythm, progressive PR prolongation occurs and culminates in a nonconducted P wave. From the His bundle recording (HBE) it is apparent that the conduction delay and subsequent block occur within the AV node. Since the increment in conduction delay does not consistently decrease, the R-R intervals do not reflect the classic Wenckebach structure. Panel *B* was recorded 5 minutes after the administration of 0.6 mg atropine intravenously. Atropine has had its predominant effect on sinus and junctional automaticity by this time, with little improvement in AV conduction. Consequently, more P waves are blocked and AV dissociation, caused by a combination of AV block and an enhanced junctional discharge rate, is present. At 8 minutes (not shown), when atropine finally improved AV conduction, 1:1 AV conduction occurred.

Figure 25-55 Type II atrioventricular (AV) block. *A,* The sudden development of a His-Purkinje block is apparent. The A-H and H-V intervals remain constant, as does the PR interval. Left bundle branch block is present. *B,* Wenckebach AV block in the His-Purkinje system. The QRS complex exhibits a right bundle branch block morphology. However, note that the second QRS complex in the 3:2 conduction exhibits a slightly different contour from the first QRS complex, particularly in V_1 . This finding is the clue that the Wenckebach AV block might be in the His-Purkinje system. The H-V interval increases from 70 milliseconds to 280 milliseconds, and then block distal to the His bundle results.

DIFFERENTIATING TYPE I FROM TYPE II AV BLOCK.

The preceding generalizations encompass the vast majority of patients with second-degree AV block. However, certain caveats must be heeded to avoid misdiagnosis because of subtle ECG changes or exceptions:

1. The 2:1 AV block can be a form of type I or type II AV block (Fig. 25-56) . If the QRS complex is normal, the block is more likely to be type I and located in the AV node, and one should search for transition of the 2:1 block to a 3:2 block, during which the PR interval lengthens in the second cardiac cycle. If a bundle branch block is present, the block can be located either in the AV node or in the His-Purkinje system.
2. AV block can occur simultaneously at two or more levels and can cause difficulty in distinguishing between types I and II.[528]
3. If the atrial rate varies, it can alter conduction times and cause a type I AV block to stimulate a type II block or change a type II AV block into type I.[529] For example, if the shortest atrial cycle length that just achieved 1:1 AV nodal conduction at a constant PR interval is decreased by as little as 10 or 20 milliseconds, the P wave of the shortened cycle can block conduction at the level of the AV node without an apparent increase in the antecedent PR interval. An apparent type II AV block in the His-Purkinje system can be converted to type I in the His-Purkinje system in some patients by increasing the atrial rate.
4. Concealed premature His depolarizations can create ECG patterns that simulate type I or type II AV block.
5. Abrupt, transient alterations in autonomic tone can cause sudden block of one or more P waves without altering the PR interval of the conducted P wave before or after the block. Thus, an apparent type II AV block would be produced at the AV node. Clinically, a burst of vagal tone usually lengthens the P-P interval, as well as producing an AV block.
6. The response of the AV block to autonomic changes either spontaneous or induced to distinguish type I from type II AV block can be misleading. Although vagal stimulation generally increases and vagolytic agents decrease the extent of type I AV block, such conclusions are based on the assumption that the intervention acts primarily on the AV node and fail to consider rate changes. For example, atropine can minimally improve conduction in the AV node and markedly increase the sinus rate, which results in an *increase* in AV nodal conduction time and the degree of AV block as a result of the faster atrial rate (see Fig. 25-54 *B*). Conversely, if an increase in vagal tone minimally prolongs AV conduction time but greatly slows the heart rate, the net effect on type I AV block may be to improve conduction. In general, however, carotid sinus massage improves and atropine worsens AV conduction in patients with His-Purkinje block, while the opposite results are to be expected in patients who have AV nodal block. These two interventions can help differentiate the site of block without invasive study, although damaged His-Purkinje tissue may be influenced by changes in autonomic tone.
7. During type I AV block with high ratios of conducted beats, the increment in PR interval can be quite small and suggest a type II AV block if only the last few PR intervals before the blocked P wave are measured. By comparing the PR interval of the first beat in the long Wenckebach cycle with that of the beats immediately preceding the blocked P wave, the increment in AV conduction becomes readily apparent.
8. The classic AV Wenckebach structure depends on a stable atrial rate and a maximal increment in AV conduction time for the second PR interval of the Wenckebach cycle, with a progressive decrease in subsequent beats. Unstable or unusual alterations in the increment of AV conduction time or in the atrial rate, often seen with long Wenckebach cycles, result in atypical forms of type I AV block in which the last R-R interval can lengthen because the PR increment *increases;* these alterations are common.
9. Finally, it is important to remember that the PR interval in the scalar ECG is made up of conduction through the atrium, the AV node, and the His-Purkinje system. An increment in H-V conduction, for example, can be masked in the scalar ECG by a reduction in the A-H interval, and the resulting PR interval will not reflect the entire increment in His-Purkinje conduction time. Very long PR intervals (200 milliseconds) are more likely to result from AV nodal conduction delay (and block), with or without concomitant His-Purkinje conduction delay, although an H-V interval of 350 milliseconds is quite possible.

Figure 25-56 A 2:1 atrioventricular (AV) block proximal and distal to the His bundle deflection in two different patients. *Top,* A 2:1 AV block seen in the scalar electrocardiogram occurs distal to the His bundle recording site in a patient with right bundle branch block and anterior hemiblock. The A-H interval (150 milliseconds) and H-V interval (80 milliseconds) are both prolonged. *Bottom,* A 2:1 AV block proximal to the bundle of His in a patient with a normal QRS complex. The A-H interval (75 milliseconds) and the H-V interval (30 milliseconds) remain constant and normal.

First-degree and type I second-degree AV block can occur in normal healthy children, and a Wenckebach AV block can be a normal phenomenon in well-trained athletes, probably related to an increase in resting vagal tone. Occasionally, progressive worsening of the Wenckebach AV conduction disorder can result and the athlete becomes symptomatic and has to decondition. In patients who have chronic second-degree AV nodal block (proximal to the His bundle) without structural heart disease, the course is relatively benign (except in older age groups), whereas in those who have structural heart disease the prognosis is poor and related to the underlying heart disease. *Advanced AV block* indicates a block of two or more consecutive P waves.

Complete AV Block

ELECTROCARDIOGRAPHIC RECOGNITION.

Complete AV block occurs when no atrial activity is conducted to the ventricles and, therefore, the atria and ventricles are controlled by independent pacemakers. Thus, complete AV block is one type of complete AV dissociation. The atrial pacemaker can be sinus or ectopic (tachycardia, flutter, or fibrillation) or can result from an AV junctional focus occurring above the block with retrograde atrial conduction. The ventricular focus is usually located just below the region of the block, which can be above or below the His bundle bifurcation. Sites of ventricular pacemaker activity that are in or closer to the His bundle appear to be more stable and can produce a

faster escape rate than can those located more distally in the ventricular conduction system. The ventricular rate in acquired complete heart block is less than 40 beats/min but can be faster in congenital complete AV block. The ventricular rhythm, usually regular, can vary in response to premature ventricular complexes, a shift in the pacemaker site, an irregularly discharging pacemaker focus, or autonomic influences.

MECHANISMS.

Complete AV block can result from block at the level of the AV node (usually congenital) (Fig. 25-57) , within the bundle of His, or distal to it in the Purkinje system (usually acquired) (Fig. 25-58) . Block proximal to the His bundle generally exhibits normal QRS complexes and rates of 40 to 60 beats/min because the escape focus that controls the ventricle arises in or near the His bundle. In complete AV nodal block, the P wave is not followed by a His deflection, but each ventricular complex is preceded by a His deflection (see Fig. 25-57). His bundle ECG can be useful to differentiate AV nodal from intrahisian block since the latter may carry a more serious prognosis than the former. Intrahisian block is recognized infrequently without invasive studies. In patients with AV nodal block, atropine usually speeds both the atrial and the ventricular rates. Exercise can reduce the extent of AV nodal block. Acquired complete AV block occurs most commonly distal to the bundle of His because of trifascicular conduction disturbance. Each P wave is followed by a His deflection, and the ventricular escape complexes are not preceded by a His deflection (see Fig. 25-58). The QRS complex is abnormal, and the ventricular rate is usually less than 40 beats/min.

Unusual forms such as paroxysmal AV block or AV block following a period of rapid ventricular rates can occur. Paroxysmal AV block in some instances can be due to hyperresponsiveness of the AV node to vagotonic reflexes. Surgery, electrolyte disturbances, myoendocarditis,[530] tumors, Chagas disease, rheumatoid nodules, calcific aortic stenosis, myxedema, polymyositis, infiltrative processes (such as amyloid, sarcoid, or scleroderma), and an almost endless assortment of common and unusual conditions can produce AV block. In adults, drug toxicity, coronary disease,

Figure 25-57 Congenital third-degree atrioventricular (AV) block. *A,* Complete AV nodal block is apparent. No P wave is followed by a His bundle potential, whereas each ventricular depolarization is preceded by a His bundle potential. *B,* Atrial pacing (cycle length of 500 milliseconds) fails to alter the cycle length of the functional rhythm. Still, no P wave is followed by a His bundle potential. *C,* After 30 seconds of ventricular pacing (cycle length of 700 milliseconds), suppression of the junctional focus results for almost 7 seconds (overdrive suppression of automaticity; see Chapter 22).

Figure 25-58 Complete anterograde atrioventricular (AV) block with retrograde ventriculoatrial conduction. All the sinus P waves are blocked distal to the His bundle, consistent with acquired complete AV block. The ventricles escape at a cycle length of approximately 1800 milliseconds (33 beats/min) and are not preceded by His bundle activation. The ventricular escape rhythm produces a QRS contour with left-axis deviation and right bundle branch block, possibly caused by impulse origin in the posterior fascicle of the left bundle branch. Of interest is the fact that the second ventricular escape beat conducts retrogradely through His (H) and to the atrium (note the low-high atrial activation sequence and the negative P wave in leads II and III). The first ventricular complex does not conduct retrogradely, probably because the His bundle is still refractory from the immediately preceding atrial impulse.

and degenerative processes appear to be the most common causes of AV heart block. The degenerative process produces partial or complete anatomical or electrical disruption within the AV nodal region, the AV bundle, or both bundle branches. Rapid rates can sometimes be followed by block, an event known as *overdrive suppression* of conduction. This form of block may be important as a cause of paroxysmal AV block after cessation of a tachycardia.

Atrioventricular Block in Children.

In children, the most common cause of AV block is congenital (see Chap. 43). Under such circumstances, the AV block can be an isolated finding or be associated with other lesions. Connective tissue disease and the presence of anti-Rh_0 -negative antibodies in the maternal sera of patients with congenital complete AV block raise the possibility that placentally transmitted antibodies play a role in some instances.[531] [532] [533] Anatomical disruption between the atrial musculature and peripheral parts of the conduction system and nodoventricular discontinuity are two common histological findings. Children are most often asymptomatic; however, in some children symptoms develop that require pacemaker implantation. Mortality from congenital AV block is highest in the neonatal period, is much lower during childhood and adolescence, and increases slowly later in life. Adams-Stokes attacks can occur in patients with congenital heart block at any age. It is difficult to predict the prognosis in an individual patient. A persistent heart rate at rest of 50 beats/min or less correlates with the incidence of syncope, and extreme bradycardia can contribute to the frequency of Adams-Stokes attacks in children with congenital complete AV block. The site of block may not distinguish symptomatic children who have congenital or surgically induced complete heart block from those without symptoms. Prolonged recovery times of escape foci following rapid pacing (see Fig. 25-57 *C*) (see discussion of sinus node recovery time, Chap. 23) slow heart rates on 24-hour ECG recordings, and the occurrence of paroxysmal tachycardias may be predisposing factors to the development of symptoms.

CLINICAL FEATURES.

Many of the signs of AV block are evidenced at the bedside. First-degree AV block can be recognized by a long *a-c* wave interval in the jugular venous pulse and by diminished intensity of the first heart sound as the PR interval lengthens. In type I second-degree AV block, the heart rate may increase imperceptibly with gradually diminishing intensity of the first heart sound, widening of the *a-c* interval, terminated by a pause, and an *a* wave not followed by a *v* wave. Intermittent ventricular pauses and *a* waves in the neck not followed by *v* waves characterize type II AV block. The first heart sound maintains a constant intensity. In complete AV block, the findings are the same as those in AV dissociation (see below).

Significant clinical manifestations of first- and second-degree AV block usually consist of palpitations or subjective feelings of the heart "missing a beat." Persistent 2:1 AV block can produce symptoms of chronic bradycardia. Complete AV block can be accompanied by signs and symptoms of reduced cardiac output, syncope or presyncope, angina, or palpitations from ventricular tachyarrhythmias. It can occur in twins.[534]

MANAGEMENT.

As discussed in Chapter 23 , drugs cannot be relied on to increase the heart rate for more than several hours to several days in patients with symptomatic heart block without producing significant side effects. Therefore, temporary or permanent pacemaker insertion is indicated in patients with symptomatic bradyarrhythmias.[535] Long-term pacing can alter cardiac function.[536] For short-term therapy when the block is likely to be evanescent but still requires treatment or until adequate pacing therapy can be established, vagolytic agents such as atropine are useful for patients who have AV nodal disturbances, whereas catecholamines such as isoproterenol can be used transiently to treat patients who have heart block at any site (see treatment for Sinus Bradycardia, above). Isoproterenol should be used with extreme caution or not at all in patients who have acute myocardial infarction. The use of transcutaneous pacing is preferable.

AV Dissociation

CLASSIFICATION.

As the term indicates, dissociated or independent beating of the atria and ventricles defines AV dissociation. AV dissociation is never a *primary* disturbance of rhythm but is a "symptom" of an underlying rhythm disturbance produced by one of three causes or a combination of causes (Fig. 25-59) that prevent the normal transmission of impulses from atrium to ventricle, as follows:

1. Slowing of the dominant pacemaker of the heart (usually the sinus node), which allows escape of a subsidiary or latent pacemaker. AV dissociation by *default* of the primary pacemaker to a subsidiary one in this manner is often a normal phenomenon. It may occur during sinus arrhythmia or sinus bradycardia and permit an independent AV junction rhythm to arise (see Fig. 25-4 *B*).
2. Acceleration of a latent pacemaker that *usurps* control of the ventricles. An abnormally enhanced discharge rate of a usually slower subsidiary pacemaker is pathological and commonly occurs during nonparoxysmal AV junctional tachycardia or VT without retrograde atrial capture (see Figs. 25-23 and 25-41).
3. Block, generally at the AV junction, that prevents impulses formed at a normal rate in a dominant pacemaker from reaching the ventricles and allows the ventricles to beat under the control of a subsidiary pacemaker. Junctional or ventricular escape rhythm during AV block, without retrograde atrial capture, is a common example in which block gives rise to AV dissociation. It is important to remember that complete AV block is *not* synonymous with complete AV dissociation; patients who have complete AV block have complete AV dissociation, but patients who have complete AV dissociation may or may not have complete AV block (see Figs. 25-57 and 25-58).
4. A combination of causes, for example, when digitalis excess results in the production of nonparoxysmal AV junctional tachycardia associated with SA or AV

block.

Figure 25-59 Diagrammatic illustration of the causes of atrioventricular (AV) dissociation. A sinus bradycardia allowing escape of an AV junctional rhythm that does not capture the atria retrogradely illustrates cause I (*top panel*). Intermittent sinus captures occur (third P wave) and produce incomplete AV dissociation (see Fig. 22-3 *B*). For cause II, ventricular tachycardia without retrograde atrial capture produces complete AV dissociation (see Figs. 25-23 and 25-41). As the third cause, complete AV block with a ventricular escape rhythm is diagrammed (see Figs. 25-57 and 25-58). The combination of causes II and III is shown in panel IV, which represents a nonparoxysmal AV junctional tachycardia and some degree of AV block.

MECHANISMS.

With this classification in mind, it is important to emphasize that the term *AV dissociation* is *not* a diagnosis and is analogous to the term *jaundice* or *fever.* One must state that "AV dissociation is present *due to*..." and then give the cause. An accelerated rate of a slower, normally subsidiary pacemaker or a slower rate of a faster, normally dominant pacemaker that prevents conduction because of physiological collision and mutual extinction of opposing wavefronts (interference) or the manifestations of AV block are the basic disturbances producing AV dissociation. The atria in all these cases beat independently from the ventricles, under control of the sinus node or ectopic atrial or AV junctional pacemakers, and can exhibit any type of supraventricular rhythm. If a single pacemaker establishes control of both atria and ventricles for one beat (capture) or a series of beats (sinus rhythm, AV junctional rhythm with retrograde atrial capture, VT with retrograde atrial capture, and so forth), AV dissociation is abolished for that period. Conversely, as stated above, whenever the atria and ventricles fail to respond to a single impulse for one beat (premature ventricular complex without retrograde capture of the atrium) or a series of beats (VT without retrograde atrial capture), AV dissociation exists for that period. The interruption of AV dissociation by one or a series of beats under the control of one pacemaker, either anterogradely or retrogradely, indicates that the AV dissociation is incomplete. Complete or incomplete dissociation can also occur in association with all forms of AV block. Commonly, when AV dissociation occurs as a result of AV block, the atrial rate exceeds the ventricular rate. For example, a subsidiary pacemaker with a rate of 40 beats/min can escape in the presence of a 2:1 AV block when the atrial rate is 78. If the AV block is bidirectional, AV dissociation results.

ELECTROCARDIOGRAPHIC AND CLINICAL FEATURES.

The ECG demonstrates the independence of P waves and QRS complexes. The P wave morphology depends on the rhythm controlling the atria (sinus, atrial tachycardia, junctional, flutter, or fibrillation). During complete AV dissociation, both the QRS complex and the P waves appear regularly spaced without a fixed temporal relationship to each other. When the dissociation is incomplete, a QRS complex of supraventricular contour occurs early and is preceded by a P wave at a PR interval exceeding 0.12 second and within a conductable range. This combination indicates ventricular capture by the supraventricular focus. Similarly, a premature P wave with retrograde morphology and a conductable RP interval may indicate retrograde atrial capture by the subsidiary focus.

Physical findings include a variable intensity of the first heart sound as the PR interval changes, atrial sounds, and *a* waves in the jugular venous pulse lacking a consistent relationship to ventricular contraction. Intermittent large (cannon) *a* waves may be seen in the jugular venous pulse when atrial and ventricular contractions occur simultaneously. The second heart sound can split normally or paradoxically, depending on the manner of ventricular activation. A premature beat representing ventricular capture can interrupt a regular heart rhythm. When the ventricular rate exceeds the atrial rate, a cyclical increase in intensity of the first heart sound is produced as the PR interval shortens, climaxed by a very loud sound (bruit de canon). This intense sound is followed by a sudden reduction in intensity of the first heart sound and the appearance of giant *a* waves as the PR interval shortens and P waves "march through" the cardiac cycle.

MANAGEMENT.

Management is directed toward the underlying heart disease and precipitating cause. The individual components *producing the AV dissociation*--not the AV dissociation per se--determine the specific type of antiarrhythmic approach. Therapy ranges from pacemaker insertion in a patient who has AV dissociation resulting from complete AV block to antiarrhythmic drug administration in a patient who has AV dissociation caused by VT.

Figure 25-60 Supernormal conduction. *A,* Atrial fibrillation with long-short R-R cycle sequences giving rise to QRS complexes conducted with a functional left bundle branch block. In each example, however, a shorter R-R cycle length is terminated by a normal QRS complex (arrow), an example of supernormal conduction. *B,* Graph of the intervals and illustrative recordings during an electrophysiological study of the patient whose electrocardiogram is shown in *A*. The H-V interval of the complexes conducted with a left bundle branch block morphology is 45 milliseconds, whereas the H-V interval of those conducted with normal morphology is 35 milliseconds. The graph indicates the premature interval (H_1 -H_2 , ordinate) plotted against the preceding cycle length (H_1 -H_1 , abscissa). All H_1 -H_1 intervals were taken from complexes with a left bundle branch block morphology. Normal complexes are represented by filled circles and left bundle branch block contours by filled triangles. Four zones of conduction are identified and illustrated by the four examples to the right. The longest H_1 -H_2 intervals are followed by normal intraventricular conduction (zone a), whereas at shorter intervals, left bundle branch block occurs (zone b). When the H_1 -H_2 interval shortens further, normal intraventricular conduction returns and the H-V intervals shorten to 35 milliseconds (zone c, supernormal conduction). At the shortest H_1 -H_2 interval, left bundle branch block again appears (zone d). *(From Miles WM, Prystowsky EN, Heger JJ, Zipes DP: Evaluation of the patient with wide QRS tachycardia. Med Clin North Am 68:1015, 1984.)*

Figure 25-61 Supernormal excitation. *A* and *B,* Noncontiguous portions of a continuous electrocardiogram recording with a middle segment removed (dotted line). The patient had a bipolar pacemaker that had exceeded end-of-life status and was no longer consistently producing ventricular depolarization (small negative deflections indicated by the upright arrow). A temporary pacemaker was implanted and set at a fixed rate (asynchronous, V00). These large deflections are indicated by the inverted arrow. The numbers in milliseconds indicate the interval between the onset of the QRS complex and the following subthreshold pacemaker stimulus. At intervals of 370 milliseconds (beginning, panel *A*) and 490 milliseconds (end, panel *B*), the subthreshold stimulus fails to produce a propagated ventricular response. However, at intervals between 380 and 480 milliseconds, ventricular depolarizations result (filled circles). Thus, the period of supernormal excitation is 100 milliseconds in duration, from 380 to 480 milliseconds after the onset of the QRS complex.

Figure 25-62 Concealed conduction. Following the first normally conducted sinus-initiated complex, a premature ventricular complex is stimulated (S). The next spontaneous sinus-initiated P wave is blocked and a fully compensatory pause is produced. The third sinus-initiated P wave is conducted normally. From the His bundle recording it is obvious that the nonconducted sinus beat is blocked distal to the His bundle recording site. Note that the A-H interval of the nonconducted sinus P wave beat is prolonged, which suggests that the premature ventricular complex retrogradely activated His and invaded the AV node, thereby making it partially refractory to the next sinus beat. Since retrograde conduction into the atrioventricular (AV) node is not recorded and can be surmised only on the basis of the increase in the following A-H interval, it is an example of concealed conduction. Furthermore, since retrograde His and AV node activation by the premature ventricular complex would not be apparent in the scalar electrocardiogram but is responsible for the compensatory pause, the blocked P wave is an example of concealed conduction.

OTHER ELECTROPHYSIOLOGICAL ABNORMALITIES LEADING TO CARDIAC ARRHYTHMIAS

Supernormal Conduction and Excitation

SUPERNORMAL CONDUCTION.

Supernormal conduction is the term applied to situations characterized by conduction that is better than expected but generally not as good as normal.[537] [538] [539] [540] The phenomenon almost always occurs when conduction is depressed but can be present in normal cardiac tissues as well. It generally occurs when conduction takes place during the relative refractory period of the preceding complex (Fig. 25-60) . The electrophysiological basis can relate, in some examples, to supernormal excitability (see below), but probably to other mechanisms as well. Supernormal conduction has commonly been invoked to explain AV (most probably His-Purkinje

rather than AV nodal) conduction that is more rapid than expected or AV conduction that results when AV block is expected.

SUPERNORMAL EXCITATION.

This phenomenon results when a stimulus, normally subthreshold, occurs during the supernormal period of recovery of the preceding complex and produces a propagated response. Stimuli occurring earlier or later fail to produce a propagated response. Demonstrated in vitro in Purkinje fibers but not ventricular muscle, supernormal excitation occurs during phase 3 of the cardiac action potential, when the membrane potential, closer to threshold at the end of repolarization, requires less current to produce a propagated response. A similar phenomenon occurs during phase 4 diastolic depolarization or during afterdepolarizations that reduce the membrane potential closer to threshold. The phenomenon is most easily recognized when a nonsensing pacemaker, failing because of battery exhaustion and reduced output, produces a propagated response only when discharge falls during a specific period in a cardiac cycle (Fig. 25-61) . Similar phenomena probably occur spontaneously with "weak" automatic foci, but recognition of these events clinically is difficult and often speculative.

Concealed Conduction

Concealed conduction describes the phenomenon during which impulses penetrate an area of the conduction tissue, the AV node commonly but other areas as well, without emerging.[541] Since transmission of the impulse is concealed, i.e., electrically silent in the standard ECG, concealed conduction becomes manifested only by its *effects* on the conduction and/or formation of subsequent impulses.[542] The most common example follows a premature ventricular complex. Partial retrograde penetration of the AV node by the premature ventricular complex is *deduced* because the following sinus-initiated P wave blocks conduction to produce a compensatory pause (Fig. 25-62) or conducts with a longer PR interval if the premature ventricular complex is interpolated. The slower ventricular response when the atrial rate increases from atrial flutter to atrial fibrillation is due to a greater number of atrial impulses being blocked (conducting into, without emerging) in the AV node and is a manifestation of concealed conduction.[543] Concealed conduction occurs in WPW syndrome and can be manifested by unidirectional block anterogradely or retrogradely in an accessory pathway.[544] Concealed junctional extrasystoles can create ECG manifestations of apparent AV block. Strict confirmation of concealed conduction should be the demonstration of conduction, such as in the form of conducted junctional extrasystoles.

Parasystole (Fig. 25-63)

Parasystole refers to a cardiac arrhythmia characterized electrocardiographically by (1) a varying coupling interval between the ectopic (parasystolic) complex and the dominant (generally, sinus-initiated) complex; (2) a common minimal time interval between interectopic intervals, with the longer interectopic intervals being multiples of this minimal interval; (3) fusion complexes; and (4) presence of the parasystolic impulse whenever the cardiac chamber is excitable. Parasystole with exit block is suspected when the parasystolic discharge focus fails to appear even though cardiac tissue is excitable. The analogy commonly invoked to represent parasystole is the behavior of a fixed-rate nonsensing (VOO) pacemaker (see Chap. 24). Parasystole can occur in the sinus and AV nodes, atrium and ventricle, and AV junction. The parasystolic mechanism presumably results from the regular discharge of an automatic focus that is independent of and protected from discharge by the dominant cardiac rhythm. A number of mechanisms have been postulated to explain the apparent protection enjoyed by the parasystolic rhythm.[545]

These "classic" definitions of parasystole now need to be modified because it has been well established that the dominant sinus beats can modulate the discharge rate of the parasystolic rhythm despite entrance block. Thus, wide variations in the modulated parasystolic cycle may occur. The "true" or unmodulated parasystolic cycle length can be determined by finding two consecutive parasystolic complexes without intervening beats. Phase response curves can be generated. Fixed coupling between the dominant and parasystolic rhythms can occur through a variety of mechanisms, including entrainment. It is possible that modulated parasystole in the presence of supernormal excitability can trigger ventricular fibrillation.

Figure 25-63 Atrial parasystole. *Top,* Atrial parasystolic impulses (filled circles under the negative P waves) are present at a fixed coupling interval to the dominant sinus rhythm. The reason for the fixed coupling is as follows: Each time that the parasystolic impulse depolarizes the atrium, it also discharges the sinus node. Diastolic depolarization in the sinus node begins at that point (reset) and results in the following sinus P wave (positive P wave). Thus, the constant parasystolic discharge rate (interectopic interval approximately 960 milliseconds), resetting of the sinus node, and constant phase 4 diastolic depolarization in the sinus node combine to result in fixed coupling. *Middle* and *bottom*, The sinus discharge rate is slightly faster. It is no longer discharged by the parasystolic impulse, which is still occurring at approximately 960 milliseconds (slightly longer interval in the *bottom* tracing). Variable coupling, the usual manifestation of parasystole, results. Lead II.

Chapter 26 - Cardiac Arrest and Sudden Cardiac Death

ROBERT J. MYERBURG
AGUSTIN CASTELLANOS

Definition

Sudden cardiac death (SCD) is natural death due to cardiac causes, heralded by abrupt loss of consciousness within 1 hour of the onset of acute symptoms. Preexisting heart disease may or may not have been known to be present, but the time and mode of death are unexpected. This definition incorporates the key elements of "natural," "rapid," and "unexpected." It consolidates previous definitions that have conflicted,[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] largely because the most useful operational definition of SCD in the past differed for the clinician, the cardiovascular epidemiologist, the pathologist, and the scientist attempting to define pathophysiological mechanisms. As causes and mechanisms began to be understood, these differences disappeared.

Four elements must be considered in the construction of a definition of SCD to satisfy medical, scientific, legal, and social considerations: (1) prodromes, (2) onset, (3) cardiac arrest, and (4) biological death (Fig. 26-1) . Because the proximate cause of SCD is a disturbance of cardiovascular function, which is incompatible with maintaining consciousness because of abrupt loss of cerebral blood flow, any definition must recognize the brief time interval between the onset of the mechanism directly responsible for cardiac arrest and the consequent loss of consciousness (Fig. 26-1 *C*). The 1-hour definition, however, refers to the duration of the "terminal event" (Fig. 26-1 *B*), which defines the interval between the onset of symptoms signaling the pathophysiological disturbance leading to cardiac arrest and the onset of the cardiac arrest itself (Fig. 26-1 *B* and *C*).

Figure 26-1 Sudden cardiac death is viewed from four temporal perspectives: (*A*) prodromes, (*B*) onset of the terminal event, (*C*) cardiac arrest, and (*D*) progression to biological death. Individual variability of the components influence clinical expression: some victims experience no prodromes, with onset leading almost instantaneously to cardiac arrest; others may have an onset that lasts up to 1 hour before clinical arrest; some patients may live weeks after the cardiac arrest before progression to biological death if there has been irreversible brain damage and life-support systems are used. These modifying factors influence interpretation of the 1-hour definition. From the perspective of the clinician, the two most relevant factors are the onset of the terminal event (*B*) and the clinical cardiac arrest itself (*C*). In contrast, legal and social considerations focus on the time of biological death (*D*).

TABLE 26-1 -- DEFINITION OF TERMS RELATED TO SUDDEN CARDIAC DEATH

TERM	DEFINITION	QUALIFIERS OR EXCEPTIONS
Death	Irreversible cessation of all biological functions	None
Cardiac arrest	Abrupt cessation of cardiac pump function, which may be reversible but will lead to death in the absence of prompt intervention	Rare spontaneous reversions; likelihood of successful intervention relates to mechanism of arrest, clinical setting, and time to intervention
Cardiovascular collapse	A (sudden) loss of effective blood flow due to cardiac and/or peripheral vascular factors that may revert spontaneously (e.g., vasodepressor or cardioinhibitory syncope) or only with interventions (e.g., cardiac arrest)	Nonspecific term that includes cardiac arrest and its consequences and also events that characteristically revert spontaneously

Premonitory signs and symptoms, which may occur during the days or weeks before a cardiac arrest,[13] tend to be nonspecific for the impending event.[8] Prodromes (Fig. 26-1 *A*), which may be more specific for an imminent cardiac arrest, are relatively abrupt changes that begin during an arbitrarily defined period of up to 24 hours before the onset of cardiac arrest.[4] [16] The fourth element, *biological death* (Fig. 26-1 *D*), was an immediate consequence of the clinical cardiac arrest in the past, usually occurring within minutes. However, since the development of community-based intervention systems, and life support systems, patients may now remain biologically alive for a long period of time after the onset of a pathophysiological process that has caused irreversible damage and will ultimately lead to death.[15] [17] [18] [19] In this circumstance, the causative pathophysiological and clinical event is the cardiac arrest itself, rather than the factors responsible for the delayed biological death. However, for legal, forensic, and certain social considerations, biological death must continue to be used as the absolute definition of death. Finally, the forensic pathologist studying *unwitnessed deaths* may use the definition of sudden death for a person known to be alive and functioning normally 24 hours before,[4] and this remains appropriate within obvious limits.[20] The generally accepted clinical-pathophysiological definition of up to 1 hour between onset of the terminal event and biological death requires qualifications for specific circumstances.

The development of community-based intervention systems also has led to inconsistencies in the use of terms considered absolute. *Death* is defined biologically, legally, and literally as an absolute and irreversible event. Thus SCD may be aborted, or a patient may survive cardiac arrest or cardiovascular collapse; however, survival after (sudden) death is a contradiction in terms. Table 26-1 provides definitions for events and terms related to the concept of SCD--death, cardiac arrest, and cardiovascular collapse.

Epidemiology and Causes of Sudden Death

EPIDEMIOLOGY

The worldwide incidence of SCD is difficult to estimate because it varies largely as a function of coronary heart disease prevalence in different countries.[21] Estimates for the United States range from 250,000 to nearly 400,000 SCDs annually,[22] [23] [24] the variation based in part on the definition of sudden death used in individual studies.[13] The most widely used estimate is 300,000 SCDs annually,[25] a figure that represents 50 percent or more of all cardiovascular deaths in the United States.

The influence of the temporal definition of SCD on epidemiological data is demonstrated by a retrospective death certificate study in a large metropolitan area in the United States reported by Kuller and colleagues. When the temporal definition was restricted to death less than 2 hours after the onset of symptoms, 12 percent of all natural deaths were sudden and 88 percent of the sudden natural deaths were due to cardiac causes. This estimate is similar to observations in a large prospective cohort study--the Framingham Study--in which 13 percent of all deaths observed during a 26-year period were "sudden," defined as death within 1 hour of the onset of symptoms.[28] [29] In contrast to deaths occurring less than 2 hours after the onset of symptoms, the application of the 24-hour definition of sudden death to the data from Kuller and colleagues increased the fraction of all natural deaths falling into the "sudden" category to 32 percent but reduced the proportion of all sudden natural deaths that were cardiac deaths to 75 percent.

Prospective studies demonstrate that about 50 percent of all coronary heart disease deaths are sudden and unexpected, occurring shortly (instantaneous to 1 hour) after the onset of symptoms. In the prospective combined Albany-Framingham Study of 4120 males, sudden deaths within 1 hour of an observed collapse were analyzed for a population of men dying between 45 and 74 years of age.[9] During a 16-year follow-up, there were 234 total coronary deaths/1000 population observed, of which 109 (47 percent) were sudden and unexpected. Because coronary heart disease is the dominant cause of both sudden and nonsudden cardiac deaths in the United States, the fraction of total cardiac deaths that are sudden is similar to the fraction of coronary heart disease deaths that are sudden, although there does appear to be a geographical variation in the fraction of coronary deaths that are sudden.[30] This 50 percent fraction may not apply to other nations or to subcultures that have a lower prevalence of coronary heart disease. It also is of interest that the recent decline in coronary heart disease mortality in the United States[31] has not changed the fraction of coronary deaths that are sudden and unexpected,[32] even though there may be a decline in out-of-hospital deaths compared with emergency department death,[26] and the number of sudden deaths from coronary heart disease that occur in victims' homes may be lower than previously thought.[23]

POPULATION POOLS AND TIME-DEPENDENCE OF RISK

Two factors are of primary importance for identifying populations at risk and when considering strategies for primary prevention of SCD: (1) the size of denominators of population subgroups (Fig. 26-2 *A*), and (2) time-dependence of risk (Fig. 26-2 *B*).

POPULATION SUBGROUPS AND SCD.

The more than 300,000 adult SCDs that occur annually in the United States can be expressed as the global incidence in an unselected adult population. Viewed this way, the overall incidence is 1 to 2/1000 population (0.1-0.2 percent) per year. This large population base includes those victims whose SCDs occur as a first cardiac event, as well as those whose SCDs can be predicted with greater accuracy because they are included in higher-risk subgroups. Any intervention designed for the general population must, therefore, be applied to the 999/1000 who will not have an event, in order

Figure 26-2 Impact of population pools and time-from-events on the clinical epidemiology of sudden cardiac death. The top panel (*A*) compares incidence and total numbers of sudden cardiac deaths in different subgroups; the lower panel (*B*) demonstrates time-dependence of risk for sudden death after major cardiovascular events. In the top panel (*A*), estimates of incidence figures (percent/year) and the total number of events/year are shown for the overall adult population in the United States, and for increasingly higher-risk subgroups. The overall adult population has an estimated sudden death incidence of 0.1 to 0.2 percent/year, accounting for a total number of events of more than 300,000/year. With the identification of increasingly powerful risk factors, the incidence *increases* progressively, but it is accomplished by a progressive *decrease* in the total number of patients identified. The inverse relation between incidence and total number of events occurs because of the progressively smaller denominator pool in the highest subgroup categories. Successful interventions among larger population subgroups will require identification of specific markers to increase the ability to identify specific patients who will be at particularly high risk for a future event. (*Note:* The horizontal axis for the incidence figures is not linear and should be interpreted accordingly.) In the lower panel (*B*), idealized curves of survival from sudden death are shown for a population of patients with known cardiovascular disease but at low risk because of freedom from major cardiovascular (CV) events (top curve) and for populations of patients who have survived a major cardiovascular event (bottom curve). Attrition over time is accelerated in both absolute and relative terms for the initial 6 to 18 months after the major cardiovascular event. After the initial attrition, the slopes of the curves for the high-risk and low-risk populations parallel each other, highlighting both the early attrition and the attenuation of risk after 18 to 24 months. These relations have been observed in diverse high-risk subgroups (cardiac arrest survivors, post-myocardial infarction patients with high-risk markers, recent onset of heart failure), and highlight the changing risk pattern as a function of time and the importance of the time dimension for recognition and intervention in strategies designed to alter outcome. (Modified from Myerburg RJ, et al: Sudden cardiac death: Structure, function and time-dependence of risk. Circulation 85[Suppl 1]:1-2, 1992. Copyright 1992 American Heart Association.)

to reach and possibly influence the 1/1000 who will. The cost and risk-to-benefit uncertainties limit the nature of such broad-based interventions and demand a higher resolution of risk identification. Figure 26-2 *A* highlights this problem by expressing the incidence (percent/year) of SCD among various subgroups and comparing the incidence figures to the total number of events that occur annually in each subgroup. By moving from the total adult population to a subgroup with high risk because of the presence of selected coronary risk factors, there may be a 10-fold or greater increase in the incidence of events annually, with the magnitude of increase dependent on the number of risk factors operating in the subgroup. The size of the denominator pool, however, remains very large, and implementation of interventions remains problematic, even at this heightened level of risk. Higher resolution is desirable and can be achieved by identification of more specific subgroups. However, the corresponding absolute number of deaths becomes progressively smaller as the subgroups become more focused (Fig. 26-2 *A*), limiting the potential benefit of interventions to a much smaller fraction of the total number of patients at risk.

TIME-DEPENDENCE OF RISK.

Risk of SCD is not linear as a function of time after a change in cardiovascular status.[25] [32] [33] Survival curves after major cardiovascular events, which identify populations at high risk for both sudden and total cardiac death, usually demonstrate that the most rapid rate of attrition occurs during the first 6 to 18 months (Fig. 26-2 *B*). Thus there is a time-dependence of risk that focuses the opportunity for maximum efficacy of an intervention during the early period after a conditioning event. Curves that have these characteristics have been generated from among survivors of out-of-hospital cardiac arrest, new onset of heart failure, and unstable angina, and from high-risk subgroups of patients having recent myocardial infarction. Even though attrition rates decrease over time, an effective intervention can still cause late diversion of treated versus control risk curves, indicating continuing benefit. *The addition of time as a dimension for measuring risk may increase the resolution within subgroups.*

AGE, HEREDITY, GENDER, AND RACE

AGE.

There are two ages of peak incidence of sudden death: between birth and 6 months of age (the sudden infant death syndrome) and between 45 and 75 years of age.[3] In the adult population the *incidence* of sudden death due to coronary heart disease increases as a function of advancing age,[31] [34] [35] [36] [346A] in parallel with the age-related increase in incidence of total coronary heart disease deaths. The incidence is 100-fold less in adolescents and adults younger than the age of 30 years (1 in 100,000 per year) than in adults older than age of 35 years (1 in 1,000 per year)[37] [38] [39] (Fig. 26-3) . However, in contrast to incidence, the *proportion* of deaths caused by coronary heart diseases that are sudden and unexpected decreases with advancing age.[31] [34] [35] [36] [346A] Kuller and colleagues[40] reported that 76 percent of coronary heart disease deaths in the 20- to 39 year age group were sudden and unexpected, and the Framingham study data demonstrated that 62 percent of all coronary heart disease deaths were sudden in the 45 to 54-year age group in men. The proportion fell progressively to 58 percent in the 55- to 64-year age group and to 42 percent in the 65- to 74-year age group.[35] [36] Age also influences the proportion of cardiovascular causes among all causes of natural sudden death in that the proportion of coronary deaths and of all cardiac causes of death that are sudden is highest in the younger age groups, whereas the fraction of total sudden natural deaths that are due to any cardiovascular cause is higher in the older age groups. In their study of sudden death in children and young adults, Neuspiel and Kuller[41] reported that only 19 percent of sudden natural deaths in children between 1 and 13 years of age were cardiac deaths; the proportion increased to 30 percent in the 14- to 21-year age group. All of these studies of age factors used a 24-hour definition of sudden death.

HEREDITY.

To the extent that SCD is an expression of underlying coronary heart disease, hereditary factors that contribute to coronary heart disease risk have been thought to operate nonspecifically for the SCD syndrome.[42] In addition, however, two population studies suggest that SCD, as an expression of coronary heart disease, clusters in specific families.[43] [44] Whether this familial pattern is genetically or environmentally determined, or both, awaits clarifications.

Among the less common causes of SCD, hereditary patterns have been reported for specific syndromes[45] such as the congenital long QT interval syndromes,[46] [47] [48] [49] [50] [51] [52] [52A] [53] [54] [55] [56] [57] [58] hypertrophic cardiomyopathy,[54] [55] [56] right ventricular dysplasia,[57] [58] the Brugada syndrome,[59] [60] [61] [62] and yet-to-be-defined

Figure 26-3 Age-specific risk of sudden cardiac death (SCD). For the general population age 35 years and older, the risk of SCD is 0.1 to 0.2 percent per year (1 per 500 to 1,000 population). Among the general population of adolescents and adults younger than the age of 30 years, the overall risk of SCD is 1 per 100,000 population, or 0.001 percent per year. The risk of SCD increases dramatically beyond the age of 35 years and continues to increase past the age of 70 years (curve A). The greatest rate of increase is between 40 and 65 years (note that the vertical axis is discontinuous). Among patients older than 30 years of age, with advanced structural heart disease and markers of high risk for cardiac arrest, the event rate may exceed 25 percent per year (curve B). This magnitude of the risk is determined to a greater extent by the nature of the established disease, rather than by age. Among adolescents and young adults at risk for SCD because of specific identified causes, it is difficult to ascertain risk for individual patient because of variable expression of the disease state and the influences of interventions. However, for many of these conditions (e.g., long QT interval syndromes, Brugada syndrome, right ventricular dysplasia, idiopathic ventricular fibrillation [VF]), the major risk is electrical; and the competing risk of mechanical dysfunction of the heart as in advanced ischemic heart disease or dilated cardiomyopathy does not contribute significantly to risk. Therefore, effective electrical interventions are expected to have a better total mortality benefit than in the latter case (see text for details).

patterns of familial SCD in children and young adults.[63] [63A] Although stable congenital conducting system abnormalities have a good prognosis,[64] progressive familial conducting system disease, which appears to have a hereditary pattern, carry an increased risk of SCD.[65] Familial sudden death associated with cardiac ganglionitis has been reported,[66] but an inheritance pattern has not been demonstrated in the reports to date. Identification of multiple specific gene abnormalities in loci on at least four chromosomes (chromosomes 3, 7, 11, and 21), and linkage analysis suggesting a locus on chromosome 4, in families with long QT interval syndromes have provided a major advance in the understanding of a genetic basis for this cause of sudden death (see Chaps. 23 and 25) . This observation may provide a screening tool for individuals at risk, as well as the potential for specific therapeutic strategies.

GENDER.

The SCD syndrome has a huge preponderance in males compared with females because of the protection females enjoy from coronary atherosclerosis before menopause.[28] [29] [35] During the first 14 years of follow-up in the Framingham Study, 59 of 66 (89 percent) sudden unexpected coronary deaths (<1 hour) occurred in men.[8] The Framingham Study at 20 years of follow-up demonstrated a 3.8-fold excess incidence of sudden coronary death in men compared with women.[35] This male/female ratio is similar to data recorded in three prospective studies of prehospital cardiac arrest in which the percentages of males observed were 75 percent (mean age 63 years),[17] 85 percent (mean age 60 years),[18] and 89 percent (mean age 58 years),[67] respectively. In the study by Kuller and colleagues,[4] 75 percent of all SCDs (using the 24-hour definition) in a 40- to 64-year-old population were in men. When the data in another study by Kuller and colleagues[68] were analyzed for survival of less than 2 hours, the proportion of men increased to 80 percent. In the Framingham Study[35] the excess risk in men peaked at 6.75:1 in the 55- to 64-year age group and then fell to 2.17:1 in the 65- to 74-year age group. Even though the overall risk is much lower in women, the classic coronary risk factors are expressed in them.[28] [29] [69] [70] Cigarette smoking, diabetes, use of oral contraceptives,[71] and reduced vital capacity[29] are particularly strong factors.

RACE.

A number of studies comparing racial differences and relative risk of SCD in whites and blacks with coronary heart disease in the United States have yielded conflicting and inconclusive data.[4] [72] [73] [74] However, a recent large study from an urban area demonstrated excess risk of cardiac arrest and SCD in blacks compared with whites.[73] An excess was observed across all age groups, but the magnitude of excess among older adults decreased with increasing age.

Data on the prevalence of coronary heart disease in Japanese men living in the United States have demonstrated that the low rates reported in those living in Japan tend to increase toward, but do not reach, levels observed in white men in the United States.[75] Thus, an interplay between race and environmental factors may be operative.

BIOLOGICAL RISK FACTORS AND SUDDEN DEATH

The known coronary risk factors cannot be used to distinguish the patients at risk for SCD from those at risk for other manifestations of coronary heart disease.[9] Using a multivariate analysis of selected risk factors (i.e., age, systolic blood pressure, heart rate, electrocardiographic abnormalities, vital capacity, relative weight, cigarette consumption, and serum cholesterol from the population in the Framingham Study data, Kannel and Schatzkin[31] determined that 53 percent of the SCDs in men and 42 percent of those in women occurred among the 10 percent of the population in the highest risk decile (Fig. 26-4) . The comparison of risk factors in the victims of SCD with those in people who developed any manifestations of coronary artery disease did not provide useful patterns, by either univariate or multivariate analysis, to distinguish victims of SCD from the overall pool.[9] In addition, data from 19,946 patients in the Coronary Artery Surgery Study identified no angiographic or hemodynamic patterns that discriminated sudden from nonsudden cardiac deaths.[36] Familial clustering of SCD as a specific manifestation, however, may lead to identification of specific genetic abnormalities that predispose to SCD.[48] [49]

Figure 26-4 Risk of sudden death by decile of multivariant risk: 26-year follow-up, the Framingham Study. ECG = electrocardiographic; I-V = intraventricular; LVH = left ventricular hypertrophy; non-spec abn = nonspecific abnormality. (From Kannel WB, Shatzkin A: Sudden death: Lessons from subsets in population studies. Reprinted by permission of the American College of Cardiology. J Am Coll Cardiol 5[Suppl 6]:141B, 1985.)

Hypertension is a clearly established risk factor for coronary heart disease and also emerges as a highly significant risk factor for incidence of SCD.?? However, there is no influence of increasing systolic blood pressure levels on the ratio of sudden deaths to total coronary heart disease deaths.[34] No relationship has been observed between cholesterol concentration and the proportion of coronary deaths that were sudden.[37] Neither the electrocardiographic pattern of left ventricular hypertrophy nor nonspecific ST-T wave abnormalities influence the proportion of total coronary deaths that are sudden and unexpected [34] ; *only intraventricular conduction abnormalities are suggestive of a disproportionate number of SCDs.*[35] A low vital capacity also suggests a disproportionate risk for sudden versus total coronary deaths.[35] This is of interest because such a relation was particularly striking in the analysis of data on women in the Framingham Study who had died suddenly.[28] [29] A

high hematocrit also was predictive in women.[30]

The conventional risk factors used in most studies of SCD are the risk factors for coronary artery disease. The rationale is based on two facts: (1) coronary disease is the structural basis for 80 percent of SCDs in the United States, and (2) the coronary risk factors are easy to identify because they tend to be present continuously over time (Fig. 26-5) . However, risk factors specific for fatal arrhythmias are dynamic pathophysiological events and occur transiently.[76] [76A] Transient pathophysiological events are being modeled epidemiologically,[77] in an attempt to express and use them as clinical risk factors[78] for both profiling and intervention.[79]

LIFE STYLE AND PSYCHOSOCIAL FACTORS

LIFE STYLE.

There is a strong association between *cigarette smoking* and all manifestations of coronary heart disease. The Framingham Study demonstrates that cigarette smokers have a twofold to threefold increase in sudden death risk in each decade of life at entry between 30 and 59 years, and that this is one of the few risk factors in which the proportion of coronary heart disease deaths that are sudden increases in association with the risk factor.[35] In addition, in a study of 310 survivors of out-of-hospital cardiac arrest, Hallstrom and associates[80] observed a 27 percent incidence of recurrent cardiac arrest at 3 years in those who continued to smoke after their index event, compared with 19 percent in those who stopped ($P<0.04$). Obesity is a second factor that appears to influence the proportion of coronary deaths that occur suddenly.[29] [35] With increasing relative weight, the percentage of coronary heart disease deaths that were sudden in the Framingham Study increased linearly from a low of 39 percent to a high of 70 percent. Total coronary heart disease deaths increased with increasing relative weight as well.

Epidemiological observations suggest a relationship between *low levels of physical activity* and increased coronary heart disease death risk.[81] The Framingham Study, however, showed an *insignificant* relationship between low levels of physical activity and incidence of sudden death but a high proportion of sudden to total cardiac deaths at higher levels of physical activity.[35] An association between acute physical exertion (especially in physically inactive individuals) and the onset of myocardial infarction has been suggested,[79] but it is not yet known if this also applies to SCD.

PSYCHOSOCIAL FACTORS.

The magnitude of recent life changes in the realms of health, work, home and family, and personal and social factors have been related to myocardial infarction and SCD.[72] There was an association between significant elevations of life-change scores during the 6 months before a coronary event, and the association was particularly striking in victims of SCD. In a study of sudden death in women,[83] those who died suddenly were less often married, had fewer children, and had greater educational discrepancies with their spouses than did age-related controls living in the same neighborhood as the sudden death victims. A history of psychiatric treatment, cigarette smoking, and greater quantities of alcohol consumption than the controls also characterized the sudden death group.[83] Ruberman and coworkers reported on the influences of psychosocial factors on sudden and total death after myocardial infarction in 2320 male survivors of myocardial infarction[84] Controlling for other major prognostic factors, including frequency of premature ventricular contractions, a greater than fourfold increase in risk of sudden and total deaths was predicted by *social isolation* and a *high level of life stress.* These psychosocial factors were inversely related to levels of education. In an earlier study, a more than threefold increase of sudden death risk during follow-up after myocardial infarction had been reported in men who had complex ventricular ectopy and low levels of education compared with better-educated men with the same arrhythmias.[85] Interestingly, there was no relation between educational level and recurrent myocardial infarction. In a survey of life style, it was found that people with lower educational levels smoked more cigarettes, drank more alcohol, exercised less, and were more overweight.[86] Alteration of modifiable lifestyle factors has been proposed as a strategy for reducing risk of SCD in patients with coronary heart disease.[86A]

Figure 26-5 Epidemiology of SCD: conventional (conditioning) risk factors versus transient (triggering) risk factors. Conventional risk factors predict risk of the disease underlying SCD; transient risk factors predict risk of the pathophysiological event that initiates the fatal event. (Modified from Myerburg RJ, Kessler KM, Kimura S, et al: Life-threatening ventricular arrhythmias: The link between epidemiology and pathophysiology. *In* Zipes DP, Jalife J [eds]: Cardiac Electrophysiology, 2nd ed. Philadelphia, WB Saunders, 1995.)

FUNCTIONAL CLASSIFICATION AND SUDDEN DEATH.

The Framingham Study demonstrated a striking relation between functional classification and death during a 2-year follow-up period. However, the proportion of deaths that were sudden did not vary with functional classification, ranging from 50 to 57 percent in all groups and from those free of clinical heart disease to those in functional Class IV.[35] Another study suggested that heart failure patients with better functional capacity are at lower risk of dying, as expected, but a higher proportion of those deaths are sudden.[87]

Sudden Death and Previous Coronary Heart Disease

Although SCD is the first clinical manifestation of coronary heart disease in 20 to 25 percent or more of all coronary heart disease patients,[9] [12] [20] [25] a previous myocardial infarction can be identified in as many as 75 percent of patients who die suddenly. The high incidence of both recognized and unrecognized prior myocardial infarction in victims of SCD has led to a search for predictors of SCD in survivors of myocardial infarction, as well as in patients with other clinical manifestations of coronary heart disease.

LEFT VENTRICULAR EJECTION FRACTION IN CHRONIC ISCHEMIC HEART DISEASE.

A marked depression of the left ventricular ejection fraction is the most powerful predictor of SCD in patients with chronic ischemic heart disease, as well as those whose SCD results from other causes (see later). Increased risk, independent of other risk factors, is measurable at ejection fractions greater than 40 percent, but the greatest rate of change of risk is between 30 and 40 percent.[88] An ejection fraction equal to or less than 30 percent is the single most powerful independent predictor for SCD, but it has a low specificity.

VENTRICULAR ECTOPY IN CHRONIC ISCHEMIC HEART DISEASE.

Most forms of ventricular ectopic activity (premature ventricular complexes [PVCs] in the absence of heart disease[89] are prognostically benign. When present in people older than the age of 30, however, PVCs select a subgroup with a higher probability of coronary artery disease and of SCD.[90] In addition, the occurrence of PVCs in survivors of myocardial infarction,[91] particularly if frequent and of complex forms such as multiform or repetitive PVCs,[88] [92] predicts an increased risk of SCD on long-term follow-up. Most of these studies have identified both *frequency* and *forms* of ventricular ectopic activity as indicators of risk, but uniformity for such classifications is lacking.[93] Although most studies cite a frequency cutoff of 10 PVCs/hr as a threshold level for increased risk, some have identified frequency cutoffs in the range of 1 to 9 PVCs/hr, 10 PVCs/1000 sinus beats, and more than 20 PVCs/hr. Forms suggestive of high risk include multiform PVCs, bigeminy, short coupling intervals (R-on-T phenomenon), and salvos of three or more ectopic beats.[93] Several investigators have emphasized that the most powerful predictors among the various forms of PVCs are salvos of three or more complexes,[88] [92] [94] although this relationship is now questioned.

Many of the reported studies have been based on a single ambulatory monitor sample recorded 1 week to several months after the onset of acute myocardial infarction, and the duration of the samples has ranged from 1 hour to 48 hours. Ruberman and coworkers[94] reported that repeated short-term (1-hour) ambulatory recordings at 6-month intervals beginning 1 month after myocardial infarction reestablished the increased risk imparted by complex forms of PVCs for the ensuing 3 1/2-year interval, as long as complex forms remained on the interval recordings. Recent data indicate that ambulatory ventricular arrhythmias in patients with heart failure do not specifically predict an increased risk of death.[94A]

The results of the Cardiac Arrhythmia Suppression Trial (CAST) (see Chap. 25) , designed to test the hypothesis that PVC suppression by antiarrhythmic drugs alters risk of SCD

Figure 26-6 Survival during 3 years of follow-up after acute myocardial infarction as a function of left ventricular dysfunction (ejection fraction, EF) and ventricular arrhythmias (VPDs/hr as measured by Holter monitoring). The survival curves were calculated as Kaplan-Meier estimates. With higher PVC frequencies and lower ejection fractions, the mortality rates increase. The number of patients in groups A, B, C, and D were 536, 136, 80, and 37, respectively. (From Bigger JT: Relation between left ventricular dysfunction and ventricular arrhythmias after myocardial infarction. Am J Cardiol 57:8B, 1986.)

after myocardial infarction, were surprising for two reasons.[95] First, the death rate in the randomized placebo group was lower than expected, and second, the death rate among patients in the encainide and flecainide arms exceeded control rates by more than three times. Thus, for these two Class IC drugs, treatment had an adverse effect for a population dominated by frequent single PVCs, and with a mean ejection fraction of about 40 percent. Subgroup analysis demonstrated increased risk in the placebo group for patients with nonsustained ventricular tachycardia (VT) and with ejection fraction of 30 percent or less, but excess risk in the treated group was still observed. The Survival with Oral*d*-Sotalol (SWORD) study, a comparison of*d*-sotalol to placebo in a postmyocardial infarction population with a low death rate, also demonstrated excess risk in the drug-treated group.[96] In the continuation of CAST (CAST II), comparing moricizine with placebo and altering enrollment to favor patients with more advanced disease, no adverse effect (other than short-term proarrhythmic risk at initiation of therapy) was observed, but no long-term benefit emerged either.[97] Whether the conclusions from CAST, CAST II, and SWORD, extend beyond the drugs studied or to other diseases remains to be learned.[98]

Left ventricular dysfunction is the major modulator of risk implied by chronic PVCs after myocardial infarction.[88] The risk of death predicted by postmyocardial infarction PVCs is enhanced by the presence of left ventricular dysfunction (Fig. 26-6) ; the latter appears to exert its influence most strongly in the first 6 months after infarction.[88] Finally, there are data suggesting that the risk associated with postinfarction ventricular arrhythmias is higher in patients who have non-Q-wave infarctions than in those with transmural infarctions.[99]

Causes of Sudden Cardiac Death

Coronary heart disease and its consequences account for at least 80 percent of SCDs in Western cultures, and the cardiomyopathies, dilated and hypertrophic, cause another 10 to 15 percent of SCDs (Table 26-2) . Coronary heart disease also is the most common cause in many areas of the world in which its prevalence is lower. Despite the established relation between coronary heart disease and SCD,[15] [17] [18] [32]

TABLE 26-2 -- CAUSES AND CONTRIBUTING FACTORS IN SUDDEN CARDIAC DEATH

I. CORONARY ARTERY ABNORMALITIES
- A. Coronary atherosclerosis
  1. Chronic ischemic heart disease with transient supply-demand imbalance--thrombosis, spasm, physical stress
  2. Acute myocardial infarction
  3. Chronic atherosclerosis with change in myocardial substrate
- B. Congenital abnormalities of coronary arteries
  1. Anomalous origin from pulmonary artery
  2. Other coronary arteriovenous fistula
  3. Origin of left coronary artery from right sinus of Valsalva
  4. Origin of right coronary artery from left sinus of Valsalva
  5. Hypoplastic or aplastic coronary arteries
  6. Coronary-intracardiac shunt
- C. Coronary artery embolism
  1. Aortic or mitral endocarditis
  2. Prosthetic aortic or mitral valves
  3. Abnormal native valves or left ventricular mural thrombus
  4. Platelet embolism
- D. Coronary arteritis
  1. Polyarteritis nodosa, progressive systemic sclerosis, giant cell arteritis
  2. Mucocutaneous lymph node syndrome (Kawasaki disease)
  3. Syphilitic coronary ostial stenosis
- E. Miscellaneous mechanical obstruction of coronary arteries
  1. Coronary artery dissection in Marfan's syndrome
  2. Coronary artery dissection in pregnancy
  3. Prolapse of aortic valve myxomatous polyps into coronary ostia
  4. Dissection or rupture of sinus of Valsalva
- F. Functional obstruction of coronary arteries
  1. Coronary artery spasm with or without atherosclerosis
  2. Myocardial bridges

II. HYPERTROPHY OF VENTRICULAR MYOCARDIUM
- A. Left ventricular hypertrophy associated with coronary heart disease
- B. Hypertensive heart disease without significant coronary atherosclerosis
- C. Hypertrophic myocardium secondary to valvular heart disease
- D. Hypertrophic cardiomyopathy
  1. Obstructive
  2. Nonobstructive
- E. Primary or secondary pulmonary hypertension
  1. Advanced chronic right ventricular overload
  2. Pulmonary hypertension in pregnancy (highest risk peripartum)

III. MYOCARDIAL DISEASES AND HEART FAILURE
- A. Chronic congestive heart failure
  1. Ischemic cardiomyopathy
  2. Idiopathic congestive cardiomyopathy
  3. Alcoholic cardiomyopathy
  4. Hypertensive cardiomyopathy
  5. Post-myocarditis cardiomyopathy
  6. Postpartum cardiomyopathy
- B. Acute cardiac failure
  1. Massive acute myocardial infarction
  2. Acute myocarditis
  3. Acute alcoholic cardiac dysfunction
  4. Ball-valve embolism in aortic stenosis or prosthesis
  5. Mechanical disruptions of cardiac structures
    (a) Rupture of ventricular free wall
    (b) Disruption of mitral apparatus
      (1) Papillary muscle
      (2) Chordae tendineae
      (3) Leaflet
    (c) Rupture of interventricular septum
  6. Acute pulmonary edema in noncompliant ventricles

IV. INFLAMMATORY, INFILTRATIVE, NEOPLASTIC, AND DEGENERATIVE PROCESSES
A. Viral myocarditis, with or without ventricular dysfunction
1. Acute phase
2. Postmyocarditis interstitial fibrosis
B. Myocarditis associated with the vasculitides
C. Sarcoidosis
D. Progressive systemic sclerosis
E. Amyloidosis
F. Hemochromatosis
G. Idiopathic giant cell myocarditis
H. Chagas' disease
I. Cardiac ganglionitis
J. Arrhythmogenic right ventricular dysplasia; right ventricular cardiomyopathy
K. Neuromuscular diseases (e.g., muscular dystrophy, Friedreich's ataxia, myotonic dystrophy)

a complete understanding of SCD requires recognition of other causes that, although less common and often quite rare (see Table 26-2) , may be recognizable before death, have therapeutic implications, and provide broad insight into the sudden death problem. Many of these entities emerge as common causes of SCD in adolescents and young adults; among whom the prevalences coronary arteriolosclerosis much lower (see Fig. 26-3) .

CORONARY ARTERY ABNORMALITIES.

Although structural abnormalities of coronary arteries other than coronary atherosclerosis are infrequent causes of SCD, the relative risk of SCD may be quite high for specific abnormalities. Nonatherosclerotic coronary artery abnormalities include congenital lesions, coronary artery embolism, coronary arteritis, and mechanical abnormalities of the coronary arteries. Among the congenital lesions, *anomalous origin of a left coronary artery from the pulmonary artery* (see Chap. 43) is relatively common[100] and has a high death rate in infancy and early childhood if not surgically treated.[101] The early risk for SCD is not excessively high,[100] but patients who survive to adulthood without surgical intervention are at risk.[101] Other forms of coronary arterial-kenous fistulas are much less frequent and have a low incidence of SCD. *Anomalous origin of a left coronary artery from the right or noncoronary aortic sinus of Valsalva* (see Chap. 12) appears to have increased risk of SCD,[102] [103] [104] particularly during exercise. When the anomalous artery passes between the aortic and the pulmonary artery root, the takeoff angle of the anomalous ostium creates a slitlike opening of the vessel, reducing the effective cross-sectional area for blood flow.[102] *Anomalous origin of the right coronary artery from the left sinus of Valsalva* also has been reported in association with SCD[102] [103] [104] but may not have the same risk as origin of the left coronary from the right sinus of Valsalva. Congenitally hypoplastic, stenotic, or atretic left coronary arteries are uncommon abnormalities that have a high risk of myocardial infarction but not of SCD.[100]

Embolism to the coronary arteries occurs most commonly in aortic valve endocarditis and from thrombotic material on diseased or prosthetic aortic or mitral valves.[105] Emboli also may originate from left ventricular mural thrombi or as a consequence of surgery or cardiac catheterization. Symptoms and signs of myocardial ischemia or infarction are the most common manifestations. In each of these categories SCD is a risk resulting from the electrophysiological consequences of the embolic ischemic event. Although embolism of platelet aggregates is a pathophysiological mechanism that has not clearly been demonstrated to be associated with SCD in clinical settings, some observations have focused attention on the feasibility of such a mechanism.

The *mucocutaneous lymph node syndrome* (Kawasaki disease)[106] (see Chap. 45) carries a risk of SCD in association with coronary arteritis. Polyarteritis nodosa and related vesiculitis syndromes (see Chap. 67) can cause SCD presumably because of coronary arteritis,[107] as can coronary ostial stenosis in syphilitic aortitis[64] (see Chap. 48) . The latter has become a very rare manifestation of syphilis.[108]

Several types of mechanical obstruction to coronary arteries must be listed among causes of SCD. Coronary dissection, with or without dissection of the aorta, occurs in Marfan's syndrome[109] (see Chap. 56) and has also been reported

TABLE 26-2 -- CAUSES AND CONTRIBUTING FACTORS IN SUDDEN CARDIAC DEATH--***Continued***

L. Intramural tumors

A. Congenital aortic or pulmonic valve stenosis
B. Right-to-left shunts with Eisenmenger's physiology
1. Advanced disease
2. During labor and delivery
C. After surgical repair of congenital lesions (e.g., tetralogy of Fallot)

VII. ELECTROPHYSIOLOGICAL ABNORMALITIES
A. Abnormalities of the conducting system
1. Fibrosis of the His-Purkinje system
(a) Primary degeneration (Lenegre's disease)
(b) Secondary to fibrosis and calcification of the "cardiac skeleton" (Lev's disease)
(c) Postviral conducting system fibrosis
(d) Hereditary conducting system disease
2. Anomalous pathways of conduction
B. Abnormalities of repolarization
1. Congenital long QT interval syndromes
(a) Romano-Ward syndrome (without deafness)
(b) Jervell and Lange-Nielsen syndrome (with deafness)
2. Acquired long QT interval syndromes
(a) Drug effect
(1) Cardiac, antiarrhythmic
(2) Noncardiac
(3) Drug interactions
(b) Electrolyte abnormality
(c) Toxic substances
(d) Hypothermia
(e) Central nervous system injury
3. Right bundle branch block and ST segment elevations in the absence of ischemia (the Brugada syndrome)
C. Ventricular fibrillation of unknown or uncertain cause
1. Absence of identifiable structural or functional causes
(a) "Idiopathic" ventricular fibrillation
(b) Short-coupled torsades de pointes, polymorphic VT
(c) Nonspecific fibrofatty infiltration in previously healthy victim (variation of RV dysplasia [?])
2. Sleep-death in Southeast Asians (see VII.B.3)
(a) Bangungut
(b) Pokkuri
(c) Nonlaitai

VIII. ELECTRICAL INSTABILITY RELATED TO NEUROHUMORAL AND CENTRAL NERVOUS SYSTEM INFLUENCES
A. Catecholamine-dependent lethal arrhythmias
B. Central nervous system-related
1. Psychic stress, emotional extremes
2. Auditory-related
3. "Voodoo" death in primitive cultures
4. Diseases of the cardiac nerves
5. Congenital QT interval prolongation

IX. SUDDEN INFANT DEATH SYNDROME AND SUDDEN DEATH IN CHILDREN
A. Sudden infant death syndrome
1. Immature respiratory control functions
2. Susceptibility to lethal arrhythmias (e.g., long QT syndrome)
3. Congenital heart disease
4. Myocarditis
B. Sudden death in children
1. Eisenmenger's syndrome, aortic stenosis, hypertrophic cardiomyopathy, pulmonary atresia
2. After corrective surgery for congenital heart disease
3. Myocarditis
4. Genetic disorders of electrical function (e.g., long QT syndrome)
5. No identified structural or functional cause

X. MISCELLANEOUS
A. Sudden death during extreme physical activity
B. Commotio cordis--blunt chest trauma
C. Mechanical interference with venous return
1. Acute cardiac tamponade
2. Massive pulmonary embolism
3. Acute intracardiac thrombosis
D. Dissecting aneurysm of the aorta
E. Toxic/metabolic disturbances
1. Electrolyte disturbances
2. Metabolic disturbances
3. Proarrhythmic effects of antiarrhythmic drugs
4. Proarrhythmic effects of noncardiac drugs
F. Mimics sudden cardiac death
1. "Cafe coronary"
2. Acute alcoholic states ("holiday heart")
3. Acute asthmatic attacks
4. Air or amniotic fluid embolism

---

in the peripartum period of pregnancy.[110] Among the rare mechanical causes of SCD is prolapse of myxomatous polyps from the aortic valve into coronary ostia,[111] as well as dissection or rupture of a sinus of Valsalva aneurysm, with involvement of the coronary ostia and proximal coronary arteries.[112] Finally, deep myocardial bridges over coronary arteries (see Chap. 12) have been reported in association with SCD occurring during strenuous exercise,[113] possibly due to dynamic mechanical obstruction. However, most myocardial bridges are inconsequential and SCD associated with this anatomy is uncommon.

Coronary artery spasm (see Chap. 37) may cause serious arrhythmias and SCD[114] [115] [116] with or without concomitant coronary atherosclerotic lesions.[115] Painless myocardial ischemia, associated with either spasm or fixed lesions, may be a cause of heretofore unexplained sudden death.[116] [117] [118] Different patterns of silent ischemia (e.g., totally asymptomatic, post-myocardial infarction, and mixed silent/anginal pattern) may have different prognostic implications.[119]

VENTRICULAR HYPERTROPHY.

Left ventricular hypertrophy is an independent risk factor for SCD, accompanies many causes of SCD,[120] and may be a physiological contributor to mechanisms of potentially lethal arrhythmias.[120] [121] The underlying states resulting in hypertrophy include hypertensive heart disease with or without atherosclerosis, valvular heart disease, obstructive and nonobstructive hypertrophic cardiomyopathy, primary pulmonary hypertension with right ventricular hypertrophy, and advanced right ventricular overload secondary to congenital heart disease. Each of these conditions is associated with risk of SCD, and it has been suggested that patients with severely hypertrophic ventricles are particularly susceptible to arrhythmic death.[120]

HYPERTROPHIC CARDIOMYOPATHY

(see Chap. 48) . Risk of SCD in obstructive and nonobstructive hypertrophic cardiomyopathy was identified in the early clinical and hemodynamic studies of this entity.[122] Two large series of the obstructive form yielded similar data on the magnitude of this risk. Goodwin[123] observed 48 deaths, of which 36 (67 percent) were sudden, among a cohort of 254 patients followed for a mean of 6 years, while Shah and associates[124] reported that 26 of 49 deaths (55 percent) among 190 patients were sudden. However, cardiac arrest survivors in this group may have better long-term outcome than do survivors with other causes. In one report

only 11/33 (33 percent) had recurrent cardiac arrest or death during a mean follow-up of 7 years.[125] More recent reports have suggested that the risk of *primary* cardiac arrest and SCD in hypertrophic cardiomyopathy is lower than previously thought.[126] [127]

A substantial proportion of patients with obstructive and nonobstructive cardiomyopathy have a family history of affected relatives or SCDs of unknown cause. Genetic studies have confirmed autosomal dominant inheritance patterns, with a great deal of allele heterogeneity. Seven gene loci on chromosomes 1, 3, 11, 12, 14, 15, and 19, encoding over 80 different mutations, and an additional undefined gene on chromosome 7, have been identified.[45] [55] Most of the defects encode proteins in the contractile protein complex, the most common being beta-myosin heavy chain and cardiac troponin T, which together account for more than half of identified abnormalities.[55] [56] Risk of SCD appears to be defect-specific, even within specific gene loci.[55] Thus, the specific defect, rather than the locus, is more relevant, and may be independent of the severity of structural hypertrophy.

Specific clinical markers have not been especially predictive of SCD in individual patients, although young age at onset,[123] [128] strong family history,[54] [128] and worsening symptoms[123] appear to indicate higher risk. In one study, however, 54 percent of the sudden deaths occurred in patients without any functional limitations.[128] The mechanism of SCD in patients with hypertrophic obstructive cardiomyopathy was initially thought to involve outflow tract obstruction, possibly as a consequence of catecholamine stimulation, but more recent data have focused on lethal arrhythmias as the common mechanism of sudden death in this disease.[120] [128] [129] [130] [131] [132] These studies have demonstrated a high prevalence of PVCs and nonsustained VT on ambulatory recording or the inducibility[130] of potentially lethal arrhythmias during programed electrical stimulation.[131] [132] However, stable and asymptomatic nonsustained VT has limited predictive power for SCD in these patients. Rapid and/or polymorphic symptomatic nonsustained tachycardias have better predictive power.

The question of whether the pathogenesis of the arrhythmias represents an interaction between electrophysiological and hemodynamic abnormalities, or is a consequence of electrophysiological derangement of hypertrophied muscle,[120] [121] is unanswered. The observation that patients with nonobstructive hypertrophic cardiomyopathy have high-risk arrhythmias and are at increased risk for SCD[130] suggests that an electrophysiological mechanism secondary to the hypertrophied muscle itself plays some role. Stafford and colleagues[133] reported exercise-related cardiac arrest in nonobstructive hypertrophic cardiomyopathy. Ventricular fibrillation (VF) was reproduced during electrophysiological testing after induction of atrial fibrillation with a rapid ventricular response. In athletes younger than 35 years of age, hypertrophic cardiomyopathy is the most common cause of SCD, in contrast to athletes over the age of 35, among whom ischemic heart disease is the most common cause.[103] [104] [134] [135]

SUDDEN DEATH IN DILATED CARDIOMYOPATHY AND HEART FAILURE.

The advent of therapeutic interventions that provide better long-term control of congestive heart failure has begun to improve long-term survival of such patients (see Chap. 18) . However, the proportion of heart failure patients with stable hemodynamics who die suddenly appears to be increasing.[136] In reports to date, as many as 47 percent of deaths in heart failure patients are categorized as SCD. The mechanism of SCD (VT/VF versus bradyarrhythmia/asystole) appears to relate to cause (i.e., ischemic versus nonischemic)[137] The absolute risk of SCD increases with deteriorating left ventricular function, but the ratio of sudden to nonsudden deaths relates inversely to the extent of impairment.[87] Among patients with cardiomyopathy who have good functional capacity (Class I and II), total mortality risk is considerably better than for those with poor functional capacity (Class III and IV). (Fig. 26-7) . Unexplained syncope has been observed to be a powerful predictor of SCD in patients who have functional Class III or IV disease due to any cause of cardiomyopathy, although ambulatory ventricular arrhythmias do not appear to indicate specific SCD risk in such patients.[94A] [138] [139] The actuarial 1-year probability of SCD was 45 percent in this study.

The interaction between post-myocardial infarction ventricular arrhythmia and depressed ejection fraction in determining risk for SCD has been described.[88] The majority of studies addressing the relation between chronic congestive heart failure and SCD focused on patients with ischemic, idiopathic, and alcoholic congestive cardiomyopathy.[87] [136] [140] [141] [142] A chronic myopathic syndrome after myocarditis has been cited as an infrequent but welldocumented cause of SCD.[143] Peripartum cardiomyopathy (see Chap. 65) also may cause SCD.

Figure 26-7 Risk of sudden cardiac death related to functional classification in heart failure. The relative probability of death being sudden is higher in the patients with better functional capacity who are at lower total mortality risk. (Modified from Kjekshus J: Arrhythmia and mortality in congestive heart failure. Am J Cardiol 65:42-1, 1990.)

Acute Heart Failure.

All causes of acute cardiac failure, in the absence of prompt interventions, can result in SCD caused by either the circulatory failure itself or secondary arrhythmias. The electrophysiological mechanisms involved have been proposed to be related to acute stretching of myocardial fibers and/or the His-Purkinje system, with its experimentally demonstrated arrhythmogenic effect,[144] but the roles of neurohumoral mechanisms and acute electrolyte shifts have not been fully evaluated.[136] Among the causes of acute cardiac failure that are associated with SCD are massive acute myocardial infarction, acute myocarditis, acute alcoholic cardiac dysfunction, and a number of mechanical causes of heart failure, such as massive pulmonary embolism, mechanical disruption of intracardiac structures secondary to infarction or infection, and ball-valve embolism in aortic or mitral stenosis (see Table 26-2) .

INFLAMMATORY, INFILTRATIVE, NEOPLASTIC, AND DEGENERATIVE DISEASES OF THE HEART.

Almost all diseases in this category have been associated with SCD, with or without concomitant cardiac failure. Acute viral myocarditis with left ventricular dysfunction (see Chap. 48) is commonly associated with cardiac arrhythmias, including potentially lethal arrhythmias. It is now recognized that serious ventricular arrhythmias or SCD can occur in myocarditis in the absence of clinical evidence of left ventricular dysfunction.[64] [143] [145] In a report of 19 SCDs among 1,606,167 previously screened US Air Force recruits, 8 of the 19 (42 percent) had evidence of myocarditis (5 nonrheumatic, 3 rheumatic) at postmortem examination, and 15 (79 percent) suffered their cardiac arrests during strenuous exertion.[146] Viral carditis also can cause damage isolated to the specialized conducting system and result in a propensity to arrhythmias; the rare association of this process with SCD has been reported.[147] The risk of potentially lethal arrhythmias is not limited to the acute phase of the disease.[143]

Myocardial involvement in collagen-vascular disorders, tumors, chronic granulomatous diseases, infiltrative disorders, and protozoan infestations varies widely, but in all instances SCD may be the initial or terminal manifestation of the disease process. Among the granulomatous diseases, *sarcoidosis* (see Chap. 48) stands out because of the frequency of SCD associated with it. Roberts and coworkers[148] reported that SCD was the terminal event in 67 percent of sarcoid heart disease deaths; the occurrence of SCD has been related to the extent of cardiac involvement.[149] In a report on the pathological findings in nine patients who died of *progressive systemic sclerosis* (see Chap. 48) , eight who died suddenly had evidence of transient ischemia and reperfusion histologically, suggesting that this might represent Raynaud-like involvement of coronary vessels.[150] *Amyloidosis* of the heart (see Chap. 48) may also cause sudden death. An incidence of 30 percent has been reported,[151] and diffuse involvement of ventricular muscle or of the specialized conducting system may be associated with SCD.[152]

Arrhythmogenic Right Ventricular Dysplasia Cardiomyopathy

(see Chaps. 23 and 25) . This condition is associated with a high incidence of ventricular arrhythmias, particularly recurrent VT.[153] [153A] Although

symptomatic VT has been well recognized in the syndrome for many years, the risk of SCD was unclear[154] and thought to be relatively low. However, the features of the disease, and risks associated with it, have been clarified by a number of studies.[153] [153A] [154] [155] [156] [157] In a high proportion of victims, perhaps as many as 80 percent, the first manifestation of the disease is "unexplained" syncope or SCD.[155] SCD is often exercise related and in some areas of the world where screening for hypertrophic cardiomyopathy has excluded those athletes from competition, right ventricular dysplasia is the most common cause of sport-related SCD.[158]

A genetic basis for right ventricular dysplasia is also being explored. A large proportion of the cases (up to an estimated 30 to 50 percent currently) appear to have a familial distribution.[45] [156] [157] The inheritance pattern is autosomal dominant except in one geographically isolated cluster that is autosomal recessive.[45] To date, no specific gene abnormalities have been characterized, but a heterogeneous distribution of loci (2 on chromosome 14, and one each on chromosomes 1 and 2) have been identified.[57] [58]

(see Chap. 46) . Before the advent of surgery for valvular heart disease, *aortic stenosis* was a relatively common noncoronary cause of SCD. Campbell reported, in 1968, that 44 of 70 (73 percent) deaths in patients with aortic stenosis were sudden.[159] The advent of safe and effective procedures for aortic valve replacement has reduced the incidence of this cause of sudden death,[160] but patients with prosthetic or heterograft aortic valve replacements remain at some risk for SCD caused by arrhythmias, prosthetic valve dysfunction, or coexistent coronary heart disease.[161] SCD has been reported to be the second most common mode of death after valve replacement surgery, accounting for 62 of 298 deaths (21 percent).[162] The incidence peaked 3 weeks after operation and then plateaued after 8 months. Nonetheless, the risk is still appreciably lower than the historical risk among patients before the advent of valve surgery. In another report analyzing outcome in patients receiving prosthetic valves for isolated severe aortic stenosis, SCD occurred at a rate of only 0.3 percent per year and was responsible for only 18 percent of late deaths.[163] A high incidence of ventricular arrhythmia has been observed during follow-up of patients with valve replacement,[163] [164] especially in those who had aortic stenosis, multiple valve surgery, or cardiomegaly.[164] Sudden death during follow-up was associated with ventricular arrhythmias and thromboembolism. Hemodynamic variables were less predictive. Stenotic lesions of other valves imply much lower risk of SCD. Regurgitant lesions, particularly chronic aortic regurgitation and acute mitral regurgitation, may cause SCD, but the risk is also lower than with aortic stenosis.

Mitral valve prolapse (see Chap. 46) is prevalent, but probably less than previously thought,[164A] and associated with a high incidence of annoying cardiac arrhythmias. However, a risk of SCD, although apparent, is quite low.[165] This uncommon complication appears to correlate with nonspecific ST-T wave changes in the inferior leads on the ECG.[166] In data reviewed from 17 reported instances of SCD in mitral valve prolapse patients, these nonspecific ST-T wave changes were present in six of eight patients who had had prior electrocardiograms.[167] An association with redundancy of mitral leaflets on echocardiogram also has been suggested.[168] Reported associations between QT interval prolongation or preexcitation and SCD in mitral prolapse syndrome are less consistent.[165]

Endocarditis of the aortic and mitral valves (see Chap. 47) may be associated with rapid death resulting from acute disruption of the valvular apparatus, coronary embolism, or abscesses of valvular rings or the septum; however, such deaths are rarely true sudden deaths as conventionally defined. Coronary embolism from valvular vegetations can trigger fatal ischemic arrhythmia on very rare occasions.

CONGENITAL HEART DISEASE.

The congenital lesions most commonly associated with SCD are aortic stenosis (see Chaps. 45 and 46) [145] [169] [170] and communications between the left and right sides of the heart with the Eisenmenger physiology (see Chap. 53) .[171] In the latter the risk of SCD is a function of pulmonary vascular disease severity; also, there is an extraordinarily high risk of maternal mortality during labor and delivery in the pregnant patient with Eisenmenger's syndrome (see Chap. 43) .[172] Potentially lethal arrhythmias and SCD have been described as late complications after surgical repair of complex congenital lesions, particularly tetralogy of Fallot (see Chap. 43) , transposition of the great arteries, and atrioventricular canal.[173] [174] These patients should be followed closely and treated aggressively when cardiac arrhythmias are identified, although the late risk of SCD may not be as high as previously thought.[175]

ELECTROPHYSIOLOGICAL ABNORMALITIES.

Acquired disease of the atrioventricular (AV) node and His-Purkinje system and the presence of accessory pathways of conduction (see Chap. 25) are two groups of structural abnormalities of specialized conduction that may be associated with SCD. Epidemiological studies have suggested that intraventricular conduction disturbances in coronary heart disease are one of the few factors that may increase the proportion of SCD in coronary heart disease.[35] A specific clinical example is the risk of VF during the first 30 days after myocardial infarction in patients with anterior infarctions and bundle branch block. Lie and associates[176] reported that 47 percent of patients who had late hospital VF had had anteroseptal infarcts with bundle branch block and that these 14 were from a total pool of only 40 patients with the combination of bundle branch block and anterior myocardial infarction. Thus there was a 35 percent incidence of VF in this subgroup, which represented only 4.1 percent of a total of 966 myocardial infarctions. This risk persists for 6 weeks after the infarction and then abates.[177] AV block or intraventricular conduction abnormalities were found in 9 of 10 patients who had recurrent VF during hospitalization after resuscitation from prehospital cardiac arrest.[15]

Primary fibrosis (Lenegre's disease)[178] or secondary mechanical injury (Lev's disease)[179] of the His-Purkinje system is commonly associated with intraventricular conduction abnormalities and symptomatic AV block and less commonly with SCD. The identification of people at risk and the efficacy of pacemakers for preventing SCD, rather than only ameliorating symptoms, had been the subjects of debate.[180] [181] However, survival appears to depend more on the nature and extent of the underlying-disease than on the conduction disturbance itself.[182]

Patients with congenital AV block (see Chap. 25) or non-progressive congenital intraventricular block usually have a low risk of SCD.[183] Progressive congenital intraventricular blocks predict a high risk,[183] as does the coexistence of structural congenital defects. A hereditary form has been reported in association with a familial propensity to SCD.[65]

The anomalous pathways of conduction, bundles of Kent in the Wolff-Parkinson-White syndrome, and Mahaim fibers, are commonly associated with nonlethal arrhythmias. However, when the anomalous pathways of conduction have short refractory periods, the occurrence of atrial fibrillation may allow the induction of VF during very rapid conduction across the bypass tract.[184] The incidence of SCD in patients with short refractory period bypass tracts is not yet known. Patients who have multiple pathways appear to be at higher risk of SCD,[184] as do patients with a familial pattern of anomalous pathways and premature SCD.[185] It is important to recognize atrial fibrillation and other markers of risk of SCD in patients with Wolff-Parkinson-White syndrome, such as family history, because catheter ablation procedures are now curative in the vast majority of affected individuals (see Chaps. 23 and 25) .

The Long QT Interval Syndromes

(see also Chaps. 22 , 23 , and 25) . The *congenital* long QT interval syndrome is a functional abnormality caused by hereditary defects of molecular structure in ion channel proteins and apparently is associated with neurogenic triggers that can cause lethal

arrhythmias. [186] [187] [188] [189] [190] [191] [191A] Two hereditary patterns have been described: the much more common autosomal dominant pattern known as the Romano-Ward syndrome[186] [191] and the rare autosomal recessive inheritance pattern, which is associated with deafness, the Jervell and Lange-Neilsen syndrome.[187] Some patients have prolonged QT intervals throughout life without any manifest arrhythmias, whereas others are highly susceptible to symptomatic and potentially fatal ventricular arrhythmias, particularly the torsades de pointes form of VT.[189] [190] [191] [191A] Moreover, genetic studies have demonstrated that penetrance may be low in some families,[45] making electrocardiographic identification of affected members difficult. The relationship between low penetrance and risk of SCD remains undefined, but susceptibility to QT-lengthening effects of drugs might be important in these patients.

Patients at higher risk are characterized by female gender, syncope, and documented torsades de pointes or prior VF, and they require aggressive medical intervention or implantable defibrillators.[191] [192] Moreover, making an effort to identify relatives at risk is an important preventive measure, given the familial pattern of the entity. A recent major advance has been the identification of specific gene defects for the Romano-Ward syndrome at loci on chromosomes 3, 7, 11 and 21.[45] [46] [47] [48] [49] [50] [51] [52] The locus on chromosome 3 encodes the cardiac Na^+ channel; the others encode K^+ channels. A locus mapped to a site on chromosome 4 appears to encode a yet-to-be-identified gene for the Romano-Ward variety of long QT syndrome.[53] The Jervell and Lange-Nielsen form, autosomal recessive with deafness, is caused by inherited abnormalities of *KvLQT1* (chromosome 11) and *minK* (chromosome 21), or homozygous *KvLQT1* mutations. [50] [51] [52] [52A] Multiple specific gene defects have been identified, attesting to the heterogeneity observed in other genetically determined electrophysiological abnormalities.

The *acquired form* of prolonged QT interval may be due to drug effects or individual patient idiosyncrasies (particularly Class IA or Class III antiarrhythmics and psychotropic drugs), electrolyte abnormalities, hypothermia, toxic substances, and central nervous system injury.[193] It also has been reported both in intensive weight reduction programs that involve the use of liquid protein diets[194] and in anorexia nervosa.[195] Lithium carbonate may prolong the QT interval and has been reported to be associated with an increased incidence of SCD in cancer patients with preexisting heart disease.[196] Drug interactions recently have been recognized as a mechanism of prolongation of the QT interval and torsades de pointes.[197] In acquired prolonged QT syndrome, as in the congenital form, the torsades de pointes form of VT is commonly the specific arrhythmia that triggers or degenerates into lethal VF.

ELECTRICAL INSTABILITY RESULTING FROM NEUROHUMORAL AND CENTRAL NERVOUS SYSTEM INFLUENCES.

Catecholamine-dependent lethal arrhythmias in the absence of QT interval prolongation, with control by beta-adrenoceptor blocking agents, have been described.[198] Several central nervous system-related interactions with cardiac electrical stability have been suggested (see Chap. 71) . Lown and coworkers identified psychic stress

as a mediating factor for advanced cardiac arrhythmias and perhaps SCD.[199] Epidemiological data also suggest an association between behavioral abnormalities and the risk of SCD, particularly in women,[83] [84] emotional extremes have been suggested as a triggering mechanism for SCD.[3] [200] Associations between auditory stimulation [145] and auditory auras[201] and SCD have been reported.[145] The auditory abnormalities in some forms of congenital QT prolongation have already been cited.[187]

A variant of torsades de pointes, characterized by short coupling intervals between a normal impulse and the initiating impulse, has been described[202] (Fig. 26-8) . It appears to have familial trends and to be related to alterations in autonomic nervous system activity. The 12-lead ECG demonstrates normal QT intervals, but VF and sudden death are common.

The syndrome of "voodoo death" in developing countries has been studied extensively.[203] [204] There appears to be an association between isolation from the tribe, a sense of hopelessness, severe bradyarrhythmias, and sudden death. With cultural changes in many of these areas, the syndrome has become less amenable to observation and study; however, there do remain pockets of cultural isolation in which the syndrome no doubt still exists.

SUDDEN INFANT DEATH SYNDROME AND SCD IN CHILDREN

The sudden infant death syndrome (SIDS) occurs between birth and 6 months of age, is more common in males, and has an incidence of 0.1 to 0.3 percent of live births.[205] Because of its abrupt nature, a cardiac mechanism has been suspected for many years,[206] but a variety of causes, with central respiratory dysfunction playing a major role, are considered likely.[207] Many cases of SIDS are believed to represent a

Figure 26-8 Short-coupled variant of torsades de pointes. This variant has been observed in people without structural heart disease and normal QT intervals. They are subject to spontaneous episodes of polymorphic ventricular tachycardia (torsades de pointes), which may degenerate into ventricular fibrillation. There is a high risk of sudden death in this uncommon syndrome.

form of "sleep apnea" that, if prolonged, may lead to hypoxia, cyanosis, and cardiac arrhythmias. Experience with "near misses" and the results of respiratory monitoring, in conjunction with the propensity of the syndrome to occur in premature infants, all suggest impaired central nervous system respiratory control reflexes, possibly owing to immaturity.[205] [207] [208] There has recently been interest, however, in the possibility of obstructive apnea as another mechanism.[207] Identification of individual infants at risk is difficult, but the risk does not persist beyond the first 6 months of life. Having infants sleep on their backs has reduced the incidence of SIDS.[208A]

A primary cardiac cause is still considered the basis of this syndrome in some victims.[206] [209] Marino and Kane[210] observed either accessory pathways (two cases) or dispersed or immature AV nodal or bundle branch cells in the annulus fibrosus (four cases) among a group of seven SIDS victims studied by detailed histopathology. A large study of electrocardiograms in infants suggests an association of risk of SIDS with prolonged QT interval.[211] A near-miss survivor was shown to have a de novo mutation of the Na^+ channel gene (SCN5A; chromosome 3), validating the concept that LQT may be one of the mechanisms of SIDS.[211A]

Sudden death in children beyond the age group at risk for SIDS often is associated with identifiable heart disease[144] [212] although one study identified cardiac causes in only 25 percent of sudden natural death victims between the ages of 1 and 21 years.[41] About 25 percent of SCDs in children occur in those who have undergone previous surgery for congenital cardiac disease. Of the remaining 75 percent, more than one half occur in children who have one of four lesions: congenital aortic stenosis, Eisenmenger's syndrome, pulmonary stenosis or atresia, or obstructive hypertrophic cardiomyopathy.[212] Neuspiel and Kuller[41] observed 14 cases of myocarditis among 51 SCDs in children (27 percent).

OTHER CAUSES OF SUDDEN DEATH

SCD in athletes during or after extreme physical activity is infrequent.[213] The majority of such individuals have a previously unrecognized cardiac abnormality, with hypertrophic cardiomyopathy with or without obstruction, valvular aortic stenosis, and occult congenital or acquired coronary artery disease as the most common causes identified after death.[104] [134] [135] [214] [215] A surprisingly large fraction of people who died suddenly during exertion had unsuspected myocarditis, according to a report of a large cohort of US Air Force recruits.[146] A small group of such victims, however, have neither previously determined functional abnormality nor structural abnormalities at postmortem examination.[19] [103] [104] [143] [144] Cardiac trauma (commotio cordis [see Chap. 59]) may be the cause in some.

When no structural or functional basis for cardiac arrest or SCD can be identified, such VF events or deaths are classified as idiopathic.[216] Although long-term survival after an idiopathic potentially fatal event is still unclear, some degree of risk appears to remain.[217] Limited data suggest that higher risk persists primarily in patients with subtle cardiac abnormalities, in contrast to patients who are truly normal.[218] [219] In addition, these events tend to occur in young, otherwise healthy people.

A specific variation of SCD has been observed in southeast Asians. Many years ago syndromes referred to as *bangungut* in young Filipino males,[220] *pokkuri* in young Japanese males,[221] and *nonlaltal* in young Laotian males[222] were reported. In each there was a tendency for sudden death to occur during sleep, and at one time a toxic cause was suspected.[220] [221] Documented cases have now been reported in Laotians who came to the United States after the Vietnam war. The mechanism was identified to be VF in some of these cases; in at least one instance electrophysiological study demonstrated inducible ventricular arrhythmia by programmed electrical stimulation.[223] Pathological examinations have revealed a high incidence of mild to significant cardiomegaly (14 of 18) and a variety of structural abnormalities of specialized conducting tissue.[224] The fact that these cases continue to occur in a new cultural setting suggests that there may be a hereditary predisposition.[244] It has now been suggested that these syndromes are variants of the syndrome of right bundle branch block and anterior ST segment elevation, associated with SCD, reported by Brugada and Brugada.[225]

There also are a number of noncardiac conditions that *mimic* SCD. These include the so-called *cafe coronary,*[226] [227] in which food, usually an unchewed piece of meat, lodges in the oropharynx and causes an abrupt obstruction at the glottis. The classic description of a cafe coronary is sudden cyanosis and collapse in a restaurant, during a meal accompanied by lively conversation. The *holiday heart syndrome* is characterized by cardiac arrhythmias, most commonly atrial, and other cardiac abnormalities associated with acute alcoholic states.[228] It has not been determined whether potentially lethal arrhythmias occurring in such settings account for reported sudden deaths associated with acute alcoholic states.[3] *Massive pulmonary embolism* (see Chap. 52) may cause acute cardiovascular collapse and sudden death; sudden death in severe acute asthmatic attacks, without prolonged deterioration of the patient's condition, is well recognized.[229] Air or amniotic fluid embolism at the time of labor and delivery may cause sudden death on rare occasions, with the clinical picture mimicking SCD.[230] Peripartum air embolism caused by an unusual sexual practice has been reported as a cause of such sudden deaths.[231]

Finally, a number of abnormalities that do not directly involve the heart may cause SCD or mimic it. These include aortic dissection (see Chap. 40) , acute cardiac tamponade (see Chap. 50) , and rapid exsanguination (see Chap. 40) .

Pathology and Pathophysiology

Pathological observations in SCD victims reflect the epidemiological and clinical preponderance of coronary heart disease as the major structural predisposing factor.[232] Liberthson and coworkers[233] reported that 81 percent of 220 autopsied victims of SCD had significant coronary heart disease, defined as more than one coronary vessel with greater than 75 percent stenosis as the primary pathological feature. At least one vessel with more than 75 percent stenosis was found in 94 percent of victims, acute coronary occlusion in 58 percent, healed myocardial infarction in 44 percent, and acute myocardial infarction in 27 percent. These observations are consistent with many other studies of the frequency of coronary disease in sudden death victims. All of the other causes of SCD (see Table 26-2) collectively account for no more than 15 to 20 percent of cases, but they have provided a large base of enlightening pathological data.[64] [143] [234]

THE PATHOLOGY OF SUDDEN DEATH CAUSED BY CORONARY HEART DISEASE

THE CORONARY ARTERIES.

Extensive atherosclerosis is the most common pathological finding in the coronary arteries of victims of SCD (Table 26-3) . In postmortem examinations of 169 hearts, sites of 75 percent or more stenosis were present in three or four major vessels in 61 percent of the hearts studied; two vessels with at least 75 percent stenosis were found in 15 percent; and 24 percent of the hearts had either single-vessel disease or no vessels having lesions producing 75 percent stenosis.[235] A distinctly higher proportion of hearts having three or four vessels with 75 percent stenotic lesions was observed in white men (70 percent) compared with white women (34 percent). In contrast, 58 percent of the hearts of both black men and black women had three or four vessels with 75 percent or more stenoses. Consistent with clinical findings in survivors of out-of-hospital cardiac arrest,[15] there was no special predilection of disease distribution for any specific coronary artery, and there was no quantitative difference between proximal and distal distribution of disease.

TABLE 26-3 -- PATHOLOGICAL FINDINGS IN SUDDEN DEATH DUE TO CORONARY HEART DISEASE

THE CORONARY ARTERIES	VENTRICULAR MYOCARDIUM
Chronic atherosclerosis	Healed myocardial infarction
Acute lesions	Left ventricular hypertrophy
Plaque fissuring/erosion	Ventricular aneurysm
Platelet aggregates	Acute myocardial infarction
Organizing thrombus	
Coronary artery spasm	

Kuller and coworkers[68] pointed out that 90 percent or greater narrowing of at least one coronary artery was found in 77 percent of autopsied victims of sudden *coronary death,* compared with 8 percent of victims of other causes of sudden death. Davies[64] reported that 61 percent of patients dying suddenly because of coronary heart disease had three vessels with 75 percent or more stenosis at any one point; an additional 18 (23 percent) had two vessels with 75 percent or more stenosis. Among 100 age- and sex-matched controls who died of trauma or cerebral tumors, only 27 percent had two- or three-vessel disease, and 52 percent had no vessels with lesions of 75 percent or more. In the same study the majority of sudden deaths caused by coronary heart disease were associated with at least one point of more than 85 percent stenosis, and Davies suggested that this parameter provided the best discrimination between hearts of SCD victims and controls.

Several studies have demonstrated no specific pattern of distribution of coronary artery lesions that preselect for SCD. In a quantitative analysis comparing coronary artery narrowing at postmortem examination in SCD victims and controls, 36 percent of the 5-mm segments of the coronary arteries from the SCD group had 76 to 100 percent cross-sectional area reductions compared with 3 percent in the controls.[236] An additional 34 percent of the sections from the SCD group had 51 to 75 percent reductions in cross-sectional areas. Only 7 percent of the sections from the SCD patients had 0 to 25 percent reductions in cross-sectional areas.

The role of *active coronary artery* lesions, such as plaque fissuring, platelet aggregation, and thrombosis, in the onset of cardiac arrest leading to SCD is becoming clarified, [237] [239] and there appears to be a poor association between risk factor for CAD, coronary artery calcification, and development of plaque fissuring or acute thrombosis.[76A] In one study of 100 consecutive sudden coronary death victims, 44 percent had major (more than 50 percent luminal occlusion) recent coronary thrombi, 30 percent had minor occlusive thrombi, and 21 percent had plaque fissuring.[236] Only 5 percent had no acute coronary artery changes; 65 percent of the thrombi occurred at sites of preexisting high-grade stenoses, and an additional 19 percent were found at sites of more than 50 percent stenosis. In a subsequent study by the same investigators, 50/168 victims (30 percent) had occlusive intraluminal coronary thrombi, and 73 (44 percent) had mural intraluminal thrombi.[238] Singlevessel disease, acute infarction at postmortem examination, and prodromal symptoms were associated with the presence of thrombi.

An overview of the major studies on the incidence of acute thrombotic occlusions, in which the definition of sudden death ranges from 15 minutes to 24 hours, reveals wide variation in the reported frequency of recant coronary thrombosis in sudden death. It ranges from 15 to 64 percent, but the majority of studies that used 6 hours or less as the definition of "sudden" had frequencies of less than 40 percent.[233] [237] [238] [239] [240] Factors that confound the analysis of such data include relations between platelet aggregates and thrombus formation and the spontaneous lysis of clots.

Baba and colleagues[241] reported the presence of *organizing* thrombus in about 31 percent of 121 sudden coronary heart disease deaths. They were commonly associated with sites of more than 75 percent chronic obstruction and with concomitant acute lesions at the same sites, leading to the speculation that clinical events 5 to 7 days before death might create a substrate for fatal acute coronal events. *Coronary artery spasm,* an established cause of acute ischemia, also may cause SCD and is recognizable in rare instances at postmortem examination.[242]

THE MYOCARDIUM.

Myocardial pathology in SCD caused by coronary heart disease reflects the extensive atherosclerosis that usually is present. Studies in victims of both out-of-hospital SCD and from epidemiological sources indicate that healed myocardial infarction is a common finding in SCD victims, with most investigators reporting, frequencies ranging from 40 to more than 70 percent.[8] [232] [242] [244] For example, Newman and coworkers[243] [244] reported that 72 percent of men in a 25- to 44-year age group who died suddenly (24 or fewer hours) with no previous clinical history of coronary heart disease had scars of large (63 percent) or small (less than 1 cm cross-sectional area, 9 percent) areas of healed myocardial necrosis. The incidence of acute myocardial infarction is considerably less, with cytopathological evidence of recent myocardial infarction averaging about 20 percent. This estimate corresponds well with studies in out-of-hospital cardiac arrest survivors, who have an incidence of new myocardial infarction in the range of 20 to 30 percent.

VENTRICULAR HYPERTROPHY.

Myocardial hypertrophy can coexist and interact with acute or chronic ischemia but appears to confer an independent mortality risk.[245] There is not a close correlation between increased heart weight and severity of coronary heart disease in SCD victims[214] ; heart weights are higher in SCD victims than in those whose death is not sudden despite similar prevalence of history of hypertension before death.[8] Hypertrophy-associated mortality risk is also independent of left ventricular function and extent of coronary artery disease.[245] Anderson[120] suggests that left ventricular hypertrophy itself may be a predisposing factor to SCD. Experimental data also suggest increased susceptibility to potentially lethal ventricular arrhythmias in left ventricular hypertrophy with ischemia and reperfusion.[246] A study of massively enlarged hearts (i.e., weighing more than 1000 gm), however, did not indicate an excess incidence of SCD,[247] but the underlying pathology in that study was dominated by lesions that produce volume overload.

SPECIALIZED CONDUCTING SYSTEM IN SCD

Pathological data on the specialized conducting system of victims of SCD are relatively sparse. Lie[248] studied the specialized conducting system of 49 of 120 SCD patients with no previous history of coronary heart disease who died within 6 hours of onset of symptoms. Thirty-nine patients had acute myocardial infarction and 10 did not. Two patients with acute anteroseptal infarctions had hemorrhage and/or infarction involving the AV node and peripheral bundle branches. Luminal narrowing of the artery to the AV node was present in 50 percent, but there were no thromboses of vessels to the specialized conducting system. Evidence of ischemic injury was present with an equal frequency in SCD[248] and myocardial infarction patients.

Fibrosis of the specialized conducting system is a common but nonspecific endpoint of multiple causes. Although this process is associated with AV block or intraventricular conduction abnormalities, its role in SCD is uncertain. Lev's and Lenegre's diseases, ischemic injury caused by small-vessel disease, and numerous infiltrative or inflammatory processes all may result in such changes. In addition, active inflammatory processes such as myocarditis and infiltrative processes such as amyloidosis, scleroderma, hemochromatosis, and morbid obesity all may damage or destroy the AV node and/or bundle of His and result in AV block.[249]

Focal diseases such as sarcoidosis, Whipple's disease, and rheumatoid arthritis also may involve the conducting system (see Chap. 25) . These various categories of conducting system disease have been considered as possible pathological substrates for SCD that may be overlooked because of the difficulty in doing careful postmortem examinations of the conducting system routinely.[249] Focal involvement of conducting tissue by tumors (especially mesothelioma of the AV node but also lymphoma, carcinoma, rhabdomyoma, and fibroma) also has been reported,[249] and rare cases of SCD have been associated with these lesions. It has been suggested that abnormal postnatal morphogenesis of the specialized conducting system may be a significant factor in some SCDs in infants and children.

CARDIAC NERVES AND SCD

Diseases of cardiac nerves have been postulated to have a role in SCD.[250] [251] Neural involvement may be the result of random damage to neural elements within the myocardium (i.e., "secondary" cardioneuropathy), or may be "primary," as in a selective cardiac viral neuropathy.[251] Secondary involvement may be a consequence of ischemic neural injury in coronary heart disease and has been postulated to result in autonomic destabilization, enhancing the propensity to arrhythmias. Some experimental data support this hypothesis, and a

clinical technique for imaging cardiac neural fibers suggests a changing pattern over time after myocardial infarction.[252] [253] [254] Involvement of neural plexuses, with or without conducting system involvement, has been observed at necropsy in 54 percent of patients who died within 24 hours of onset of myocardial infarction.[250] Specific causes for primary cardioneuropathies are less obvious. Viral, neurotoxic, and hereditary causes (e.g., progressive muscular dystrophy and Friedreich's ataxia) have been emphasized.

Disordered extrinsic neural involvement of the heart usually is considered to be functional. Nonetheless, stellate ganglion inflammation has been observed in some tissues removed surgically for symptomatic QT prolongation in hereditary QT syndrome[255] or after myocardial infarction.[256] The possible significance of such extrinsic cardiac neural involvement is not yet clear.

MECHANISMS AND PATHOPHYSIOLOGY

The occurrence of potentially lethal tachyarrhythmias, or of severe bradyarrhythmia or asystole, is the end of a cascade of pathophysiological abnormalities that result from complex interactions between coronary vascular events, myocardial injury, variations in autonomic tone, and/or the metabolic and electrolyte state of the myocardium. There is no uniform hypothesis regarding mechanisms by which these elements interact to lead to the final pathway of lethal arrhythmias. However, Figure 26-9 shows a model of the pathophysiology of SCD, in which the central event is the initiation of a potentially fatal arrhythmia. The risk of this event is conditioned by the presence of *structural abnormalities* and modulated by *functional variations.*[257]

Pathophysiological Mechanisms of Lethal Tachyarrhythmias

CORONARY ARTERY STRUCTURE AND FUNCTION.

Among the 80 percent of SCDs associated with coronary atherosclerosis, the distribution of chronic arterial narrowing has been well defined by pathological studies.[64] [233] [235] However, the specific mechanisms by which these lesions lead to potentially lethal disturbances of electrical stability are poorly understood. Steady-state reductions in regional myocardial blood flow, in the absence of superimposed acute lesions, creates a setting in which alterations in the metabolic or electrolyte state of the myocardium or neural fluctuations may result in loss of electrical stability.[136] Increased myocardial oxygen demand with a fixed supply may be a mechanism of exercise-induced arrhythmias and sudden death during intense physical activity in athletes or others whose heart disease had not previously become clinically manifested.[103] [104] [134] [135] [146] [214] [215] [258] Vasoactive events leading to acute reduction in regional myocardial blood flow in the presence of a normal or previously compromised circulation constitute a common cause of transient ischemia, angina pectoris, arrhythmias, and perhaps SCD.[116] [117] [118] [119] Coronary artery spasm or modulation of coronary collateral flow exposes the myocardium to the double hazard of transient ischemia and reperfusion (Fig. 26-10) .[116] [245] [259] Sites of endothelial disease appear to predispose. [260] Neurogenic influences may play a role, but do not appear to be a sine qua non for the production of spasm. Vessel susceptibility and humoral factors, particularly those related to platelet activation and aggregation,[261] also appear to be important mechanisms.

Transition of stable atherosclerotic plaques to an "active" state because of endothelial damage, with plaque fissuring leading to platelet activation and aggregation followed by thrombosis, is among the more important mechanisms for SCD.[262] In addition to initiating the thrombus, platelet activation produces a series of biochemical alterations that may enhance or retard susceptibility to VF by means of vasomotor modulation. Hammon and Oates studied the effects of thromboxane synthetase inhibitors[263] and demonstrated protection against the induction of experimental VF, presumably by blocking conversion of prostaglandin H_2 (PGH_2) to thromboxane A_2 , which theoretically shunts accumulated PGH_2 to metabolic pathways that favor conversion to prostacyclin. Inhibition of cyclooxygenase by concurrent indomethacin administration gave further support to the hypothesis that PGH_2 shunting to other prostaglandin pathways might protect against VF by prostacyclin production. The possibility that inhibition of prostacyclin production might enhance the risk of VF[263] is supported by the finding from the Aspirin-Myocardial Infarction Study that the incidence of recurrent myocardial infarction was reduced by aspirin but the relative and perhaps absolute numbers of SCD tended to increase.[264]

A number of pieces of indirect evidence support the possibility that more than the mechanical consequences to flow is involved in platelet-activated thrombosis of coronary arteries in SCD. Davies and Thomas[237] pointed out that 95 of 100 subjects who died suddenly (fewer than 6 hours after the onset of symptoms) had acute coronary thrombi, plaque fissuring, or both. This incidence was considerably higher than in many previous reports, but it is noteworthy that only 44 percent of the patients had the largest thrombus occluding 51 percent or more of the cross-sectional area of the involved vessel, and only 18 percent of the patients had more than 75 percent occlusion. This raises questions whether mechanical obstruction to flow was dominant or whether the high incidence of nonoccluding thrombi simply reflected the state of activation of the platelets. The discrepancy between the relatively high incidence of acute thrombi in postmortem studies and the low incidence of evolution of new myocardial infarction among survivors of out-of-hospital VF[19] [265] highlights this question. Spontaneous thrombolysis, a dominant role of spasm induced by platelet products, or a combination may explain this discrepancy.

ACUTE ISCHEMIA AND INITIATION OF LETHAL ARRHYTHMIAS.

The onset of acute ischemia produces immediate electrical, mechanical, and biochemical dysfunction

Figure 26-9 Biological model of sudden cardiac death. Structural cardiac abnormalities are commonly defined as the causative basis for SCD. However, functional alterations of the abnormal anatomic substrate usually are required to alter stability of the myocardium, permitting a potentially fatal arrhythmia to be initiated. In this conceptual model, short- or long-term structural abnormalities interact with functional modulations to influence the probability that premature ventricular contractions (PVCs) initiate ventricular tachycardia or fibrillation (VT/VF). (From Myerburg RJ, et al: A biological approach to sudden cardiac death: Structure, function, and cause. Am J Cardiol 63:1512, 1989.)

Figure 26-10 Life-threatening ventricular arrhythmias associated with acute myocardial ischemia due to coronary artery spasm and with reperfusion. *A,* Continuous lead II electrocardiographic monitor recording during ischemia [time 0 to 55 sec] due to spasm of the right coronary artery (*B*). There is an abrupt transition [time 56 sec to 72 sec] from repetitive ventricular ectopy to a rapid polymorphic, prefibrillatory tachyarrhythmia [time 80 sec to 130 sec] associated with nitroglycerin-induced reversal of the spasm (*C*).

of cardiac muscle (Figs. 26-9 and 26-10) . The specialized conducting tissue is more resistant to acute ischemia than is working myocardium, and therefore the electrophysiological consequences are less intense and delayed in onset in specialized conduction tissue.[266] Experimental studies also have provided data on the long-term consequences of left ventricular hypertrophy and healed experimental myocardial infarction. Tissue exposed to chronic stress produced by long-term left ventricular pressure overload[267] and tissue that has healed after ischemic injury[249] [268] both show lasting cellular electrophysiological abnormalities, including regional changes in transmembrane action potentials and refractory periods. Moreover, acute ischemic injury or acute myocardial infarction in the presence of healed myocardial infarction is more arrhythmogenic than is the same extent of acute ischemia in previously normal tissue.[269] In addition to the direct effect of ischemia on normal or previously abnormal tissue, reperfusion after transient ischemia may cause lethal arrhythmias[116] [270] [271] (Fig. 26-10) . Reperfusion of ischemic areas may occur by three mechanisms: (1) spontaneous thrombolysis, (2) collateral flow from other coronary vascular beds to the ischemic bed, and (3) reversal of vasospasm. Some mechanisms of reperfusion-induced arrhythmogenesis appear to be related to the duration of ischemia before reperfusion.[271] [272] Experimentally, there is a window of vulnerability beginning 5 to 10 minutes after the onset of ischemia and lasting up to 20 to 30 minutes.

ELECTROPHYSIOLOGICAL EFFECTS OF ACUTE ISCHEMIA.

Within the first minutes after experimental coronary ligation there is a propensity to ventricular arrhythmias that abates after 30 minutes and reappears after several hours.[273] The initial 30 minutes of arrhythmias is divided into two periods, the first of which lasts for about 10 minutes and is presumably directly related to the initial ischemic injury. The second period (20 to 30 minutes) may be related either to reperfusion of ischemic areas or to the evolution of differing injury patterns in the epicardial and endocardial muscle. Multiple mechanisms of reperfusion arrhythmias have been observed experimentally.[245] [274] [275]

At the level of the myocyte, the immediate consequences of ischemia, which include loss of integrity of cell membranes with efflux of K^+ , influx of Ca^{2+} , acidosis, reduction of transmembrane resting potentials, and enhanced automaticity in some tissues, are followed by a separate series of changes during reperfusion. Those of particular interest are the possible continued influx of Ca^{2+} which may produce electrical instability[270] [276] ; responses to alpha- and/or beta-adrenoceptor stimulation[252] [253] [277] [278] [279] ; and neurophysiologically induced afterdepolarization as triggering responses for Ca^{2+} -dependent arrhythmias.[275] [278] Other possible mechanisms studied experimentally include formation of superoxide radicals in reperfusion arrhythmias[280] [281] and differential responses of endocardial and epicardial muscle activation times and refractory periods during ischemia or reperfusion.[274] [282]

The importance of the myocardial response to the onset of ischemia has been emphasized, on the basis of the demonstration of dramatic cellular electrophysiological changes during the early period after coronary occlusion.[273] [274] [283] However, the state of the myocardium at the time of onset of ischemia is a critical additional factor. Tissue healed after previous injury appears to be more susceptible to the electrical destabilizing effects of acute ischemia, as is chronically hypertrophied muscle. There are data suggesting that remodeling-induced local stretch, regional hypertrophy, or intrinsic cellular alteration may contribute to this vulnerability. Of more direct clinical relevance is the suggestion that K^+ depletion by diuretics and clinical hypokalemia may make ventricular myocardium more susceptible to potentially lethal arrhythmias.[284] [285]

The association of metabolic and electrolyte abnormalities, as well as neurophysiological and neurohumoral changes,[286] [287] [288] with SCD emphasizes the importance of changes in the myocardial substrate in

the propensity to lethal arrhythmias. Most direct among myocardial metabolic changes in response to ischemia are local acute increase in interstitial K^+ levels to values exceeding 15 mM, a fall in tissue pH to below 6.0, changes in adrenoceptor activity, and alterations in autonomic nerve traffic,[144] all of which tend to create and maintain electrical instability, especially if regional in distribution. Other metabolic changes such as cyclic adenosine monophosphate elevation, accumulation of free fatty acids and their metabolites, formation of lysophosphoglycerides, and impaired myocardial glycolysis also have been suggested as myocardial destabilizing influences.[289]

Local myocardial and systemic influences integrate to establish operational mechanisms. Associations between systemic patterns of autonomic fluctuation are expressed as patterns of heart rate variability,[290] [291] identifying subsets of patients at higher risk for SCD.

TRANSITION FROM MYOCARDIAL INSTABILITY TO LETHAL ARRHYTHMIAS.

The combination of a triggering event and a susceptible myocardium is evolving as a fundamental electrophysiological concept for the mechanism of initiation of potentially lethal arrhythmias (see Figs. 26-5 and 26-9) . The endpoint of their interaction is disorganization of patterns of myocardial activation, often by premature impulses (i.e., the "trigger"), into multiple uncoordinated reentrant pathways (i.e., VF). Clinical,[93] [292] experimental,[268] [293] and pharmacological[292] data all suggest that triggering events in the absence of myocardial instability do not permit the evolution of lethal arrhythmias. Therefore, in the absence of myocardial vulnerability, many triggering events, such as frequent and complex PVCs, may be innocuous.[257]

The onset of ischemia is accompanied by abrupt reduction in transmembrane resting potential and amplitude, and in duration of the action potentials in the affected area,[283] [293a] with little change in remote areas. When ischemic cells depolarize to resting potentials less than -60 mV, they may become inexcitable and of little electrophysiological importance. As they are depolarizing to that range, however, or repolarizing as a consequence of reperfusion, the membranes pass through ranges of reduced excitability, upstroke velocity, and time courses of repolarization. These characteristics result in slow conduction and electrophysiological heterogeneity. These events that occur regionally in ischemic myocardium, adjacent to nonischemic tissue, create a setting for the key elements of reentry--slow conduction and unidirectional block--which makes them vulnerable to reentrant arrhythmias. When premature impulses are generated in this environment, they may further alter the dispersion of recovery between ischemic tissue, chronically abnormal tissue, and normal cells,[269] ultimately leading to complete disorganization and VF. VF is probably not a consequence only of reentry.[144] Rapid-enhanced automaticity caused by ischemic injury to the specialized conducting tissue, or Ca^{2+} channel-triggered activity in partially depolarized tissue, may result in rapid bursts of automatic activity that also could lead to failure of coordinated conduction and VF.

The dispersion of refractory periods produced by acute ischemia, which provides the substrate for reentrant tachycardias and VF, may be further enhanced by a healed ischemic injury. The time course of repolarization is lengthened after healing of ischemic injury[269] and shortened by acute ischemia.[269] [271] [283] The coexistence of the two appears to make the ventricle more susceptible to sustained arrhythmias in some experimental models.[269]

Bradyarrhythmias and Asystolic Arrest

The basic electrophysiological mechanism in this form of arrest is failure of normal subordinate automatic activity to assume pacemaking function of the heart in the absence of normal function of the sinus node and/or AV junction. Bradyarrhythmic and asystolic arrests are more common in severely diseased hearts and probably represent diffuse involvement of subendocardial Purkinje fibers. Systemic influences that increase extracellular K+ concentration, such as anoxia, acidosis, shock, renal failure, trauma, and hypothermia, may result in partial depolarization of normal or already diseased pacemaker cells in the His-Purkinje system, with a decrease in the slope of spontaneous phase 4 depolarization and ultimate loss of automaticity.[294] These processes may produce global dysfunction of automatic cell activity, in contrast to the regional dysfunction more common in acute ischemia. Functionally depressed automatic cells (e.g., owing to increased extracellular K+ concentration) are more susceptible to overdrive suppression. Under these conditions, brief bursts of tachycardia may be followed by prolonged asystolic periods, with further

depression of automaticity by the consequent acidosis and increased local K+ concentration, or by changes in adrenergic tone. The ultimate consequence may be degeneration into VF or persistent asystole.

Pulseless Electrical Activity

Pulseless electrical activity, formerly called electromechanical dissociation (EMD), is separated into *primary* and *secondary forms*. The common denominator in both is continued electrical rhythmicity of the heart in the absence of effective mechanical function. The secondary form includes those causes that result from an abrupt cessation of cardiac venous return, such as massive pulmonary embolism, acute malfunction of prosthetic valves, exsanguination, and cardiac tamponade from hemopericardium. The primary form is the more familiar; in it none of these obvious mechanical factors are present, but ventricular muscle fails to produce an effective contraction despite continued electrical activity (i.e., *failure of electromechanical coupling*).[295] It usually occurs as an end-stage event in advanced heart disease, but it can occur in patients with acute ischemic events or, more commonly, after electrical resuscitation from a prolonged cardiac arrest. Although not thoroughly understood, it appears that diffuse disease, metabolic abnormalities, or global ischemia provides the pathophysiological substrate. The proximate mechanism for failure of electromechanical coupling may be abnormal intracellular Ca^{2+} metabolism, intracellular acidosis, or perhaps adenosine triphosphate depletion.

Clinical Characteristics of the Patient with Cardiac Arrest

The advent of community-based emergency rescue systems, such as those in Seattle[18] and Miami, [265] have demonstrated that only a minority of survivors of out-of-hospital VF had clinical evidence indicating that a new transmural myocardial infarction was associated with the cardiac arrest. In the Seattle study, only one of five survivors had new transmural infarctions.[18] Thus, in the majority of such patients, transient pathophysiological events are responsible for cardiac arrest. The recurrence rate in survivors of out-of-hospital cardiac arrest is low in the subgroup of patients who had documentation of a new transmural myocardial infarction. In contrast, it was found to be 30 percent at 1 year and 45 percent at 2 years in those survivors who did not have a new transmural myocardial infarction.[17] [18] Recurrence rates decreased subsequently,[67] possibly owing in part to long-term interventions. However, it is not known whether this results from a change in the natural history,[296] [297] [298] changes in preventive strategies for underlying disease, or long-term interventions for controlling arrhythmic risk.[25]

Clinical cardiac arrest and SCD are best described in the framework of the same four phases of the event used to

establish definitions (see Fig. 26-1) : prodromes, onset of the terminal event, the cardiac arrest, and progression to biological death or survival.

Prodromal Symptoms

Patients at risk for SCD may have prodromes such as chest pain, dyspnea, weakness or fatigue, palpitations, syncope, and a number of nonspecific complaints. Several epidemiological and clinical studies demonstrated that such symptoms can presage coronary events, particularly myocardial infarction and SCD,[8] [68] [98] and result in contact with the medical system weeks to months before SCD.

In a prospective study in Edinburgh, Scotland, however, only 12 percent of victims of SCD had consulted a physician because of new or worsening angina pectoris during periods of up to 6 months before death.[299] In contrast, 33 percent of myocardial infarction patients had consulted their physicians for this complaint. Nonetheless, 46 percent of victims of SCD had seen a physician within 4 weeks before death, but three fourths of them had sought medical help for complaints that appeared to be unrelated to the heart. Liberthson and associates, associates,[17] in a study of patients successfully resuscitated after out-of-hospital cardiac arrest, noted that 28 percent reported retrospectively that they had had new or changing angina pectoris or dyspnea in the 4 weeks before arrest and that 31 percent had seen a physician during this time but only 12 percent because of these symptoms.

Patients who have chest pain as a prodrome to SCD appear to have a higher probability of intraluminal coronary thrombosis at postmortem examination.[238] Attempts to identify early prodromal symptoms that are more specific for the patient at risk for SCD have not yet been successful. Fatigue has been a particularly common symptom in the days or weeks before SCD in a number of studies,[298] but this symptom is nonspecific. The symptoms that occur within the last hours or minutes before cardiac arrest are more specific for heart disease and may include symptoms of arrhythmias, ischemia, or heart failure.[16] [300] Liberthson and associates[233] reported specific cardiac symptoms at a mean interval of about 3.8 hours before collapse in 24 percent of victims of SCD. However, most studies have reported such symptoms even less commonly, particularly when victims whose deaths were instantaneous are included.[8]

Onset of the Terminal Event

The period of 1 hour or less between acute changes in cardiovascular status and the cardiac arrest itself, which has been defined as the "onset of the terminal event," is a subject about which there is limited information. Reports from ambulatory recordings fortuitously obtained at the time of unexpected cardiac arrest indicate dynamic change in cardiac electrical activity during the minutes or hours before the onset of cardiac arrest.[301] [302] [303] These reports suggest that increasing heart rate and advancing grades of ventricular ectopy are common antecedents of VF. Although these recordings suggest transient electrophysiological destabilization of the myocardium, the extent to which these objective observations are paralleled by clinical symptoms is less well documented. SCDs caused by either arrhythmias or acute circulatory failure mechanisms involve a high incidence of acute myocardial disorders at the onset of the terminal event; such disorders are more likely to be ischemic when the death is due to arrhythmias and to be associated with low-output states or myocardial anoxia when the deaths are due to circulatory failure.[16] [304]

Abrupt, unexpected loss of effective circulation may be caused by cardiac arrhythmias or mechanical disturbances, but the majority of such events that terminate in SCD are arrhythmic. Hinkle and Thaler[304] classified cardiac deaths among 142 subjects who died during a follow-up of 5 to 10 years. Class I was labeled arrhythmic death and Class II was death caused by circulatory failure. The distinction between the two classes was based on whether circulatory failure preceded (Class II) or followed (Class I) the disappearance of the pulse. Among deaths that occurred less than 1 hour after the onset of the terminal illness, 93 percent were due to arrhythmias; in addition, 90 percent of deaths caused by heart disease were initiated by arrhythmic events rather than circulatory failure. Table 26-4 demonstrates

TABLE 26-4 -- DIFFERENCES IN CLINICAL STATUS IMMEDIATELY BEFORE DEATH IN PATIENTS DYING OF ARRHYTHMIA AND CIRCULATORY FAILURE

CLINICAL STATUS IMMEDIATELY BEFORE DEATH	ARRHYTHMIC DEATHS (N=82) (CLASS I)	CIRCULATORY FAILURE DEATHS (N=59) (CLASS II)
Comatose	0/82 (0%)	56/59 (95%)
Standing or actively moving	39/82 (48%)	0/59 (0%)
Terminal arrhythmia		
Ventricular fibrillation	15/18 (83%)	3/9 (33%)
Asystole	3/18 (17%)	6/9 (67%)
Duration of terminal illness		
<1 hour	53/82 (65%)	4/59 (7%)
>24 hours	17/82 (21%)	48/59 (81%)
Nature of terminal illness		
Acute cardiac events	80/82 (98%)	8/59 (14%)
Noncardiac events	1/82 (1%)	51/59 (86%)

Data from Hinkle LE, Thaler HT: Clinical classification of cardiac deaths. Circulation 65:457, 1982. Copyright 1982, American Heart Association.

Hypotension (systolic BP <100 mm Hg)

that deaths caused by circulatory failure occurred predominantly among patients who could be identified as having terminal illnesses (95 percent were comatose), were associated more frequently with bradyarrhythmias than with VF as the terminal arrhythmias, and were dominated by noncardiac events as the terminal illness. In contrast, 98 percent of the arrhythmic deaths were associated primarily with cardiac disorders.

Clinical Features of Cardiac Arrest

The cardiac arrest itself is characterized by abrupt loss of consciousness from lack of adequate cerebral blood flow. It is an event that uniformly leads to death in the absence of an active intervention, although spontaneous reversions occur rarely. The most common cardiac mechanism is VF, followed by bradyarrhythmias or asystole, and sustained VT.[15] Other, less frequent mechanisms include electromechanical dissociation, rupture of the ventricle,[305] cardiac tamponade, acute mechanical obstruction to flow, and acute disruption of a major blood vessel.[3] [64] [143]

The potential for successful resuscitation is a function of the setting in which cardiac arrest occurs, the mechanism of the arrest, and the underlying clinical status of the victim.[306] Closely related to the potential for successful resuscitation is the decision of whether to attempt to resuscitate.[307]

At present there are fewer low-risk patients with otherwise uncomplicated myocardial infarctions weighting in-hospital cardiac arrest statistics than previously.[306] Bedell and coworkers[308] reported that only 14 percent of in-hospital cardiopulmonary resuscitation (CPR) patients were discharged from the hospital alive, and that 20 percent of these died within the ensuing 6 months. Although 41 percent of the patients had suffered an acute myocardial infarction, 73 percent had a history of congestive heart failure and 20 percent had had prior cardiac arrests. The mean age of 70 years (10 years older than the populations in several major prehospital cardiac arrest studies[17] [18] [67]) may have influenced the outcome statistics, but the patient population at risk for in-hospital cardiac arrest was heavily influenced by patients with high-risk complicated myocardial infarction or patients with other high-risk markers. Noncardiac clinical diagnoses were dominated by renal failure, pneumonia, sepsis, diabetes, and a history of cancer. The strong male preponderance consistently reported in out-of-hospital cardiac arrest studies is not present in in-hospital patients, but the better prognosis of VT or VF mechanisms, compared with bradyarrhythmic or asystolic mechanisms, persists (27 percent survival versus 8 percent survival). However, the proportion of arrests that are due to in-hospital VT or VF is considerably less (33 percent), with the combination of respiratory arrest, asystole, and electromechanical dissociation dominating the statistics (61 percent). In a more recent report, de Vos and colleagues[309] observed a 22 percent survival to hospital discharge. Adverse risks were age older than 70 years, prior stroke or renal failure, or heart failure on admission. Better

outcomes were predicted by prior angina pectoris or admission because of ventricular arrhythmias.

The important risk factors for death after CPR are listed in Table 26-5 . The facts that the fraction of out-of-hospital cardiac arrest survivors who are discharged from the hospital alive may now equal or exceed the fraction of in-hospital cardiac arrest victims who are discharged alive[310] and that the postdischarge mortality rate for in-hospital cardiac arrest survivors is higher than that for out-of-hospital cardiac arrest survivors[67] [308] [311] are telling clinical statistics. Not only do they emphasize the success of preventive measures for cardiac arrest in low-risk in-hospital patients, causing those statistics to be dominated by higher-risk patients, but they also emphasize the improvement in pre-hospital and in-hospital care of out-of-hospital cardiac arrest victims.[312]

Cardiac arrest associated with coronary heart disease in the hospitalized elderly patient has a similar outcome. Gulati and colleagues[313] reported that 14 of 52 (27 percent) elderly patients (mean age, 76 years) were successfully resuscitated, although only 9 (17 percent) remained alive after 1 week. Similar outcome was observed in another report comparing patients younger and older than 70 years.[314] Coronary heart disease was the cause in 48 patients (92 percent); 5 of 22 patients (23 percent) with VF arrests survived and only 1 of 19 (5 percent) with asystole survived.[313] Among those patients 70 years of age or older, survival to discharge from hospital after out-of-hospital cardiac arrest was lower (29 percent) than among younger patients (47 percent).[315] However, long-term neurological status, survival, and length of hospitalization were similar among older and younger patients.

Progression to Biological Death

The time course for progression from cardiac arrest to biological death relates to the mechanism of the cardiac arrest, the nature of the underlying disease process, and the delay between onset and resuscitative efforts. Unattended VF characteristically leads to the onset of irreversible brain damage within 4 to 6 minutes, and biological death follows within a matter of minutes. In large series, however, it has been demonstrated that a limited number of victims may remain biologically alive for longer periods and may be resuscitated after delays in excess of 8 minutes before beginning basic life support and in excess of 16 minutes before advanced life support.[316] Despite these exceptions, it is clear that the probability for a favorable outcome deteriorates rapidly as a function of time after unattended cardiac arrest. Younger patients with less severe cardiac disease and the absence of coexistent multisystem disease appear to have a higher probability of a favorable outcome after such delays. Irreversible injury of the central nervous system usually occurs before biological death, and the interval may extend to a period of weeks in those patients who are resuscitated during the temporal gap between brain damage

TABLE 26-5 -- PREDICTORS OF MORTALITY AFTER IN-HOSPITAL CARDIOPULMONARY RESUSCITATION

BEFORE ARREST

Hypotension (systolic BP <100 mm Hg)

and biological death (see Definition, p. 890). In-hospital cardiac arrest caused by VF is less likely to have a protracted course between the arrest and biological death, with patients either surviving after a prompt intervention or succumbing rapidly because of inability to stabilize cardiac rhythm or hemodynamics.[308]

Those patients whose cardiac arrest is due to sustained VT with cardiac output inadequate to maintain consciousness can remain in VT for considerably longer periods, with flow that is marginally sufficient to maintain viability. This allows a longer interval between the onset of cardiac arrest and the end of the period that will allow successful resuscitation. The lives of such patients usually end in VF or an asystolic arrest if the VT is not actively or spontaneously reverted. Once the transition from VT to VF or to a bradyarrhythmia occurs, the subsequent course to biological death is similar to that in patients in whom VF or bradyarrhythmias are the initiating event.

The progression in patients with asystole or bradyarrhythmias as the initiating event is more rapid. Such patients, whether in an in-hospital[308] or out-of-hospital[15] [317] environment, have a very poor prognosis because of advanced heart disease or coexistant multisystem disease. They tend to respond poorly to interventions, even if the heart is successfully paced.[318] Although a small subgroup of patients with bradyarrhythmias associated with electrolyte or pharmacological abnormalities may respond well to interventions, the majority progress rapidly to biological death.[317] The infrequent cardiac arrests caused by mechanical factors such as tamponade, structural disruption, and impedance to flow by major thromboembolic obstructions to right or left ventricular outflow are reversible only in those instances in which the

mechanism is recognized and an intervention is feasible. The vast majority of these events lead to rapid biological death, although prompt relief of tamponade may save some lives.

Hospital Course of Survivors of Cardiac Arrest

The conditions of patients who are resuscitated immediately from *primary* VF associated with acute myocardial infarction usually stabilize promptly, and they require no special management after the early phase of the infarction (see Chap. 35) . The management after *secondary cardiac arrest in myocardial infarction* is dominated by the hemodynamic status of the patient. Among survivors of *out-of-hospital cardiac arrest,* the initial 24 to 48 hours of hospitalization are characterized by a tendency to ventricular arrhythmias, which usually respond well to antiarrhythmic therapy. The overall rate of recurrent cardiac arrest is low, 10 to 20 percent, but the mortality rate in patients who have recurrent cardiac arrests is about 50 percent.[15] [265] [300] Only 5 to 10 percent of in-hospital deaths after out-of-hospital resuscitation are due to recurrent cardiac arrhythmias.[15] [17] [18] Patients who have recurrent cardiac arrest have a high incidence of either new or preexisting AV or intraventricular conduction abnormalities.[15]

The most common causes of death in hospitalized survivors of out-of-hospital cardiac arrest are noncardiac events related to central nervous system injury resulting from the cardiac arrest itself. These include anoxic encephalopathy and sepsis related to prolonged intubation and hemodynamic monitoring lines.[15] [19] Fifty-nine percent of deaths during index hospitalization after prehospital resuscitation have been reported to be due to such causes.[15] Thirty-nine percent of 457 consecutive patients in coma never awakened after admission to the hospital and died after a median survival of 3.5 days.[319] Two thirds of the 61 percent who awakened had no gross deficits, and an additional 21

Figure 26-11 Hemodynamic data from prehospital cardiac arrest victims studied during initial post-arrest hospitalization. These data indicate a broad range of cardiac function and a statistically insignificant difference between EF at entry in long-term survivors and in recurrent cardiac arrest victims. However, patients who died suddenly had significantly higher EF than those who died of non-sudden cardiac causes. (From Myerburg RJ et al: Clinical, electrophysiologic, and hemodynamic profile of patients resuscitated from prehospital cardiac arrest. Am J Med 68:568, 1980.)

percent had persisting cognitive deficits only. Of the patients who did awaken, 25 percent had done so by admission, 71 percent by the first hospital day, and 92 percent by the third day. A small number of patients awakened after prolonged hospitalization. Of the 206 hospital deaths (45 percent of the 457 patients), 80 percent had not awakened before death.

Cardiac causes of delayed death during hospitalization after out-of-hospital cardiac arrest are most commonly related to hemodynamic deterioration, which accounts for about one third of deaths in hospitals.[15] [19] Among all deaths, those that occurred within the first 48 hours of hospitalization usually were due to hemodynamic deterioration or arrhythmias, regardless of the neurological status; later deaths were related to neurological complications. Admission characteristics most predictive of subsequent awakening included motor response, pupillary light response, spontaneous eye movement, and blood glucose level below 300 mg/dl.[320]

Clinical Profile of Survivors of Out-of-Hospital Cardiac Arrest

The clinical features of survivors of out-of-hospital cardiac arrest are heavily influenced by the type and extent of the underlying disease associated with the event. Causation is dominated by coronary heart disease, which accounts for approximately 80 percent of out-of-hospital cardiac arrest in the United States[265] and is commonly extensive. The cardiomyopathies collectively account for another 10 to 15 percent, with all other structural heart diseases, plus functional abnormalities and toxic/environmental causes, accounting for the remainder (see Table 26-2) .[232]

Ambient ventricular arrhythmias have been reported in the majority of survivors of prehospital cardiac arrest who had serial ambulatory monitor recordings.[265] [321] [322] These arrhythmias show trends to higher grades of ventricular ectopy in victims of recurrent cardiac arrest compared with long-term survivors.[67] [322] Repetitive PVCs were strongly associated with a history of congestive heart failure or previous myocardial infarction. The strongest predictors of subsequent mortality were use of digitalis, elevated blood urea nitrogen levels, cerebrovascular accident, previous myocardial infarction, and age; however, the presence of complex PVCs or frequent ectopy (
25 PVCs/hr) added strongly to risk.

LEFT VENTRICULAR FUNCTION.

This is abnormal in the majority of survivors of out-of-hospital cardiac arrest, often severely so, but there is a wide variation, ranging from severe dysfunction to normal or near-normal measurements. From data reported in a number of largeseries, the mean ejection fraction has been in the range of 32 to 35 percent (Fig. 26-11) .[67] The ejection fraction of those who died during follow-up was lower than that of the long-term survivors (38 versus 45 percent, respectively).[15] [67] Patients who died of recurrent cardiac arrest had higher ejection fractions than non-SCD victims. Ritchie and coworkers[323] reported on studies of left ventricular function by radionuclide techniques in 154 survivors of out-of-hospital VF, 91 of whom had both rest and exercise studies. The mean ejection fraction at rest was 40 percent, with 20 percent having values greater than 50 percent. Only 3 of 91 patients (3 percent) studied had a normal increase (>5 percent) in ejection fraction during exertion; 18 percent had normal resting wall motion. The ejection fraction at rest was the best predictor of death during follow-up.[305]

CORONARY ANGIOGRAPHY.

Studies in survivors of out-of-hospital cardiac arrest have shown that as a group this population tends to have extensive disease but no specific pattern of abnormalities. Moderate to severe stenosis of the left main coronary artery was present in only 9 percent in one study,[15] a frequency not different from that observed in the overall population of coronary heart disease patients. Significant lesions in two or more vessels were present in 74 percent of the patients who had any coronary lesion.[15] Among patients who had recurrent cardiac arrests, the incidence of triple-vessel disease was higher than among those who did not.

EXERCISE TESTING.

This is commonly used to evaluate the need for and response to antiischemic therapy in survivors of out-of-hospital cardiac arrest. The incidence of positive tests related to ischemia is relatively low, although termination of testing because of fatigue is common.[265] [323] [324] Mortality during follow-up was greater in patients who had angina or failure of a normal rise in systolic blood pressure occurring during exercise.[324]

Figure 26-12 Time-dependence of recurrences among survivors of cardiac arrest. Actuarial analysis of occurrences among a population of 101 cardiac arrest survivors with coronary artery disease is demonstrated. The risk was highest in the first 6 months (11.2 percent) and then fell to 3.3 percent/6 months for the next three 6-month blocks. After 24 months the rate fell to 0.8 percent/6 months. A low ejection fraction (EF) was the most powerful predictor of death during the first 6 months; subsequently, persistent inducibility during programmed stimulation, despite drug therapy or surgery, was the most powerful predictor. (Modified from Furukawa T, et al: Time-dependent risk of and predictors for cardiac arrest recurrence in survivors of out-of-hospital cardiac arrest with chronic coronary artery disease. Circulation 80:599, 1989. The figure is reproduced from Myerburg RJ, et al: Sudden cardiac death: Structure, function and time-dependence of risk. Circulation 85[Suppl I]:1-2, 1992. Copyright 1992 American Heart Association.)

ELECTROCARDIOGRAPHIC OBSERVATIONS.

Among survivors of out-of-hospital cardiac arrest 12-lead electrocardiograms have proved of value only for discriminating risk of recurrence among those whose cardiac arrest was associated with new transmural myocardial infarction. Patients who develop documented new Q waves. In association with a clinical picture suggesting that an acute ischemic event began before the cardiac arrest itself, are at much lower risk for recurrence.[17] [265] A higher incidence of repolarization abnormalities (ST-segment depression, flat T waves, prolonged QT) occurs in out-of-hospital cardiac arrest survivors than in post-myocardial infarction patients, and these might be markers for increased risk.[325]

BLOOD CHEMISTRY.

Lower serum K^+ levels were observed in survivors of cardiac arrest than in patients with acute myocardial infarction or stable coronary heart disease.[326] The investigators concluded that this was a consequence of resuscitation interventions, rather than a preexisting state owing to chronic diuretic use. Low ionized Ca^{2+} levels, with normal total calcium levels, also were observed during resuscitation from out-of-hospital cardiac arrest.[327] Higher resting lactate levels have been reported in out-of-hospital cardiac arrest survivors than in normal subjects.[328] Lactate levels correlated inversely with ejection fractions and directly with PVC frequency and complexity.

LONG-TERM PROGNOSIS.

Studies from the early 1970s in both Miami [17] and Seattle[18] indicated that the risk of recurrent cardiac arrest in the first year after surviving an initial event was about 30 percent and at 2 years was 45 percent. Total mortality at 2 years was about 60 percent in both studies. In both of these studies, less than half of the patients followed were being treated with long-term antiarrhythmic therapy; beta-adrenoceptor blocker therapy was in its infancy, and Ca^{2+} entry blockers were not yet available. Thus these figures appear to be as close to valid natural history figures as possible. However, they can serve only as historical control figures for current observations, and thus are of limited value, because the risk of recurrent cardiac arrest likely is lower now than it was in the early 1970s.[329] Moreover, the risk of recurrent cardiac arrest/SCD appears to be lower for survivors with hypertrophic cardiomyopathy--about 33 percent during a mean follow-up period of 7 years. [125] The interval risk of recurrent cardiac arrest or SCD is greater during the first 6 to 18 months after the initial event than during later time blocks (i.e., time-dependent risk)[330] (Fig. 26-12) .

Management of Cardiac Arrest

COMMUNITY-BASED INTERVENTIONS

The initial[331] systems responding to out-of-hospital cardiac arrests as developed in the United States were integrated into fire departments as primary emergency rescue systems. They employ paramedical personnel or emergency medical technicians trained in CPR and the use of CPR monitoring equipment, defibrillators, and specific intravenous drug therapy. Although the initial out-of-hospital intervention experience in Miami and Seattle[17] [18] reported in the early 1970s yielded only 14 and 10 percent survivals to discharge, respectively, later improvements in the systems saved more lives[310] (Fig. 26-13) . By the mid 1970s, both had increased survival rates to about 25 percent,[15] [310] and by the early 1980s to 30 percent or more.[310] Survival rates decreased since then, presumably because of the extension of rescue systems into less densely populated regions.[332] Generally, rural areas have lower success rates,[333] and the national success rate for the United States is likely 5 percent or less.

Recent reports from very densely populated areas (i.e., Chicago and New York City) have also provided disturbing

Figure 26-13 Annual number of emergency rescue responses to out-of-hospital cardiac arrest (vertical bars) and the percent of patients discharged alive (solid line), from 1970 through 1992 in Seattle, Washington. Patients were in cardiac arrest when initially examined by emergency rescue personnel. (Courtesy of Leonard A. Cobb, M.D., Seattle, Washington.)

outcomes data. The Chicago study reported that only 9 percent of out-of-hospital cardiac arrest victims survived to be hospitalized and that only 2 percent were discharged alive.[73] Moreover, outcomes in blacks were far worse than in whites (0.8 percent vs. 2.6 percent). The fact that a large majority had bradyarrhythmias, asystole, or pulseless electrical activity on initial emergency medical services contact suggests prolonged times between collapse and emergency medical services arrival and/or absent or ineffective bystander interventions. The New York City report indicated a survival-to-hospital discharge rate of only 1.4 percent.[334] Among those who had bystander CPR, the rate increased to 2.9 percent, and bystander CPR plus VF as the initial rhythm yielded a further increase to 5.3 percent. Finally, for those whose arrests occurred after emergency medical services arrival, the success rate increased further to 8.5 percent. These trends suggest that delays and breaks in the "chain of survival"[312] exert a major negative impact on emergency medical services results in densely populated areas.

IMPORTANCE OF ELECTRICAL MECHANISMS.

The electrical mechanism of out-of-hospital cardiac arrest, as defined by the initial rhythm recorded by emergency rescue personnel, has a powerful impact on outcome. The subgroup of patients who are in sustained VT at the time of first contact, although small, has the best outcome (Fig. 26-14) . Eighty-eight percent of patients in cardiac arrest due to VT were successfully resuscitated and admitted to the hospital alive, and 67 percent were ultimately discharged alive.[15] However, this relatively low-risk group represents only 7 to 10 percent of all cardiac arrests. Because of the inherent time lag between collapse and initial recordings, it is likely that many more cardiac arrests begin as rapid sustained VT and degenerate into VF before arrival of rescue personnel.

Patients who have a bradyarrhythmia or asystole at initial contact have the worst prognosis; only 9 percent of such patients in the Miami study were admitted to the hospital alive and none was discharged.[15] In a later experience there was some improvement in outcome, although the improvement was strictly limited to those patients in whom the initial bradyarrhythmia recorded was an idioventricular rhythm that responded promptly to chronotropic agents in the field.[317] Bradyarrhythmias also have adverse prognostic implications after defibrillation from VF in the field. Patients who developed a heart rate less than 60 beats/min after defibrillation regardless of the specific bradyarrhythmic mechanism, had a poor prognosis, with 95 percent of such patients dying either before hospitalization or in the hospital.[17]

Figure 26-14 Survival after out-of-hospital cardiac arrest as function of the intial electrophysiological mechanism recorded by emergency rescue personnel. The mechanisms among 352 out-of-hospital cardiac arrest victims are separated into three categories: ventricular fibrillation (n = 220; 62 percent), ventricular tachycardia (n = 24; 7 percent), and bradycardia/asystole/pulseless electrical activity (PEA) (n = 108; 31 percent). The white bars illustrate the total number of events in each category. The light-colored bars illustrate the number and per cent of patients who were initially resuscitated in the field and reached the hospital alive in each category, and the dark bars illustrate the percentage of total events in which patients were discharged from the hospital alive for each category. The data are derived from the Miami, Florida, experience.[20]

The outcome in the largest group of patients, those in whom VF is the initial rhythm recorded, is intermediate between sustained VT and bradyarrhythmia and asystole. Figure 26-14 demonstrates that 40 percent of such patients were successfully resuscitated and admitted to the hospital alive and 23 percent were ultimately discharged alive.[15] More recent data indicate improvement in outcome. The proportion of each of the electrophysiological mechanisms responsible for cardiac arrest varied among the earlier reports, with VF ranging from 65 to greater than 90 percent of the study populations, and bradyarrhythmia and asystole ranging from 10 to 30 percent.[15] [300] [310] However, in recent reports from very densely populated metropolitan areas, the ratios of tachyarrhythmic to bradyarrhythmic/pulseless activity events were reversed, and outcomes were far worse.[73] [334]
Processed, ng, 3/27/00

Both improved prehospital care and improvements in in-hospital technology and practices can contribute to better outcomes, as described in the "chain of survival" concept.[312] Of these two general factors; the influence of prehospital care has been studied in more detail. Elsenberg and coworkers[316] compared initial resuscitation and ultimate discharge alive in two subgroups of patients, those who had standard CPR continuously from the arrival of emergency rescue personnel through transport to an emergency department where defibrillation took place and another group in whom paramedics or emergency rescue personnel trained to defibrillate were allowed to do so at the scene of the cardiac arrest. The standard CPR technique resulted in only 23 percent of patients arriving at the hospital alive and 7 percent discharged alive, in contrast to the immediate defibrillation group in which 53 percent arrived at the hospital alive and 26 percent were discharged alive. Subsequent data continue to support the concept that early defibrillation is a key element in improving survival rates (Fig. 26-15) .[310] [316] The importance of early defibrillation for improving outcome is supported by a number of studies.[335] [336] [337] [338] [339] [340] In rural communities, earlier defibrillation by ambulance technicians yielded a 19 percent survival, compared with only 3 percent from standard CPR.[332] In another report, an analysis of the relationship between response delay and survival to hospital discharge revealed a 48 percent survival for response times of 2 minutes or less, compared with less than 10 percent survival when responses are longer than 10 minutes[336] (Fig. 26-16 *A*). Mean response time was approximately 13 minutes, and overall survival was 5 percent. It was 9.5 percent for those in VT or VF on first contact. These observations have motivated the search for strategies that shorten response times, such as deploying automatic external defibrillators in public places[340] and in police vehicles.[337] [338] Preliminary data suggest that this strategy may improve outcome by substantial increments.[338] The rationale for this approach is the documentation that police vehicles arrive at cardiac arrest scenes faster[337] (see Fig. 26-16 *B*).

A second element in prehospital care that appears to contribute to outcome is the role of bystander CPR by laypeople awaiting the arrival of emergency rescue personnel. It has been reported that although there was no significant difference in the percentage of patients successfully resuscitated and admitted to the hospital alive with (67 percent) or without (61 percent) bystander intervention, almost twice as many prehospital cardiac arrest victims were ultimately discharged alive when they had had bystander CPR (43 percent) than when such support was not provided (22 percent).[19] Central nervous system protection, expressed as early regaining

of consciousness, appears to be the major protective element of bystander CPR.[19] The rationale for bystander intervention is further highlighted by the relation between time to defibrillation and survival, when analyzed as a function of time to initiation of basic CPR. It has been reported that more than 40 percent of victims whose defibrillation and other advanced life support activities were instituted more than 8 minutes after collapse survived if basic CPR had been initiated less than 2 minutes after onset of the arrest.[310] A brief period of CPR before defibrillation may also be helpful.[339]

The time from onset of cardiac arrest to advanced life support influences outcome statistics. Improvement in both early neurological status and survival occurs in the patient defibrillated by first responders, even if they are minimally trained emergency technicians allowed to carry out defibrillation as part of basic life support, compared with outcomes associated with awaiting more highly trained paramedics.[335] Thus the time to defibrillation plays a central role in determining outcome in cardiac arrest caused by VF. The development and deployment of automatic external defibrillators (see Chap. 24) In the community holds promise for progress in the future.[340] This technology is a natural extension of lay bystander CPR.

Figure 26-15 Impact of emergency rescue system design and immediate defibrillation on out-of-hospital cardiac arrest survival. *A,* Percent survival to hospital discharge with rescue activities by standard emergency medical technician (EMT) trained in cardiopulmonary resuscitation (CPR), EMTs allowed to defibrillate immediately (EMT_{dfib}), initial response by paramedics (P-MED), two-tiered system with EMT and P-MED, and two-tiered system with EMTs allowed to defibrillate if they are the first responders plus P-MED. Training of first-responders (EMT_{dfib}) and a two-tiered system have the best outcome. *B,* Comparison of outcomes observed in five geographic areas with EMT providing only CPR (dark color) versus EMT trained to defibrillate as first-responders (light color). In each group, there was a marked improvement in outcome when EMT personnel were trained and permitted to defibrillate. (Modified from Ornato JP, Om A: Community experience in treating out-of-hospital cardiac arrest. *In* Akhtar M, Myerburg RJ, Ruskin J N [eds]: Sudden Cardiac Death: Prevalence, Mechanisms and Approach to Diagnosis and Management. Baltimore, Williams & Wilkins, 1994, p 450, with permission of the publisher.)

Figure 26-16 Influence of response time on survival from out-of-hospital cardiac arrest. *A,* The time from onset of cardiac arrest to initial defibrillation attempt is related to 1-month survival, based on data from the Swedish Cardiac Arrest Registry.[336] The cumulative survival rate was 5 percent, and the survival rate for victims whose initial rhythm was ventricular tachycardia (VT) or ventricular fibrillation (VF) was 9.5 percent. The median response time was nearly 13 minutes. Thirty-day survival ranged from a maximum of 48 percent with responses of less than 2 minutes to less than 5 percent for response time greater than 15 minutes. *B,* The potential for faster response systems, based on the Amsterdam Resuscitation Study, is demonstrated, comparing response times of police vehicles with those of conventional emergency medical systems. At the 50th percentile of response times, polices vehicles provided a nearly 5 minute improvement in arrival time (approximately 6 minutes).[337] Preliminary data suggest that improved response times of this type translate to improved survival.[338]

MANAGEMENT OF CARDIAC ARREST AND POST-CARDIAC ARREST CARE

Management of the cardiac arrest victim is divided into five elements: (1) initial assessment, (2) basic life support, (3) advanced life support and definitive resuscitative efforts, (4) post-cardiac arrest care, and (5) long-term management. The first of these can be applied by a broad population base, which includes physicians and nurses as well as paramedical personnel, emergency rescue technicians, and laypeople educated in bystander intervention. The requirements for specialized knowledge and skills become progressively more focused as the patient moves through post-cardiac arrest management and into long-term follow-up care.

Initial Assessment and Basic Life Support

This activity includes both diagnostic maneuvers and elementary interventions. The first action of the person(s) in attendance when an individual collapses unexpectedly must be *confirmation that collapse is due to (or suspected to be due to) a cardiac arrest.* A few seconds of evaluation for response to voice, observation for respiratory movements and skin color, and simultaneous palpation of major arteries for the presence or absence of a pulse, yield sufficient information to determine whether a life-threatening incident is in progress. Once suspected or confirmed, contact with an available emergency medical rescue system (911) should be an immediate priority.[306]

The absence of a carotid or femoral pulse, particularly if confirmed by the absence of an audible heartbeat, is the primary diagnostic criterion and can be performed accurately by trained laypeople. Skin color may be pale or intensely cyanotic. Absence of respiratory efforts, or the presence of only agonal respiratory efforts, in conjunction with an absent pulse, is diagnostic of cardiac arrest; however, respiratory efforts can persist for a minute or more after the onset of the arrest. In contrast, absence of respiratory efforts or severe stridor with persistence of a pulse suggests a primary respiratory arrest that will lead to a cardiac arrest in a short time. In the latter circumstance, initial efforts should include exploration of the oropharynx in search of a foreign body and the Heimlich maneuver, particularly if this occurs in a setting in which aspiration is likely (e.g., restaurant death or "cafe coronary").[226] [227]

THUMPVERSION.

Once the diagnosis of a pulseless collapse (presumed cardiac arrest) is established, a blow to the chest (precordial thump, "thumpversion"[344]) may be attempted by a properly trained rescuer. It has been recommended to be reserved as an advanced life support activity.[306] Caldwell and coworkers supported its use on the basis of a prospective study in 5000 patients.[341] Precordial thumps successfully reverted VF in 5 events, VT in 11, asystole in 2, and undefined cardiovascular collapse in 2 others in which the electrical mechanism was unknown. In no instance was conversion of VT to VF observed. Because the latter is the only major concern of the precordial thump technique, and electrical activity can be initiated by mechanical stimulation in the asystolic heart, the technique is considered optional for responding to a *pulseless* cardiac arrest in the absence of monitoring when a defibrillator is not immediately available. It should not be used unmonitored for the patient with a rapid tachycardia without complete loss of consciousness. For attempted thumpversion in cardiac arrest, one or two blows should be delivered firmly to the junction of the middle and lower thirds of the sternum from a height of 8 to 10 inches, but the effort should be abandoned if the patient does not immediately develop a spontaneous pulse and begin breathing. Another mechanical method, which requires that the patient is still conscious, is "cough-induced cardiac compression"[342] or "cough-version."[341] In the former a conscious act of forceful coughing by the patient in VF may support forward flow by

cyclic increases in intrathoracic pressure[342] ; the same act during sustained VT may cause conversion.[341]

THE ABCs OF CPR.

The goal of this activity is to maintain viability of the central nervous system, heart, and other vital organs until definitive intervention can be achieved. The activities included within basic life support encompass both the initial responses outlined earlier and their natural flow into establishing ventilation and perfusion.[306] This range of activities can be carried out not only by professional and paraprofessional personnel but also by trained emergency technicians and laypeople. Time is the key issue, and there should be minimal delay between the diagnosis and preparatory efforts in the initial response and the institution of basic life support. If only one witness is present, contact of emergency personnel (telephone 911) is the only activity that should precede basic life support.

AIRWAY.

Clearing the airway is a critical step in preparing for successful resuscitation. This includes tilting the head backward and lifting the chin, in addition to exploring the airway for foreign bodies--including dentures--and removing them. The Heimlich maneuver should be performed if there is reason to suspect a foreign body lodged in the oropharynx. This entails wrapping the arms around the victim from the back and delivering a sharp thrust to the upper abdomen with a closed fist.[343] If it is not possible for the person in attendance to carry out the maneuver because of insufficient physical strength, mechanical dislodgment of the foreign body can sometimes be achieved by abdominal thrusts with the unconscious patient in a supine position. The Heimlich maneuver is not entirely benign: Ruptured abdominal viscera in the victim have been reported,[344] as has an instance in which the rescuer disrupted his own aortic root and died.

If there is strong suspicion that respiratory arrest precipitated cardiac arrest, particularly in the presence of a mechanical airway obstruction, a second precordial thump should be delivered after the airway is cleared.

BREATHING.

With the head properly placed and the oropharynx clear, mouth-to-mouth respiration can be initiated if no specific rescue equipment is available. To a large extent, the

procedure used for establishing ventilation depends on the site at which the cardiac arrest occurs. A variety of devices are available, including plastic oropharyngeal airways, esophageal obturators, the masked Ambu bag, and endotracheal tubes. Intubation is the preferred procedure, but time should not be sacrificed even in the in-hospital setting while awaiting an endotracheal tube or a person trained to insert it quickly and properly. Thus, in the in-hospital setting, temporary support with Ambu bag ventilation is the usual method until endotracheal intubation can be carried out, and in the out-of-hospital setting mouth-to-mouth resuscitation is used while awaiting emergency rescue personnel. The effect of the acquired immunodeficiency syndrome and hepatitis B transmission on attitudes toward mouth-to-mouth resuscitation by bystanders and even professional personnel in hospitals is an area of concern,[306] but currently available data assessing risk of infection suggest that it is minimal.[345] The impact of this concern on attitudes toward, and outcomes of, resuscitative efforts has not been assessed.

Conventional CPR ventilatory techniques require that the lungs be inflated 10 to 12 times/min whether one or two rescuers are present.[306] For one-rescuer resuscitation, a pause for ventilation (two breaths) is taken after every 15 chest compressions; for two rescuers, one breath is administered after every fifth compression. Techniques of CPR based on the hypothesis that increased intrathoracic pressure is the prime mover of blood, rather than cardiac compression itself,[346] have been evaluated; the cyclic ventilatory techniques are altered in these procedures (see later). However, clinical applicability is still not clarified.[346A]

CIRCULATION

(Fig. 26-17) . This element of basic life support is intended to maintain blood flow (i.e., circulation) until definitive steps can be taken. The rationale is based on the hypothesis that chest compression allows the heart to maintain an externally driven pump function by sequential emptying and filling of its chambers, with competent valves favoring the forward direction of flow. In fact, the application of this technique has proved successful when used as recommended.[306] The palm of one hand is placed over the lower sternum and the heel of the other rests on the dorsum of the lower hand. The sternum is then depressed with the resuscitator's arms straight at the elbows to provide a less tiring and more forceful fulcrum at the junction of the shoulders and back (see Fig. 26-17) . By using this technique, sufficient force is applied to depress the sternum about 3 to 5 cm, with abrupt relaxation, and the cycle is carried out at a rate of about 80 to 100 compressions/min. [306] Despite the fact that this conventional technique produces measurable carotid artery flow and a record of successful resuscitations, the absence of a pressure gradient across the heart in the presence of an extrathoracic arterial-venous pressure gradient has led to a concept that it is not cardiac compression per se but rather a

Figure 26-17 External chest compression. *Left,* Locating the correct hand position on the lower half of the sternum. *Right,* Proper position of the rescuer, with shoulders directly over the victim's sternum and elbows locked. (From Standards and guidelines for cardiopulmonary resuscitation [CPR] and emergency cardiac care [ECC]. JAMA 255:2906, 1986. Copyright 1986, the American Medical Association.)

pumping action produced by pressure changes in the entire thoracic cavity that optimizes systemic blood flow during resuscitation.[346] [347] Experimental work in which the chest is compressed during ventilations rather than between them (simultaneous compression-ventilation [SCV]) demonstrates better extrathoracic arterial flow.[347] [348] However, increased carotid artery flow does not necessarily equate with improved cerebral perfusion,[346] [349] and the reduction in coronary blood flow caused by elevated intrathoracic pressures by certain techniques[346] may be too high a price for the improved peripheral flow. In addition, a high thoracoabdominal gradient has been demonstrated during experimental SCV,[350] which could divert flow from the brain in the absence of concomitant abdominal binding. The comparative hemodynamics of models of conventional cardiac compression and techniques based on chest (thoracic) compression suggest that blood movement is based on both mechanisms in experimental and clinical studies.[351] Based on these observations, new mechanically assisted techniques, including an active decompression phase (i.e., active compression-decompression [ACD]), are being evaluated for improved circulation during CPR.[352] [353] [354] [355] More clinical studies are needed before establishing their general clinical applications.

Advanced Life Support and Definitive Resuscitation

This next step in the resuscitative sequence is designed to achieve definitive stabilization of the patient.[306] The implementation of advanced life support does not indicate abrupt cessation of basic life support activities but rather a transition from one level of activity to the next. In the past, advanced life support required judgments and technical skills that removed it from the realm of activity of lay bystanders and even emergency medical technicians, limiting these activities to specifically trained paramedical personnel, nurses, and physicians. With further education of emergency technicians, most community-based CPR programs now permit them to carry out advanced life support activities.[306] [316] In addition, the development and testing of automatic external defibrillators that have the ability to sense and analyze cardiac electrical activity, and prompt the user to deliver definitive electrical intervention,[356] provides a role for less highly trained rescue personnel (i.e., police, ambulance drivers) and even trained lay bystanders[340] in advanced life support.

The general goals of advanced life support are to revert the cardiac rhythm to one that is hemodynamically effective, optimize ventilation, and maintain and support the restored circulation. Thus, during advanced life support, the patient's cardiac rhythm is promptly cardioverted or defibrillated as the first priority, if appropriate equipment is immediately available. It has been observed that a few seconds of closed-chest cardiac compression may enhance odds of survival when administered immediately before defibrillation in the field.[339] After the intial attempt to restore a hemodynamically effective rhythm, the patient is intubated and oxygenated, if needed, and the heart is paced if a bradyarrhythmia or asystole occurs. An intravenous line is established to deliver medications. After intubation, the goal of ventilation is to reverse hypoxemia and not merely achieve a high alveolar P_{O_2} . Thus oxygen rather than room air should be used to ventilate the patient; if possible, the arterial P_{O_2} should be monitored. Respirator support in hospital and an Ambu bag by means of an endotracheal tube or face mask in the out-of-hospital setting usually are used.

DEFIBRILLATION-CARDIOVERSION

(Fig. 26-18) . Rapid conversion to an effective cardiac electrical mechanism is a key step for successful resuscitation.[310] Delay should be

Figure 26-18 Advanced life support for ventricular fibrillation (VF) and pulseless ventricular tachycardia (VT). If initial defibrillation fails, the patient should be intubated and intravenous (IV) access immediately established while cardiopulmonary resuscitation (CPR) is continued. Epinephrine, 1 mg intravenously, should be administered, and may be repeated several times with additional attempts to defibrillate with 360-Joule shocks. If the conversion is still unsuccessful, epinephrine may be administered again, although it is unlikely that higher doses would provide any further benefit. [358] Sodium bicarbonate should be administered at this time only if the patient is known to be hyperkalemic, but intravenous antiarrhythmic drugs should be tried (see text). Additional attempts to defibrillate should follow the administration of each drug attempted. (Modified from Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Guidelines for cardiopulmonary resuscitation and emergency cardiac care. JAMA 268:2172, 1992. Copyright 1992 American Medical Association. See original reference for further details.)

minimal, even when conditions for CPR are optimal. When VF or a rapid VT is recognized on a monitor or by telemetry, defibrillation should be carried out immediately with a shock of 200 joules. Up to 90 percent of VF victims weighing up to 90 kg can be successfully resuscitated with a 200-joule shock,[357] and a 300- or 360-joule shock may be used if this is not successful.[306] Failure of the initial shocks to successfully cardiovert to an effective rhythm is a poor prognostic sign.[306] After failure of three shocks up to a maximum of 360 joules of energy, CPR should be continued while the patient is intubated and intravenous access achieved. Epinephrine, 1 mg intravenously, is administered and followed by repeated defibrillation attempts at 360 joules. Epinephrine may be repeated at 3- to 5-minute intervals with defibrillator shocks in between, but high-dose epinephrine does not appear to provide added benefit.[358]

Simultaneously, the rescuer should focus on ventilation to correct the chemistry of the blood, efforts that render the heart more likely to reestablish a stable rhythm (i.e., improved oxygenation, reversal of acidosis, and improvement of the underlying electrophysiological condition). Although adequate oxygenation of the blood is crucial in the immediate management of the metabolic acidosis of cardiac arrest, additional correction can be achieved if necessary by intravenous administration of sodium bicarbonate. This is recommended for circumstances of known or suspected preexisting bicarbonate-responsive causes of acidosis, certain drug overdoses, and prolonged resuscitation runs.[306] The more general role for bicarbonate during cardiac arrest has been questioned,[359] [360] but in any circumstance, much less sodium bicarbonate than was previously recommended is adequate for treatment of acidosis in this setting. Excessive quantities can be deleterious.[360] Although some investigators have questioned the use of sodium bicarbonate at all because risks of alkalosis, hypernatremia, and hyperosmolality may outweigh its benefits,[361] the circumstances cited may benefit from administration of 1 mEq/kg of sodium bicarbonate while CPR is being carried out. Up to 50 percent of this dose may be repeated every 10 to 15 minutes during the course of CPR.[362] When possible, arterial pH, P_{O_2} , and P_{CO_2} should be monitored during the resuscitation.

PHARMACOTHERAPY.

For the patient who continues to have VT or VF despite direct-current (DC) cardioversion after epinephrine, electrical stability of the heart may be achieved by intravenous administration of antiarrhythmic agents during continued resuscitation (see Fig. 26-18). As a matter of routine, lidocaine is tried first as an intravenous bolus, at a dose of 1.0 to 1.5 mg/kg (see Chap. 23) , with the dose repeated in 3 to 5 minutes in those in whom resuscitation remains unsuccessful or unstable electrical activity persists. If a total loading dose of 3.0mg/kg has failed to support successful defibrillation, intravenous amiodarone,[363] or bretylium tosylate[364] should be given next. Intravenous amiodarone is administered as an initial dose of 150 mg over 10 minutes (15 mg/min), or 15 mg/kg over 10 minutes, followed by an infusion of 10 mg/kg/day. Another regimen is 1 mg/min over the next 3 hours, followed by a maintenance dose of 0.5 mg/min over the next 18 hours, and for several days as necessary (see Chaps. 23 and 25) . Additional bolus dosing, to a maximum of 500 mg, can be tried if the intial bolus is unsuccessful. Bretylium tosylate is given as an initial bolus of 5 mg/kg IV and repeated 5 minutes later at a dose of 5 to 10 mg/kg if the initial bolus is tolerated hemodynamically but unsuccessful electrophysiologically.

If failure to control the arrhythmia continues, procainamide hydrochloride[365] may be tried as a 30-mg/min intravenous infusion, to a maximum of 17 mg/kg, but it is unlikely to be successful if the other drugs have failed (see also Chap. 23 for other acceptable intravenous dosing regimens of these drugs). In patients in whom acute hyperkalemia is the triggering event for resistant VF, or who have hypocalcemia or are toxic from Ca^{2+} -entry blocking drugs, 10 percent calcium gluconate, 5 to 20 ml infused at a rate of 2 to 4 ml/min, may be helpful.[306] Calcium should not be used routinely during resuscitation,[366] even though ionized Ca^{2+} levels may be low during resuscitation from cardiac arrest. [327] Some resistant forms of polymorphic VT or torsades de pointes, rapid monomorphic VT or ventricular flutter (rate 260/min), or resistant VF may respond to intravenous beta-blocker therapy (propranolol, 1 mg IV boluses to a total dose of up to 15 to 20 mg; metoprolol, 5 mg IV, up to 20 mg) or intravenous $MgSO_4$ (1 to 2 gm IV given over 1 to 2 minutes).

BRADYARRHYTHMIC AND ASYSTOLIC ARREST; PULSELESS ELECTRICAL ACTIVITY

(Fig. 26-19) . The approach to the patient with bradyarrhythmic or asystolic arrest, or pulseless electrical activity, differs from the approach to patients with tachyarrhythmic events (VT/VF).[306] Once this form of cardiac arrest is recognized, efforts should focus first on establishing control of the cardiorespiratory status (i.e., continue CPR, intubate, and establish intravenous access), then reconfirming the rhythm (in two leads if possible), and finally taking actions that favor the emergence of a stable spontaneous rhythm or attempt to pace the heart. Possible reversible causes, particularly for bradyarrhythmia and asystole, should be considered and excluded (or treated) promptly. These include hypovolemia, hypoxia, cardiac tamponade, tension pneumothorax, preexisting acidosis, drug overdose, hypothermia, and hyperkalemia. Epinephrine (1.0 mg IV every 3 to 5 minutes) and atropine (1.0 to 2.0 mg intravenously) are commonly used in an attempt to elicit spontaneous electrical activity or increase the rate of a bradycardia. These have had only limited success, as have intravenous isoproterenol infusions in doses up to 15 to 20 mug/min. In the absence of an intravenous line, epinephrine (1 mg [i.e., 10 ml of a 1:10,000 solution]) may be given by the intracardiac route, but there is danger of coronary or myocardial laceration. Sodium bicarbonate, 1 mEq/kg, may be tried for known or strongly suspected preexisting hyperkalemia or bicarbonate-responsive acidosis.

Pacing of the bradyarrhythmic or asystolic heart has been limited in the past by the unavailability of personnel capable of carrying out such procedures at the scene of cardiac arrests. With the development of more effective external pacing systems in recent years, the role of pacing and its influence on outcome must now be reevaluated. Unfortunately all data to date suggest that the *asystolic* patient continues to have a very poor prognosis, despite new techniques.[308] [317] [318] [367]

The published standards for CPR and emergency cardiac care[306] included a series of teaching algorithms to be used as guides to appropriate care. Figures 26-18 and 26-19 provide the algorithms for VF and pulseless VT, asystole (or cardiac standstill), and pulseless electrical activity. These general guides are not to be interpreted as inclusive of all possible approaches or contingencies. The special circumstance of CPR in pregnant women requires additional attention to effects of drugs on the gravid uterus and the fetus, mechanical and physiological influences of pregnancy on efficacy of CPR, and risk of complications such as ruptured uterus and lacerated liver.[368]

STABILIZATION.

As soon as electrical resuscitation from VT, VF, bradycardia, asystole, or pulseless electrical activity is achieved, the focus of attention shifts to maintaining a stable electrical and hemodynamic status. For electrical stability, a continuous infusion of an effective drug, based on observation during the cardiac arrest run, is commonly used. This may be lidocaine, 1 to 4 mg/min depending on size and clinical factors; intravenous amiodarone, 10 mg/kg/day (if this drug was required in the initial resuscitation); or procainamide, 2 to 4 mg/min. Occasionally, a continuous infusion of propranolol or esmolol is used. Catecholamines

Figure 26-19 Advanced cardiac life support for patients with severe bradyarrhythmia, asystole, and pulseless electrical activity. The patient in any of these states should have continued cardiopulmonary resuscitation (CPR) and be intubated, with intravenous (IV) access established, before pharmacological treatment. The initial activity is to confirm persisting asystole or to attempt to assess blood flow in patients thought to have pulseless electrical activity. An immediate attempt should be made to identify and treat reversible or treatable causes of these forms of cardiac arrest. Epinephrine is generally administered first, and atropine and/or bicarbonate may be subsequently administered. An attempt to pace the heart with an external device or an intracardiac pacing catheter is advisable, although usually not successful, except for certain reversible bradyarrhythmias. (Modified from Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Guidelines for cardiopulmonary resuscitation and emergency cardiac care. JAMA 268:2172, 1992. Copyright 1992, American Medical Association. See original reference for further details.)

are used in cardiac arrest not only in an attempt to achieve better electrical stability (e.g., conversion from fine to coarse VF, or increasing the rate of spontaneous contraction during bradyarrhythmias), but also for their inotropic and peripheral vascular effects. Epinephrine is the first choice among the catecholamines for use in cardiac arrest because it increases myocardial contractility, elevates perfusion pressure, may convert electromechanical dissociation to electromechanical coupling, and improves chances for defibrillation. Because of its adverse effects on renal and mesenteric flow, norepinephrine is a less desirable agent despite its inotropic effects. When the chronotropic effect of epinephrine is undesirable, dopamine or dobutamine is preferable to norepinephrine for inotropic effect. Isoproterenol may be used for the treatment of primary or postdefibrillation bradycardia when heart rate control is the primary goal of therapy intended to improve cardiac output. Calcium chloride, 2 to 4 mg/kg, is sometimes used in patients with pulseless electrical activity that persists after administration of catecholamines. The efficacy of this intervention is uncertain. Stimulation of alpha-adrenoceptors may be important during definitive resuscitative efforts.[369] For instance, the alpha-adrenoceptor-stimulating effects of epinephrine and higher dosages of dopamine, producing elevation of aortic diastolic pressures by peripheral vasoconstriction with increased cerebral and myocardial flow,[369] have recently been reemphasized.[346] [369]

Post-Cardiac Arrest Care

For successfully resuscitated cardiac arrest victims, whether the event occurred in or out of hospital, post-cardiac arrest care includes admission to an intensive care unit and continuous monitoring for a minimum of 48 to 72 hours. Some elements of post-arrest management are common to all resuscitated patients, but prognosis and certain details of management are specific for the clinical setting in which the cardiac arrest occurred. The major management categories include (1) primary cardiac arrest in acute myocardial infarction, (2) secondary cardiac arrest in acute myocardial infarction, (3) cardiac arrest associated with noncardiac disorders, and (4) survival after out-of-hospital cardiac arrest.
Processed, ng, 3/27/00

PRIMARY CARDIAC ARREST IN ACUTE MYOCARDIAL INFARCTION

(see also Chap. 35) . VF in the absence of preexisting hemodynamic complications (i.e., primary VF) currently is less common in hospitalized patients than the 15 to 20 percent incidence that existed before availability of cardiac care units (CCUs). Early aggressive treatment--antiarrhythmic, thrombolytic, or both--probably contribute, and those events that do occur are almost always successfully reverted by prompt interventions in properly equipped emergency departments or CCUs.[370] After resuscitation, patients are often maintained on a lidocaine infusion at 2 to 4 mg/min. Antiarrhythmic support is usually discontinued after 24 hours if arrhythmias do not recur (see Chaps. 23 and 25) . The occurrence of VF in the early phase of myocardial infarction is not an indication for subsequent electrophysiological testing or long-term antiarrhythmic or device therapy.[371] Rapid VT producing the clinical picture of cardiac arrest in acute myocardial infarction is treated similarly; its intermediate and long-term implications are the same as those of VF. Cardiac arrest caused by bradyarrhythmias or asystole in acute inferior wall myocardial infarction, in the absence of primary hemodynamic consequences, is uncommon and may respond to either atropine or pacing. The prognosis is good, with no special long-term care required in most instances. Rarely, symptomatic bradyarrhythmias that require permanent pacemakers persist in survivors. In contrast to inferior myocardial infarction, bradyarrhythmic cardiac arrest associated with large anterior wall infarctions (and AV or intraventricular block) has a very poor prognosis (see Chap. 35) .

(see also Chap. 35) . This is defined as cardiac arrest occurring in association with, or as a result of, hemodynamic or mechanical dysfunction. The immediate mortality among patients in this setting ranges from 59 to 89

percent, depending on severity of the hemodynamic abnormalities and size of the myocardial infarction.[372] Resuscitative efforts commonly fail in such patients, and when they are successful, the post-cardiac arrest management often is difficult. When secondary cardiac arrest occurs by the mechanisms of VT or VF, lidocaine in standard dosages is used, although the dose may have to be reduced in the presence of severe heart failure.[373] Other antiarrhythmics may have to be used in addition to or instead of lidocaine if complex arrhythmias persist or cardiac arrest recurs. The success of interventions and prevention of recurrent cardiac arrest relate closely to the outcome of managing the hemodynamic status. The incidence of cardiac arrest caused by bradyarrhythmias or asystole, or by electromechanical dissociation, is higher in the secondary form of cardiac arrest in acute myocardial infarction.[374] Such patients usually have large myocardial infarctions and major hemodynamic abnormalities and may be acidotic and hypoxemic. Even with aggressive therapy the prognosis after a bradyarrhythmic or asystolic arrest in such patients is very poor, and patients are resuscitated only rarely from electromechanical dissociation. All patients in circulatory failure at the onset of arrest are in a high-risk category, with only a 2 percent survival rate among hypotensive patients in one study.[308]

CARDIAC ARREST AMONG IN-HOSPITAL PATIENTS WITH NONCARDIAC ABNORMALITIES.

These patients fall into two major categories: (1) those with life-limiting diseases such as malignancies, sepsis, organ failure, end-stage pulmonary disease, and advanced central nervous system disease; and (2) those with acute toxic or proarrhythmic states that are potentially reversible. In the former category, the ratio of tachyarrhythmic to bradyarrhythmic cardiac arrest is low,[308] and the prognosis for surviving cardiac arrest is poor. Although the data may be somewhat skewed by the practice of assigning "do not resuscitate" orders to patients with end-stage disease, available data for attempted resuscitations show a poor outcome. Bedell and associates[308] reported that only 7 percent of cancer patients, 3 percent of renal failure patients, and no patients with sepsis or acute central nervous system disease were successfully resuscitated and discharged from the hospital. For the few successfully resuscitated patients in these categories, post-arrest management is dictated by the underlying precipitating factors.

Most antiarrhythmic drugs (see Chap. 23) ,[189] [190] [192] [375] [376] a number of drugs used for noncardiac purposes,[192] [196] [197] and electrolyte disturbances can precipitate potentially lethal arrhythmias and cardiac arrest. Quinidine[377] and the other Class IA antiarrhythmic drugs, and the Class III drugs, are proarrhythmic by the generation of torsades de pointes, the Class IA drugs generally producing a dose-independent idiosyncratic response and the Class III drugs, a dose-dependent adverse effect. The Class IC drugs rarely cause torsades de pointes[378] but cause excess SCD risk in patients with recent myocardial infarction,[95] possibly by interacting with ischemia or other transient risk factors.[379] [380] [381] Among other categories of drugs,[192] [382] the phenothiazines, tricyclic antidepressants, lithium,[196] terfenadine interacting with ketoconazole, or other blockers of enzymes in the hepatic P450 system),[197] pentamidine,[383] cocaine,[384] erythromycin,[385] and cardiovascular drugs that are not antiarrhythmics--such as lidoflazine--are recognized causes. Beyond these, a broad array of pharmacological and pathophysiological/metabolic causes have been reported.[382] Hypokalemia, hypomagnesemia, and perhaps hypocalcemia are the electrolyte disturbances most closely associated with cardiac arrest. Acidosis and hypoxia can potentiate the vulnerability associated with electrolyte disturbances. Proarrhythmic effects may be prewarned by prolongation of the QT interval, although this electrocardiographic change is not always present.[194]

Cardiac arrest caused by *torsades de pointes* is managed by intravenous administration of magnesium, pacing, or treatment with isoproterenol and removal of the offending agent. Class IC drugs may cause a rapid, sinusoidal VT pattern, especially among patients with poor left ventricular function. This VT has a tendency to recur repetitively after cardioversion until the drug has begun to clear; this proarrhythtmic form has been controlled by propranolol in some patients.[386]

When the patient's condition can be stabilized until the offending factor is removed (e.g., proarrhythmic drugs) or corrected (e.g., electrolyte imbalances, hypothermia), the prognosis is excellent. The recognition of torsades de pointes (see Chap. 25) and the identification of its risk by prolongation of the QT interval in association with the offending agent are helpful in managing these patients. No long-term prophylaxis is required in most patients. In contrast, beta-adrenoceptor blocking drugs are required for long-term management of patients with congenital forms of long QT interval syndromes,[190] [191A] and implantable defibrillators are used for the subgroups who have manifested life-threatening arrhythmias or have strong family histories of SCD[192]

POST-CARDIAC ARREST CARE IN SURVIVORS OF OUT-OF-HOSPITAL CARDIAC ARREST.

The initial management of survivors of out-of-hospital cardiac arrest centers on stabilizing the cardiac electrical status, supporting hemodynamics, and providing supportive care for reversal of organ damage that has occurred as a consequence of the cardiac arrest. The in-hospital risk of recurrent cardiac arrest is relatively low, and arrhythmias account for only 10 percent of in-hospital deaths after successful prehospital resuscitation.[15] [316] However, the mortality rate during the index hospitalization is 50 percent, indicating that nonarrhythmic mortality dominates the mechanisms of early postresuscitation deaths (30 percent hemodynamic; 60 percent central nervous system related).[15] Antiarrhythmic therapy is used in an attempt to prevent recurrent cardiac arrest in patients who demonstrate residual electrophysiological instability and recurrent arrhythmia during the first 48 hours of post-arrest hospitalization. Lidocaine is the drug of choice for initial management, followed by intravenous amiodarone, procainamide, or bretylium if initial drug therapy fails. Patients who have either preexisting or now atrioventricular or intraventricular conduction disturbances are at particularly high risk for recurrent cardiac arrest.[15] The routine use of temporary pacemakers has been evaluated in such patients but was not found to be useful for preventing early recurrent cardiac arrest. Invasive techniques for hemodynamic monitoring are used in a patient whose condition is unstable but not routinely for those whose condition is stable on admission.

Respiratory support by conventional methods is used as necessary. During the convalescent period, attention to central nervous system status, including physical rehabilitation, is of primary importance to an optimal outcome. Bass[387] summarized the neurological sequelae to cardiac arrest, including a review of various interventions. Management of other organ system injury (e.g., renal, hepatic), as well as early recognition and treatment of infectious complications, also contributes to ultimate survival.

LONG-TERM MANAGEMENT OF SURVIVORS OF OUT-OF-HOSPITAL CARDIAC ARREST.

When the survivor of an out-of-hospital cardiac arrest has awakened and achieved electrical and hemodynamic stability, usually between 1 and 7 days after the event, decisions must be made regarding the nature and extent of the work-up required to establish a long-term management strategy. The goals of the work-up are to identify the specific etiological and triggering cause of the cardiac arrest,[381] clarify the functional status of the patient's cardiovascular system, and establish long-term therapeutic strategies (Fig. 26-20) . The extent of the work up

Figure 26-20 General management algorithm for cardiac arrest survivors. Flow diagram for the diagnostic activities and initial management of survivors of out-of-hospital cardiac arrest. After return of spontaneous circulation and achieving clinical stabilization, attempts are made to establish etiology, mechanism, and initial therapy. Patients who have cardiac arrest associated with new acute transmural myocardial infarction or with reversible nonstructural arrhythmogenic factors are managed by conventional techniques and usually do not require specialized studies. All patients with chronic ischemic heart disease in the absence of a precipitating new transmural myocardial infarction, and many with nonischemic forms of heart disease, enter a diagnostic pathway that includes cardiac catheterization, various imaging studies, and special studies as indicated. Ischemic risk and ventricular dysfunction are managed by conventional techniques. Diagnostic electrophysiologic evaluation and therapy are carried out next (see text for details). In some patients with nonischemic heart disease, definitive medical or surgical management is possible without specialized studies. (Modified from Myerburg RJ, Kessler KM: Management of patients who survived cardiac arrest. Mod Concepts Cardiovasc Dis 55:61, 1996.)

is largely dictated by the degree of central nervous system recovery and the factors already known to have contributed to the cardiac arrest. For instance, patients who have limited return of central nervous system function usually do not undergo extensive work-ups, and patients whose cardiac arrests were triggered by an acute transmural myocardial infarction have work-ups similar to those for other patients with acute myocardial infarction (see Chap. 35) .

Survivors of out-of-hospital cardiac arrest not associated with acute myocardial infarction who have good return of neurological function undergo extensive diagnostic work-ups to define long-term therapy. The work-up normally includes cardiac catheterization with coronary angiography, an evaluation of functional significance of coronary lesions by stress-imaging techniques, determination of functional and hemodynamic status, and estimation of baseline susceptibility to life-threatening

arrhythmias and of the expected response to long-term therapy.

GENERAL CARE.

The general management of survivors of cardiac arrest is determined by the specific cause and the pathophysiology of the underlying process (see Fig. 26-20) . For patients with ischemic heart disease (who constitute approximately 80 percent of cardiac arrest victims), control of episodes of myocardial ischemia, optimization of therapy for left ventricular dysfunction, and attention to general medical status are all addressed. Ischemic risk may be managed by catheter intervention techniques, surgically, or medically, depending on the anatomy and physiology of the disease process. Although there are limited data suggesting that coronary bypass surgery may improve the recurrence rate and total mortality rates after survival from out-of-hospital cardiac arrest[388] [389] [390] no properly controlled prospective studies have validated this impression for either bypass surgery or angioplasty. Moreover, a randomized trial of prophylactic implantable defibrillators versus usual therapy in patients undergoing coronary bypass surgery in the absence of a history of cardiac arrest or other life-threatening arrhythmia or arrhythmia markers (the Coronary Artery Bypass Graft Patch Trial [CABG-Patch]), revealed no benefit of implantable defibrillators in those patients.[390] Therefore, indications for surgery are limited to two groups of patients: (1) those who have a generally accepted indication for angioplasty or surgery[265] (including a documented ischemic mechanism for the cardiac arrest) and (2) those who meet specific criteria for surgery directed to arrhythmia control.[391]

Medical antiischemic therapy includes nitrates, beta-adrenoceptor blocking agents, and Ca^{2+} entry blockers. Beta-adrenoceptors may have an antianginal effect and also influence the role of sympathetic nervous system activity on the genesis of potentially lethal arrhythmias. Although no placebo-controlled data are available to define a benefit of beta-blockers or other medical antiischemic therapy for long-term survival after out-of-hospital cardiac arrest, Morady and colleagues[114] suggested that medical or surgical antiischemic therapy, rather than antiarrhythmic therapy, should be the primary approach to long-term management of the subgroup of prehospital cardiac arrest survivors in whom transient myocardial ischemia was the inciting factor. Moreover, in an uncontrolled observation comparing cardiac arrest survivors who had ever been on beta-blockers after the index event with those who had not received the drug, a significant improvement in long-term outcome was observed among those who had received beta-blockers.[392]

In a report from the Coronary Artery Surgery Study (CASS), Holmes and associates[393] compared sudden death rates in medically and surgically treated patients in the CASS registry. This study did not directly address the issue of surgery in survivors of out-of-hospital cardiac arrest, but there was a significant difference at 5 years, with a 98 percent sudden death-free survival in the surgical group versus 94 percent in the medical group ($p < 0.0001$). The differences were minimal in the groups with one- or two-vessel disease and no history of heart failure, but expanded to 91 and 69 percent, respectively. In patients with three-vessel disease and a history of heart failure. The question of how to apply these data to indications for surgery for cardiac arrest survivors remains unanswered at this time. The problem is further confounded by the fact that assignment of the 13,476

analyzable patients to medical versus surgical groups was not randomized (i.e., it was based instead on clinical judgment). Further evaluation of the specific role of revascularization procedures after out-of-hospital cardiac arrest is needed.

The long-term management of the consequences of left ventricular dysfunction by conventional means such as digitalis preparations and chronic diuretic use has been evaluated in several studies. Data from the Multiple Risk Factor Intervention Trial (MRFIT) suggested a higher mortality rate in the special intervention group,[394] presumably related to diuretic use and R+ depletion, and other data regarding the relation between K+ depletion and arrhythmias have focused attention on routine use of such drugs. Although the facts currently are far from conclusive, it is advisable that diuretic use should be accompanied by careful monitoring of electrolytes. The use of digoxin in survivors of out-of-hospital cardiac arrest should be tailored to specific indications for left ventricular dysfunction.[395] [396] [397]

THERAPY FOR PREVENTION OF CARDIAC ARREST AND SUDDEN CARDIAC DEATH

Therapeutic strategies to prevent SCD can be classified into five categories: (1) prevention of recurrent events in survivors of cardiac arrest or hemodynamically comprising VT (secondary prevention); (2) prevention of an initial event among patients at high risk because of advanced heart disease with ejection fractions less than or equal to 35 percent (primary prevention); (3) primary prevention in patients with less advanced common or uncommon structural heart diseases and ejection fractions more than 35 percent; (4) primary prevention in patients with structurally normal hearts, subtle or minor structural abnormalities, or molecular disorders associated with electrophysiological properties that establish risk for ventricular arrhythmias; and (5) primary prevention among the general population (Table 26-6) .

Four modes of antiarrhythmic therapy, which are not mutually exclusive, may be considered for patients at risk of cardiac arrest: antiarrhythmic drug therapy, surgery, catheter ablation, and implantable defibrillator therapy. The choice of therapy is based on estimation of potential benefit determined by individual patient evaluation and available efficacy and safety data.

Antiarrhythmic Drug Strategies

The earliest approach, historically, to the management of risk of out-of-hospital cardiac arrest and VT with hemodynamic compromise was the use of pharmacological agents. This approach was based initially on the assumption that the high frequency of ambient ventricular arrhythmias constituted a triggering mechanism for potentially lethal arrhythmias and that electrophysiological instability of the myocardium that predisposed to potentially lethal arrhythmias could be modified by antiarrhythmic drugs.[292] [321] The therapeutic strategy for the former was the suppression of ambient ventricular arrhythmias by antiarrhythmic drug, and the strategy for the latter was the suppression of inducibility of VT or VF during programmed electrical stimulation studies. Observational data suggested that suppression of ambient arrhythmias, identified on ambulatory recorders,[398] could be achieved by the empirical use of amiodarone,[399] [400] beta-adrenergic blocking agents,[392] [401] or membrane-active antiarrhythmic drugs.[292] [321] [392] Based on historical expectations, it was suggested, but not proven, that such suppressive techniques would improve mortality risk. For the membrane-active drugs, the observations that post-cardiac arrest survivors who had been treated with Class I antiarrhythmic drugs had a worse outcome than those who were not treated served as a challenge to the concept of benefit,[392] and such skepticism was further supported by the results of CAST,[95] [97] which demonstrated that the Class I antiarrhythmic drugs at best were neutral (moricizine) and at worst did harm (flecainide, encainide). In contrast, beta-blocker therapy might have some benefit in such patients,[392] [401] and amiodarone might also be effective. [399] [400]

Unfortunately, all of the early data regarding these assumptions and therapeutic approaches were observational or retrospective, and no concurrently controlled data were available. Nonetheless, a *relative* benefit of amiodarone over Class I drugs was suggested by the Cardiac Arrest in Seattle, Conventional versus Amiodarone Drug Evaluation (CASCADE), a post-cardiac arrest survivor study comparing these two therapeutic classes.[400] Another study, the Electrophysiological Study Versus Electrocardiographic Monitoring (ESVEM) trial, designed to compare the value of ambulatory monitoring to programmed electrical stimulation techniques for predicting therapeutic outcome,[402] suggested that the Class III antiarrhythmic drug sotalol was superior to Class I membrane-active antiarrhythmic agents for patients with life-threatening ventricular tachyarrhythmias but provided no comparison to amiodarone or beta blockers.[403] In summary, ambient arrhythmia suppression as a technique for prediction reduction of risk enjoyed a short period of popularity for such patients but in time yielded to

TABLE 26-6 -- CATEGORIES OF THERAPEUTIC STRATEGIES FOR PREVENTION OF RECURRENT CARDIAC ARREST AND SUDDEN CARDIAC DEATH (SCD)

PREVENTION TARGETS	CLINICAL EXAMPLES	ESTIMATE OF RISK	DATA SOURCES
Secondary*	Survivors of cardiac arrest; VF/VT	High	Observational; RCT: (+) control
Primary			
Advanced structural cardiac disease	CAD/DCM, EF<35%	High	Observational; RCT: (+) control RCT: (-) control
Lower-grade structural disease	CAD/DCM, EF 35% RVD, sarcoidosis, HCM	Variable	Observational; RCT: Subgroup analyses
Functional cardiac disorders	Long QT syndrome, Brugada syndrome	Variable	Observational
SCD as primary event in CAD	Family history of SCD, risk factors for CAD	Low	Epidemiological; genetic (?)

DCM=dilated cardiomyopathy; EF=ejection fraction; HCM=hypertrophic cardiomyopathy; RVD=right ventricular dysplasia; VF=ventricular fibrillation; VT=ventricular tachycardia.

*Much of the data for secondary prevention, identified as a high-risk population because of the occurrence of a prior cardiac arrest, has derived from observational data and, more recently, from randomized controlled trials (RCT), all of which have employed an active-therapy control group [(+) control], comparing outcomes between groups treated with implantable cardioverter-defibrillators (ICDs) and antiarrhythmic drugs (see Table 26-7) .

RCTs are not feasible for primary prevention in patients with these lower-risk conditions. However, some information can be acquired from subgroup analysis of larger studies. Decisions for ICD implantation in these patients must be judgment-based rather than evidence-based. Recent suggestions of familial clustering of sudden death, as a specific expression of coronary artery disease (CAD), raises the question of primary prevention in patients at risk for SCD using epidemiological and perhaps genetic markers in the future.

the apparent greater benefits of amiodarone, and perhaps beta blockers,[404] prescribed empirically.

Ambulatory Electrocardiographic Recording and Empirical Therapy

The development of reliable methods of analysis of ambulatory recordings led some investigators to study suppressibility of ambient arrhythmias as a specific and individualized means of evaluating drug therapy. Graboys and associates[398] reported outcome in a group of 123 patients with advanced ambient ventricular arrhythmias who had survived one or more cardiac arrests. Suppression of specific forms of complex ventricular ectopy (then defined as three or more consecutive beats and early-cycle PVCs) identified on either ambulatory recording or exercise testing was accompanied by a significantly lower mortality rate compared with those in whom suppression was not achieved. The mortality rate was more than 80 percent at 3 years in patients whose complex forms could not be suppressed, compared with a nearly 90 percent survival among the patients in whom complex PVCs were suppressed.

Other investigators provided data suggesting the possibility that ambient arrhythmia suppression might be equivalent to suppression of inducible arrhythmias by programmed electrical stimulation for predicting outcome.[402] [405] Moreover, analysis of the CAST data base also suggested an association between the ease of suppression of ambient ventricular arrhythmias and survival,[406] supporting the notion of a meaningful relationship between *suppressibility* of ambient arrhythmias and survival. Data from the Electrophysiologic Study versus Electrocardiographic Monitoring (ESVEM) trial[402] did demonstrate a minor trend favoring outcome prediction by programmed stimulation compared with ambulatory recording techniques in coronary artery disease patients, most evident in the interval of the first 2 years of follow-up. For nonischemic diseases, no benefit was observed. In another randomized trial comparing invasive and noninvasive techniques among patients who had symptomatic tachyarrhythmias, the invasive technique was superior in prevention of recurrences.[407] However, the qualifying arrhythmias were not restricted to cardiac arrests, and therefore the applicability to cardiac arrest survivors remains uncertain.

Although a higher fraction of patients will have successful suppression of the targeted arrhythmias using ambulatory recording techniques, compared with programmed electrical stimulation, more patients will have electrically inducible arrhythmias to use as targets than ambient ventricular ectopy.[402] [403] [405] Thus, programmed electrical stimulation still maintains preference as the method of choice for estimating antiarrhythmic efficacy against life-threatening arrhythmias. The question of whether *suppressibility* rather than *suppression*[406] is the meaningful marker remains uncertain for both techniques.

Finally, empirical antiarrhythmic therapy, predominantly amiodarone, has been observed to have a relative benefit in several studies.[399] [400] Whether it has an absolute mortality benefit can only be determined by placebo-controlled data, which are not available. Moreover, several controlled trials have now suggested that empirical amiodarone is less effective than implantable defibrillators in reducing risk of death among survivors of life-threatening arrhythmic events (Antiarrhythmics Versus Implantable Defibrillators [AVID], Canadian Implantable Defibrillator Study [CIDS], and the Cardiac Arrest Study of Hamburg [CASH]), particularly when the ejection fraction is less than 35 percent (see Chap. 25) .[408] [409] [410]

Programmed Electrical Stimulation

The second major antiarrhythmic strategy was based on suppression of inducibility of sustained ventricular arrhythmias, considered to be a marker of risk during electrophysiological testing.[411] [412] The use of programmed electrical stimulation to identify benefit on the basis of suppression of inducibility by an antiarrhythmic drug gained popularity for evaluating long-term therapy among survivors of out-of-hospital cardiac arrest.[411] [412] [413] [414] [415] [416] [417] [418] It evolved as the preferred method of management despite concerns about the sensitivity and specificity of the various pacing protocols[419] and the extent to which the myocardial status at the time of the programmed electrical stimulation study reflected that present at the time of the clinical cardiac arrest.[420] Nonetheless, among a series of six early reports,[411] [412] [413] [414] [415] [416] induction of sustained VT or VF at baseline study ranged from 31 to 79 percent and successful suppression of inducibility ranged from 18 to 78 percent. The mortality rate during follow-up of those patients in whom inducibility was suppressed by antiarrhythmic therapy ranged from 0 to 22 percent (mean= 9 percent), compared with the range of 22 to 78 percent (mean= 43 percent) in those patients in whom VT or VF was still inducible on any antiarrhythmic therapy.

The evaluation of these data is significantly influenced by definitions of inducibility and noninducibility and also by the clinical features of the patient population in each of the studies, which varied considerably. In most reports, VF or sustained VT could *not* be induced in 25 to 30 percent of the patients. It is probable that differences are determined in part by the numbers of patients who have anatomically discrete versus ischemic substrates among various populations studied.[313] Careful attention to protocol details, anatomy of the disease processes, and definitions of inducibility may help clarify these discrepancies in the future. For the present, however, 50 to 70 percent of unselected survivors of cardiac arrest caused by VF or sustained VT can be anticipated to have inducible sustained ventricular arrhythmias. For the subgroup with discrete ventricular aneurysms, more than 90 percent may have inducible ventricular arrhythmias.[265] [413] The clinical significance of induced VF, as opposed to a sustained VT or VF that evolves from an induced VT, is often difficult to interpret. Induced VF is commonly considered nonspecific when the induction protocol is aggressive and the patient has not had a clinical cardiac arrest. However, most accept it as a valid positive endpoint among survivors of out-of-hospital cardiac arrest, especially when the protocol is less aggressive (e.g., double extra stimuli or triple extra stimuli in which coupling intervals are not excessively short), and the induction is reproducible. Most investigators agree that inducibility of a sustained *clinical* arrhythmia provides an indication of risk. Drug-suppression of inducibility was also considered to indicate a beneficial endpoint for therapy, but the results of the Multicenter Unsustained Tachycardia Trial (MUSTT) now provides skepticism about that conclusion[421] (see Primary Prevention of Out-of-Hospital Cardiac Arrest; see also Chaps. 23 and 25) .

The implications of induced nonsustained forms of VT are more controversial. Although it has been suggested that induction of nonsustained ventricular rhythms may indicate risk, it generally is considered nonspecific in the absence of structural heart disease or when an aggressive protocol is used.[419] The use of the suppression of nonsustained arrhythmias as an endpoint of therapy is not considered valid.

The significance of *non*inducibility at baseline electrophysiological stimulation testing in relation to risk and long-term management also is controversial. Opinions have ranged from the conclusion that patients free of inducible ventricular arrhythmias are electrophysiologically stable and require no long-term antiarrhythmic therapy[114] [411] [416] [422] [423] to the other extreme that such patients remain at risk but do not have an objective endpoint of therapy by this method, and therefore must be treated by other techniques.[67] [265] [321] [398] Despite these conflicting opinions, it is generally accepted now that survivors of cardiac arrest with ejection fraction of 35 percent or less remain at high risk

regardless of inducibility status.[418] [423] [424] [425] Some out-ofhospital cardiac arrests can be clearly demonstrated to result from transient ischemia, and this subgroup requires only antiischemic therapy.[114]

In the six early reports cited, 24-month mortality in patients without inducible VT or VF ranged from 3 to 38 percent, which was higher than in patients in whom inducible arrhythmias could be suppressed by antiarrhythmic therapy (average 9 percent) but lower than in those in whom inducibility could not be suppressed (average 43 percent). In one study, left ventricular ejection fraction discriminated high risk from low risk in patients with no inducible ventricular arrhythmias; in another, reversible causes of the index event predicted noninducibility.[418] [423] A later report[426] demonstrated that patients in whom ventricular arrhythmias could not be induced were at risk for recurrent cardiac arrest, although the risk was lower than would be anticipated for patients in whom arrhythmias could be induced. There was a 12 percent event rate at 24 months in the patient population reported. When patients with structural heart disease and low ejection fractions do not have inducible VT or VF after cardiac arrest, it is generally agreed that high risk of recurrence persists.

Surgical Intervention Strategies

Direct antiarrhythmic surgical techniques (see Chaps. 23 and 25) for control of recurrent sustained VT have included map-guided endocardial resection,[427] encircling endocardial ventriculotomy,[428] and intraoperative map-guided cryoablation techniques.[429] This last approach is limited primarily to those patients who have inducible, hemodynamically stable sustained monomorphic VT during electrophysiological testing and are unresponsive to drug therapy and have suitable ventricular and coronary artery anatomy. Whereas the outcome using this technique has been much better than that of previous techniques,[429] it has very little applicability to survivors of out-of-hospital cardiac arrest because the type of arrhythmia favoring this surgical approach is infrequently observed among cardiac arrest survivors. The less specific antiarrhythmic surgical techniques used previously demonstrate less efficacy and higher mortality. In contrast, coronary revascularization procedures have a clearly defined role for cardiac arrest survivors in whom an ischemic mechanism was responsible for the event and suitable surgical anatomy is present.[114] [430]

Catheter Ablation Therapy

The use of catheter ablation techniques to treat ventricular tachyarrhythmias has been most successful for the benign focal tachycardias that originate in the right ventricle or left side of the interventricular septum (see Chaps. 23 and 25) . Treatment of higher-risk ventricular tachyarrhythmias has been a goal that has met with only limited success. For VT caused by bundle branch reentrant mechanisms, which occur in cardiomyopathies as well as other structural cardiac disorders, ablation of the right bundle branch to interrupt the reentrant cycle has been quite successful.[431] However, this has limited applicability to the large number of patients with structural heart disease at risk for SCD or those who have survived a cardiac risk. For patients with reentrant tachycardias originating in the left ventricle in the presence of coronary artery disease, there had been increasing success as mapping procedures have improved,[432] but the application of this technique as preventive therapy for recurrent cardiac arrest or for primary prevention of cardiac arrest is limited at the present time. The nature of the underlying disease predicts that multiple reentrant pathways may be present, or may emerge over time, limiting the predictability of success of the procedure when it is used for potentially lifesaving strategies. On the other hand, the use of catheter ablation techniques for patients with ICDs who are having multiple tachyarrhythmic events is an appropriate and helpful treatment strategy.[433] Thus, catheter ablation therapy presently must be viewed as largely adjunctive for patients receiving other forms of therapy, rather than as a preferred primary therapy for prevention of SCD.

Implantable Defibrillators

The development of reliable ICDs added a new dimension to the management of patients at high risk of cardiac arrest. Since early reports by Mirowski and coworkers[434] and Echt and colleagues,[435] multiple observational studies have confirmed that ICDs could achieve sudden death rates consistently less than 5 percent at 1 year and total death rates in the 10 to 20 percent range among populations who have high mortality risks, as predicted by mortality surrogates such as historical controls or time to first appropriate shock.[436] [437] [438] [439] Yet, determination of the value of ICDs in terms of their mortality benefit remained uncertain and debated for many years.[440] [441] [442] Sixteen years elapsed between the first clinical use of an implantable defibrillator[443] and publication of the first major randomized clinical trial comparing implantable defibrillator therapy to antiarrhythmic drug therapy.[444] Through that period of time, reports had documented the ability of implantable devices to successfully revert potentially fatal arrhythmias but could not identify a valid relative or absolute mortality benefit because of confounding factors such as competing risks for sudden and nonsudden death[25] and determination of whether appropriate shocks represented the interruption of an event that would have been fatal.[441] Despite these limitations, ICD therapy continued to increase its relative position among other forms of therapy for survivors of out-of-hospital cardiac arrest and, to a lesser extent, for those considered to be at high risk for a primary cardiac arrest based on specific clinical markers. With publication of the results of the Multicenter Antiarrhythmic Drug Versus Implantable Defibrillator Trial (MADIT),[444] information on the relative benefit of defibrillators over antiarrhythmic drug therapy (largely amiodarone) became available (Table 26-7) . The outcome demonstrated a 59 percent reduction in relative risk of total mortality at 2 years of follow-up (54 percent cumulative) and a 19 percent reduction in absolute risk of dying at 2 years of follow-up. One year later, the first adequately powered secondary prevention trial of ICDs versus antiarrhythmic drugs was published. This study, the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, demonstrated a 27 percent reduction in relative risk of total mortality at 2 years of follow-up, with an absolute risk reduction of 7 percent.[408] The AVID was followed shortly by reports of two other studies--CIDS[409] and CASH[410] --both limited by the power of the enrollment numbers but suggesting trends toward similar benefits (see Table 26-7) . As a consequence of the secondary prevention trials, ICDs have emerged as the preferred therapy for survivors of out-of-hospital cardiac arrest or hemodynamically important VT. A subgroup analysis of AVID suggested that the benefit is limited to patients with ejection fractions of less than 35 percent; above that value the outcome with either amiodarone or an ICD might be equivalent.[425]

Whereas the studies cited documented the ability of implantable devices to successfully revert potentially fatal arrhythmias, and subsequently showed a relative benefit over amiodarone in some patient groups, the absence of placebo-controlled trials still prevents the quantitation of the true magnitude of any mortality benefit, because of the inability of positive-controlled trials to identify the absolute benefit of an intervention.[445] Despite these limitations, implantable

TABLE 26-7 -- SUMMARY OF MAJOR IMPLANTABLE CARDIOVERTER DEFIBRILLATOR (ICD) TRIALS FOR PREVENTION OF SUDDEN CARDIAC DEATHS

TRIAL	STUDY GROUP	2-YEAR OUTCOMES			
		Control	ICDS	Rel RR	Abs RR
Secondary Prevention *

Two other large primary prevention trials are in progress (along with a number of smaller trials): the Sudden Cardiac Death in Heart Failure Trail (SCD-HeFT) and the Multicenter Automatic Defibrillator Implantation Trial-2 (MADIT-2).

Abs RR=absolute risk reduction; CHF=congestive heart failure; EF=ejection fraction; EP=electrophysiological; MI=myocardial infarction; NS=nonsustained; Rel RR=relative risk reduction; SAECG=signal-averaged electrocardiogram; VF=ventricular fibrillation.

See also Table 24-17 .

*Three major randomized trials for secondary prevention among survivors of out-of-hospital cardiac arrest, or high-risk ventricular tachycardia (VT), have been completed: the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, the Canadian Implantable Defibrillator Study (CIDS), and the Cardiac Arrest Study of Hamburg (CASH). Each used an active control, randomized design comparing ICDs to antiarrhythmic drug (AAD) therapy, primarily amiodarone. The cumulative data, as well as the individual data from the larger studies, support the notion that the ICD is preferable to drug therapy for this high-risk population. However, the large relative benefits translated to more modest absolute benefits, with a large residual risk among the ICD-treated groups in each study.

Three primary prevention trials among patients presumed to be at high risk but who have not had spontaneous life-threatening ventricular arrhythmias have been completed: the Multicenter Automatic Defibrillator Implantation Trial (MADIT), the Multicenter Unsustained Tachycardia Trial (MUSTT), and the coronary artery bypass surgery/implantable defibrillator trial (CABG-Patch). MADIT showed an advantage of ICD therapy over AAD therapy, MUSTT showed a superiority of electrophysiologically (EP) guided evaluation leading to ICD therapy compared with that leading to drug therapy, and

defibrillator therapy is now the preferred therapy for survivors of cardiac arrest at risk for recurrences. Major questions still unanswered include the relative benefit of amiodarone versus defibrillators among lower risk subgroups of survivors of out-of-hospital cardiac arrest, the role of beta blockers, and the role of antiischemic surgical and medical therapy as definitive approaches.

A much larger issue, and one that has not yet been defined, is the use of implantable defibrillators among patients thought to be at various levels of risk for cardiac arrest but who have not yet had an event. A number of trials are in progress in an attempt to determine whether preventive defibrillator therapy is an effective means of preventing the first cardiac arrest. Many of the trials are studying cost efficacy in addition to medical efficacy. One of the more important strategies being tested is a comparison of defibrillator therapy and empirical amiodarone therapy to placebo in heart failure patients without symptomatic arrhythmias or a history of cardiac arrest (see Chaps. 23 and 25) .

Application of Therapeutic Strategies to Specific Patient Groups

Secondary Prevention After Surviving Cardiac Arrest

Among survivors of out-of-hospital cardiac arrest not associated with acute transmural myocardial infarction, the risk of recurrent cardiac arrest was reported to be 30 percent at 1 year and 45 percent at 2 years in the early 1970s.[17] [18] Total mortality among these patients exceeded 50 percent at 2 years. The value of these data resides in the fact that they represent a reasonable estimate of natural history risk, since most of the interventions now available were not then in use. Moreover, the risk estimates were consistent in two independent large studies. Although no data are available to determine whether this widely quoted natural history risk has remained the same during subsequent decades, it is generally accepted that the risk of recurrence is still substantial, despite general therapies such as reperfusion during acute myocardial infarction, revascularization in patients with chronic coronary artery disease, use of beta-adrenergic blocking agents,[446] and long-term afterload reduction.

As populations of cardiac arrest survivors began to accumulate from community-based emergency rescue activities, long-term therapeutic strategies intended to reduce recurrent cardiac arrest rates and total mortality risks quickly emerged as a mandate for clinical investigators. The problem that impinges on all long-term strategies, however, is the lack of a reliable current natural history denominator against which to compare the results of interventions. This is a consequence of ethical concerns about withholding therapy in a placebo control study model for patients at such high risk of dying,[445] in conjunction with the likelihood that general therapies used in such patients may also improve total mortality risk. Earlier approaches to long-term therapy centered around the use of antiarrhythmic drug therapy, largely guided by the results of the electrophysiologic testing and the empirical use of antiarrhythmic drugs, particularly amiodarone. During the evolution of therapeutic strategies, various observational and positive-controlled studies suggested first that suppression of inducible ventricular arrhythmias yielded a better outcome than failure of suppression,[411] [412] [413] [414] [415] [416] then that amiodarone was better than Class I antiarrhythmic drugs,[399] [400] and finally that ICDs were better than amiodarone. [408] [409] [410] Therefore, ICD therapy has emerged as preferred therapy, absent absolute benefit data. Electrophysiological testing for secondary prevention--once routine--is now considered of questionable necessity.[408] [421] Unfortunately, none of the large trials over many

Figure 26-21 Relative and absolute benefit of implantable cardioverter-defibrillators (ICDs) in AVID. *A,* ICD-treated subgroup had an 18 percent mortality at 2 years versus 25 percent in drug-treated group, a 27 percent *relative* reduction among the population having events. *B,* When relative reduction is extrapolated to total target population, *absolute* reduction of fatal events among total population is 7 percent. (From Myerburg RJ, Mitrani R, Interian A Jr, Castellanos A: Interpretation of outcomes of antiarrhythmic clinical trials: Design features and population impact. Circulation 97:1514, 1998. Copyright 1998, American Heart Association.)

years have provided a satisfactory and finite answer to this dilemma.

Antiarrhythmic surgery enjoyed a short period of popularity for secondary prevention, limited by the observation that surgical antiarrhythmic procedures appeared to provide benefit to only a small subset of such patients.[447] As the implantable defibrillator came into wider use, it also began to supplant pharmacological antiarrhythmic approaches, with the possible exception of amiodarone, even before the randomized clinical trials demonstrated relative ICD benefit. In the late 1990s, the AVID study report provided the first information from a large randomized clinical trial supporting the use of ICDs as preferred therapy for secondary prevention of cardiac arrest,[408] as noted earlier (Fig. 26-21) . A prior small study from the Netherlands[448] had suggested benefit of ICDs over conventional therapy, but the numbers in that study had been too small to be considered definitive. Two other studies--CIDS[409] and CASH[410] --suggested benefit but were underpowered.

Primary Prevention of Out-of-Hospital Cardiac Arrest with Advanced Heart Disease

Because of the frequency with which SCD is the initial clinical expression of underlying structural heart disease, there has been a long-standing interest in therapeutic strategies targeted to primary prevention. After the disappointing outcome of CAST[95] [97] and the disturbing suggestions of lack of efficacy or adverse effects of the Class I antiarrhythmic drugs generally when used for primary or secondary prevention,[96] [392] interest shifted to the use of amiodarone and implantable defibrillators. Two major trials of amiodarone in post-myocardial infarction patients,[449] [450] one of which required ejection fractions less than 40 percent, demonstrated no total mortality benefit, even though both trials demonstrated antiarrhythmic benefit, expressed as a reduction in arrhythmic deaths or resuscitated VF. Subgroup analyses suggest that the concomitant use of beta blockers did confirm a mortality benefit.[451]

In parallel with the amiodarone trials, the randomized controlled trial comparing antiarrhythmic therapy (primarily amiodarone) to ICD therapy (MADIT) was carried out[444] (see Table 26-7) . This trial randomized patients with ejection fractions of less than 35 percent, nonsustained VT during ambulatory recording, and inducible VT that was not suppressible by procainamide. This very high risk group demonstrated a 54 percent reduction in total mortality with ICD therapy compared with drug therapy, primarily amiodarone as noted earlier. At the same time, a trial comparing ICD implantation to no specific therapies for arrhythmias among patients with ejection fractions less than 36 percent, who were undergoing coronary bypass surgery (CABG-Patch), demonstrated no benefit of defibrillators for total mortality.[390] The only marker for arrhythmic risk required for entry into the study was a positive signal-averaged ECG. A third trial, the Multicenter Unsustained Tachycardia Trial (MUSTT),[421] was a complex study designed to determine whether electrophysiologically guided therapy provides an improved outcome among patients with nonsustained VT, inducible VT, and a history of prior myocardial infarction. The results demonstrated that while there was a statistically significant benefit on total mortality achieved by guiding therapy according to the results of electrophysiologic testing, compared with patients with inducible tachycardia who did not receive therapy, the subgroup patients who received ICDs because they failed drug therapy did significantly better. There was a 24 percent mortality among ICD-treated patients at 5 years of follow-up, compared with 55 percent among those receiving electrophysiologically guided drug therapy and 48 percent among those randomized to no therapy. Other trials are ongoing. The Sudden Cardiac Death-Heart Failure Trial (SCD-HeFT) is designed to test the potential benefit of implantable defibrillators versus amiodarone, compared with placebo, among patients with functional Class II or III congestive heart failure and ejection fractions less than 35 percent. MADIT II is studying the potential benefits of ICD therapy compared with conventional therapy among patients with prior myocardial infarction and ejection fractions less than 30 percent. The results of these studies are expected to further refine indications for ICD therapy for primary prevention in high-risk subgroups.

Primary Prevention in Patients with Less Advanced Common Heart Diseases or Uncommon Diseases

Primary prevention trials have focused largely on patient populations with advanced heart disease who were, as a consequence of the severity of the disease, considered to be at very high risk for SCD and total mortality. Most of the clinical trials testing the question of relative efficacy of antiarrhythmic versus ICD therapy have used the ejection fraction as the marker for advanced disease, and a qualifying criteria of less than 35 percent has characterized most of the studies. Moreover, in the secondary prevention trial, AVID, a subgroup analysis suggested that there was no relative benefit of ICD therapy over amiodarone for patients with ejection fractions between 35 and 40 percent, all of the benefits accruing to those with ejection fraction of 35 percent or less.[425] This observation is important because it establishes a question about appropriate therapy for patients with ejection fractions greater than 35 percent.

Whereas the risk for SCD and total mortality is highest among patients with structural heart disease and ejection fractions of 35 percent or less, there is still considerable risk among patients with coronary heart disease and with the various cardiomyopathies when the ejection fraction is between 35 and 40 percent, and even higher. In addition, among patients with heart failure due to various forms of cardiomyopathy, whereas the total mortality risk is considerably lower among patients who are functional Class I or early Class II, than among those with late Class III or Class IV disease, the probability that a death will be sudden is

higher in the former group.[87] [452] Despite this observation, there are no data available to guide therapy for primary prevention of cardiac arrest in such patients.[453] [454] In addition, certain other structural entities that are associated with some elevation of risk of sudden death in the absence of a severely reduce ejection fraction, such as right ventricular dysplasia, sarcoidosis, hypertrophic cardiomyopathy, and myocarditis, are managed without the benefit of clinical trials to guide therapeutic approaches (see Table 26-6) . Patients with symptomatic ventricular arrhythmias due to structural disorders such as right ventricular dysplasia, in which most of the risk is an arrhythmic mortality risk, are often advised to have ICDs, even in the absence of a prior cardiac arrest or hemodynamically significant VT. Whether antiarrhythmic therapy would be just as effective remains unknown, but the judgment of using defibrillators in patients with a disorder whose fatal expression is primarily arrhythmic carries the strength of logic. Among those entities in which family history is helpful for defining risk, the clinical judgment is made easier when there is a strong family history of SCD. Specific support for this approach derives from genetic studies in hypertrophic cardiomyopathy, in which a limited number of the known mutations appear to be associated with specific risk of SCD.[55] In addition, clinical observational data support the use of ICDs in high-risk subsets of patients with hypertrophic cardiomyopathy.[454A]

Primary Prevention in Patients with Structurally Normal Hearts or Molecular Disorders of Cardiac Electrical Activity

In recent years, a new category of interest in primary preventive therapy has emerged. Clinically subtle or inapparent structural disorders, or entities with pure electrophysiological expression, such as the congenital long QT interval syndromes, the Brugada syndrome, and idiopathic VF, have received increasing attention. In secondary prevention strategies for entities such as the long QT interval syndrome, the decision-making process is relatively easy. Those individuals who had a cardiac arrest or potentially fatal arrhythmic event, especially when there is a family history of sudden death, are generally treated with ICDs. Beta blockers are still considered useful for affected family members who have not had an event and perhaps for some subgroups with patients with syncope of undocumented mechanism.[192] [386a] A more difficult decision is the electrocardiographically affected individual without a family history of SCD and/or the absence of symptomatic arrhythmias. In general, such patients are treated with beta blocker therapy at this time, but given the complexity of the pathophysiology of potentially fatal arrhythmias in such patients, the threshold for considering ICD therapy is decreasing.[191A] Specific genetic screening may prove useful for identifying specific risk ultimately, particularly if arrhythmic risk is modified by multiple factors, as opposed to the defect responsible for the long QT interval itself. For the present, if there is a single clinical marker that is useful for the decision-making process for preventive therapy in this general category of patients, it is a family history of sudden death.

Primary Prevention Among the General Population

To have a major impact on the problem of SCD among the general population, we need to move beyond the identification of high-risk patients who have specific clinical entities, advanced or subtle, that predict a high risk of SCD. Rather, it will be necessary to find among the general population small subgroups of patients at specific risk for SCD as a manifestation of underlying heart disease, if and when that disease becomes manifest. As an example, the studies that have recently demonstrated familial clustering of SCD as the first expression of underlying coronary artery disease, suggesting genetic or behavioral predisposition, may provide some help for the future.[43] [44] If highly specific markers can be found, preventive therapy before the first expression of an underlying disease may lead to a major impact on the population problem of SCD. Short of that, successes will be limited to community-based intervention and to those subgroups who are more easy to identify and in whom it is more justifiable to use prophylactic interventional therapy based on population size and magnitude of risk.[232] [454B]

SUDDEN DEATH AND PUBLIC SAFETY

The unexpectedness of SCD has raised questions concerning secondary risk to the public created by people in the throes of a cardiac arrest. There are no controlled data available to guide public policy regarding people at high risk for potentially lethal arrhythmias and for abrupt incapacitation. Myerburg and Davis[455] reported observations on 1348 sudden deaths caused by coronary heart disease in people 65 years of age or younger during a 7-year period in Dade County, Florida. One hundred one (7.5 percent) of these deaths occurred in people who were engaged in activities at the time of death that were potentially hazardous to the public (e.g., 56 were driving private automobiles or taxis, 15 were driving trucks, 10 were working at altitude, 2 were piloting aircraft), and 122 (9.1 percent) of the victims had occupations that could create potential hazards to others if an abrupt loss of consciousness had occurred while at work (e.g., 57 taxi and truck drivers, 8 aircraft pilots, 9 bus drivers, 9 policemen and firemen). There were no catastrophic events as a result of these cardiac arrests, only minor property damage in 19 and minor injuries in 5.

Levy and associates [456] reported a case of a bus driver with a strong history of coronary heart disease who caused the deaths of himself and several others, but they did not conclusively demonstrate that unexpected cardiac arrest was the proximate cause of the accident. Furthermore, Waller[457] studied an elderly population and demonstrated that cardiac disease alone was not responsible for a significant increase in accident: senility, or senility plus cardiovascular disease, was much more important. Several other studies also have led to the conclusion that risk to the public is small.[458] [459] In specific reference to private automobile drivers, most of the data show that sudden death at the wheel usually involves enough of a prodrome to allow the driver to get to the roadside before losing consciousness.[455] [458] [459] [460] [461] A recent analysis of recurrent VT/VF events among cardiac arrest survivors suggested limitation of driving privileges for the first 8 months after the index event,[33] based on the clustering of recurrent event rates early after the index event.[32] [33] Therefore, although there are likely to be isolated instances in which cardiac arrest causes public hazards in the future, the risk appears to be small; and because it is difficult to identify specific individuals at risk, sweeping restrictions to avoid such risks appear unwarranted. The exceptions are people with multisystem disease, particularly senility, and individual circumstances that require specific consideration, such as high-risk patients who have special responsibilities--school bus drivers, aircraft pilots, trainmen, and truck drivers.[455] [459] [462]

Chapter 27 - Hypotension and Syncope

HUGH CALKINS
DOUGLAS P. ZIPES

Syncope is a sudden transient loss of consciousness and postural tone with spontaneous recovery. Loss of consciousness results from a reduction of blood flow to the reticular activating system located in the brain stem and does not require electrical or chemical therapy for reversal. The metabolism of the brain, in contrast to that of many other organs, is exquisitely dependent on perfusion. Consequently, cessation of cerebral blood flow leads to loss of consciousness within approximately 10 seconds. Syncope is an important clinical problem because it is common, is costly, is often disabling, may cause injury, and may be the only warning sign before sudden cardiac death.[1] [2] [3] [4] [14A] [21A] [21B] [28A] Patients with syncope account for 1 percent of hospital admissions and 3 percent of emergency department visits.[1] Elderly persons have a 6 percent annual incidence of syncope. Surveys of young adults have revealed that up to 50 percent report a prior episode of loss of consciousness, most of which are isolated events that never come to medical attention. The annual cost of evaluating and treating patients with syncope has been estimated to be $800 million dollars.[2] Patients who experience syncope also report a markedly reduced quality of life, similar to that experienced by patients with chronic diseases such as rheumatoid arthritis and chronic obstructive pulmonary disease.[3]

CLASSIFICATION OF THE CAUSES OF SYNCOPE

The causes of syncope can be classified into four primary groups: vascular, cardiac, neurologic/cerebrovascular, and metabolic/miscellaneous (Table 27-1) . Vascular causes of syncope can be further subdivided into anatomical, orthostatic, and reflex-mediated causes. A similar approach to subclassification of the causes of syncope can be applied to the other three diagnostic groups. The probable cause of syncope can be identified in approximately 75 percent of patients.[5] [6]

Vascular Causes of Syncope

Vascular causes of syncope, particularly reflex-mediated syncope and orthostatic hypotension, are by far the most common causes of syncope, accounting for at least one third of all syncopal episodes. In contrast, subclavian steal syndrome is an exceedingly uncommon cause of syncope, accounting for less than 0.1 percent of syncopal episodes.

Orthostatic Hypotension

When a person stands, 500 to 800 ml of blood is displaced to the abdomen and lower extremities, resulting in an abrupt drop in venous return to the heart. This leads to a decrease in cardiac output and stimulation of aortic, carotid, and cardiopulmonary baroreceptors that trigger a reflex increase in sympathetic outflow. As a result, heart rate, cardiac contractility, and vascular resistance increase to maintain a stable systemic blood pressure on standing.[7] Orthostatic hypotension, which is defined as a 20-mm Hg drop in systolic blood pressure or a 10-mm Hg drop in diastolic blood pressure within 3 minutes of standing, results from a defect in any portion of this blood pressure control system.[8] Orthostatic hypotension may be asymptomatic or may be associated with symptoms such as lightheadedness, dizziness, blurred vision, weakness, palpitations, tremulousness, and syncope. These symptoms are often worse immediately on arising in the morning and/or after meals or exercise. Syncope that occurs after meals, particularly in the elderly, may result from a redistribution of blood to the gut. A decline in systolic blood pressure of about 20 mm Hg approximately 1 hour after eating has been reported in up to one third of elderly nursing home residents.[9] Although usually asymptomatic, it may result in lightheadedness or syncope.

Drugs that either cause volume depletion or result in vasodilation are the most common cause of orthostatic hypotension (Table 27-2) . Elderly patients are particularly susceptible to the hypotensive effects of drugs because of reduced baroreceptor sensitivity, decreased cerebral blood flow, renal sodium wasting, and an impaired thirst mechanism that develops with aging.[10] Orthostatic hypotension may also result from neurogenic causes, which can be subclassified into primary and secondary autonomic failure.[8] [11] Primary causes are generally idiopathic, whereas secondary causes are associated with a known biochemical or structural anomaly or are seen as part of a particular disease or syndrome. There are three types of primary autonomic failure. Pure autonomic failure (Bradbury-Eggleston syndrome) is an idiopathic sporadic disorder characterized by orthostatic hypotension, usually in conjunction with evidence of more widespread autonomic failure such as disturbances in bowel, bladder, thermoregulatory, and sexual function. Patients with pure autonomic failure have reduced supine plasma norepinephrine levels. Multiple system atrophy (Shy-Drager syndrome) is a sporadic, progressive, adultonset disorder characterized by autonomic dysfunction, parkinsonism, and ataxia in any combination. The third type of primary autonomic failure is Parkinson's disease with autonomic failure. A small subset of patients with Parkinson's disease may also develop autonomic failure, including orthostatic hypotension. In addition to these forms of chronic autonomic failure is a rare acute panautonomic neuropathy.[12] This generally presents in young people and results in a widespread severe sympathetic and parasympathetic failure with orthostatic hypotension, loss of sweating, disruption of bladder and bowel function, fixed heart rate, and fixed dilated pupils.

Postural orthostatic tachycardia syndrome (POTS) is a milder form of chronic autonomic failure and orthostatic intolerance characterized by the presence of symptoms of orthostatic intolerance, a 28-beats/min or greater increase in heart rate, and the absence of a significant change in blood pressure within 5 minutes of standing or upright tilt.[13] [14] POTS appears to result from a failure of the peripheral vasculature to appropriately vasoconstrict under orthostatic

stress. POTS may also be associated with syncope due to neurally mediated hypotension (see later). In some patients, the postural orthostatic tachycardia syndrome may result from an abnormality in the clearance of norepinephrine from the synaptic cleft.[14A] Approximately 90 percent of norepinephrine that is released into the synaptic cleft is cleared by uptake into the neuron by the norepinephrine transporter. A recent report identified a mutation in the norepinephrine transporter gene in a family with several affected family members.[14A]

REFLEX-MEDIATED SYNCOPE.

There are many reflex-mediated

TABLE 27-2 -- CAUSES OF ORTHOSTATIC HYPOTENSION

syncopal syndromes (see Table 27-1) . In each case, the reflex is composed of a trigger (the afferent limb) and a response (the efferent limb). This group of reflex-mediated syncopal syndromes has in common the response limb of the reflex, which consists of increased vagal tone and a withdrawal of peripheral sympathetic tone and leads to bradycardia, vasodilation, and, ultimately, hypotension, presyncope, or syncope. What distinguishes these causes of syncope are the specific triggers. For example, micturition syncope results from activation of mechanoreceptors in the bladder; defecation syncope results from neural inputs from gut wall tension receptors; and swallowing syncope results from afferent neural impulses arising from the upper gastrointestinal tract. The two most common types of reflex-mediated syncope, carotid sinus hypersensitivity and neurally mediated hypotension, are discussed later.

The term*neurally mediated hypotension/syncope* (also known as neurocardiogenic, vasodepressor, and vasovagal syncope and as "fainting") has been used to describe a common abnormality of blood pressure regulation characterized by the abrupt onset of hypotension with or without

bradycardia. Triggers associated with the development of neurally mediated syncope are those that either reduce ventricular filling or increase catecholamine secretion. These include the sight of blood, pain, prolonged standing, a warm environment or hot shower, and stressful situations. Under these types of situations, patients with this condition develop severe lightheadedness and/or syncope. It has been proposed that these clinical phenomena result from a paradoxical reflex that is initiated when ventricular preload is reduced by venous pooling. This leads to a reduction in cardiac output and blood pressure, which is sensed by arterial baroreceptors. The resultant increased catecholamine levels, combined with reduced venous filling, leads to a vigorously contracting volume-depleted ventricle. The heart itself is involved in this reflex by virtue of the presence of mechanoreceptors, or C-fibers, consisting of nonmyelinated fibers found in the atria, ventricles, and the pulmonary artery.[15] [16] [17] [18] [19] It has been proposed that vigorous contraction of a volume-depleted ventricle leads to activation of these receptors in susceptible individuals. These afferent C-fibers project centrally to the dorsal vagal nucleus of the medulla, leading to a "paradoxic" withdrawal of peripheral sympathetic tone and an increase in vagal tone, which, in turn, causes vasodilation and bradycardia. The ultimate clinical consequences are syncope or presyncope. Not all neurally mediated syncope results from activation of mechanoreceptors. In humans, it is well known that the sight of blood or extreme emotion can trigger syncope. These observations suggest that higher neural centers can also participate in the pathophysiology of vasovagal syncope. In addition, central mechanisms can contribute to the production of neurally mediated syncope.[18] [20]

Syncope due to carotid sinus hypersensitivity results from stimulation of carotid sinus baroreceptors, which are located in the internal carotid artery above the bifurcation of the common carotid artery. This condition is diagnosed by applying gentle pressure over the carotid pulsation just below the angle of the jaw, where the carotid bifurcation is located. Pressure should be applied unilaterally for approximately 5 seconds, after first listening for a carotid bruit. It has recently been reported that the sensitivity of diagnosing carotid sinus hypersensitivity can be increased, with no change in specificity, by performing carotid sinus massage during 60- or 70-degree upright tilt.[21A] [21B] The normal response to carotid sinus massage is a transient decrease in the sinus rate and/or slowing of atrioventricular (AV) conduction. Three types of abnormal responses have been described: (1) the cardioinhibitory response, characterized by marked bradycardia (>3-second pause); (2) the vasodepressor type, characterized by a 50-mm Hg fall in the systolic blood pressure in the absence of bradycardia; and (3) the mixed response. Carotid sinus hypersensitivity is commonly detected in patients with syncope. One study reported the presence of carotid sinus hypersensitivity in 65 of 279 patients (23 percent) who presented to the emergency department with falls.[21] It is important to recognize that carotid sinus hypersensitivity is also commonly observed in asymptomatic elderly patients, with carotid sinus hypersensitivity identified in one study in more than one third of asymptomatic patients undergoing cardiac catheterization for coronary artery disease. Because of this, the diagnosis of carotid sinus hypersensitivity should be approached cautiously after excluding alternative causes of syncope.

Cardiac Causes of Syncope

Cardiac causes of syncope, particularly tachyarrhythmias and bradyarrhythmias, are the second most common causes, accounting for 10 to 20 percent of syncopal episodes. Ventricular tachycardia is the most common tachyarrhythmia that can cause syncope. Supraventricular arrhythmias can also cause syncope, although the great majority of patients with supraventricular arrhythmias present with less severe symptoms such as palpitations, dyspnea, and lightheadedness. Bradyarrhythmias that can result in syncope include sick sinus syndrome as well as AV block. Anatomical causes of syncope result from obstruction to blood flow, such as a massive pulmonary embolus, an atrial myxoma, and/or aortic stenosis.

Neurological Causes of Syncope

Neurological causes of syncope, including migraines, seizures, Arnold Chiari malformations, and transient ischemic attacks, are surprisingly uncommon causes of syncope, accounting for less than 10 percent of all cases of syncope. The majority of patients in whom a "neurological" cause of syncope is established are found in fact to have had a seizure rather than true syncope.[5]

Metabolic/Miscellaneous Causes of Syncope

Metabolic causes of syncope are rare, accounting for less than 5 percent of syncopal episodes. The most common metabolic causes of syncope are hypoglycemia, hypoxia, and hyperventilation. The establishment of hypoglycemia as the cause of syncope requires demonstration of hypoglycemia during the syncopal episode. Although the mechanism of hyperventilation-induced syncope has been generally considered to be due to a reduction in cerebral blood flow, a recent study demonstrated that hyperventilation alone was not sufficient to cause syncope. This suggests that hyperventilation-induced syncope may also have a psychological component.[22] Psychiatric disorders may also cause syncope. It has been reported that up to 25 percent of patients with syncope of unknown origin may have psychiatric disorders for which syncope is one of the presenting symptoms.[23] Cerebral syncope is a rare, recently described cause of syncope resulting from cerebral vasoconstriction induced by orthostatic stress.[24]

Relationship Between Prognoses and the Cause of Syncope

The prognosis of patients with syncope varies greatly with diagnosis. Syncope of unknown origin or syncope due to a noncardiac etiology (including reflex mediated syncope) is generally associated with a benign prognosis. In contrast, syncope due to a cardiac cause is associated with a 30 percent mortality at 1 year.

DIAGNOSTIC TESTS

Identification of the precise cause of syncope is often challenging. Because syncope usually occurs sporadically and infrequently, it is extremely difficult to either

examine a patient or obtain an electrocardiogram (ECG) during an episode of syncope. For this reason, the primary goal in the evaluation of a patient with syncope is to arrive at a presumptive determination of the cause of syncope.

History and Physical Examination

The history and physical examination is the most important component of the evaluation of a patient with syncope.[5] [25] [26] [27] In one prospective series of 433 patients a diagnosis was established based on the history and physical examination in 144 patients, representing 58 percent of those patients in whom a diagnosis was established.[5] When taking a clinical history, particular attention should then be focused on (1) determining if the patient experienced true syncope as compared with a transient alteration in consciousness without loss of postural tone; (2) determining if the patient has a history of cardiac disease or if a family history of cardiac disease, syncope, or sudden death exists;

TABLE 27-3 -- DIFFERENTIATING SYNCOPE DUE TO NEURALLY MEDIATED HYPOTENSION, ARRHYTHMIAS, AND SEIZURES

	NEURALLY MEDIATED HYPOTENSION	ARRHYTHMIAS	SEIZURE
Demographics/Clinical Setting	Female>male gender Younger age (<55 yr) More episodes (>2) Standing, warm room, emotional upset	Male>female gender Older age (>54 yr) Fewer episodes (<3) Any setting	Younger age (<45 yr) Any setting
Premonitory Symptoms	Longer duration (>5 sec) Palpitations Blurred vision Nausea Warmth Diaphoresis Lightheadedness	Shorter duration (<6 sec) Palpitations less common	Sudden onset or brief aura (deja vu, olfactory, gustatory, visual)
Observations During the Event	Pallor Diaphoretic Dilated pupils Slow pulse, low blood pressure Incontinence may occur Brief clonic movements may occur	Blue, not pale Incontinence can occur Brief clonic movements can occur	Blue face, no pallor Frothing at the mouth Prolonged syncope (duration >5 minutes) Tongue biting Horizontal eye deviation Elevated pulse and blood pressure Incontinence more likely* Tonic clonic movements if grand mal
Residual Symptoms	Residual symptoms common Prolonged fatigue common (>90%) Oriented	Residual symptoms uncommon (unless prolonged unconsciousness) Oriented	Residual symptoms common Aching muscles Disoriented Fatigue Headache Slow recovery

*May be observed with any of these causes of syncope buy more common with seizures.

(3) identifying medications that may have played a role in syncope; (4) quantifying the number and chronicity of prior episodes; (5) identifying precipitating factors including body position; and (6) quantifying the type and duration of prodromal and recovery symptoms. The features of the clinical history that are most useful in determining whether syncope resulted from neurally mediated hypotension, an arrhythmia, or a seizure are summarized in Table 27-3` . It is also important to search to identify additional precipitating factors that may suggest a specific type of syncope. For example, carotid sinus syncope should be suspected if a patient reports syncope in response to head rotation and cough syncope should be suspected if syncope occurs in association with cough. The presence of akinetic or petit mal seizures can be recognized by the patient's lack of responsiveness in the absence of a loss of postural tone. Temporal lobe seizures last several minutes and are characterized by confusion, changes in the level of consciousness, and autonomic signs such as flushing. Vertebrobasilar insufficiency should be considered as the cause of syncope if syncope occurs in association with other symptoms of brain stem ischemia (i.e., diplopia, tinnitus, focal weakness or sensory loss, vertigo, or dysarthria). Migraine-mediated syncope is often associated with a throbbing unilateral headache, scintillating scotomata, and nausea.

After obtaining a careful history, evaluation should continue with a physical examination including the determination of orthostatic vital signs. Particular attention should focus on determining if structural heart disease is present, defining the patient's level of hydration and orthostatic vital signs, and detecting the presence of significant neurologic abnormalities suggestive of a dysautonomia or a cerebrovascular accident.

Blood Tests

The routine use of blood tests, such as serum electrolytes, glucose, and hematocrit levels generally has low diagnostic value. Nonetheless, these tests are commonly obtained as part of the evaluation of a patient with syncope.

Carotid Sinus Massage

Carotid sinus hypersensitivity is diagnosed by carotid massage, as outlined earlier.

Tilt-Table Testing (See Chap. 23.)

Tilt-table testing is a standard diagnostic test for evaluating patients with syncope.[28] [28A] [29] [30] [31] To the extent that tilt-table testing provides diagnostic evidence indicating susceptibility to neurally mediated syncope, it is generally considered the "gold standard" for establishing this diagnosis. The American College of Cardiology recently published an Expert Consensus Document that contains specific recommendations for performing and interpreting the results of this test.[28] Upright tilt-table testing is performed for 30 to 45 minutes at an angle of approximately 70 degrees. In general, a positive response to tilt-table testing is defined as the development of syncope or presyncope in association with hypotension and/or bradycardia. Positive responses to tilt-table testing can be divided into mixed, cardioinhibitory, and vasodepressor categories[31] (Table 27-4) . The sensitivity of the test can be increased, with an associated fall in specificity, by the use of longer tilt durations, steeper tilt angles, and provocative agents such as isoproterenol, nitroglycerin, or edrophonium.[28] [28A] In the absence of pharmacologic provocation, the specificity of the test has been estimated to be 90 percent.[28] [29] There is general agreement that

TABLE 27-4 -- CLASSIFICATION OF HEART RATE AND HEMODYNAMIC RESPONSES TO TILT-TABLE TESTING

Type 1: Mixed
Heart rate rises initially and then falls, but the ventricular rate does not fall to less than 40 beats/min or falls to 40 beats/min for less than 10 seconds with or without asystole for less than 3 seconds. Blood pressure rises initially and then falls before heart rate falls.
Type 2A: Cardioinhibitory

Heart rate rises initially and then falls to a ventricular rate of less than 40 beats/min for greater than 10 seconds, or asystole occurs for greater than 3 seconds. Blood pressure rises initially and then falls before heart rate falls.
Type 2B: Cardioinhibitory
Heart rate rises initially and then falls to a ventricular rate of less than 40 beats/min for more than 10 seconds, or asystole occurs for more than 3 seconds. Blood pressure rises initially and only falls to hypotensive levels less than 80 mm Hg systolic at or after onset of rapid and severe heart rate fall.
Type 3: Pure Vasodepressor
Heart rate rises progressively and does not fall more than 10% from peak at time of syncope. Blood pressure falls to cause syncope.

upright tilt-table testing is indicated in patients with (1) recurrent syncope or a single syncopal episode in a high-risk patient who either has no evidence of structural heart disease or in whom other causes of syncope have been excluded, (2) evaluation of patients in whom the causes of syncope have been determined (e.g., asystole) but in whom the presence of neurally mediated syncope on upright tilt would influence treatment, and (3) as part of the evaluation of patients with exercise-related syncope. There is also general agreement that upright tilt-table testing is not necessary for patients who have experienced only a single syncopal episode that was highly typical for neurally mediated syncope and during which no injury occurred. Tilt-table testing is not useful in establishing a diagnosis of situation syncope (i.e., postmicturition syncope[32]).

Echocardiography

Although echocardiograms are commonly used in the evaluation of patients with syncope, little objective evidence exists to support their use in patients with a normal physical examination and a normal ECG.[33] [34] [35] [36] The rationale for obtaining an echocardiogram in patients with syncope is to risk stratify the patient by excluding the possibility of occult cardiac disease not apparent after the history, physical examination, and electrocardiography. If detected, the presence of impaired ventricular function or significant valvular dysfunction would suggest a cardiac cause of syncope that would predict a worse long-term prognosis.

Stress Tests, Cardiac Catheterization

Myocardial ischemia is an unlikely cause of syncope and, when present, is usually accompanied by angina. As such, exercise stress testing and cardiac catheterization are unlikely to establish a diagnosis in patients presenting with syncope unless the clinical suspicion of ischemia is high. The use of stress tests in the evaluation of a patient with syncope is best reserved for patients in whom syncope or presyncope occurred during or immediately after exertion or in association with chest pain. They might also be considered in young individuals with recurrent syncope during exertion when other causes of syncope have been excluded to rule out anomalous coronary arteries. Even among patients with syncope during exertion it is highly unlikely that exercise stress testing will trigger another event. Patients suspected of having severe aortic stenosis or obstructive hypertrophic cardiomyopathy should not undergo exercise stress testing, because it may precipitate a cardiac arrest.

Electrocardiography

The 12-lead ECG is a standard component in the work-up of a patient with syncope. The initial ECG results in establishment of a diagnosis in approximately 5 percent of patients and suggests a diagnosis in another 5 percent of patients.[5] Specific findings that may identify the probable cause of syncope include QT prolongation (long QT syndrome), the presence of a short PR interval and a delta wave (Wolff-Parkinson-White syndrome), evidence of an acute myocardial infarction, and high-grade AV block. Less specific findings that may suggest potential causes of syncope that can be later confirmed with directed testing include evidence for a prior myocardial infarction, bundle branch block, ventricular hypertrophy, ventricular premature beats, and T wave inversion in the right precordial leads with an incomplete right bundle branch block pattern, suggestive of right ventricular dysplasia. Another recently identified syndrome that should be searched for is the Brugada syndrome, which is characterized by a right bundle branch block pattern with persistent ST segment elevation in leads V_1 to V_3 . This syndrome is associated with a high incidence of sudden cardiac death.[37] [38] The finding of a normal ECG suggests that a cardiac cause of syncope is unlikely.

Signal-Averaged Electrocardiography

Signal-averaged electrocardiography (SAECG) is a noninvasive technique used for detection of low-amplitude signals in the terminal portion of the QRS complex (late potentials), which are a substrate for malignant ventricular arrhythmias. In contrast to a standard ECG, obtaining a SAECG is not considered a standard part of the evaluation of a patient with syncope.[39]

Holter Recording

Continuous ECG monitoring using telemetry and/or Holter recording is commonly performed in patients with syncope. The information provided by ECG recording at the time of syncope is extremely valuable because it allows an arrhythmic cause of syncope to be established or excluded. However, because of the infrequent and sporadic nature of syncope, the diagnostic yield of Holter recording is low. The likelihood of experiencing an episode of syncope while wearing a Holter recorder in an unselected population of patients with syncope is approximately 0.1 percent. Although detection of asymptomatic sinus bradycardia, AV block, or nonsustained supraventricular or ventricular arrhythmias can suggest an arrhythmic cause of syncope, it is important to recognize that unless syncope or presyncope accompanies these arrhythmias they are likely to be incidental findings and should not be assumed to be the cause of syncope. Another inherent limitation of Holter recording is that it requires that the patient experience another episode of syncope to establish a diagnosis. For these reasons, the clinical situation in which Holter recording is most likely to be diagnostic is when used in the occasional patient with very frequent (i.e., daily) episodes of syncope or presyncope.

Event Recorders

Transtelephonic event recorders are small, portable ECG recording devices that are carried or worn continuously by the patient and can be activated by the patient to record a rhythm strip. The tracings can be stored and transmitted over telephone lines at a later time. Some event recorders, referred to as continuous loop event recorders, are worn

continuously and allow capture of both retrospective and prospective ECG recordings, whereas other types of event recorders record only when activated by the patient. Continuous loop event recorders are preferred when used in the evaluation of a patient with syncope. Event recorders are especially useful for patients with infrequent episodes of presyncope or syncope, particularly once potentially malignant causes of syncope have been excluded.[40] [41] One recent study reported the diagnostic utility of event recorders in 62 patients with syncope.[41] The device was recommended either after a nondiagnostic electrophysiology (EP) test or in patients with syncope that occurred in the absence of structural heart disease. During a recording period of 4 weeks, 20 patients (32 percent) experienced symptoms and activated the device. An arrhythmia was observed in association with symptoms in 8 of these patients.

Implantable Event Recorders

In some patients, episodes of syncope are extremely infrequent, occurring once or twice a year. In this patient population a traditional event recorder is unlikely to be diagnostic because of the prolonged length of recording that would be needed to successfully record an event. To address this, an implantable event recorder has been developed (Medtronic Reveal, Minneapolis, MN). This smaller device (61×19×8 mm) with a projected longevity of 24 months incorporates two electrodes within its can and is implanted in the subcutaneous tissue of the chest.[42]

Electrophysiology Testing

The results of EP testing can be useful in establishing a diagnosis of sick sinus syndrome, heart block, supraventricular tachycardia, or ventricular tachycardia in patients with syncope. The indications for EP testing in the evaluation of patients with syncope have recently been established based on an American College of Cardiologists/American Heart Association Task Force report.[43] There is general agreement that EP testing should be performed in patients with suspected structural heart disease and unexplained syncope (Class I indication) and that it should not be performed in patients with a known cause of syncope for whom treatment will not be influenced by the findings of the test (Class III indication). The role of EP testing in evaluating patients with recurrent unexplained syncope who do not have

structural heart disease and have had a negative tilt test remains controversial (see Chap. 23) .

Sinus node function is evaluated during EP testing primarily by determining the sinus node recovery time (SNRT). The SNRT is defined as the interval between the last paced atrial depolarization and the first spontaneous atrial depolarization resulting from activation of the sinus node. A corrected SNRT (SNRT -- sinus cycle length) greater than 525 msec is generally considered abnormal.[43] Identification of sinus node dysfunction as the cause of syncope is an uncommon finding during EP tests (<5 percent).[44] [45] It is also important to note that the absence of evidence of sinus node dysfunction during EP testing does not exclude a bradyarrhythmia as the cause of syncope. During EP testing, AV conduction is assessed by measuring the His bundle to ventricular conduction time (HV interval) and also by determining the response of AV conduction to incremental atrial pacing. The findings obtained during EP testing that allow AV block to be established as the probable cause of syncope include an HV interval greater than or equal to 100 msec or an infra-His block observed spontaneously or during atrial pacing.[43] [44] [45] [46] Completion of a standard EP test will allow accurate identification of most types of supraventricular arrhythmias that may have caused syncope. The study should be repeated during an isoproterenol infusion to increase the sensitivity of the study, particularly for detecting idiopathic ventricular tachycardia or AV nodal reentrant tachycardia. A supraventricular arrhythmia is diagnosed as the probable cause of syncope in less than 5 percent of patients who undergo EP testing for evaluation of syncope of unknown origin.[6] [43] [44] [45] [47] Ventricular tachycardia is the most common abnormality uncovered during EP testing in patients with syncope. An EP test is interpreted as positive for ventricular tachycardia when sustained monomorphic ventricular tachycardia is induced. The induction of polymorphic ventricular tachycardia, ventricular fibrillation, and nonsustained ventricular tachycardia have been considered to represent nonspecific responses to EP testing. Among studies that have reported the results of EP testing in evaluating patients with syncope, identification of ventricular tachycardia as the probable cause of syncope is reported in approximately 20 percent of patients.[6] [43] [44] [45]

Approximately one third of patients with syncope of unknown origin referred for EP testing will have a presumptive diagnosis established.[6] Clinical factors that have been identified as predictors of a positive response to EP testing include impaired ventricular function, male sex, prior myocardial infarction, bundle branch block, injury, and nonsustained ventricular tachycardia. The remaining two thirds of patients with a normal response to EP testing are generally considered to be at low risk of sudden cardiac death. It is important to recognize however that EP testing does not always identify the arrhythmic cause of syncope because transient abnormalities such as those caused by ischemia or fluctuations in autonomic tone may be missed.[48] In addition, recent studies have suggested that EP testing may have less predictive value in patients with markedly impaired ventricular function and particularly those with an idiopathic dilated cardiomyopathy. Middlekauff and colleagues[49] [50] have called attention to the strong link between syncope and sudden cardiac death in patients with syncope and congestive heart failure and also to the poor negative predictive value of EP testing in patients with reduced ventricular function. Another recent study[51] reported that 7 of 14 patients with an idiopathic dilated cardiomyopathy who presented with syncope, had a negative EP test, and underwent placement of an implantable defibrillator received appropriate shocks for ventricular arrhythmias during 24 months of follow-up.[51] These findings suggest that more sensitive diagnostic tests to evaluate patient risk of sudden death and/or greater use of implantable defibrillators may be needed in patients with an idiopathic dilated cardiomyopathy who present with syncope.

Tests to Screen for Neurological Causes of Syncope

Syncope, as an isolated symptom, is rarely due to a neurological cause. In most large published series, neurological causes of syncope are established in less than 5 percent of patients. As a result, widespread use of tests to screen for neurologic conditions rarely are diagnostic. In many institutions, computed tomography, electroencephalography, and carotid duplex scans are overused, being obtained in more than 50 percent of patients with syncope. A diagnosis is almost never uncovered that was not first suspected based on a careful history and neurologic examination.[5] [52] One study indicated that 29 percent of patients with treatment-resistant epilepsy or suspected nonepileptic seizures have an underlying cardiovascular cause of syncope such as neurally mediated hypotension, carotid sinus hypersensitivity, or transient AV block.[53]

APPROACH TO THE EVALUATION OF PATIENTS WITH SYNCOPE

Figure 27-1 outlines an approach to the diagnostic evaluation of a patient presenting with syncope. The initial evaluation

Figure 27-1 Diagnostic evaluation of syncope. TTT=tilt table testing, EPS=electrophysiologic studies.

begins with a careful history, physical examination, and 12-lead ECG. Various clinical features can help suggest a specific cause of the syncope (Table 27-5) . Based on this initial evaluation performed either in an emergency department or outpatient setting, the probable cause of syncope can be identified in approximately 30 percent of patients. Common causes of syncope that can be identified at this initial stage include orthostatic hypotension, situational syncope, and often neurally mediated syncope. This initial evaluation should also allow identification of patients who likely had a seizure, rather than syncope. In another large group of patients the probable cause of syncope can be suspected and later confirmed with directed diagnostic testing. Causes of syncope that would fall into this category include syncope due to critical aortic stenosis, neurally mediated syncope with a suggestive but not diagnostic clinical presentation, arrhythmias due to the Wolff-Parkinson-White syndrome, or right ventricular dysplasia, as well as neurologic causes of syncope that can be further evaluated with directed testing. Among the remaining patients, the next step in the evaluation depends on the presence of structural heart disease as well as the physician's clinical suspicion that an arrhythmia may have been the cause of syncope. An echocardiogram is often obtained at this point to help determine if structural heart disease is present. If the patient has significant structural heart disease or a clinical history suggestive of an arrhythmia, an EP test would be an appropriate next step. On the other hand, if structural heart disease is absent and the clinical history is not suggestive of an arrhythmia, the evaluation can be continued either with a tilt test, event monitor, or clinical follow-up, depending on the severity and chronicity of the patient's symptoms. With the use of this approach a probable cause of syncope can be determined in 75 percent of patients.[6]

PATIENT MANAGEMENT

The approach to treatment of a patient with syncope depends largely on the diagnosis that is established. For example,

TABLE 27-5 -- CLINICAL FEATURES SUGGESTIVE OF SPECIFIC CAUSES

SYMPTOM OR FINDING	DIAGNOSTIC CONSIDERATION
After sudden unexpected pain, unpleasant sight, sound, or smell	Vasovagal syncope
During or immediately after micturition, cough, swallow, or defecation	Situational syncope
With neuralgia (glossopharyngeal or trigeminal)	Bradycardia or vasodepressor reaction
On standing	Orthostatic hypotension
Prolonged standing at attention	Vasovagal syncope
Well-trained athlete after exertion	Neurally mediated
Changing position (from sitting to lying, bending, turning over in bed)	Atrial myxoma, thrombus
Syncope with exertion	Aortic stenosis, pulmonary hypertension, pulmonary embolus, mitral stenosis, idiopathic hypertrophic subaortic stenosis, coronary artery disease, neurally mediated
With head rotation, pressure on carotid sinus (as in tumors, shaving, tight collars)	Carotid sinus syncope
Associated with vertigo, dysarthria, diplopia, and other motor and sensory symptoms of brain stem ischemia	Transient ischemic attack, subclavian steal, basilar artery migraine
With arm exercise	Subclavian steal
Confusion after episode	Seizure

From Kapoor WN: Syncope and hypotension.In Braunwald E (ed): Heart Disease: A Textbook of Cardiovascular Medicine. 5th ed. Philadelphia, WB Saunders, 1997, p 868.

the appropriate treatment of a patient with syncope due to AV block or sick sinus syndrome would likely involve placement of a permanent pacemaker; treatment of a patient with syncope due to the Wolff-Parkinson White syndrome would likely involve catheter ablation; and treatment of a patient with syncope due to ventricular tachycardia would likely involve placement of an implantable defibrillator. For other types of syncope, optimal patient management may involve discontinuation of an offending pharmacological agent, an increase in salt intake, or patient education.

Other issues that need to be considered include the indication for hospitalization of a patient with syncope and duration of driving restrictions. There have been no studies that have evaluated the indications for hospital admission among patients with syncope. Generally, hospital admission is indicated when there is concern regarding a potentially life-threatening cause of syncope or when significant injury has occurred. It would therefore be prudent to hospitalize a 65-year-old man with a prior history of a myocardial infarction and heart failure who presents with an initial episode of syncope that occurs without warning or residual symptoms. In this type of patient, the probability of ventricular tachycardia as the cause of syncope is high. On the other hand, the evaluation of a young patient who presents with a clinical history suggestive of neurally mediated syncope and no clinical evidence of cardiac disease could be performed as an outpatient.

Physicians who care for patients with syncope are after asked to address the issue of driving risk. Patients who experience syncope while driving pose a risk both to themselves and to others. Although some would argue that all patients with syncope should never drive again because of the theoretical possibility of developing a recurrence, this is an impractical solution that will be ignored by many patients. Factors that should be considered when making a recommendation for a particular patient include (1) the potential for recurrent syncope, (2) the presence and duration of warning symptoms, (3) whether syncope occurs while seated or only when standing, (4) how often and in what capacity does the patient drive, and (5) are there any state laws that may be applicable? When considering these issues, physicians should note that acute illnesses, including syncope, are unlikely to cause a motor vehicle accident. The American Heart Association and the Canadian Cardiovascular Society have published guidelines concerning this issue.[54] [55] For noncommercial drivers, it is generally recommended that driving be restricted for several months. If the patient remains asymptomatic, driving can be resumed several months later.

Neurally Mediated Syncope

Because neurally mediated syncope is so common, therapy will be outlined in detail. Treatment begins with a careful history with particular attention focused on identifying precipitating factors, quantifying the degree of salt intake and current medication use, and determining if the patient has a prior history of peripheral edema, hypertension, asthma, or other conditions that may alter the approach used to treat neurally mediated syncope. For many patients, particularly those with infrequent episodes associated with an identifiable precipitant, education about avoidance of predisposing factors and a moderate increase in salt intake is effective treatment. For others, treatment involves removal or avoidance of drugs that predispose one to orthostatic hypotension or volume depletion, such as vasodilators and diuretics. Treatment with pharmacologic agents is usually targeted at patients in whom syncope is recurrent or has been associated with physical injury. The medications that are generally considered to be most effective in the treatment of neurally mediated syncope include beta blockers, serotonin reuptake inhibitors, and midodrine.[56] [57] [58] [59] [60] [61] [61A] Although fludrocortisone is widely used in the treatment of neurally mediated syncope, particularly in children, its efficacy has never been demonstrated with a randomized clinical trial.[61] A recent study has reported that "orthostatic training," performed by standing the patient for 40 minutes twice daily, is effective in the treatment of neurally mediated hypotension in adolescents.[61B] For most patients, first-line therapy includes a combination of increased salt intake (>3 gm/day) and beta-blocker therapy. If ineffective, treatment with fludrocortisone, midodrine, or a serotonin reuptake inhibitor such as paroxetine can be considered. Although pacemakers have also been demonstrated to be valuable in the treatment of some patients with neurally mediated syncope, they are generally considered in patients who fail attempts at pharmacologic therapy and have demonstrated a predominantly cardioinhibitory response during tilt-table testing.[62] Because of the profound implications of pacemaker implantation, particular restraint should be exercised when considering the implantation of a pacemaker in a young person. The development of asystole during tilt-table testing is not considered to be an absolute indication for pacemaker implantation.[63]

Part IV - HYPERTENSIVE AND ATHEROSCLEROTIC CARDIOVASCULAR DISEASE

Chapter 28 - Systemic Hypertension: Mechanisms and Diagnosis

NORMAN M. KAPLAN

Definitions, Prevalence, and Consequences of Hypertension

Hypertension, despite its widely recognized high prevalence and associated danger, remains inadequately treated in the majority of patients. In the representative sample of the U.S. population examined in the 1991-1994 National Health and Nutrition Examination Survey (NHANES III), only 27 percent of hypertensives had their blood pressure well controlled, as defined by a reading below 140/90 mm Hg[1] (Fig. 28-1) . Although most cases of hypertension had been identified previously, only about half of hypertensives were currently being treated. Similarly inadequate rates of control have been noted among patients managed in health maintenance organizations[2] and Veterans Affairs clinics.[3] Moreover, cardiovascular mortality remains higher even in presumably well treated hypertensives than in nonhypertensives.[4]

Despite these disturbing figures, management of hypertension is now the leading indication for both visits to physicians and the use of prescription drugs in the United States. According to the National Ambulatory Care Survey, over 100 million office visits related to hypertension were made in 1997.[5] Clearly, more attention is being directed toward hypertension, but adequate hypertension control remains elusive, in large part because of the asymptomatic nature of the disease for the first 15 to 20 years, even as it progressively damages the cardiovascular system.[6] Asymptomatic patients are often unwilling to alter life style or take medication to forestall some far-off, poorly perceived danger, particularly when they are made uncomfortable in the process.

In view of these built-in barriers to effective control of the individual patient, population-wide application of preventive measures becomes inherently more attractive. Although the specific mechanisms for most hypertension remain unknown, it is highly likely that the process could be slowed, if not prevented, by the prevention of obesity, moderate reduction in sodium intake, higher levels of physical activity, and avoidance of excessive alcohol consumption.[6] Since hypertension will eventually develop in most people during their lifetime, the need for more widespread adoption of potentially effective and totally safe preventive measures is obvious. In the meantime, better management

Figure 28-1 Percentages of U.S. adult men and women aged 18 to 74 years identified in the National Health and Nutrition Examination Survey (NHANES), 1991-1994, with hypertension diagnosed (left-hand bars), treated (middle), and controlled (right). Hypertension was defined as blood pressure of 140/90 or above. (Adapted from Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure: The Sixth Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI). Arch Intern Med 157:2413, 1997. Copyright 1997, American Medical Association.)

of those already afflicted must be practiced, starting with careful documentation of the diagnosis.

DEFINITION OF HYPERTENSION

Blood pressure is distributed in a typical bell-shaped curve within the overall population (Fig. 28-2) . As seen in the 12-year experience of the almost 350,000 men screened for the Multiple Risk Factor Intervention Trial (MRFIT), the long-term risks for cardiovascular mortality associated with various levels of pressure rise progressively over the entire range of blood pressure, with no threshold that clearly identifies potential danger. Therefore, the definition of hypertension is somewhat arbitrary and usually taken as that level of pressure associated with a doubling of long-term risk. Perhaps the best operational definition is "the level at which the benefits (minus the risks and costs) of action exceed the risks and costs (minus the benefits) of inaction."

The issue of what blood pressure level should be taken to signify hypertension is further complicated by its typically marked variability. Such variability is seldom recognized by the relatively few office readings taken by most practitioners but can easily be identified by automatically recorded measurements taken throughout the day and night (Fig. 28-3) . This variability can often be attributed to physical activity or emotional stress but is frequently without obvious cause.

In a few patients, markedly elevated levels clearly indicate serious disease requiring immediate treatment. However, in most cases, initial readings are not high enough to indicate immediate danger, and the diagnosis of hypertension should be substantiated by repeated readings. The reason for such caution is obvious: The diagnosis of hypertension imposes psychological and socioeconomic burdens on an individual and usually implies the need for commitment to lifelong therapy.

Both transient and persistent elevations in pressure are common when it is taken in the physician's office or hospital. To identify "white coat" hypertension, more widespread use of out-of-the-office readings, either with semiautomatic inexpensive devices or with automatic ambulatory recorders, is encouraged both to establish the diagnosis and to monitor the patient's response to therapy.[1] A large body of data provides normal ranges for both home self-recorded[7] and automatic ambulatory measurements.[8] Both average about 10/5 mm Hg lower than the average of multiple office readings. A closer correlation between the presence of various types of target organ damage, specifically, left ventricular hypertrophy (LVH), carotid wall thickness, proteinuria, and retinopathy, has been noted with ambulatory levels than with office levels.[9] However, in the absence of adequate long-term follow-up evidence of the risks associated with either home or ambulatory monitoring, office readings should continue to be the basis for the diagnosis and management of hypertension.

OUT-OF-THE-OFFICE MEASUREMENTS.

Whenever possible, office readings should be supplemented by out-of-the-office measurements, particularly when there is an apparent

Figure 28-2 *Left,* Percent distribution of systolic blood pressure (SBP) for men screened for the Multiple Risk Factor Intervention Trial who were 35 to 57 years old and had no history of myocardial infarction (*n* = 347,978) *(shaded bars)* and corresponding 12-year rates of cardiovascular mortality by SBP level adjusted for age, race, total serum cholesterol level, cigarettes smoked per day, reported use of medications for diabetes mellitus, and estimated household income (using census tract of residence). *Right,* Same as at the *left,* except distribution of diastolic blood pressure (DBP) (*n* = 356,222). (From National High Blood Pressure Education Program Working Group: National High Blood Pressure Education Program Working Group report on primary prevention of hypertension. Figure 28-3 Computer printout of blood pressure readings obtained by ambulatory blood pressure monitoring over a 24-hour period beginning at 9 A.M. in a 50-year-old man with hypertension receiving no therapy. The patient slept from midnight until 6 A.M.*Solid circles* = heart rate. (From Zachariah PK, Sheps SG, Smith RL: Defining the roles of home and ambulatory monitoring. Diagnosis 10:39, 1988. © Medical Economics Publishing Company, Inc., Pradell, NJ. All rights reserved.)

discrepancy between the level of blood pressure and the degree of target organ damage, in which case white coat hypertension should be suspected. Pickering has provided a scheme for the use of home and ambulatory monitoring in such a circumstance[10] (Fig. 28-4) . In as many as half of patients with office readings that remain elevated despite the use of three or more drugs, hypertension in as many as half is found to be well controlled by out-of-the-office readings.[11] Purely white coat hypertension, that is, persistently elevated office readings but persistently normal out-of-the-office readings, is found in 20 to 30 percent of patients. Most are found to be free of the target organ damage and metabolic abnormalities (dyslipidemia, hyperinsulinemia) that are often found in patients with sustained hypertension,[12] and follow-up for up to 10 years has found no increase in cardiovascular events.[13] Therefore, close observation and life style modifications but not antihypertensive drug therapy seem appropriate management for such patients.

Figure 28-4 Schema for evaluation of hypertensive patients by use of clinic, home, and ambulatory monitoring of blood pressure. (From Pickering TG: Blood pressure measurement and detection of hypertension. Lancet 344:31, 1994. © by The Lancet Ltd., 1994.)

In addition to their role in the recognition of white coat hypertension, out-of-the-office readings are essential for the recognition of persistently elevated pressures soon after awakening, when the largest proportion of sudden deaths, myocardial infarctions, and strokes occur.[14] Increased awareness of the role of the abrupt and marked rise in pressure after awakening in the etiology of these early morning cardiovascular catastrophes has prompted therapeutic strategies to ensure control of hypertension at that time, including late evening dosing with currently available medications and the development of tablets that are delayed in releasing active drug so that they can be taken at bedtime but not become active until the hours before awakening.[15]

In view of the usual nocturnal fall in pressure (see Fig. 28-3) , addition of the maximal antihypertensive effect of medication taken before bedtime could incite myocardial and cerebral ischemia during sleep. Therefore, the best way to blunt the early morning surge in pressure is to use formulations that provide full 24-hour coverage and to take them as early in the morning as possible.

Although a nocturnal fall in pressure is usual, various groups of hypertensives who have a more serious degree of target organ damage or subsequent major cardiovascular events have been noted to have little or no nocturnal fall.[16] These groups include patients with LVH, diabetes, or renal damage and blacks. Recognition of abnormal nocturnal patterns of blood pressure, presumably adding an additional stress to the cardiovascular system, is a potential indication for more widespread use of automatic recordings.

BLOOD PRESSURE RESPONSE TO EXERCISE.

Another source of potentially useful prognostic information is the blood pressure response to exercise, usually ascertained by treadmill testing. An exaggerated response in normotensive adults, defined as a systolic pressure rise of more than 60 mm Hg at 5 minutes of exercise (6.3 METs) or more than 70 mm Hg at 10 minutes (8.1 METs) or a diastolic rise of more than 10 mm Hg at any time, was associated with a 3-fold greater likelihood of hypertension developing over the next 5 to 15 years.[17] Such patients had a 3.6 times greater risk ratio for major cardiovascular events over an 8-year follow-up than did those without an exaggerated response during exercise.[18]

DOCUMENTATION OF HYPERTENSION.

For most patients who are in no immediate danger from markedly elevated pressure, i.e., below approximately 170/110 mm Hg, the following guidelines are offered:

TABLE 28-1 -- GUIDELINES IN MEASURING BLOOD PRESSURE

Conditions for the Patient
Posture
For patients who are older than 65 yr, diabetic, or receiving antihypertensive therapy, check for postural changes by taking readings immediately and 2 min after patient stands
Sitting pressures are usually adequate for routine follow-up. Patient should sit quietly with back supported for 5 min and arm supported at level of heart
Circumstances
No caffeine for preceding hour
No smoking for preceding 15 min
No exogenous adrenergic stimulants, e.g., phenylephrine in nasal decongestants or eyedrops for pupillary dilation
Quiet, warm setting
Home readings taken under varying circumstances and 24-hr ambulatory recordings may be preferable and more accurate in predicting subsequent cardiovascular disease
Equipment
Cuff size: The bladder should encircle and cover two-thirds of the length of the arm; if not, place the bladder over the brachial artery; if bladder is too small, spuriously high readings may result
Manometer: Aneroid gauges should be calibrated every 6 mo against a mercury manometer
For infants, use ultrasound equipment, e.g., the Doppler method
Technique
Number of readings
On each occasion, take at least 2 readings separated by as much time as practical. If readings vary by more than 5 mm Hg, take additional readings until 2 are close
For diagnosis, obtain at least 3 sets of readings at least a week apart
Initially, take pressure in both arms; if pressure differs, use arm with higher pressure

	If arm pressure is elevated, take pressure in one leg, particularly in patients younger than 30 yr
Performance	
	Inflate the bladder quickly to a pressure 20 mm Hg above the systolic, as recognized by disappearance of the radial pulse
	Deflate the bladder 3 mm Hg every second
	Record the Korotkoff phase V (disappearance) except in little children, in whom use of phase IV (muffling) may be preferable
	If Korotkoff sounds are weak, have the patient raise the arm and open and close the hand 5-10 times, after which the bladder should be inflated quickly
Recordings	
	Note the pressure, patient position, which arm, and cuff size (e.g., 140/90, seated, right arm, large adult cuff)

1. Multiple readings should be obtained with appropriate technique (Table 28-1) . If possible, the readings should be taken under varying conditions and at various times for at least 4 to 6 weeks with a semiautomatic home device. If the diagnosis must be established more rapidly, a set of readings obtained by an automatic monitor over a single 24-hour period will be adequate.
2. Although the logical approach would be to calculate the average values from multiple readings when deciding whether hypertension is present, even a single high measurement should not be disregarded. In large populations, a single set of casual measurements has been found to predict a greater likelihood of subsequent cardiovascular disease.[19] However, such elevated measurements do not necessarily predict either fixed hypertension or increased risk for each individual. For example, in one study only 10.8 percent of 719 men aged 18 to 30 with initial systolic values of 140 to 170 began to exhibit systolic pressures persistently above 140 over the next 12 to 15 years.[20] Nonetheless, persistently elevated pressures were found 2.3 times more often among those with initially high readings, obviously placing them at higher risk.
3. Systolic elevations pose a risk that is equal to or greater than that posed by diastolic elevations, and a wide pulse pressure is the most potent predictor of cardiovascular risk.[21] isolated systolic hypertension, as commonly seen among the elderly, presents a risk for both stroke and myocardial infarction.[19]
4. The elderly often have sclerotic brachial arteries that may not become occluded until very high pressures are exerted by the balloon; therefore, cuff diastolic levels may be considerably higher than those measured intraarterially. In patients with high cuff readings but little or no hypertensive retinopathy, cardiac hypertrophy, or other evidence of longstanding hypertension, "pseudohypertension" should be suspected and ruled out before treatment is begun.
5. Elderly persons with elevated systolic pressure should be monitored carefully for significant falls in pressure either with sudden upright posture or after meals.[22] These changes probably reflect a progressive loss of baroreceptor responsiveness with age. This condition makes the elderly particularly susceptible to marked orthostatic hypotension after even small decreases in vascular volume.

For the individual patient, hypertension can be definitively diagnosed when most readings are at a level known to be associated with a significantly higher cardiovascular risk without treatment. The recommendations of the Sixth Joint National Committee (JNC/6) are shown in Table 28-2 .[1] Note that systolic levels of 130 to 139 mm Hg and diastolic levels of 85 to 89 mm Hg are classified as *high normal blood pressure,* a recommendation stemming from prospective observations of over 420,000 people for 6 to 25 years wherein a doubling of the risk for stroke was seen among those with mean diastolic blood pressure of 85 mm Hg when compared with those with a mean of 76 mm Hg.[23] Therefore, persons with relatively high systolic or diastolic pressures should be advised that they may be at increased risk and counseled to follow better health habits in the hope of slowing the progression toward definite hypertension.

The criteria shown in Table 28-2 are based on at least three sets of measurements taken over at least a 3-month interval. Even more readings may be needed to establish a patient's usual level.

Even though they are diagnosed as hypertensive, not all persons with usual levels above 140/90 mm Hg need be treated with drugs, although all should be advised to use the various life style modifications described in Chapter 29 . As recommended in both the 1997 JNC-6 report[1] and the 1999 World Health Organization-International Society of Hypertension (WHO-ISH) guidelines,[24] the threshold for institution

TABLE 28-2 -- CLASSIFICATION OF BLOOD PRESSURE FOR ADULTS AGED 18 YEARS AND OLDER*

	BLOOD PRESSURE (mm Hg)		
CATEGORY	**Systolic**		**Diastolic**
Optimal	<120	and	<80
Normal	<130	and	<85
High-normal	130-139	or	85-89
Hypertension			
Stage 1	140-159	or	90-99
Stage 2	160-179	or	100-109
Stage 3	180	or	N 110

*Not taking antihypertensive drugs and not acutely ill. When systolic and diastolic blood pressure levels fall into different categories, the higher category should be selected to classify the individual's blood pressure status. For example, 160/92 mm Hg should be classified as stage 2 hypertension, and 174/120 mm Hg should be classified as stage 3 hypertension. Isolated systolic hypertension is defined as systolic blood pressure 140 mm Hg or greater and diastolic blood pressure less than 90 mm Hg and staged approximately (e.g., 170/82 mm Hg is defined as stage 2 isolated systolic hypertension). In addition to classifying stages of hypertension on the basis of average blood pressure levels, clinicians should specify the presence or absence of target organ disease and additional risk factors. This specificity is important for risk classification and treatment (see Table 28-5) .

Optimal blood pressure with respect to cardiovascular risk is less than 120/80 mm Hg. However, unusually low readings should be evaluated for clinical significance.

Based on the average of two or more readings taken at each of two or more visits after an initial screening.

TABLE 28-3 -- NINTY-FIFTH PERCENTILE OF BLOOD PRESSURE BY SELECTED AGES IN GIRLS AND BOYS IN THE 50TH AND 75TH HEIGHT PERCENTILES

	GIRLS'SBP/DBP		BOYS' SBP/DBP	
AGE (yr)	**50th Percentile for Height**	**75th Percentile for Height**	**50th Percentile for Height**	**75th Percentile for Height**
1	104/58	105/59	102/57	104/58
6	111/73	112/73	114/74	115/75
12	123/80	124/81	123/81	125/82
17	129/84	130/85	136/87	138/88

of drug therapy should be based on the overall cardiovascular risk profile, as noted on p. 973 .

BORDERLINE HYPERTENSION.

In view of the usual variability in blood pressure levels, the term *labile* is inappropriate for describing diastolic pressures that only occasionally exceed 90 mm Hg.

Instead, the term *borderline* should be used. In 30 to 40 percent of patients whose initial diastolic measurement exceeds 90 mm Hg, repeat readings taken soon after will be well below this value.[25] Such patients should be advised that their blood pressure level is *borderline elevated* and should be checked at least annually while they follow general health measures.

HYPERTENSION IN CHILDREN AND ADOLESCENTS (see also Chap. 45).

Upper limits of normal in children of various ages were proposed in the JNC-6 report[1] (Table 28-3) . Premature labeling of children whose readings are above these limits as hypertensive should be avoided since long-time tracking is only now being carried out.[26] Appropriate management for asymptomatic children with sustained elevations in blood pressure has not been established. Although many maintain similarly high readings over 3- to 4-year periods, most become normotensive. Such patients should be monitored carefully, with particular emphasis placed on regular exercise and weight reduction for those who are overweight in the hope of preventing progression of the disease. If life style modifications are not successful, antihypertensive agents should probably be prescribed for those with sustained hypertension.

PREVALENCE OF HYPERTENSION

From the criteria shown in Table 28-2 , the prevalence of hypertension in the United States rises progressively with age in both men and women[27] (Fig. 28-5) . The prevalence of hypertension among blacks is greater at every age beyond adolescence, and they have a higher proportion of more severe disease with a higher mortality rate than whites at every level of income.[28]

SECONDARY HYPERTENSION.

Among the large number of people with hypertension, it is helpful to know whether some secondary process--perhaps curable by surgery or more easily controlled by a specific drug--may be present (Table 28-4) so that the clinician can determine whether more definitive diagnostic testing is in order. Most surveys to determine the relative proportion of various secondary diseases are biased as a result of the selection process, with only the increasingly suspect population "funneled" to an investigator interested in a particular disease. Thus, estimates as high as 20 percent for certain secondary forms of hypertension have been reported; however, these figures do not reflect the incidence in the population at large. Estimates more likely to be indicative of the situation in usual clinical practice are shown in Table 28-5 .[29] [30] [31] The closest approximation of usual medical practice is the survey by Rudnick and associates of middle-class white patients seen in a family practice in Hamilton, Ontario, Canada, from 1965 to 1974.[29] In this as in the other surveys, many of the

Data from Rudnick KV, Sackett DL, Hirst S, Holmes C: Hypertension in family practice. Can Med Assoc J 117:492, 1977; Sinclair AM, Isles CG, Brown I, et al: Secondary hypertension in a blood pressure clinic. Arch Intern Med 147:1289, 1987; Anderson GH Jr, Blakemann N, Streeten DHP: The effect of age on prevalence of secondary forms of hypertension in 4429 consecutively referred patients. J Hypertens 12:609, 1994.

*The patients screened by Anderson and colleagues were referred for evaluation of secondary causes; those screened by Rudnick and Sinclair were all those seen in a primary setting.

missed, the similarity of data strongly supports the view that more than 90 percent of all hypertensive persons will have no recognizable cause; i.e., they have essential or primary hypertension.

THE CHANGING NATURE OF CHILDHOOD HYPERTENSION (see also p. 956).

Even among children, secondary hypertension is less common than indicated by previous surveys of hospital-based populations. As more apparently normal children are being screened and more are found to be hypertensive, the clinical manifestation of childhood hypertension is changing from that of a rare and serious disease, usually related to renal damage, to a more common and generally asymptomatic process, in most cases without recognizable cause.[26] Some prepubertal hypertensive children do not have recognizable secondary diseases, whereas most identified after puberty have primary hypertension.

SCREENING FOR SECONDARY HYPERTENSION

Because of the relatively low frequency of the various secondary diseases, the clinician should be selective in carrying out various screening and diagnostic tests. The presence of features *inappropriate* for the usual uncomplicated primary hypertension is an indication for additional tests (Table 28-6) . However, for the 9 in 10 hypertensive patients without these features, a hematocrit, urine analysis, automated blood biochemical profile (including plasma glucose, potassium, creatinine, and total and high-density lipoprotein cholesterol), and an electrocardiogram are all that is required. Although some would include other tests, an inordinate number of screening tests for relatively rare diseases will increase the likelihood of a false-positive result. For example, according to Bayes' theorem, at a prevalence rate of 2 percent for renovascular hypertension, which is probably higher than seen in the overall hypertensive population, the predictive

TABLE 28-6 -- FEATURES OF "INAPPROPRIATE" HYPERTENSION

Onset before age 20 or after age 50
Level of blood pressure >180/110 mm Hg
Organ damage
Funduscopic findings of grade 2 or higher
Serum creatinine >1.5 mg/100 ml
Cardiomegaly (on radiograph) or left ventricular hypertrophy (on electrocardiogram)
Features indicative of secondary causes
Unprovoked hypokalemia
Abdominal bruit
Variable pressures with tachycardia, sweating, tremor
Family history of renal disease
Poor response to therapy that is usually effective

value of an IVP or isotopic renogram suggestive of this diagnosis is only 10 percent, and an abnormal IVP or renogram is more likely to be a false-positive result than be true-positive and indicate a specific diagnosis.[32]

NATURAL HISTORY OF UNTREATED HYPERTENSION

A meta-analysis of nine major prospective observational studies involving 420,000 individuals free of known coronary or cerebral vascular disease at baseline who were monitored for 6 to 25 years (mean of 10 years) shows a "direct, continuous and apparently independent association" of diastolic blood pressure with both stroke and coronary heart disease[23] (Fig. 28-6) . The data indicate that prolonged increases in the usual diastolic pressure of 5 and 10 mm Hg were associated with at least 34 and 56 percent increases in stroke risk and with at least 21 and 37 percent increases in coronary heart disease risk, respectively.

SYMPTOMS AND SIGNS.

Because uncomplicated hypertension is almost always asymptomatic, a person may be unaware of the consequent progressive cardiovascular damage for as long as 10 to 20 years. Only if blood pressure is measured frequently and people are made aware that hypertension may be harmful even if asymptomatic will the majority of people with unrecognized or inadequately treated hypertension be managed effectively. Symptoms often attributed to hypertension--headache, tinnitus, dizziness, and fainting--may be observed just as commonly in the normotensive population. Moreover, many symptoms attributed to the elevated blood pressure are psychogenic in origin, often reflecting hyperventilation induced by anxiety over the diagnosis of a lifelong, insidious disease that threatens well-being and survival.[33] Even headache, long considered a frequent symptom of hypertension, is poorly related to the level of blood pressure, as noted in 10 to 20 percent of those with diastolic blood pressure levels from below 90 to above 120 mm Hg.[34]

COURSE OF UNTREATED HYPERTENSION.

As noted in Figure 28-6 , even minimal hypertension is accompanied by significant increases in coronary disease and stroke. However, these figures may be misleading since they seem to imply that most hypertensives, including those with minimally elevated pressure, will experience adverse consequences of hypertension, and rather quickly. The issue is well identified in the data from the Pooling Project,[35] which includes multiple prospective follow-up studies, including the Framingham cohort. These data indicate that white men with diastolic pressures of 80 to 87 mm Hg had a 52 percent greater *relative* risk of having a major coronary event over an 8.6-year period than did those with diastolic pressures below 80. However, this large increased *relative* risk translates to an *absolute* excess risk of only 3.5 men per 100 over the 8.6-year interval. Obviously, the majority of those with even higher diastolic pressures did not suffer a major coronary event.

Nonetheless, because so many persons have hypertension, the fact that even a minority of them will suffer a premature cardiovascular event in the course of their disease makes hypertension a major societal problem. In fact, when the death rates for various levels of diastolic blood pressure are multiplied by the proportion of people in the population who have these various levels, the majority of excess deaths attributable to hypertension are found to occur among those with minimally elevated pressure (see Fig. 28-2).

As the public and the medical profession have become aware of the overall societal consequences of even mild hypertension, enthusiasm for early recognition and aggressive treatment of hypertension has continued to mount. A closer look at the issue of deciding on the need for therapy is provided in Chapter 29 . However, further consideration of the natural course of hypertension, as it applies to the individual patient, is needed to answer a basic question: Are the blood pressure and the consequent risk high enough to justify medical intervention? Unless the risk is high enough to mandate some form of intervention, there seems to be no need to identify and label the person as hypertensive since psychological and socioeconomic burdens accompany this label; unless risks clearly outweigh these burdens, caution is obviously advised. A cogent view of this issue has been offered by Rose.[36]

> In reality the care of the symptomless hypertensive person is preventive medicine, not therapeutics. If a preventive mea- sure exposes many people to a small risk, the harm it does may readily . . . outweigh the benefits, since these are re- ceived by relatively few. . . . We may thus be unable to iden- tify that small level of harm to individuals from long-term in- tervention that would be sufficient to make that line of prevention unprofitable or even harmful. Consequently we cannot accept long-term mass preventive medication.

We are thus left with a dilemma: For hypertensive individuals as a group, even those with the least elevated pressures, risk is increased; for the individual hypertensive, the risk may not justify the labeling or treatment of the condition.

ASSESSMENT OF INDIVIDUAL RISK

Guidelines are available to help practitioners resolve this dilemma in dealing with the individual patient. These guidelines are based on the overall assessment of cardiovascular risk and the biological aggressiveness of the hypertension. They are intended to apply only to those with stage 1 (formerly referred to as mild) hypertension, that is, diastolic

Figure 28-6 The relative risks of stroke and coronary heart disease (CHD), estimated from the combined results of prospective observational studies, for each of five categories of diastolic blood pressure (DBP). (Estimates of the usual DBP in each baseline DBP category are taken from mean DBP values 4 years postbaseline in the Framingham Study.) The solid squares represent disease risks in each category relative to risk in the whole study population; the sizes of the squares are proportional to the number of events in each DBP category, and 95 percent confidence intervals for the estimates of relative risk are denoted by vertical lines. (From MacMahon S, Peto R, Cutler J, et al: Blood pressure and coronary heart disease: Part 1, prolonged differences in blood pressure: Prospective observational studies corrected for the regression dilution bias. Lancet 335:765, 1990. © by the Lancet Ltd., 1990.)

Figure 28-7 Estimated 10-year risk of coronary artery disease in hypothetical 55-year-old men and women according to levels of various risk factors. Lipid units are milligrams per deciliter. (From O'Donnell CJ, Kannel WB: Cardiovascular risks of hypertension: Lessons from observational studies. J Hypertens 16(Suppl 6):3, 1998.)

pressure between 90 and 99 mm Hg; those with diastolic levels persistently at or above 100 mm Hg have been shown to be at high enough risk from the hypertension per se to justify immediate intervention. Recall, however, that most hypertensives are in the range between 90 and 99 mm Hg (see Fig. 28-2). On the other hand, patients at high overall cardiovascular risk even with high normal blood pressure are deemed to be in need of active drug therapy.[1]

OVERALL CARDIOVASCULAR RISK.

The Framingham Study and other epidemiological surveys have clearly defined certain risk factors for premature cardiovascular disease in addition to hypertension

(see Chap. 31). For varying levels of blood pressure, the Framingham data (available in the *Coronary and Stroke Risk Handbooks* published by the American Heart Association) show the increasing likelihood of a vascular event over the next 10 years for both men and women at various ages as more and more risk factors are added.[19] For example, a 55-year-old man with a systolic blood pressure of 160 mm Hg who is otherwise at low risk would have a 13.7 percent chance of a vascular event in the next 10 years (Fig. 28-7) . A man of the same age with the same pressure but with all the additional risk factors (elevated serum total cholesterol, low high-density lipoprotein cholesterol, cigarette smoking, glucose intolerance, and LVH on the electrocardiogram) has a 59.5 percent chance. Obviously, the higher the overall risk, the more intensive the interventions should be.

An interesting--and disturbing--connection between untreated hypertension and *hypercholesterolemia* has been noted in multiple populations.[37] This connection may be mediated through insulin resistance and hyperinsulinemia and is anticipated in those with upper body obesity[38] but may also be found in nonobese hypertensives. Clearly, through this association, hypertensives are often burdened with an even greater risk than that imposed by their blood pressure alone.

Complications of Hypertension

The higher the level of blood pressure, the more likely that various cardiovascular diseases will develop prematurely through acceleration of atherosclerosis, the pathological hallmark of uncontrolled hypertension. If untreated, about 50 percent of hypertensive patients die of coronary heart disease or congestive failure, about 33 percent of stroke, and 10 to 15 percent of renal failure. Those with rapidly accelerating hypertension die more frequently of renal failure, as do those who are diabetic once proteinuria or other evidence of nephropathy develops. It is easy to underestimate the role of hypertension in producing the underlying vascular damage that leads to these cardiovascular catastrophes. Death is usually attributed to stroke or myocardial infarction instead of to the hypertension that was largely responsible. Moreover, hypertension may not persist after a myocardial infarction or stroke.

In general, the vascular complications of hypertension can be considered as either "hypertensive" or "atherosclerotic" (Table 28-7) . The former are more directly caused by the increased blood pressure per se and can be prevented by lowering this level; the latter have more multiple causations. Although hypertension may represent the most significant of the known risk factors for atherosclerosis in quantitative terms, lowering blood pressure may not by itself halt the atherosclerotic process.

The path from hypertension to vascular disease probably involves three interrelated processes: *pulsatile flow, endothelial cell dysfunction,* and *smooth muscle cell hypertrophy.* Higher systolic pressures are probably more responsible for these changes than are lower diastolic levels, which provides an explanation for the closer approximation of cardiovascular risk to systolic pressure and pulse pressure.

These three interrelated processes are probably responsible for the arteriolar and arterial sclerosis that is the usual consequence of longstanding hypertension; the subsequent target organ damage (see below) should be included in the overall assessment of hypertension risk. Beyond damage to the eyes, heart, brain, and kidney, large vessels such as the aorta may be directly affected and be at risk for aneurysms and dissection.

Target Organ Damage

The biological aggressiveness of a given level of hypertension varies among individuals. This inherent propensity to induce vascular damage can best be ascertained by examination of the eyes, heart, and kidney.

FUNDUSCOPIC EXAMINATION.

As described by Keith and associates in 1939, vascular changes in the fundus reflect both hypertensive retinopathy and arteriosclerotic retinopathy[39] (see Fig. 4-1). The two processes first induce

TABLE 28-7 -- VASCULAR COMPLICATIONS OF HYPERTENSION

HYPERTENSIVE	ATHEROSCLEROTIC
Accelerated-malignant phase	Coronary heart disease
Hemorrhagic stroke	Sudden death
Congestive heart failure	Other arrhythmias
Nephrosclerosis	Atherothrombotic stroke
Aortic dissection	Peripheral vascular disease

narrowing of the arteriolar lumen (grade 1) and then sclerosis of the adventitia and/or thickening of the arteriolar wall, visible as arteriovenous nicking (grade 2). Progressive hypertension induces rupture of small vessels, seen as hemorrhage and exudate (grade 3) and eventually papilledema (grade 4). The grade 3 and 4 changes are clearly indicative of an accelerated-malignant form of hypertension, whereas the lesser changes have been correlated with other evidence of target organ damage.[40]

CARDIAC INVOLVEMENT.

Hypertension places increased tension on the left ventricular myocardium that is manifested as stiffness and hypertrophy, which accelerates the development of atherosclerosis within the coronary vessels. The combination of increased demand and lessened supply increases the likelihood of myocardial ischemia and thereby leads to a higher incidence of myocardial infarction, sudden death, arrhythmias, and congestive failure in hypertensives (see Figs. 28-2 and Fig. 28-6).

Abnormalities in Left Ventricular Function.

Even before LVH develops, changes in both systolic and diastolic function may be seen. Those with minimally increased left ventricular muscle mass may have supernormal contractility as reflected by an increased inotropic state with a high percentage of fractional shortening and increased wall stress.[41] The earliest functional cardiac changes in hypertension are in left ventricular diastolic function, with prolongation and incoordination of isovolumic relaxation, a reduced rate of rapid filling, and an increase in the relative amplitude of the *a* wave, probably caused by increased passive stiffness[42] (see Chap. 15).

With increasing hemodynamic load, either systolic or diastolic dysfunction may evolve and progress to different forms of congestive heart failure[43] (Fig. 28-8) . In addition, impaired coronary flow reserve and thallium perfusion defects may be observed in hypertensives without obstructive coronary disease.[44] The syndrome of severe concentric hypertrophy with a small ventricular cavity leading to dyspnea and pulmonary congestion has been most frequently

Figure 28-8 Consequences of systolic and diastolic dysfunction related to hypertension. *A,* Systolic dysfunction and congestive heart failure caused by impaired ventricular contraction may occur late in the evolution of hypertensive heart disease. *B,* Diastolic dysfunction is the most common manifestation of the effect of hypertension on cardiac function and can also lead to congestive heart failure from increased filling pressures. LV = left ventricular. (From Shepherd RFJ, Zachariah PK, Shub C: Hypertension and left ventricular diastolic function. Mayo Clin Proc 64:1521, 1989. By permission of the Mayo Foundation.)

Figure 28-9 Mean left ventricular mass by sex and by systolic pressure, including participants taking antihypertensive medications. These data were obtained by M-mode echocardiograms taken on 2226 men and 2746 women aged 17 to 90 years in the Framingham Study, cohort examination 16 and offspring cycle 2, 1979 to 1983. (From Savage DD, Levy D, Danneberg AL, et al,: Association of echocardiographic left ventricular mass with body size, blood pressure and physical activity [the Framingham Study]. Am J Cardiol 65:371, 1990.)

reported in black hypertensive women.[45] Moreover, blacks are at a higher risk for progression to heart failure and death from left ventricular dysfunction than are

similarly treated whites.[46]

Left Ventricular Hypertrophy.

Hypertrophy as a response to the increased afterload associated with elevated systemic vascular resistance can be viewed as necessary and protective up to a certain point. Beyond that point, a variety of dysfunctions accompany LVH.

In the past, LVH was recognized on electrocardiography (see Chap. 5) by increased voltage of QRS complexes, intrinsicoid deflection over lead V_2 or V_3 greater than 0.06 seconds, and ST segment depression greater than 0.5 mm. Increasingly, echocardiography is being used (see Chap. 7) because it is much more sensitive in recognizing early cardiac involvement. By echocardiography, left ventricular mass is shown to progressively increase with increases in blood pressure[47] (Fig. 28-9) . Left ventricular mass is greater in those whose pressure does not fall during sleep because of a more persistent pressure load.[48]

The pathogenesis of LVH involves a number of variables other than the pressure load, one of which is hemodynamic volume load. Devereux and colleagues[48] found a closer correlation between left ventricular stroke volume and left ventricular mass with diastolic than with systolic blood pressure. Other determinants are obesity,[49] levels of sympathetic nervous system and renin-angiotensin activity, and whole blood viscosity, presumably by way of its influence on peripheral resistance. The correlation is much closer between LVH and pressure readings taken during the stress of work by ambulatory monitoring than between LVH and casual pressure readings.[50]

Different patterns of hypertrophy may evolve, often starting with asymmetrical left ventricular remodeling from isolated septal thickening, which has been noted in 22 percent of untreated hypertensives with normal total left ventricular mass.[51] The pattern of LVH may have important prognostic implications. In a 10-year follow-up of 253 hypertensives, all-cause mortality was higher and cardiovascular events were most frequent in those with *concentric* LVH.[52] The degree of increased muscle mass is a strong and independent risk factor for cardiac mortality over and above the extent of coronary artery disease.[47] In addition, the risk of ventricular arrhythmias is increased at least twofold in the presence of LVH.[53]

Since the presence of LVH may connote a number of deleterious effects of hypertension on cardiac function, a great deal of effort has been expended in showing that treatment of hypertension will cause LVH to regress. Treatment with all antihypertensive drugs except those that further activate sympathetic nervous system activity, e.g., direct vasodilators such as hydralazine when used alone, has been shown to cause LVH regression.[54] With regression, left ventricular function usually improves and cardiovascular morbidity decreases.[55]

Features of Coronary Artery Disease.

As detailed elsewhere (see Chap. 31), hypertension is a major risk factor for myocardial ischemia and infarction. Moreover, in the Framingham cohort, the prevalence of silent myocardial infarction was significantly increased in hypertensive subjects, and they were also more susceptible to silent ischemia and sudden death,[56] as well as having a greater risk for mortality after an initial myocardial infarction.[57] Beyond these multiple additional risks associated with hypertension, a higher incidence of cardiovascular mortality has also been recognized when elevated diastolic blood pressures are reduced to levels below 80 mm Hg.[58] This J-shaped curve probably reflects a reduction in perfusion pressure through coronary vessels either narrowed or having impaired vasodilatory reserve in the presence of hypertrophied myocardium.

RENAL FUNCTION.

Renal dysfunction too subtle to be recognized may be responsible for the development of most cases of essential hypertension. As discussed on p. 952 , increased renal retention of salt and water may be a mechanism initiating primary hypertension, but the retention is so small that it escapes detection. With detailed study, both structural damage and functional derangements reflecting intraglomerular hypertension often reflected by microalbuminuria can be found in most hypertensive persons. Microalbuminuria in hypertensives has been correlated with both insulin resistance[59] and evidence of endothelial cell dysfunction.[60] As hypertension-induced nephrosclerosis proceeds, the plasma creatinine level begins to rise, and eventually, renal insufficiency with uremia may develop, thus making hypertension a leading cause of end-stage renal disease (ESRD), particularly in blacks.[61]

CEREBRAL INVOLVEMENT.

Hypertension may accelerate cognitive decline with age.[62] Hypertension, particularly systolic, is a major risk factor for initial and recurrent stroke and for transient ischemic attacks caused by extracranial atherosclerosis.[63] Usually with, but sometimes without, hypertension, increasing left ventricular mass on echocardiography is associated with a progressively higher risk for stroke.[64] Blood pressure usually rises further during the acute phases of a stroke, and caution is advised in lowering blood pressure during this crucial period.

On the basis of the aforementioned assessments of overall cardiovascular risk and severity of hypertension, it should be possible to determine the approximate risk status and prognosis for individual patients, which can most easily be accomplished with the Framingham data, as described on page 948 .

SHORT-TERM COURSE OF LOW-RISK HYPERTENSION.

Data on the 4-year experiences of over 1600 "low-risk" hypertensives who served as controls in the Australian Therapeutic Trial document the validity of this assessment.[65] To enter this placebo-versus-drug trial, the patients had to be free of all identifiable cardiovascular disease, with the second set of diastolic pressures between 95 and 109 mm Hg. Thus, they could be considered "low-risk" hypertensives. Over the next 4 years, in the majority of these patients, who were given placebo tablets but neither nondrug nor drug therapy, blood pressures *dropped progressively* from an average of 157/102 to 144/91 mm Hg. Diastolic pressure was below 95 mm Hg in 47.5 percent at the end of the trial. The fall in blood pressure was not related to any recognizable change in the patients' status; similar decreases occurred independent of changes in or stability of body weight. Of great interest was the lack of excess morbidity and mortality among those whose diastolic pressure remained below 100 mm Hg.

These results strongly support the view that certain patients can be characterized as being at relatively low risk and can therefore safely do without drug therapy long enough for the clinician to monitor both their blood pressure levels over time and the effectiveness of nondrug measures, if indicated. The large number of patients whose pressure fell and the high average degree of fall may seem surprising, but none of these patients started with any identifiable cardiovascular disease or complications of hypertension. Moreover, placebo may be more effective than no therapy.

THE POTENTIAL FOR PROGRESSION.

Although these data reflect the benign nature of "low-risk" hypertension over the short term, it should be noted that diastolic blood pressure rose above 110 mm

TABLE 28-8 -- COMPONENTS OF CARDIOVASCULAR RISK STRATIFICATION IN PATIENTS WITH HYPERTENSION

Major Risk Factors
Smoking
Dyslipidemia
Diabetes mellitus
Age >60 yr
Sex (men and postmenopausal women)
Family history of cardiovascular disease:
Women <65 yr or men >55 yr

Target Organ Damage/Clinical Cardiovascular Disease
Heart diseases
Left ventricular hypertrophy
Angina or prior myocardial infarction
Prior coronary revascularization
Heart failure
Stroke or transient ischemic attack
Nephropathy
Peripheral arterial disease
Retinopathy

Hg in 12 percent of the non-drug-treated patients in the Australian trial. Therefore, continued monitoring of blood pressure levels is obviously needed for all patients with even the mildest "low-risk" hypertension.

A SYNTHESIS OF RISK.

As first clearly articulated by a group of New Zealand physicians,[66] the degree of risk from hypertension can be categorized with reasonable accuracy by taking into account (1) the level of blood pressure, (2) the biological nature of the hypertension based on the degree of target organ damage, and (3) the coexistence of other risks. The JNC-6 report provides a stratification of risk into three groups based on known components of risk (Table 28-8) and levels of blood pressure, which are, in turn, used as the basis for deciding upon initial treatment (Table 28-9) . According to this stratification, active drug therapy is recommended for high-risk patients even if blood pressure is only high normal, whereas life style modifications are recommended for low-risk patients even if blood pressure is as high as 159/99 mm Hg. Similar recommendations have been made in the 1999 WHO-ISH guidelines.[24]

It is obvious that since the course of the blood pressure cannot be predicted with certainty, even hypertensives who are not treated should be monitored, and recognition of their hypertension should motivate them to follow good health habits. In this way, no harm should be done, and the potential benefit may be considerable if progression of the disease can be slowed by life style modifications.

MECHANISMS OF PRIMARY (ESSENTIAL) HYPERTENSION

No single or specific cause is known for most hypertension, and the condition is referred to as *primary* in preference to *essential.* Since persistent hypertension can develop only in response to an increase in cardiac output or a rise in peripheral resistance, defects may be present in one or more of the multiple factors that affect these two forces (Fig. 28-10) . The interplay of various derangements in factors affecting cardiac output and peripheral resistance may precipitate the disease, and these abnormalities may differ in both type and degree in different patients.

TABLE 28-9 -- RISK STRATIFICATION AND TREATMENT*

BLOOD PRESSURE STAGES (mm Hg)	RISK GROUP A (NO RISK FACTORS: NO TOD/CCD)	RISK GROUP B (AT LEAST 1 RISK FACTOR, NOT INCLUDING DIABETES: NO TOD/CCD)	RISK GROUP C (TOD/CCD AND/OR DIABETES, WITH OR WITHOUT OTHER RISK FACTORS)
High normal (130-139/85-89)	Life style modification	Life style modification	Drug therapy
Stage 1 (140-159/90-99)	Life style modification (up to 12 mo)	Life style modification (up to 6 mo)	Drug therapy
Stages 2 and 3 (>160/>100)	Drug therapy	Drug therapy	Drug therapy

CCD=clinical cardiovascular disease; TOD=target organ disease.*From The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure. Arch Intern Med 157:2413. 1997. Copyright 1997, American Medical Association.*

*Note: For example, a patient with diabetes and a blood pressure of 142/94 mm Hg plus left ventricular hypertrophy should be classified as having stage 1 hypertension with target organ disease (left ventricular hypertrophy) and with another major risk factor (diabetes). This patient would be categorized as "stage 1, risk group C," and recommended for immediate initiation of pharmacological treatment. Life style modification should be adjunctive therapy for all patients recommended for pharmacological therapy.

Hemodynamic Patterns

Before describing specific abnormalities in the various factors shown in Figure 28-10 to affect the basic equation blood pressure = cardiac output × peripheral resistance (BP = CO × PR), the hemodynamic patterns that have been measured in patients with hypertension will be considered. One cautionary factor should be kept in mind: Development of the disease is slow and gradual. By the time that blood pressure becomes elevated, the initiating factors may no longer be apparent because they may have been "normalized" by multiple compensatory interactions. Nonetheless, when a group of untreated young hypertensive patients was studied initially, cardiac output was normal or slightly increased and peripheral resistance was normal.[67] Over the next 20 years, cardiac output fell progressively while peripheral resistance rose. In a much larger study involving over 2600 subjects in Framingham who were monitored for 4 years by echocardiography, an increased cardiac index and end-systolic wall stress were related to the development of hypertension,[68] and in a 10-year follow-up of 4700 young people, an increased heart rate, presumably associated with a reflection of increased cardiac output, has been found to be a predictor of future hypertension.[69]

Regardless of how hypertension begins, the eventual primacy of increased resistance can be shown even in models of hypertension that feature an initial increase in fluid volume and cardiac output.[6]

Genetic Predisposition

As discussed in Chapter 56 and shown in Fig. 28-10 , genetic alterations may initiate the cascade to permanent hypertension. In studies of twins and family members in which the degree of familial aggregation of blood pressure levels is compared with the closeness of genetic sharing, the genetic contributions have been estimated to range from 30 to 60 percent.[70] Unquestionably, environment plays some role, and Harrap[70] offers as a working model an interaction between genes and environment "in which the average population pressure is determined by environment, but blood pressure rank within the distribution is decided largely by genes."

Three rare forms of hypertension have been found to be

Figure 28-10 Some of the factors involved in the control of blood pressure that affect the basic equation Blood pressure = cardiac output (CO) × peripheral resistance (PR). Cellular hyperplasia may be seen along with hypertrophy. (From Kaplan NM: Clinical Hypertension. 7th ed. Baltimore, Williams & Wilkins, 1998, p 45.)

caused by a monogenic abnormality: glucocorticoid-remediable aldosteronism, Liddle syndrome, and apparent mineralocorticoid excess.[71] In addition, polymorphism of genes involving the renin-angiotensin system,[72] aldosterone synthesis,[73] and adrenergic receptors[74] has been noted to be more common in hypertensive than normotensive patients.

If genetic markers of a predisposition for the development of hypertension are found, specific environmental manipulations could then be directed toward susceptible subjects.[75] For now, children and siblings of hypertensives should be more carefully screened. They should be vigorously advised to avoid environmental factors known to aggravate hypertension and increase cardiovascular risk (e.g., smoking, inactivity, and excess sodium).

The Fetal Environment

Environmental factors may come into play very early. Low birth weight as a consequence of fetal undernutrition is followed by an increased incidence of high blood pressure later in life.[76] Brenner and Chertow hypothesized that a decreased number of nephrons from intrauterine growth retardation could very well serve as this permanent, irreparable defect that eventuates in hypertension [77] (Fig. 28-11) . In their words:

> This hypothesis draws on observations suggesting (1) a direct relationship between birth weight and nephron number, (2) an inverse relationship between birth weight and childhood, adolescent, and adult blood pressures, and (3) an inverse relationship between nephron number and blood pressure, irrespective of whether neph- ron number is reduced congenitally or in postnatal life (as from partial renal ablation or acquired renal disease).

This hypothesis fits nicely with Brenner's explanation for the inexorable progression of renal damage once it begins and the concept that hypertension may begin by renal sodium retention induced by the decreased filtration surface area.[78]

Renal Retention of Excess Dietary Sodium

A considerable amount of circumstantial evidence supports a role for sodium in the genesis of hypertension (Table 28-10) . To induce hypertension, some of that excess sodium must be retained by the kidneys. Such retention could arise in a number of ways, including

Figure 28-11 The risk of essential hypertension and progressive renal injury developing in adult life is increased as a result of congenital oligonephropathy, an inborn deficit of filtration surface area (FSA) caused by impaired renal development. Low birth weight resulting from intrauterine growth retardation or prematurity contributes to this oligonephropathy. Systemic and glomerular hypertension in later life results in progressive glomerular sclerosis, further reducing FSA and thereby perpetuating a vicious cycle that leads, in the extreme, to end-stage renal failure. (From Brenner BM, Chertow GM: Congenital oligonephropathy: An inborn cause of adult hypertension and progressive renal injury? Curr Opin Nephrol Hypertens 2:691, 1993.)

TABLE 28-10 -- EVIDENCE FOR A ROLE OF SODIUM IN PRIMARY (ESSENTIAL) HYPERTENSION

In multiple populations, the rise in blood pressure with age is directly correlated with increasing levels of sodium intake.
Multiple, scattered groups who consume little sodium (less than 50 mmol/d) have little or no hypertension. When they consume more sodium, hypertension appears.
Hypertension develops in animals given sodium loads, if genetically predisposed.
In some people, large sodium loads given over short periods cause an increase in vascular resistance and blood pressure.
An increased concentration of sodium is present in the vascular tissue and blood cells of most hypertensives.
Sodium restriction to a level below 100 mmol/d will lower blood pressure in most people. The antihypertensive action in diuretics requires an initial natriuresis.

> A decrease in filtration surface by a congenital or acquired deficiency in nephron number or function.[78]
>
> A resetting of the normal pressure-natriuresis relationship wherein a rise in pressure invokes an immediate increase in renal sodium excretion, thereby shrinking fluid volume and returning the pressure to normal. Guyton has long argued for a resetting of this relationship as a fundamental defect that must be present to explain the persistence of elevated pressure.[79]
>
> Nephron heterogeneity, which is hypothesized by Sealey and coworkers[80] as the presence of "a subpopulation of nephrons that is ischemic either from afferent arteriolar vasoconstriction or from an intrinsic narrowing of the lumen. Renin secretion from this subgroup of nephrons is tonically elevated. This increased renin secretion then interferes with the compensatory capacity of intermingled normal nephrons to adaptively excrete sodium and, consequently, perturbs overall blood pressure homeostasis."
>
> An acquired inhibitor of the sodium pump[81] or other abnormalities in sodium transport.[82]
>
> Deficient responsiveness to atrial natriuretic hormone.[83]

Thus, more than enough ways are available to incite renal retention of even a very small bit of the excess sodium typically ingested that could eventually expand body fluid volume. Variations in sensitivity to sodium have also been noted and may explain why only some people respond to excess sodium and others do not.[84]

Those who are more sodium sensitive have been found to have more markers of endothelial damage,[85] nondipping of nocturnal blood pressure, [86] and increased mortality[87] than do those who are less sodium sensitive. Sodium sensitivity is more common among normotensive blacks and is associated with sodium-induced renal vasoconstriction.[88] Both the pressor sensitivity and renal vasoconstriction were reversed by increased intake of potassium bicarbonate, thus supporting a role for reduced potassium intake as a contributor to the excess number of cases of hypertension found in people of low-socioeconomic status.[89]

Vascular Hypertrophy

Both excess sodium intake and renal sodium retention would presumably work primarily on increasing fluid volume and cardiac output. A number of other factors may work primarily on the second part of the equation BP = CO × PR (see Fig. 28-10). Most of these factors can cause both functional contraction and structural remodeling and hypertrophy.

Multiple vasoactive substances act as growth factors for vascular hypertrophy. These pressor-growth promoters may result in both vascular contraction and hypertrophy simultaneously,

but perpetuation of hypertension involves hypertrophy. Various hormonal mediators may serve as the initiator of what eventuates as increased peripheral resistance. From the study of certain "pure" forms of hormonally induced hypertension, Lever and Harrap[90] have postulated that

> Most forms of secondary hypertension have two pressor mecha- nisms: a primary cause, e.g., renal clip, and a second process, which is slow to develop, capable of maintaining hypertension after removal of the primary cause, and probably self-perpetuating in nature. We suggest that essential hypertension also has two mechanisms, both based upon cardiovascular hypertrophy: (1) a growth-promoting process in children (equivalent to the primary cause in secondary hypertension) and (2) a self-perpetuating mech- anism in adults.

These investigators have built on the original proposal of Folkow[91] of a "positive feedback interaction" wherein even mild functional pressor influences, if repeatedly exerted, may lead to structural hypertrophy, which in turn reinforces and perpetuates the elevated pressure (Fig. 28-12) . Lever and Harrap[90] have added two hypotheses to Folkow's first: a reinforcement of the hypertrophic response to stimuli that initially raise the pressure, e.g., defects in the vascular cell membrane, and the action of various trophic mechanisms that may cause vascular hypertrophy directly (the "slow pressor mechanism").

This scheme to explain an immediate pressor action and a slow hypertrophic effect is thought to be common to the action of pressor-growth promoters. When present in high concentrations over long periods, as with angiotensin II in renal artery stenosis, each of these pressor-growth promoters causes hypertension. Moreover, when the source of the excess pressor-growth promoter is removed, hypertension may recede slowly, presumably reflecting the time needed to reverse vascular hypertrophy.

No marked excess of any known pressor hormone is identifiable in the majority of hypertensive patients. Nonetheless, a lesser excess of one or more may have been

responsible for initiation of a process sustained by the positive feedback postulated by Folkow[91] and the trophic effects emphasized by Lever and Harrap.[90] This sequence encompasses a variety of specific initiating mechanisms that accentuate and maintain the hypertension by a nonspecific feedback-trophic mechanism (Fig. 28-12) . If this double process is fundamental to the pathogenesis of primary hypertension, the difficulty in recognizing the initiating causal factor is easily explained. As formulated by Lever[92]

> The primary cause of hypertension will be most apparent in the early stages; in the later stages, the cause will be con- cealed by an increasing contribution from hypertrophy... A particular form of hypertension may wrongly be judged to have "no known cause" because each mechanism considered is insufficiently abnormal by itself to have produced the hyper- tension. The cause of essential hypertension may have been considered already but rejected for this reason.

Figure 28-12 Hypotheses for the initiation and maintenance of hypertension. *A,* Folkow's first proposal that minor overactivity of a pressor mechanism (A) raises blood pressure slightly, which initiates positive feedback (BCB) and a progressive rise in blood pressure. *B,* As in *A* with two additional signals: D, an abnormal or "reinforced" hypertrophic response to pressure; and E, increase in a humoral agent causing hypertrophy directly. (From Lever AF and Harrap SB: Essential hypertension: A disorder of growth with origins in childhood? J Hypertens 10:101, 1992.)

Neurohumoral Causes of Primary Hypertension

A large number of circulating hormones and locally acting substances may be involved in the development of hypertension. Support exists for each of those shown as potential instigators in Figure 28-10 . They will be considered in the order shown without attempting to prioritize their role. In addition to these hypertrophic changes, capillary rarefaction[93] and impaired microvascular dilation [94] may also be involved in the pathogenesis of hypertension.

Sympathetic Nervous Hyperactivity

Young hypertensives tend to have increased levels of circulating catecholamines, augmented sympathetic nerve traffic in muscles, faster heart rate,[69] and heightened vascular reactivity to alpha-adrenergic agonists.[95] These changes could raise blood pressure in a number of ways--either alone or in concert with stimulation of renin release by catecholamines--by causing arteriolar and venous constriction, by increasing cardiac output, or by altering the normal renal pressure-volume relationship. In addition to cardiac stimulation by sympathetic activity, vagal inhibitory responses to baroreceptors and other stimuli may also be important. In humans with denervated transplanted hearts, both pulse and blood pressure fail to display the usual nocturnal fall, and hypertension is frequent.[96] The transient increase in epinephrine during stress reactions may invoke a more prolonged pressor response by facilitating the release of norepinephrine from sympathetic neurons but this mechanism could not be demonstrated in humans.[97]

Repetitive stress or an accentuated, exaggerated response to stress is the logical means by which sympathetic activation would arise. Young hypertensives tend to be hyperresponsive,[95] and at least among middle-aged men in Framingham, the development of hypertension over an 18- to 20-year period was associated with heightened anxiety and anger intensity and suppressed expression of anger at baseline.[98] Moreover, in the 29-year-old normotensives in the Tecumseh Blood Pressure study, increased sympathetic activity was closely correlated with higher hematocrit levels, presumably reflecting a decrease in plasma volume from vasoconstriction[99]

The Tecumseh subjects with higher plasma catecholamine levels also tended to have higher plasma renin activity (PRA). Other investigators have noted that hypertensives with high PRA had more anxiety, suppressed anger, and susceptibility to emotional distress.[100] Obviously, the sympathetic and renin mechanisms may be connected in various ways.

Sympathetic nervous activity could be activated from the brain without the mediation of stress or emotional distress. Hypertension has been induced in animals by various neurogenic defects. An intriguing association has been reported but not documented between essential hypertension and compression of the ventrolateral medulla by loops of the posterior inferior cerebellar artery or an ectatic vertebral artery seen by magnetic resonance tomography.[101]

Whatever the specific role of sympathetic activity in the pathogenesis of hypertension, it appears to be involved in the increased cardiovascular morbidity and mortality that affect hypertensive patients during the early morning hours. Increased alpha-sympathetic activity occurs in the early morning in association with the preawakening increase in rapid eye movement (REM) sleep and the assumption of upright posture after overnight recumbency.[102] As a consequence of the increased sympathetic activity, blood pressure rises abruptly and markedly. This rise must be at least partly responsible for the increase in cardiovascular catastrophes in the early morning hours.[14]

Renin-Angiotensin System

Both as a direct pressor and as a growth promoter, the renin-angiotensin mechanism may also be involved in the pathogenesis of hypertension. All functions of renin are mediated through the synthesis of angiotensin II. This system is the primary stimulus for the secretion of aldosterone and hence mediates mineralocorticoid responses to varying sodium intake and volume load. When sodium intake is reduced or effective plasma volume shrinks, the increase in renin-angiotensin II stimulates aldosterone secretion, which in turn is responsible for a portion of the enhanced

Figure 28-13 Overall scheme of the renin-angiotensin mechanism indicating the site of action of angiotensin II type I receptor antagonist.

renal retention of sodium and water (Fig. 28-13) . As noted elsewhere (see Chap. 64), aldosterone may have additional roles including a contribution to myocardial fibrosis and to baroreceptor dysfunction.[103]

According to the feedback shown in Fig. 26-13 , any rise in blood pressure inhibits release of renin from the renal juxtaglomerular cells. Therefore, primary (essential) hypertension would be expected to be accompanied by low, suppressed levels of PRA. However, when large populations of hypertensives are surveyed, only about 30 percent have low PRA, whereas 50 percent have normal levels and the remaining 20 percent have high levels.[104]

NORMAL- AND HIGH-RENIN HYPERTENSION

A number of explanations have been offered for these "inappropriately normal" or high levels, beyond the proportion expected in a normal gaussian distribution curve. One of the more attractive is the concept of "nephron heterogeneity" described by Sealey and colleagues,[80] which assumes a mixture of normal and ischemic nephrons caused by afferent arteriolar narrowing. Excess renin from the ischemic nephrons could raise the total blood renin level to varying degrees and cause some persons to have normal- or high-renin hypertension.

This hypothesis is similar to that proposed by Goldblatt, who believed that "the primary cause of essential hypertension in man is intrarenal obliterative vascular disease, from any cause, usually arterial and arteriolar sclerosis, or any other condition which brings about the same disturbance of intrarenal hemodynamics."[105] When Goldblatt placed the clamp on the main renal arteries in canine studies, he was trying to explain the pathogenesis of primary (essential) hypertension rather than what he ended up explaining: the pathogenesis of renovascular hypertension. Nonetheless, his experimental concept is the basis for the more modern model of Sealey and colleagues. The elevated renin from the ischemic population of nephrons, although diluted in the systemic circulation, provides the "normal" renin levels that are usual in patients with primary hypertension who would otherwise be expected to shut down renin secretion and in whom levels would be low. These diluted levels are still high enough to impair sodium excretion in the nonischemic hyperfiltering nephrons but are too low to support efferent tone in the ischemic nephrons, thereby reducing sodium excretion in them as well.

Sealey and associates' concept of nephron heterogeneity differs from Brunner and associates' concept of nephron scarcity previously noted.[105] Nevertheless, Sealey and colleagues agree that "a reduction in nephron number related to either age or ischemia could amplify the impaired sodium excretion and promote hypertension."[80]

The renin-angiotensin system is active in multiple organs, either from in situ synthesis of various components or by transport from renal juxtaglomerular cells through the circulation. Most of the important pathophysiological effects are mediated through the angiotensin II type I receptor,[106] but some effects may involve the type II receptor[107] (Fig. 28-13) . The presence of the complete system in endothelial cells, the brain, the heart, and the adrenal cortex[108] broadens the potential roles of this

mechanism far beyond its previously accepted boundaries.

Hyperinsulinemia/Insulin Resistance

An association between hypertension and hyperinsulinemia has been recognized for many years, particularly with accompanying obesity but also in nonobese hypertensives.[37] The association does not apply to some ethnic groups such as Pima Indians, but it has been found in blacks and Asians, as well as whites.

All obese people are hyperinsulinemic secondary to insulin resistance and even more so if the obesity is predominantly visceral, i.e., abdominal or upper body, wherein decreased hepatic uptake of insulin contributes to the hyperinsulinemia. The hyperinsulinemia of hypertension also arises as a consequence of resistance to the effects of insulin on peripheral glucose utilization.[109] The cause of the insulin resistance is unknown. It could reflect a simple inability of insulin to reach skeletal muscle cells, wherein its major peripheral actions on glucose metabolism occur. This impairment may in turn result from a defect in the usual vasodilatory effect of insulin mediated through increased synthesis of nitric oxide (NO), which normally counters the multiple pressor effects of insulin[110] (Fig. 28-14) . These pressor effects, in addition to activation of sympathetic activity, include a trophic action on vascular hypertrophy, increased renal sodium reabsorption, and structural changes in the myocardium.[111]

Figure 28-14 *Left,* Insulin's actions in normal humans. Although insulin causes a marked increase in sympathetic neural outflow, which would be expected to increase blood pressure, it also causes vasodilation, which would decrease blood pressure. The net effect of these two opposing influences is no change or a slight decrease in blood pressure. There may be an imbalance between the sympathetic and vascular actions of insulin in conditions such as obesity or hypertension. *Right,* Insulin may cause potentiated sympathetic activation or attenuated vasodilation. An imbalance between these pressor and depressor actions of insulin may result in elevated blood pressure. (From Anderson EA, Mark AL: Cardiovascular and sympathetic actions of insulin: The insulin hypothesis of hypertension revisited. Cardiovasc Risk Factors 3:159, 1993.)

Figure 28-15 Endothelium-derived vasoactive substances. Various blood- and platelet-derived substances can activate specific receptors (open circles) on the endothelial membrane to release relaxing factors such as nitric oxide (NO), prostacyclin (PGI_2), and an endothelium-derived hyperpolarizing factor (EDHF). Other contracting factors are released, such as endothelin-1 (ET-1), angiotensin (A), and thromboxane A_2 (TXA_2), as well as prostaglandin H_2 (PGH_2). ACE = angiotensin-converting enzyme; Ach = acetylcholine; 5HT = 5-hydroxytryptamine, or serotonin; BK = bradykinin; ECE = endothelin-converting enzyme; L -Arg = L - arginine; NOS = nitric oxide synthase; O_2^- = superoxide; TGF-beta = transforming growth factor-beta; Thr = thrombin. (From Ruschitzka F, Corti R, Noll G, Luscher TF: A rationale for treatment of endothelial dysfunction in hypertension. J Hyperten 17(Suppl 1):25-35, 1999.)

The failure of vasodilation to antagonize the multiple pressor effects of insulin presumably eventuates in a rise in blood pressure that may be either a primary cause of hypertension or, at least, a secondary potentiator. In addition, the underlying insulin resistance is often associated with a full syndrome, including dyslipidemia and diabetes along with hypertension, which combine to be a major risk factor for premature coronary disease.[37]

Endothelial Cell Dysfunction

The impairment of normal vasodilation seen in the insulin resistance syndrome has been shown to involve failure to synthesize the normal endothelium-derived relaxing factor NO.[112] Lack of NO synthesis is one of the rapidly increasing pieces of evidence for an active role for endothelial cells, now known to be the source of multiple relaxing and constricting substances, most having a local, paracrine influence on underlying smooth muscle cells (Fig. 28-15) .

NITRIC OXIDE (see Chap. 34).

Hypertensive patients have been shown to have a reduced vasodilatory response to various stimuli of NO release that appears to be independent of the etiology of the hypertension and the degree of gross vascular structural alteration.[113] [114] Impaired NOmediated vasodilation may promote abnormal vascular remodeling[115] and may be involved in the greater propensity for vascular damage in blacks than in white.[116] NO-mediated forearm responsiveness has been restored by normalization of blood pressure by antihypertensive drugs with different modes of action.[117]

ENDOTHELIN.

A number of endothelium-derived constricting factors are shown in the middle portion of Fig. 28-15 . Of these, endothelin-1 appears to be of particular importance because it causes pronounced and prolonged vasoconstriction and because inhibitors of its synthesis or binding cause significant vasodilation.[118] Its role in human hypertension, however, remains uncertain.

OTHER POSSIBLE MECHANISMS

The preceding description of the possible roles of the various mechanisms portrayed in Figure 28-10 does not exhaust the list of putative contributors to the pathogenesis of primary hypertension.

The role of other pressor hormones in human hypertension remains unknown. Similarly, a number of vasodepressor hormones are known, but their function, too, remains uncertain. These hormones include kallikrein,[119] medullipin, a renomedullary lipid,[120] and adrenomedullin.[121]

Contributions from excesses of various minerals, particularly lead,[122] and changing ratios among dietary sodium, potassium, calcium, and magnesium have also been postulated.[123] Support for these and other proposed mechanisms is meager, and the overall schemes involving intracellular sodium and calcium and the pressor-growth promoter mechanisms for vascular hypertrophy seem more than adequate to explain the pathogenesis of primary hypertension. However, a number of associations between hypertension and other conditions have been noted and may offer additional insight into the potential causes and possible prevention of the disease.

ASSOCIATION OF HYPERTENSION WITH OTHER CONDITIONS

OBESITY.

Hypertension is more common among obese individuals and adds to their increased risk for ischemic heart disease, particularly if it is abdominal or visceral in location.[124] In the Framingham offspring study, adiposity, as measured by subscapular skinfold thickness, was the major controllable contributor to hypertension.[125] Even small amounts of weight gain are associated with a marked increase in the incidence of hypertension[126] and coronary mortality.[127] Unfortunately, there is a worldwide epidemic of obesity, perhaps most widespread in the United States, where the prevalence of obesity, defined as a body mass index above 30, increased by 50 percent from 1980 to 1995.[128] Obesity is rapidly increasing among U.S. children, and children seem particularly vulnerable to the hypertensive effects of weight gain.[26] Therefore, avoidance of childhood obesity in the hope of avoiding subsequent hypertension is important. The evidence that weight reduction will lower established hypertension is discussed on p. 976 .

SLEEP APNEA.

One of the contributors to the hypertension in obese persons is sleep apnea. Snoring and sleep apnea are often associated with hypertension, which may in turn be induced by increased sympathetic activity and

endothelin release in response to hypoxemia during apnea.[129]

PHYSICAL INACTIVITY.

Physical fitness may help prevent hypertension, and persons who are already hypertensive may lower their blood pressure by means of regular isotonic exercise. The relationship may involve insulin resistance because increased resistance was coupled with low physical fitness in normotensive men with a family history of hypertension.[130] Regular exercise may prevent hypertension and thereby protect against the development of cardiovascular disease. Among 16,936 Harvard male alumni monitored for 16 to 50 years, those who did not engage in vigorous sports play were at 35 percent greater risk for the development of hypertension regardless of whether they had higher blood pressures while at Harvard, a family history of hypertension, or obesity--factors that also increased the risk of hypertension.[131]

ALCOHOL INTAKE.

Alcohol in small amounts (less than two usual portions a day) provides protection from coronary disease, stroke, and atherosclerosis[132] but in larger amounts (more than two portions a day and even more so when drunk in binges), alcohol increases blood pressure.[133] The reduction in coronary disease in persons who ingest small amounts of alcohol may reflect an improvement in lipid profile, a reduction in factors that encourage thrombosis, and an improvement in insulin sensitivity.[134]

The pressor effect of larger amounts of alcohol primarily reflects an increase in cardiac output and heart rate, possibly a consequence of increased sympathetic nerve activity.[135] Alcohol also alters cell membranes and allows more calcium to enter, perhaps by inhibition of sodium transport.[136]

SMOKING (see also p. 976).

Cigarette smoking raises blood pressure, probably through the nicotine-induced release of norepinephrine from adrenergic nerve endings. In addition, smoking causes an acute and marked reduction in radial artery compliance independent of the increase in blood pressure.[137] When smokers quit, a trivial rise in blood pressure may occur, probably reflecting a gain in weight.

HEMATOLOGICAL FINDINGS.

Polycythemia vera is frequently associated with hypertension (see Chap. 69). More common is a "pseudo-" or "stress" polycythemia with a high hematocrit[99] and increased blood viscosity but contracted plasma volume, as well as normal red cell mass and serum erythropoietin levels. High white blood cell counts are predictive of the development of hypertension.[138]

HYPERURICEMIA.

Hyperuricemia is present in 25 to 50 percent of individuals with untreated primary hypertension, about five times the frequency found in normotensive persons. Hyperuricemia probably reflects decreased renal blood flow, presumably a reflection of nephrosclerosis. In addition to these conditions often associated with hypertension, distinctive features of hypertension may be important in various special groups of people.

HYPERTENSION IN SPECIAL GROUPS

Blacks

Although, on average, blood pressure in blacks is not higher than that in whites during adolescence,[26] adult blacks have hypertension more frequently, with higher rates of morbidity and mortality. These higher rates may reflect a higher incidence of low birth weight from intrauterine growth retardation[76] a lesser tendency for the pressure to fall during sleep,[139] greater degrees of LVH, [46] and impaired NO-induced vasodilation,[116] but the lower socioeconomic status and lesser access to adequate, health care of blacks as a group are probably more important.[28] In particular, blacks suffer more renal damage, even with effective blood pressure control, which leads to a significantly greater prevalence of end-stage disease.[61] When given a high-sodium diet, most blacks but not whites tend to have renal vasoconstriction[88] and an increase in the glomerular filtration rate (GFR),[140] thus providing a possible mechanism for increased glomerular sclerosis.[140] Hypertension in blacks has been characterized as having a relatively greater component of fluid volume excess, including a higher prevalence of low PRA and greater responsiveness to diuretic therapy.[84]

Perhaps blacks evolved the physiological machinery that would offer protection in their ancestral habitat, i.e., hot, arid climates in which avid sodium conservation was necessary for survival because the diet was relatively low in sodium. When they migrate to areas where sodium intake is excessive, they are then more susceptible to "sodium overload." In addition, blacks may also be more susceptible to hypertension because as a group they tend to ingest less potassium.[89]

Women

In general, women suffer less cardiovascular morbidity and mortality than men do for any degree of hypertension.[19] Moreover, before menopause, hypertension is less common in women than in men, perhaps reflecting the lower blood volume afforded women by menses. Eventually, however, more women than men have a hypertension-related cardiovascular complication because there are more elderly women than elderly men and hypertension is both more common and more dangerous in the elderly.[141]

Children and Adolescents (see also Chap. 45)

As in adults, care is needed in establishing the presence of persistently elevated blood pressure in children when using the upper limits of normal shown in Table 28-3 . Recall that these are the averages of the first blood pressure value obtained; since the pressure usually falls on repeated measurements, levels below those shown in Table 28-3 may be abnormally high for a given child. In addition, the recent inclusion of height along with age and weight to the nomograms for children and adolescents probably improves their diagnostic accuracy.[1] The significance of readings above the 95th percentile in an asymptomatic child remains uncertain since tracking of blood pressure as children grow older does not tend to be persistent; the positive predictive value of a blood pressure reading above the 95th percentile in a 10-year-old boy being at a hypertensive level at age 20 is only 0.44.[142] Moreover, the sensitivity of this high blood pressure in a 10-year-old to detect hypertension 10 years later is only 0.17.

Nonetheless, most authorities[26] agree that children with "significant" hypertension (levels above the 95th percentile) should be given a limited work-up for target organ damage and secondary causes (perhaps including an echocardiogram and probably including a renal isotopic scan); if these tests are negative, the children should be carefully monitored and given nonpharmacological therapy. Those with "severe" hypertension (levels above the 99th percentile) should be more rapidly and completely evaluated and given appropriate pharmacological therapy.

EPIDEMIOLOGY.

The older the child, the more likely the hypertension is of unknown cause, i.e., primary or essential. In prepubertal children, chronic hypertension is more likely caused by congenital or acquired renal parenchymal or vascular disease[143] (Table 28-11) .

In adolescents, primary hypertension is the most likely diagnosis. Factors that increase the likelihood for early onset of hypertension include a positive family history of hypertension, obesity, poor physical fitness, and an increase in thickness of the interventricular septum during systole on echocardiography. Among black children, a greater blood pressure reactivity to stress may also be predictive.[144]

TABLE 28-11 -- MOST COMMON CAUSES OF CHRONIC HYPERTENSION IN CHILDHOOD

Newborn

Renal artery stenosis or thrombosis
Congenital renal structural abnormalities
Coarctation of the aorta
Bronchopulmonary dysplasia

Infancy to 6 yr

Renal structural and inflammatory diseases
Coarctation of the aorta
Renal artery stenosis
Wilms tumor

6-10 yr

MANAGEMENT.

Once persistently elevated blood pressure is identified in children and adolescents and an appropriate work-up has been performed, weight reduction if the patient is overweight, regular dynamic exercise, and moderate restriction of dietary sodium should be encouraged. Those deemed to be in need of drug therapy are usually treated in the way adults are managed, as described in the next chapter and in Chapter 45 .

The Elderly

As more people live longer, more hypertension, particularly systolic, will be seen. By the usual criteria of the average of three blood pressure measurements on one occasion at or above 140 mm Hg systolic and/or 90 mm Hg diastolic or the taking of antihypertensive medication, 54 percent of men and women aged 65 to 74 have hypertension; among blacks, the prevalence is 72 percent.[27] In elderly patients with significant hypertension of recent onset, chronic renal disease or atherosclerotic renovascular disease is more likely to be found.

The risks of both pure systolic and combined systolic and diastolic hypertension at every level are greater in the elderly than in younger patients as a result of the adverse effects of age-related atherosclerosis and concomitant conditions. It comes as no surprise that the elderly achieved even greater reductions in coronary disease and heart failure by effective therapy than did younger hypertensives in multiple clinical trials.[1]

The elderly may display two features that reflect age-related cardiovascular changes. The first is pseudohypertension from markedly sclerotic arteries that do not collapse under the blood pressure cuff and therefore result in much higher cuff pressures than present within the vessels. If the arteries feel rigid but the patient has few retinal or cardiac findings to go along with marked hypertension, direct intraarterial measurements may be needed before therapy is begun to avoid inordinate lowering of a blood pressure that is not in fact elevated. The second feature, seen in 20 to 30 percent of the elderly, is postural and postprandial hypotension, which usually reflects a progressive loss of baroreceptor responsiveness with age.[22] A standing blood pressure should always be taken in patients older than 65 years, particularly if seated or supine hypertension is noted; if postural hypotension is present, maneuvers to overcome the precipitous falls in pressure should be attempted before the seated and supine hypertension is cautiously treated. More about the special therapeutic challenges often found in the elderly is provided in the next chapter.

Patients with Diabetes Mellitus (see also Chap. 63)

Hypertension and diabetes coexist more commonly than predicted by chance. They act in a synergistic manner to markedly accelerate cardiovascular damage, which is in turn responsible for the premature disabilities and higher rates of mortality that afflict diabetics. Among some 1500 diabetics monitored by Danish investigators, 51 percent of the insulin-dependent diabetics and 80 percent of the noninsulin-dependent diabetics had blood pressures above 140/90 mm Hg.[145] In more than half of these hypertensive diabetics, isolated systolic hypertension was noted.

Not only is hypertension more common in diabetics, but it also tends to be more persistent, with less of the usual nocturnal fall in pressure. The absence of a nocturnal fall in pressure may reflect autonomic neuropathy or incipient diabetic nephropathy.

The presence of hypertension increases all of the microvascular and macrovascular complications observes in diabetes. Even at the initial diagnosis of diabetes, the presence of hypertension is associated with about a doubling of the prevalence of microalbuminuria, LVH, and electrocardiographic signs of myocardial ischemia.[146] These newly diagnosed diabetics were monitored for about 5 years, and those with hypertension suffered almost a twofold greater incidence of cardiovascular morbidity and mortality than did the nonhypertensive diabetics.

When hypertensive, patients with diabetes mellitus may confront some unusual problems. With progressive renal insufficiency, they may have few functional juxtaglomerular cells, and as a result, the syndrome of hyporeninemic hypoaldosteronism may appear, usually manifested by hyperkalemia. If hypoglycemia develops because of too much insulin or other drugs, severe hypertension may occur as a result of stimulated sympathetic nervous activity.

Diabetics are also susceptible to special problems associated with antihypertensive therapy. High doses of both diuretics and beta blockers may worsen diabetic control, probably by inducing further insulin resistance.[146A] Those who are prone to hypoglycemia may have difficulties with beta-blocking agents since these drugs blunt their protective catecholamine response, and severe hypoglycemia may develop with sweating as the only warning. Diabetic neuropathy may add to the postural hypotension and impotence that frequently complicate antihypertensive therapy. Diabetic nephropathy will impair sodium excretion and diminish the effectiveness of diuretics. On the other hand, successful control of hyperglycemia and blood pressure reduction will protect such patients from the otherwise inexorable progress of diabetic nephropathy. As will be noted in the next chapter, diabetic hypertensives are provided even better protection against cardiovascular morbidity and mortality than are nondiabetics when their blood pressure is lowered with antihypertensive drugs.[147]

Braunwald: Heart Disease: A Textbook of Cardiovascular Medicine, 6th ed., Copyright © 2001 W. B. Saunders Company

Identifiable (Secondary) Forms of Hypertension (See Tables 28-4 and 28-5 , p. 946)

Oral Contraceptive and Postmenopausal Estrogen Use

The use of estrogen-containing oral contraceptive pills is probably the most common cause of secondary hypertension in young women. Most women who take them experience a slight rise in blood pressure, and hypertension develops in about 5 percent (i.e., blood pressure above 140/90 mm Hg) within 5 years of oral contraceptive use. This incidence is more than twice that seen among women of the same age who do not use these agents. Although the hypertension is usually mild, it may persist after oral contraceptive use is discontinued, it may be severe, and it is almost certainly a factor in the increased cardiovascular mortality seen among young women who take these agents.[148] Despite these facts, these drugs have provided effective and safe birth control for millions of women, and the need for oral contraceptives remains.

The dangers of oral contraceptives should be kept in proper perspective. While it is true that use of these drugs is associated with increased morbidity and mortality, the *absolute* numbers are quite small, and overall mortality from cardiovascular disease has been declining progressively among women in the United States at a rate equal to that noted among American men. Moreover, the risks appear to have been lessened by more careful selection of users and lower doses of hormones.[149] Most adverse effects occur in women who smoke and have other cardiovascular risk factors and who take formulations with more than 50 mug of estrogen. Thus, the currently used low-estrogen and low-progesterone forms seem quite safe for the purposes of temporary birth control.

INCIDENCE.

The best data on the incidence of oral contraceptive-induced hypertension came from a large study of the Royal College of General Practitioners. The incidence of hypertension was 2.6 times greater among 23,000 pill users than 23,000 nonusers, with pill users having a 5 percent incidence over 5 years of oral contraceptive use.[150] In addition, this incidence increased with longer duration of pill use, being only slightly higher than that in controls during the first year but rising to almost 3 times higher by the fifth year. In a much smaller, but more carefully performed, prospective study of 186 Scottish women, systolic pressure rose in 164 (by more than 25 mm Hg in 8) and diastolic pressure rose in 150 (by more than 20 mm Hg in 2) during the first 2 years of oral contraceptive use.[151] After 3 years, the mean rise in 83 of these women was 9.2 mm Hg. The current use of smaller amounts of estrogen (20 to 35 mug) than the 50 mug taken by most of these women may induce less hypertension.

CLINICAL FEATURES.

The likelihood of hypertension developing among women using oral contraceptives is much greater in those who are older than 35 or obese or who drink large quantities of alcohol. The presence of hypertension during a prior pregnancy increases this likelihood, but not enough to preclude pill use in such women who require contraception. In most women the hypertension is mild; however, in some it may accelerate rapidly and cause severe renal damage. When use of the pill is discontinued, blood pressure falls to normal within 3 to 6 months in about half the patients. Whether the pill caused permanent hypertension in the other half or just uncovered primary hypertension at an earlier time is not clear.

MECHANISMS OF HYPERTENSION.

Oral contraceptive use probably causes hypertension by volume expansion since both estrogens and the synthetic progestogens used in oral contraceptive pills cause sodium retention. Although plasma renin levels rise in response to increased levels of angiotensinogen, angiotensin-converting enzyme (ACE) inhibition did not alter blood pressure any more in women with oral contraceptive-induced hypertension than in women with essential hypertension.[152] In keeping with the probable role of hyperinsulinemia in other hypertensive states (see p. 954) hyperinsulinemia may be involved in oral contraceptive-induced hypertension as well because plasma insulin levels are increased after the start of oral contraceptive use, a finding reflective of peripheral insulin resistance.[153]

MANAGEMENT.

The use of estrogen-containing oral contraceptives should be restricted in women older than 35, particularly if they also smoke or are hypertensive or obese. Women given the pill should be properly monitored as follows: (1) The supply should be limited initially to 3 months and thereafter to 6 months; (2) they should be required to return for a blood pressure check before an additional supply is provided; and (3) If blood pressure has risen, an alternative contraceptive should be offered. If the pill remains the only acceptable contraceptive, the elevated blood pressure can be reduced with appropriate therapy. In view of the possible role of aldosterone, use of a diuretic-spironolactone combination seems appropriate. In those who stop taking oral contraceptives, evaluation for secondary hypertensive diseases should be postponed for at least 3 months to allow changes in the renin-angiotensin-aldosterone system to remit. If the hypertension does not recede, additional work-up and therapy may be needed.

POSTMENOPAUSAL ESTROGEN USE.

Millions of women use estrogen for its potential benefits after menopause. It does not appear to induce hypertension, even though it does induce the various changes in the renin-angiotensin-aldosterone system seen with oral contraceptive use.[154] Moreover, the majority of case-control studies have shown a significantly *lower* mortality rate from coronary artery disease among postmenopausal estrogen users than nonusers.[155] Such cardioprotection probably reflects improvement in endothelium-dependent, flow-mediated vasodilation, either from a direct effect on endothelial function or through changes in blood lipids.[156]

Renal Parenchymal Disease

In the overall population, renal parenchymal disease is the most common cause of secondary hypertension and is responsible for 2 to 5 percent of cases (see Table 28-5). As chronic glomerulonephritis has become less common, hypertensive nephrosclerosis and diabetic nephropathy have become the most common causes of ESRD.[157] The higher prevalence of hypertension among U.S. blacks is probably responsible for their significantly higher rate of ESRD, with hypertension as the underlying cause in as many as half of these patients.[61]

Not only does hypertension cause renal failure and renal failure cause hypertension, but also more subtle renal dysfunction may be involved in patients with primary hypertension. As discussed earlier (see p. 952), the kidneys may initiate the hemodynamic cascade eventuating in primary hypertension. As that disease progresses, some renal dysfunction is demonstrable in most patients; progressive renal damage is the end result and is the cause of death in perhaps 10 percent of hypertensives. Since early treatment of hypertension will probably protect against nephrosclerosis, there is hope that improved control of hypertension will slow the progression and reduce the frequency of ESRD.

In hypertension with renal parenchymal disease the sequence of progressively worsening renal damage is (1) acute renal diseases that are often reversible, (2)

unilateral and bilateral diseases without renal insufficiency, (3) chronic renal disease with renal insufficiency, and

(4) hypertension in the anephric state and after renal transplantation.

ACUTE RENAL DISEASES.

Hypertension may appear with any sudden, severe insult to the kidneys that either markedly impairs excretion of salt and water, which leads to volume expansion, or reduces renal blood flow, which sets off the renin-angiotension-aldosterone mechanism. Bilateral ureteral obstruction is an example of the former; sudden bilateral renal artery occlusion, as by emboli, is an example of the latter. Relief of either may dramatically reverse severe hypertension. Such reversal of hypertension has been particularly striking in men with high-pressure chronic retention of urine, who may manifest both renal failure and severe hypertension, both of which may be ameliorated by relief of the obstruction.[158] Some of the collagen diseases may also produce rapidly progressive renal damage. The more common acute processes are glomerulonephritis and oliguric renal failure.

ACUTE GLOMERULONEPHRITIS.

Although the classic syndrome of type-specific poststreptococcal nephritis has become much less common, glomerular lesions of various types may be associated with hypertension. Moreover, although the epidemic poststreptococcal disease is usually self-limited, the disease in some patients follows a progressive, smoldering course that may lead to renal insufficiency. Typically, hypertension accompanies the fluid retention of acute renal injury and is best relieved by sodium and fluid restriction and potent diuretics. Dialysis and parenteral antihypertensive drugs may be needed if encephalopathy supervenes. In milder cases, the hypertension recedes as the edema is relieved.

ACUTE OLIGURIC RENAL FAILURE.

Acute renal failure may occur after hypotension, particularly in patients in whom renin levels are already high, such as those with cirrhosis and ascites or at the end of pregnancy. The release of even more renin by decreased blood pressure and effective circulating blood volume may flood the renal vasculature and cause such intense renal vasoconstriction that renal function shuts down. Hypertension in this setting is not usually an important problem and can be controlled by preventing volume overload. High doses of furosemide may be helpful, but dialysis is often needed. When acute renal failure occurs in the setting of accelerated or malignant hypertension, aggressive therapy (including dialysis) may be followed by sustained recovery of renal function.[159] The use of nonsteroidal antiinflammatory agents may cause acute renal failure, usually in the setting of chronic renal damage.[160]

VASCULITIS.

Rapidly progressive renal deterioration with severe hypertension occurs not infrequently during the course of scleroderma and other forms of vasculitis (see Chap. 67). Therapy with antihypertensives, particularly ACE inhibitors, may reverse the process.[161]

EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY.

As this procedure has been increasingly used to treat nephrolithiasis, at least transient rises in blood pressure have been observed in 20 to 30 percent of patients, but persistent hypertension is unusual.[162]

RENAL DISEASE WITHOUT RENAL INSUFFICIENCY.

Although an entire kidney may be removed without obvious effect and no rise in blood pressure, hypertension may be associated with unilateral and bilateral renal parenchymal diseases in the absence of significant renal insufficiency. Even though such hypertension may reflect other unrecognized processes, most likely it is caused by activation of the renin-angiotensin-aldosterone mechanism. However, in some patients whose hypertension has been relieved by correction of a renal defect, the levels of renin have not been high.

UNILATERAL PARENCHYMAL RENAL DISEASE.

A number of unilateral kidney diseases may be associated with hypertension, and in some of these diseases the affected kidney is shrunken. Nonetheless, most small kidneys do not cause hypertension, and when they are indiscriminately removed from patients with hypertension, the condition is relieved in only about 25 percent. Of that 25 percent, most have arterial occlusive disease, either as the primary cause of the renal atrophy or secondary to irregular scarring of the parenchyma.

POLYCYSTIC KIDNEY DISEASE.

Although patients with adult polycystic kidney disease usually progress to renal insufficiency, some retain reasonably normal GFRs and display no azotemia. Hypertension, although more common in those with renal failure, is present in perhaps half of those with a normal GFR and probably reflects variable degrees of both renin excess and fluid retention.[163]

CHRONIC PYELONEPHRITIS.

The relationship between pyelonephritis and hypertension is multifaceted: Pyelonephritis, either unilateral or bilateral, may cause hypertension, and hypertensive individuals may be more susceptible to renal infection. In pyelonephritic patients with hypertension but fairly normal renal function, renin levels are high,[164] probably from interstitial scarring with obstruction of intrarenal vessels.

CHRONIC RENAL DISEASES WITH RENAL INSUFFICIENCY.

Because dialysis and transplantation prolong the lives of more patients with renal insufficiency, their hypertension must be dealt with over much longer periods. In most patients with renal insufficiency, hypertension is predominantly caused by volume overload resulting from an inability of the reduced functioning renal mass to handle the usual sodium and water intake. With proper attention to sodium and water intake and, if needed, adequate dialysis, control of blood pressure may not be particularly difficult. Unfortunately, some patients are much more fragile and alternate between low and high pressure, and some are much more resistant, presumably because of a greater contribution of high renin levels to the hypertension. Moreover, their pressures may not fall much during sleep, which poses an additional burden on the heart and vasculature. Nonetheless, with judicious use of available therapy, hypertension should not be a major problem for most patients with renal insufficiency.

Three aspects of hypertension with ESRD should be recognized: (1) Hypertension contributes to the cardiovascular diseases that are the cause of death in about half of patients with ESRD; (2) renal damage may progress despite apparent control of hypertension, particularly among blacks;[165] and (3) a significant proportion of cases of ESRD may reflect bilateral renovascular disease that may be made worse by antihypertensive drug therapy but markedly improved by revascularization.[166]

In view of increasing evidence that glomerular capillary hypertension is responsible for the progressive loss of renal function once renal damage begins (see Fig. 28-11), aggressive reduction of intraglomerular hypertension to prevent further renal loss is being actively pursued. ACE inhibitors maybe particularly effective in this regard.[165]

Diabetic Nephropathy (see also Chap. 63).

Hypertension often accompanies diabetic nephropathy as a result of an inability to handle volume loads because of loss of nephrons secondary to progressive intercapillary glomerulosclerosis. As shown in Figure 28-16 , intrarenal hypertension accelerates the progress of the glomerulosclerosis, and antihypertensive therapy has been shown to slow the progression of renal damage.[167] Although more effective relief of glomerular capillary hypertension may be possible with ACE inhibitors, long-term protection has been obtained with traditional antihypertensive drugs, not including ACE inhibitors.[168] As common as it is, hypertension may not be as severe or as likely to progress to an accelerated-malignant phase in diabetics with nephropathy for two reasons: First, these patients often have diminished intravascular

volume because of the hypoalbuminemia of the nephrotic syndrome, and second, they have low renin levels, presumably because of hyalinization of juxtaglomerular cells, which may be manifested as hyporeninemic hypoaldosteronism.

Analgesic Nephropathy.

In addition to the acute renal insufficiency that may accompany the inhibition of renal prostaglandins by nonsteroidal antiinflammatory agents,[160] permanent interstitial renal damage may supervene after prolonged exposure to analgesics, particularly phenacetin and, to a lesser degree, acetaminophen.[169] Until late in their course, these patients have a greater propensity for salt wasting and may therefore have less severe hypertension.

HYPERTENSION DURING CHRONIC DIALYSIS AND AFTER RENAL TRANSPLANTATION.

In patients with ESRD, blood pressure depends mainly on body fluid volume. Hypertension may be accentuated by the accumulation of endogenous inhibitors of nitric oxide (NO) synthase because of withdrawal of the vasodilation provided by NO. As these inhibitors are removed during dialysis, NO may contribute to hemodialysis-induced hypotension.[170] With neither the vasoconstrictor effects of renal renin nor the vasodepressor actions of various renal hormones, blood pressure may be particularly labile and sensitive to changes in adrenergic activity. Among patients receiving maintenance

Figure 28-16 Pivotal role of glomerular hypertension in the initiation and progression of structural injury. (From Anderson S, Brenner BM: Progressive renal disease: A disorder of adaptation. QJM 70:185, 1989.)

hemodialysis every 48 hours, elevated blood pressures tend to fall progressively after dialysis is completed, remain depressed during the remainder of the first 24 hours, and rise again during the second day as a consequence of excessive fluid retention.[171] Thus, antihypertension therapy may be needed only on the days between dialysis.

Although successful renal transplantation may cure primary hypertension, various problems may result, with about half of the recipients becoming hypertensive within 1 year.[172] These problems include stenosis of the renal artery at the site of anastomosis, rejection reactions, high doses of adrenal steroids and cyclosporine, and excess renin derived from the retained diseased kidneys. ACE inhibitor therapy may obviate the need to remove the native diseased kidneys to relieve hypertension caused by their persistent secretion of renin. The source of the donor kidney may also play a role in the subsequent development of hypertension in the recipient: More hypertension has been observed when donors had a family history of hypertension or when the donors had died of subarachnoid hemorrhage and had probably been hypertensive.[173]

Renovascular Hypertension

Renovascular hypertension is among the most common secondary forms of hypertension and is not easily recognizable. Although no more than 1 percent of all adults with hypertension have renovascular hypertension (see Table 28-5), the prevalence is much higher in those with sudden onset of severe hypertension and other suggestive features[174] (Table 28-12) . Mann and Pickering classified patients into those with a low, moderate, and high "clinical index of suspicion" as a guide to the selection of additional work-up for renovascular hypertension. Those with characteristics listed under moderate are considered to have a 5 to 15 percent likelihood of the diagnosis and are therefore in need of a noninvasive screening test. Those with characteristics listed under high are considered to have a greater than 25 percent likelihood of the diagnosis and renal arteriography should be the initial test.

Renovascular disease is found less commonly in black hypertensives than in whites,[175] but it should be looked for when accompanied by the features described in Table 28-12 .

CLASSIFICATION.

In adults, the two major types of renovascular disease tend to appear at different times and affect the sexes differently (Table 28-13) . Atherosclerotic disease affecting mainly the proximal third of the main renal artery is seen mostly in older men. Fibroplastic disease involving mainly the distal two-thirds and branches of the renal arteries appears most commonly in younger women. Overall, about two-thirds of cases are caused by atherosclerotic disease and one-third by fibroplastic disease. While the nonatherosclerotic stenoses involve all layers of the renal artery, the most common is medial fibroplasia.

A number of other intrinsic and extrinsic causes of renovascular hypertension are known, including cholesterol emboli

TABLE 28-12 -- TESTING FOR RENOVASCULAR HYPERTENSION: CLINICAL INDEX OF SUSPICION AS A GUIDE TO SELECTING PATIENTS FOR WORK-UP

Low (Should Not Be Tested)

Borderline, mild, or moderate hypertension, in the absence of clinical clues

Moderate (Noninvasive Tests Recommended)

Severe hypertension (diastolic blood pressure greater than 120 mm Hg)
Hypertension refractory to standard therapy
Abrupt onset of sustained, moderate to severe hypertension at age <20 or age >50
Hypertension with a suggestive abdominal bruit (long, high pitched, and localized to the region of the renal artery)
Moderate hypertension (diastolic blood pressure exceeding 105 mm Hg) in a smoker, in a patient with evidence of occlusive vascular disease (cerebrovascular, coronary, peripheral vascular), or in a patient with unexplained but stable elevation of serum creatinine
Normalization of blood pressure by an angiotensin-converting enzyme inhibitor in a patient with moderate or severe hypertension (particularly a smoker or a patient with recent onset of hypertension)

High (May Consider Proceeding Directly to Arteriography)

Severe hypertension (diastolic blood pressure greater than 120 mm Hg with either progressive renal insufficiency or refractoriness to aggressive treatment, particularly in a patient who has been a smoker or has other evidence of occlusive arterial disease)
Accelerated or malignant hypertension (grade III or IV retinopathy)
Hypertension with recent elevation of serum creatinine, either unexplained or reversibly induced by an angiotensin-converting enzyme inhibitor
Moderate to severe hypertension with incidentally detected asymmetry of renal size

Reproduced with permission from Mann SJ, Pickering TG: Detection of renovascular hypertension. State of the art: 1992. Ann Intern Med *117*:845, 1992.

TABLE 28-13 -- FEATURES OF THE TWO MAJOR FORMS OF RENAL ARTERY DISEASE

CAUSE	INCIDENCE (%)	AGE (yr)	LOCATION OF LESION IN RENAL ARTERY	NATURAL HISTORY
Atherosclerosis	65	>50	Proximal 2 cm; branch disease rare	Progression in 50%, often to total occlusion
Fibromuscular dysplasias				
Intimal	1-2	Birth-25	Midportion of main renal artery and/or branches	Progression in most cases; dissection and/or thrombosis common
Medial	30	25-50	Distal segment of main renal artery and/or branches	Progression in 33%; dissection and/or thrombosis rare

Periarterial	1-2	15-30	Middle to distal segments of main renal artery or branches	Progression in most cases; dissection and/or thrombosis common

From Kaplan NM: Clinical Hypertension. 7th ed. Baltimore, Williams & Wilkins, 1998, p 306.

within the renal artery or compression of this vessel by nearby tumors. Most renovascular hypertension develops from partial obstruction of one main renal artery, but only a branch need be involved; segmental disease was found in 11 percent of cases in one large series.[176] On the other hand, if apparent complete occlusion of the renal artery is slow in developing, enough collateral flow will become available to preserve viability of the kidney. In this way, the seemingly nonfunctioning kidney may be responsible for continued renin secretion and hypertension. If recognized, such totally occluded vessels can sometimes be repaired, with return of renal function and relief of hypertension. [177]

Renovascular stenosis is often bilateral, although usually one side is clearly predominant. The possibility of bilateral disease should be suspected in those with renal insufficiency, particularly if rapidly progressive oliguric renal failure develops without evidence of obstructive uropathy and even more so if it develops after the start of ACE inhibitor therapy.[178]

MECHANISMS.

After Goldblatt produced renovascular hypertension in the dog in 1934, confusion arose because of the use of one-kidney models, which are more appropriate to the study of renal parenchymal hypertension. The sequence of changes in the two-kidney (one-clip) model and in patients with renovascular hypertension almost certainly starts with the release of increased amounts of renin when sufficient ischemia is induced to diminish pulse pressure against the juxtaglomerular cells in the renal afferent arterioles. A reduction in renal perfusion pressure by 50 percent leads to an immediate and persistent increase in renin secretion from the ischemic kidney, along with suppression of secretion from the contralateral one. With time, renin levels fall (but not to the low level expected from the elevated blood pressure), accompanied by an expanded body fluid volume and increased cardiac output.

DIAGNOSIS.

The presence of the clinical features listed under moderate suspicion for renovascular hypertension in Table 28-12 , found in perhaps 5 to 10 percent of all hypertensives, indicates the need for a screening test for renovascular hypertension. A positive screening test, or very strong clinical features, calls for more definitive confirmatory tests. Recurrent flash pulmonary edema has been associated with renovascular hypertension,[179] so this clinical manifestation should be added to the indication for diagnostic work-up.

Some patients have renovascular hypertension but none of the clinical features listed in Table 28-12 , and they clinically resemble patients with mild primary hypertension. Nonetheless, these features should be used to exclude the majority of hypertensives from additional work-up and to identify the 10 percent or so who should undergo a work-up.

Functional Diagnostic Tests.

Isotopic renography and plasma renin measurements after an oral captopril challenge are currently the best initial tests in patients with the suggestive clinical features listed under moderate in Table 28-12 , to be followed by renal arteriography and then renal vein renin assays. The latter procedure may not be needed if isotopic renography after captopril indicates significant renal ischemia in the kidney with renal artery disease by arteriography. In some centers with facilities dedicated to the performance of renal artery duplex sonography, that procedure is being used for initial screening,[180] and in the future, intravascular ultrasound will probably be used.[181] In addition, contrast-enhanced magnetic resonance arteriography may be even more reliable, particularly for visualizing accessory renal arteries.[182]

The captopril challenge test depends on abrupt inhibition of circulating angiotensin II by the ACE inhibitor, which removes the major support for perfusion through a stenotic renal artery to a kidney. The acutely ischemic kidney immediately releases more renin and undergoes a marked decrease in glomerular filtration and renal blood flow. Therefore, both plasma renin level and isotopic flow through the kidneys 1 hour after a single 50-mg dose of the ACE inhibitor should be measured. To measure the plasma renin response, the patient should have normal sodium dietary intake and not be taking diuretics and ACE inhibitors; if possible, other antihypertensive medications should be withdrawn for at least a week.[183] After the patient sits for 30 minutes, venous blood is obtained for basal PRA, and 50 mg of captopril is given orally. At 60 minutes, another blood sample for stimulated PRA is obtained. The authors have subsequently reported a high prevalence of false-positive responses in patients with high baseline renin levels.[183] Others report sensitivity ranging from 0.73 to 1.0 and specificity ranging from 0.73 to 0.95.[184]

Performance of isotopic renography 1 hour after the oral captopril dose provides additional diagnostic information in most but not all series.[185] The renogram may use labeled hippurate, a measure of renal blood flow, or diethylenetriaminepentaacetic acid (DTPA) or mercaptoacetyltriglycine (MAG3), measures of the GFR. If the postcaptopril test shows a significant difference between the two kidneys, the procedure should be repeated without captopril to document the ischemic origin of the differences in blood flow or GFR. With captopril renography, renal vein renin measurements are needed less often to localize the affected side when renovascular disease is bilateral.

MANAGEMENT

Medical.

The availability of ACE inhibitors may be considered a two-edged sword; one edge provides better control of renovascular hypertension than may be possible with other antihypertensive medications, while the other edge exposes the already ischemic kidney to further loss of blood flow by removing the high levels of angiotensin II that were supporting its circulation. Calcium entry blockers and other antihypertensive drugs may be almost as effective as ACE inhibitors and perhaps safer.[186]

Angioplasty (see also Chap. 42).

Angioplasty has been shown to improve (at least transiently) 60 to 70 percent of patients, more with fibromuscular disease than with atherosclerosis, as is also the case for surgery. Ostial lesions may be successfully managed by placement of an arterial stent, which will probably be performed more frequently to improve the results of angioplasty.[187]

Surgery.

Surgical repair has been shown to relieve renovascular hypertension in an increasing number of patients, including the elderly and those with renal insufficiency.[188] Most agree that surgery is indicated in patients whose hypertension is not well controlled or whose renal function deteriorates with medical therapy and in those with only a transient response to angioplasty or in whom lesions are not amenable to that procedure, more to preserve renal function than to relieve hypertension and before serum creatinine rises above 3 mg/dl.[189]

RENIN-SECRETING TUMORS

Made up of juxtaglomerular cells or hemangiopericytomas, these tumors have been found mostly in young patients with severe hypertension, very high renin levels in both peripheral blood and the kidney harboring the tumor, and secondary aldosteronism manifested by hypokalemia.[190] The tumor can generally be recognized by selective renal angiography, usually performed for suspected renovascular hypertension, although a few are extrarenal. More commonly, children with Wilms tumors (nephroblastoma) may have hypertension and high plasma renin and prorenin levels that revert to normal after nephrectomy.[191]

Adrenal Causes of Hypertension (see Chap. 64)

Adrenal causes of hypertension include primary excesses of aldosterone, cortisol, and catecholamines; more rarely, excess deoxycorticosterone (DOC) is present along with congenital adrenal hyperplasia. Together, these conditions cause less than 1 percent of all hypertensive diseases, although as will be noted, primary aldosteronism may be more common than previously thought. Each can usually be recognized with relative ease, and patients suspected of having these disorders can be screened by readily available tests. More of a problem than the diagnosis of these adrenal disorders is the need to exclude their presence because of the increasing

identification of incidental adrenal masses when abdominal computed tomography (CT) is done to diagnose intraabdominal pathology. Unsuspected adrenal tumors have been found in 1 to 2 percent of abdominal CT scans obtained for reasons unrelated to the adrenal gland. Most of these "incidentalomas" appear to be nonfunctional on the basis of normal basal adrenal hormone levels. However, when more detailed studies are done, a significant number show incomplete suppression of cortisol by dexamethasone, i.e., subclinical Cushing disease that does not appear to progress to overt hypercortisolism, and a few have unsuspected catecholamine hypersecretion.[192] Nonfunctioning adenomas have significantly less lipid content than do functioning adenomas by chemical-shift magnetic resonance imaging (MRI),[193] so this procedure may have clinical usefulness. The threat of malignancy can probably be best excluded by adrenal scintigraphy with NP-59, a radioiodinated derivative of cholesterol.[194] Benign lesions almost always take up the isotope, while malignant ones almost always do not. Most tumors larger than 4 cm are resected since a significant number of them are malignant.

Primary Aldosteronism (See also Chap. 64)

This disease is relatively rare in unselected populations (see Table 28-5), although it has been recognized in considerably more patients screened by a plasma aldosterone/renin activity ratio.[195]

PATHOPHYSIOLOGY.

Primary aldosterone excess usually arises from solitary benign adenomas. As diagnostic tests have improved and become more readily available, larger numbers of patients with minimal features have been recognized.[196] Many of these patients have been found to have bilateral adrenal hyperplasia, the number averaging about one-third of all cases of aldosteronism.

MINERALOCORTICAL HYPERTENSION.

In addition to the usual forms of primary aldosteronism, two unusual but interesting variants have been identified. One, familial glucocorticoid-suppressible aldosteronism, is caused by a mutation in the genes involved in coding for the aldosterone synthase enzyme normally found only in the outer zone glomerulosa and the 11-beta-hydroxylase enzyme in the zone fasciculata.[197] The chimeric gene induces an enzyme that catalyzes the synthesis of 18-hydroxylated cortisol in the zona fasciculata. Since this zone is under the control of adrenocorticotropic hormone (ACTH), the glucocorticoid suppressibility of the syndrome is explained. Since a few patients with classic primary aldosteronism show glucocorticoid suppression, the diagnosis should be made by genetic testing for the chimeric gene.[198]

The other unusual form of mineralocorticoid hypertension is caused by deficiency of the enzyme 11-beta-hydroxysteroid dehydrogenase (11beta-OHSD) in the renal tubule, where it normally converts cortisol (which has the ability to act on the mineralocorticoid receptor) to cortisone (which does not). Persistence of high levels of cortisol induces all the features of mineralocorticoid excess. The 11beta-OHSD enzyme may be congenitally absent (the syndrome of apparent mineralocorticoid excess) or inhibited by the glycyrrhetenic acid contained in licorice.[199] Another unusual syndrome with hypertension and hypokalemia but suppressed mineralocorticoid secretion is Liddle syndrome, wherein the kidney reabsorbs excess sodium and wastes potassium because of a mutation in the beta or gamma subunits of the epithelial sodium channel.[200]

Whatever the source, excess mineralocorticoid usually causes hypertension and hypokalemia, defined as a plasma potassium level below 3.2 mEq/liter. Very rarely, mineralocorticoid excess has been recognized in normotensive persons.[201] Not so rarely, hypokalemia may be absent or only intermittent, but in most patients with adenomas, persistent hypokalemia is observed.[196]

The hypertension begins as a volume overload but soon converts, as apparently do all forms of hypertension, to increased peripheral resistance. Hypertension may be severe, and cardiovascular complications, particularly stroke, common.[202] In association with the increased pressure and expanded blood volume, renin secretion is suppressed. Although this finding has been almost invariable with hyperaldosteronism, the overwhelming majority of hypertensive patients with suppressed renin do not have mineralocorticoid excess.

DIAGNOSIS.

Serious consideration should be given to the diagnosis of primary aldosteronism when hypertension and hypokalemia coexist. If normokalemic patients with the disease are missed, little will be lost as long as the patients are protected by appropriate treatment of the hypertension. Since such treatment is likely to include a diuretic, significant hypokalemia will probably soon become manifested and make the diagnosis obvious. If hypokalemia is present, excessive urinary potassium excretion (above 30 mmol/day) is strongly suggestive of mineralocorticoid excess.

A high plasma aldosterone/renin ratio in plasma is a useful screening test that can be performed immediately upon recognition of hypokalemia in a hypertensive patient, but with the knowledge that a high ratio may reflect only a suppressed renin level. Therefore, not only should plasma renin levels be low, but plasma aldosterone levels should be elevated, with a ratio of well above 30.[203] Although this ratio is being increasingly used to screen for primary aldosteronism,

it has not always been found to be abnormal in patients with the syndrome.[204] Therefore, the finding of increased urinary aldosterone levels or failure to suppress plasma aldosterone levels by volume expansion or by a single dose of an ACE inhibitor also may be useful.[203]

ESTABLISHING THE PATHOLOGY.

Once the diagnosis of primary aldosteronism is made, the type of adrenal pathology should be determined, and only patients with a tumor should be subjected to surgery and those with bilateral hyperplasia treated by medical therapy. The best initial study is adrenal CT or MRI (Fig. 28-17) . However, the ability of these scans to identify hitherto hidden degrees of adrenal pathology may engender confusion; the usual nodularity seen in the remainder of a gland that harbors a solitary adrenal adenoma may give the appearance of bilateral hyperplasia, and some larger hyperplastic nodules may look like adenomas.[205] Therefore, unless the scan is unequivocal, additional tests to discriminate between adenoma and hyperplasia should be done (Fig. 28-17) .

Various maneuvers are available.[196] Basal levels of serum 18-hydroxycorticosterone (18-OHB) and changes in plasma aldosterone levels after 2 hours of upright posture from 8 A.M. to 10 A.M. usually distinguish patients with adenomas (who generally have basal 18-OHB levels above 65 ng/dl and falls in plasma aldosterone in the upright posture) from those with bilateral hyperplasia (who usually have basal 18-OHB levels below 50 ng/dl and postural rises in plasma aldosterone presumably invoked by their supersensitivity to posture-mediated rises in renin-angiotensin). In addition, most adenomas but few hyperplastic glands secrete increased amounts of 18-hydroxylated cortisol, which suggests that they harbor similar mutant genes as found in the glucocorticoid-suppressible syndrome. If the type of adrenal disorder is still uncertain, bilateral adrenal vein catheterization with analysis of venous aldosterone and cortisol levels should be performed by radiologists who are experienced with the technique.

THERAPY.

Once the diagnosis of primary aldosteronism is made and the type of adrenal disorder has been established, the choice of therapy is fairly easy: Patients with a solitary adenoma should have the tumor resected, now more and more frequently done by laparoscopic surgery. Those with bilateral hyperplasia should be treated with spironolactone (see Chap. 64) and, if necessary, a thiazide diuretic or other antihypertensive drugs. Fortunately, the doses of spironolactone required for chronic therapy are usually low enough to avoid bothersome side effects. When an adenoma is resected, about half of patients will become normotensive, while the others, although improved, remain hypertensive, either from preexisting primary hypertension or from renal damage caused by prolonged secondary hypertension.[206]

CUSHING SYNDROME (see also Chap. 64)

Hypertension occurs in about 80 percent of patients with Cushing syndrome.[207] If left untreated, it can cause marked LVH and congestive heart failure. As with hypertension of other endocrine causes, the longer it is present, the less likely it is to disappear when the underlying cause is relieved.

MECHANISM OF HYPERTENSION.

Blood pressure may increase for a number of reasons. Secretion of mineralocorticoids may also be increased along with cortisol. The excess cortisol may overwhelm the ability of renal 11beta-OHSD to convert it to the inactive cortisone, and renal mineralocorticoid receptors are activated by the excess cortisol to retain sodium and

expand fluid volume.[199] Cortisol stimulates the synthesis of renin substrate and the expression of angiotensin II receptors, which may be responsible for enhanced pressor effects.[208]

DIAGNOSIS.

The syndrome should be suspected in patients with truncal obesity, thin skin, muscle weakness, and osteoporosis. If clinical features are suggestive, the diagnosis can be either ruled out or virtually ensured by the measurement of free cortisol in a 24-hour urine sample or the simple overnight *dexamethasone suppression test.* [209] In normal subjects, the level of plasma cortisol in a sample drawn at 8 A.M.after a bedtime dose of 1 mg of dexamethasone should be below 2 mug/100 mg. If the level is higher, additional work-up is in order to establish both the diagnosis of cortisol excess and the pathological type. The 1-mg overnight suppression test has a specificity of 87%; the traditional 2-mg/day (0.5 mg every 6 hours) or 48-hour low-dose dexamethasone screening test has been recommended since it provides almost 100% specificity.[207]

When an abnormal screening test is present, some would immediately perform pituitary and adrenal CT or MRI scans to elucidate the type of pathology. However, most authorities continue to recommend as additional high-dose dexamethasone suppression test at 2.0 mg every 6 hours for 2 days, with measurement of urinary free cortisol excretion and plasma cortisol levels. If Cushing syndrome is caused by excess pituitary ACTH drive with bilateral adrenal hyperplasia, urinary free cortisol will be suppressed to below 40 percent of the control value with the 2.0-mg dose. Plasma ACTH assays provide an additional means of differentiating pituitary and ectopic ACTH excess from adrenal tumors with ACTH suppression.[207] The response to corticotropin-releasing hormone and inferior petrosal sinus sampling may help identify a pituitary cause of the syndrome.

THERAPY.

In about two-thirds of patients with Cushing syndrome, the process begins with overproduction of ACTH by the pituitary, which leads to bilateral adrenal hyperplasia. Although pituitary hyperfunction may reflect a hypothalamic disorder, the majority of patients have discrete pituitary adenomas that can usually be resected by selective transsphenoidal microsurgery.

If an adrenal tumor is present, it should be removed surgically. With earlier diagnosis and more selective surgical therapy, it is hoped that more patents with Cushing syndrome will be cured without a need for lifelong glucocorticoid replacement therapy and with permanent relief of their hypertension. Temporarily and rarely permanently, therapy may require one of a number of medical approaches.[210]

CONGENITAL ADRENAL HYPERPLASIA.

Two other enzymatic defects may induce hypertension by interfering with cortisol biosynthesis. Low levels of cortisol lead to increased ACTH, which increases the accumulation of precursors

Figure 28-17 Flow diagram for the progressive work-up of confirmed primary aldosteronism, with additional steps to take when initial studies are aberrant. Rare, angiotensin II-responsive adenomas may demonstrate features of hyperplasia but lateralize by venous sampling or scintigraphy. On the other hand, primary adrenal hyperplasia may demonstrate features of an adenoma except for equally high steroid levels by venous sampling. *GRA* = glucocorticoid-remediable aldosteronism; *18-OH-B* = 18-hydroxycorticosterone; *18-oxo-F* = 8-hydrocortisol. (From Kaplan NM: Primary aldosteronism. *In* Kaplan NM [ed]: Clinical Hypertension. 7th ed. Baltimore, Williams & Wilkins, 1998, p 378.)

proximal to the enzymatic block, specifically, DOC, which induces mineralocorticoid hypertension. The more common of these is *11-hydroxylase deficiency* which has been attributed to various mutations in the gene [211] and leads to virilization (from excessive androgens) and hypertension with hypokalemia (from excessive DOC). The other is *17-hydroxylase deficiency,* which also causes hypertension from excess DOC but, in addition, causes failure of secondary sexual development because sex hormones are also deficient.[212] Affected children are hypertensive, but the defect in sex hormone synthesis may not become obvious until after puberty. Thereafter, affected males display ambiguity of sexual development and fail to mature.

PHEOCHROMOCYTOMA (see also Chap. 64)

The wild fluctuations in blood pressure and dramatic symptoms of pheochromocytoma usually alert both the patient and the physician to the possibility of this diagnosis. However, such fluctuations may be missed, or as occurs in half the patients, the hypertension may be persistent.[212A] The symptoms may be incorrectly ascribed to psychoneurosis by practitioners not sensitized to "spells," which usually represent menopausal hot flushes or anxiety-induced hyperventilation.[33] Panic attacks may simulate a "pheo spell."[213] Unfortunately, if the diagnosis of pheochromocytoma is missed, severe complications may arise from exceedingly high blood pressure and damage to the heart by catecholamines (see Chap. 64). Stroke and hypertensive crises with encephalopathy and retinal hemorrhage may occur, probably because blood pressure levels soar in vessels unprepared by a chronic hypertensive condition. Fortunately, a simple and inexpensive test will detect the disease with virtual certainty, so diagnostic indecision should be minimized.

PATHOPHYSIOLOGY.

The cells of the sympathetic nervous system arise from the primitive neural crest as primitive stem cells called *sympathogonia.* These cells differentiate into ganglion cells, neuroblasts, and chromaffin cells. Tumors develop from each of these cell types; ganglioneuromas and neuroblastomas usually occur in children, whereas tumors arising from chromaffin cells, i.e., pheochromocytomas, occur at all ages anywhere along the sympathetic chain and rarely in aberrant sites.[214] About 15 percent of pheochromocytomas are extraadrenal; nonsecreting ones are called *paragangliomas* or *chemodectomas*.

Of the 85 percent of pheochromocytomas that arise in the adrenal medulla, 10 percent are bilateral and another 10 percent are malignant. Multiple adrenal tumors are particularly common in patients with simple familial pheochromocytoma and multiple endocrine neoplasia (MEN) type 2A in association with medullary carcinoma of the thyroid (Sipple syndrome) or with mucosal ganglioneuromas in addition (type 2B). The MEN-2 syndromes are inherited as autosomal dominants with mutations on chromosome 10.[215] Diffuse medullary hyperplasia may precede the development of tumors, and the tumors may in fact reflect extreme degrees of nodular hyperplasia. About 20% of cases of Von Hippel-Lindau disease with retinal angiomas and multiple other tumors are associated with a pheochromocytoma[216] as are 1% of cases of type 1 neurofibromatosis.[217]

Secretion from nonfamilial pheochromocytomas varies considerably, with small tumors tending to secrete larger proportions of active catecholamines. If the predominant secretion is epinephrine, which is formed primarily in the adrenal medulla, the symptoms reflect its effects--mainly systolic hypertension caused by increased cardiac output, tachycardia, sweating, flushing, and apprehension. If norepinephrine is predominantly secreted, as from some of the adrenal tumors and from almost all extraadrenal tumors, the symptoms include both systolic and diastolic hypertension from peripheral vasoconstriction but less tachycardia, palpitations, and anxiety. The hemodynamic features of 24 untreated patients with surgically proven pheochromocytomas were quite similar to those found in 24 untreated patients of similar sex, age, weight, and blood pressure with primary hypertension, with increased total peripheral resistance as the primary mechanism in both groups.[218]

DIAGNOSIS.

Many more hypertensive patients have variable blood pressure and "spells" than the 0.1 percent or so who harbor a pheochromocytoma. Spells with paroxysmal hypertension may occur with a number of stresses, and a large number of conditions may involve transient catecholamine release. A pheochromocytoma should be suspected in patients with hypertension that is either paroxysmal or persistent and accompanied by the symptoms and signs listed in Table 28-14 . In addition, children and patients with rapidly accelerating hypertension should be screened. Those whose tumors secrete predominantly epinephrine are prone to postural hypotension from a contracted blood volume and blunted sympathetic reflex tone. Suspicion should be heightened if activities such as bending over, exercise, palpation of the abdomen, smoking, or dipping snuff cause repetitive spells that begin abruptly, advance rapidly, and subside within minutes.

High levels of catecholamines may induce myocarditis (Chap. 48) , which may progress to cardiomyopathy and left ventricular failure.

TABLE 28-14 -- FEATURES SUGGGESTIVE OF PHEOCHROMOCYTOMA

Hypertension: Persistent or Paroxysmal
Markedly variable blood pressures (± orthostatic hypotension)
Sudden paroxysms (± subsequent hypertension) in relation to
Stress: anesthesia, angiography, parturition
Pharmacological provocation: histamine, nicotine, caffeine, beta blockers, glucocorticoids, tricyclic antidepressants
Manipulation of tumors: abdominal palpation, urination
Rare patients persistently normotensive
Unusual settings
Childhood, pregnancy, familial
Multiple endocrine adenomas: medullary carcinoma of the thyroid (MEN-2), mucosal neuromas (MEN-2B)
Neurocutaneous lesions: neurofibromatosis
Associated Symptoms
Sudden spells with headache, sweating, palpitations, nervousness, nausea, and vomiting
Pain in chest or abdomen
Associated Signs
Sweating, tachycardia, arrhythmia, pallor, weight loss
MEN=multiple endocrine neoplasia.

Electrocardiographic changes of ischemia may also be seen. Beta blockers given to such patients may raise the pressure and induce coronary spasm through blockade of beta-mediated vasodilation.

LABORATORY CONFIRMATION.

The easiest and best procedure is either a 24-hour or spot urine assay for total metanephrine.[219] This catecholamine metabolite is least affected by various interfering substances, including antihypertensive drugs, with the exception of labetalol, which may cause markedly elevated levels of all catecholamines.[220] In addition to the effects of labetalol, urinary metanephrine excretion is increased if patients are taking sympathomimetic or dopaminergic drugs or are under acute, severe stress such as an acute myocardial infarction or severe congestive heart failure. Interference with the measurement of metanephrine may occur for the next few days after the use of radiographic contrast media containing methylglucamine and lead to a falsely low value. Therefore, the urine should be collected before coronary angiography or other such procedures are done.

If urine assays are equivocal, measurement of a plasma norepinephrine level 3 hours after a single 0.3-mg oral dose of the adrenergic inhibitor clonidine has been shown to separate nonpheochromocytoma patients, whose levels are suppressed, from those with disease whose levels are not suppressed.[218]

LOCALIZATION OF THE TUMOR.

Once the diagnosis has been made, medical therapy should be started and the tumor localized by CT or MRI, which usually demonstrates these typically large tumors with ease. Radioisotopes that localize in chromaffin tissue are available and of additional help in the few patients in whom localization is not possible by CT or MRI.

THERAPY.

Once diagnosed and localized, pheochromocytomas should be resected. Although preoperative alpha-adrenergic blockade has been recommended, fewer operative and postoperative problems were encountered in patients who had been treated with a calcium channel blocker.[221] If the tumor is unresectable, chronic medical therapy with the alpha blocker phenoxybenzamine (Dibenzyline) or the inhibitor of catechol synthesis alphamethyltyrosine (Demser) can be used.

Other Causes of Hypertension

A host of other causes of hypertension are known (see Table 28-4). One that is probably becoming more common is ingestion of various drugs--prescribed (e.g., cyclosporine or tacrolimus[222] and erythropoietin[223]), over the counter (e.g., phenylpropanolamine), and illicit (e.g., cocaine). Obstructive sleep apnea has been well characterized as a cause of significant, but reversible, hypertension. [224]

COARCTATION OF THE AORTA (seeChaps. 43 and 44).

Congenital narrowing of the aorta may occur at any level of the thoracic or abdominal aorta. It is usually found just beyond the origin of the left subclavian artery or distal to the insertion of the ligamentum arteriosum. The coarctation may be localized or more diffuse. Other cardiac anomalies usually accompany the latter and give rise to considerable mortality during the first year of life, although operative

treatment of both the coarctation and associated anomalies may reduce the mortality rate. With less severe postductal lesions, damage is more insidious, and symptoms may not appear until the teenage years or later.

Hypertension in the arms and weak or absent femoral pulses are the classic features of coarctation. The pathogenesis of the hypertension may be more complicated than simple mechanical obstruction; a generalized vasoconstrictor mechanism is likely to be involved and may be either renin-angiotensin or sympathetic nervous activity.[225] The lesion may be detected by two-dimensional echocardiography, and aortography proves the diagnosis. The obstruction should be corrected in early childhood either by surgery[226] or by angioplasty.[227] Immediately after either, blood pressure may transiently rise even further, and mesenteric arteritis may develop. These changes may reflect very high levels of renin-angiotensin and catecholamines and can be prevented by the prophylactic use of beta blockers.

HORMONAL DISTURBANCES.

Hypertension is seen in as many as half of patients with a variety of hormonal disturbances, including acromegaly,[228] hypothyroidism,[229] and hyperparathyroidism. Diagnosis of the latter two conditions has been made easier by readily available blood tests, and affected hypertensives may be relieved of their high blood pressure by correction of the hormonal disturbance. Such relief happens more frequently with hypothyroidism than with hyperparathyroidism.[230]

Hypertension after Cardiac Surgery

Transient hypertension may develop postoperatively for various reasons: pain, physical and emotional excitement, hypoxia, hypercapnia, and excessive volume loads. More severe hypertension has been noted to follow a number of cardiovascular surgical procedures:

1. *Coronary bypass surgery.* The incidence, exceeding 33 percent, is far higher than after other major cardiac or noncardiac surgery, except after heart transplantation. The hemodynamic pattern of increased peripheral resistance can be explained by the markedly elevated plasma catecholamine levels measured in such patients in the presence of normal renin-angiotensin levels.[231] In patients who had previously received beta blocker therapy, postoperative hypertension may also reflect a rebound phenomenon. Therefore, continuation of beta blocker therapy through the perioperative period is likely to reduce the frequency of the problem. If it occurs, parenteral therapy is often required, and intravenous nicardipine has been found to be very effective.[232]
2. *Aortic valve replacement.* Transient hypertension may give way to more permanent hypertension. In one series, 53 percent of 116 patients were hypertensive 5 years after surgery, and hypertension was a major determinant of late failure of the homograft valve.[233]
3. *Closure of an atrial septal defect.*[234]
4. *Cardiac transplantation.* After cardiac denervation and with current immunosuppression consisting of cyclosporine or tacrolimus and high doses of adrenal steroids, hypertension is almost invariable and can be resistant to intensive therapy.[235] Ambulatory monitoring should be performed since a considerable "white coat" effect has been noted and, therefore, more intensive therapy may not be required.[236]

HYPERTENSION DURING PREGNANCY (see also Chap. 65)

In as many as 10 percent of first pregnancies in previously normotensive women, hypertension appears after 20 weeks, i.e., *gestational hypertension,* and may progress to *preeclampsia* when the hypertension is complicated by proteinuria, edema, or hematological or hepatic abnormalities or progress to *eclampsia,* with cerebral symptoms leading to convulsions.[237] Women with hypertension predating pregnancy have an even higher incidence of *preeclampsia* and a greater likelihood of early delivery of small-for-gestational-age babies,[238] who are in turn more prone to the development of hypertension as adults.[76]

Gestational hypertension is of unknown cause but occurs more frequently in primigravid women or in subsequent pregnancies with a different father, thus suggesting an immunological mechanism. Additional predisposing factors include increased age, black race, multiple gestations, concomitant heart or renal disease, and chronic hypertension.[239] Endothelial cell dysfunction may be an underlying defect.[240]

The diagnosis is usually based on a rise in pressure of 30/15 mm Hg or more to a level above 140/90. Although some measure the Korotkoff fourth sound (muffling), the fifth sound (disappearance) is closer to the true diastolic and should be used.

CLINICAL FEATURES.

The features shown in Table 28-15 should help distinguish gestational hypertension and preeclampsia from chronic, primary hypertension. The distinction should be made because management and prognosis are different: Gestational hypertension is self-limited and rarely recurs in subsequent pregnancies, whereas chronic hypertension progresses and usually complicates subsequent pregnancies. Separation may be difficult because of a lack of knowledge of prepregnancy blood pressure and because of the usual tendency for high pressure to fall considerably during the middle trimester so that hypertension present before pregnancy may not be recognized.

In gestational hypertension, the blood pressure usually rises only late in pregnancy. Among 84 patients with an onset of hypertension before 37 weeks' gestation, 55 had renal disease documented by kidney biopsy 6 months postpartum, when morphological changes caused solely by gestational hypertension should have subsided.[241] Gestational hypertension was the diagnosis in only 10 percent of primiparous women with onset of hypertension before 37 weeks, whereas it was the diagnosis in three-fourths of primigravid women with onset of hypertension after 37 weeks.

The hemodynamic features of gestational hypertension are a further rise in cardiac output than usually seen in normal pregnancy, accompanied by profound vasoconstriction that reduces intravascular capacity even more than blood volume.[242] The mother may be particularly vulnerable to encephalopathy because of her previously normal

TABLE 28-15 -- DIFFERENCES BETWEEN PREECLAMPSIA AND CHRONIC HYPERTENSION

FEATURE	PREECLAMPSIA	CHRONIC HYPERTENSION
Age (yr)	Young (<20)	Older (>30)
Parity	Primigravida	Multigravida
Onset	After 20 wk of pregnancy	Before 20 wk of pregnancy
Weight gain and edema	Sudden	Gradual
Systolic blood pressure	<160	>160
Funduscopic findings	Spasm, edema	Arteriovenous nicking, exudates
Proteinuria	Present	Absent
Plasma uric acid	Increased	Normal
Blood pressure after delivery	Normal	Elevated

blood pressure. As is described in more detail below, cerebral blood flow is normally maintained constant over a fairly narrow range of mean arterial pressure, roughly between 60 and 100 mm Hg in normotensive individuals. In a previously normotensive young woman, an acute rise in blood pressure to 150/100 mm Hg may exceed the upper limit of autoregulation and result in a "breakthrough" of cerebral blood flow (acute dilation) that leads to cerebral edema, convulsions, and all the clinical manifestations of eclampsia.

PREVENTION.

Beyond delay of pregnancy until after the teens and better prenatal care, no other manuever has been shown to prevent preeclampsia, including low doses of aspirin[243] or supplemental calcium.[244]

Treatment

GESTATIONAL HYPERTENSION.

Women with gestational hypertension and their fetuses can be protected from excessive morbidity and mortality by maneuvers that lower blood pressure without impairing uteroplacental perfusion. These maneuvers include modified bed rest, a nutritious diet with normal amounts of sodium, and antihypertensive agents when diastolic blood pressure above 100 mm Hg indicates impairment in renal function and predisposition to overt eclampsia.

> However, as noted by Redman and Roberts, the cure is achieved by delivery, which removes the diseased tissue--the placenta. In short, the need is to deliver before it is too late. To achieve this apparently simple end, the clinician must detect the symptomless prodromal condition by screening all pregnant women, admit to hospital those with advanced preeclampsia so as to keep track of an unpredictable situation, and time preemptive delivery to maxi- mize the safety of mother and baby.[245]

Caution is advised in the use of drugs for mild gestational hypertension, traditionally limited to methyldopa. Drug treatment of maternal blood pressure does not improve perinatal outcome and may be associated with fetal growth retardation. Most authorities recommend antihypertensive drugs only if diastolic pressures remain above 100 mm Hg.[246] The only drugs that are contraindicated are ACE inhibitors and angiotensin II receptor blockers because of their propensity to induce neonatal renal failure.[246]

If the syndrome advances and eclampsia threatens before the 32nd week of gestation, expectant management (bed rest, oral antihypertensives, and intensive fetal monitoring) provides better eventual outcomes than does more aggressive therapy (glucocorticoids for 48 hours followed by delivery either by induction or cesarean section).[246] If parenteral antihypertensives are needed, hydralazine works well.

CHRONIC HYPERTENSION.

If pregnancy begins while a woman is receiving antihypertensive drug therapy, the medications, including diuretics, are usually continued in the belief that the mother should be protected and that the fetus will not suffer from any sudden hemodynamic shifts such as occur when therapy is first begun. However, despite modern treatment, the incidence of perinatal mortality and fetal growth retardation remains higher in patients with chronic hypertension.[238]

MANAGEMENT OF ECLAMPSIA.

With appropriate care of gestational hypertension, eclampsia hardly ever supervenes; when it does, however, maternal and fetal mortality remain very high. Excellent results have been reported with the use of magnesium sulfate to prevent convulsions.[247] Patients with severe eclampsia who have persistent oliguria after a fluid

challenge should undergo hemodynamic monitoring since management may require additional volume or a reduction in preload or afterload.

CONSEQUENCES OF PREGNANCY-RELATED HYPERTENSION.

The long-term prognosis of women with gestational hypertension is excellent. When 200 women with the most severe form, eclampsia, were monitored for up to 44 years, the distribution of blood pressure was identical to that in the general population.[248] Chesley concluded that "eclampsia neither is a sign of latent essential hypertension nor causes hypertension." Nonetheless, when compared with women who were normotensive, the overall prognosis for women who had hypertension during pregnancy is not as good, probably because of causes other than preeclampsia, including unrecognized chronic primary hypertension.[249]

After delivery, transient or persistent hypertension may develop in the mother. In many, early primary hypertension may have been masked by the hemodynamic changes of pregnancy. Postpartum heart failure may develop in some women; the heart failure may be an idiopathic cardiomyopathy but is usually related to hypertension, preexisting heart disease, or complications of pregnancy.[250]

HYPERTENSIVE CRISIS

DEFINITIONS.

A number of clinical circumstances may require rapid reduction of blood pressure (Table 28-16) . These circumstances may be separated into *emergencies,* which require immediate reduction of blood pressure (within 1 hour), and *urgencies,* which can be treated more slowly. A persistent diastolic pressure exceeding 130 mm Hg is often associated with acute vascular damage; some patients may suffer vascular damage from lower levels of pressure, while others manage to withstand even higher levels without apparent harm. As discussed below, the rapidity of the rise may be more important than the absolute level in producing acute vascular damage. Therefore, in practice, all patients with diastolic blood pressure above 130 mm Hg should be treated, some more rapidly with parenteral drugs and others more slowly with oral agents, as described on p. 991 .

When the rise in pressure causes retinal hemorrhage, exudates, or papilledema, the term *accelerated-malignant hypertension* is used. *Hypertensive encephalopathy* is characterized

TABLE 28-16 -- CIRCUMSTANCES REQUIRING RAPID TREATMENT OF HYPERTENSION

Accelerated-malignant hypertension with papilledema
Cerebrovascular
Hypertensive encephalopathy
Atherothrombotic brain infarction with severe hypertension
Intracerebral hemorrhage
Subarachnoid hemorrhage
Cardiac
Acute aortic dissection
Acute left ventricular failure
Acute or impending myocardial infarction
After coronary bypass surgery
Renal
Acute glomerulonephritis
Renal crises from collagen-vascular diseases
Severe hypertension after kidney transplantation
Excessive circulating cathecholamines
Pheochromocytoma crisis
Food or drug interactions with monoamine oxidase inhibitors
Sympathomimetic drug use (cocaine)
Rebound hypertension after sudden cessation of antihypertensive drugs
Eclampsia
Surgical
Severe hypertension in patients requiring immediate surgery
Postoperative hypertension
Postoperative bleeding from vascular suture lines
Severe body burns
Severe epistaxis

From Kaplan NM: Management of hypertensive emergencies. Lancet 344:1335, 1994. © by the Lancet Ltd., 1994.

by headache, irritability, alterations in consciousness, and other manifestations of central nervous dysfunction with sudden and marked elevations in blood pressure. Symptoms can be reversed by a reduction in pressure.

INCIDENCE.

In less than 1 percent of patients with primary hypertension, the disease progresses to an accelerated-malignant phase. Although the incidence is probably falling as a consequence of more widespread treatment of hypertension, no difference was found in the numbers of patients seen in Birmingham, England, from 1970 to 1993,[251] reflecting the very low rates of control of hypertension in England.

Any hypertensive disease can initiate a crisis. Some, including pheochromocytoma and renovascular hypertension, do so at a higher rate than seen with primary hypertension. However, since hypertension is of unknown cause in over 90 percent of all patients, most hypertensive crises appear in the setting of preexisting primary hypertension.

PATHOPHYSIOLOGY.

Whenever blood pressure rises and remains above a critical level, various processes set off a series of local and systemic effects that cause further rises in pressure and vascular damage eventuating in accelerated-malignant hypertension

Studies in animals and humans by Strandgaard and Paulson have elucidated the mechanism of hypertensive encephalopathy.[252] First, they directly measured the caliber of pial arterioles over the cerebral cortex in cats whose blood pressure was varied over a wide range of infusion by vasodilators or angiotensin II. As the pressure fell, the arterioles became dilated; as the pressure rose, they become constricted. Thus, constant cerebral blood flow was maintained by means of autoregulation, which is dependent on the cerebral sympathetic nerves. However, when mean arterial pressure rose above 180 mm Hg, the tightly constricted vessels could no longer withstand the pressure and suddenly dilated. This dilation began in an irregular manner, first in areas with less muscle tone and then diffusely with production of generalized vasodilation. This "breakthrough" of cerebral blood flow hyperperfuses the brain under high pressure and thereby causes leakage of fluid into the perivascular tissue and results in cerebral edema and the syndrome of hypertensive encephalopathy.

In human subjects, cerebral blood flow was measured repetitively by an isotopic technique while blood pressure was lowered or raised with vasodilators or vasoconstrictors in a manner similar to that used in the animal studies.[252] Curves depicting cerebral blood flow as a function of arterial pressure demonstrated autoregulation with a constancy of flow over mean pressures in normotensive persons from about 60 to 120 mm Hg and in hypertensive patients from about 110 to 180 mm Hg (Fig. 28-18) . This "shift to the right" in hypertensive patients is the result of structural thickening of the arterioles as an adaptation to the chronically elevated pressure. When pressure was raised beyond the upper limit of autoregulation, the same "breakthrough"

Figure 28-18 Idealized curves of cerebral blood flow at varying levels of systemic blood pressure in normotensive and hypertensive subjects. Rightward shift is shown in autoregulation with chronic hypertension. (Adapted from Strandgaard S, Olesen J, Skinhtoi E, Lassen NA: Autoregulation of brain circulation in severe arterial hypertension. BMJ 1:507, 1973.)

TABLE 28-17 -- CLINICAL CHARACTERISTICS OF HYPERTENSIVE CRISIS

Blood pressure: Usually >140 mm Hg diastolic
Funduscopic findings: Hemorrhage, exudate, papilledema
Neurological status: Headache, confusion, somnolence, stupor, visual loss, focal deficits, seizures, coma
Cardiac findings: Prominent apical impulse, cardiac enlargement, congestive failure
Renal: Oliguria, azotemia
Gastrointestinal: Nausea, vomiting

From Kaplan NM: Clinical Hypertension. 6th ed. Baltimore, Williams & Wilkins, 1994, p 283.

with hyperperfusion occurred as was seen in the animal studies. In previously normotensive persons whose vessels have not been altered by prior exposure to high pressure, breakthrough occurred at a mean arterial pressure of about 120 mm Hg; in hypertensive patients, the breakthrough occurred at about 180 mm Hg.

These studies confirm clinical observations. In previously normotensive persons, severe encephalopathy occurs with relatively little hypertension. In children with acute glomerulonephritis and in women with eclampsia, convulsions may occur as a result of hypertensive encephalopathy with blood pressure readings as low as 150/100 mm Hg. Obviously, chronically hypertensive patients withstand such pressures without difficulty; however, when pressure increases significantly, encephalopathy may also develop even in these patients.

MANIFESTATIONS AND COURSE.

The symptoms and signs of hypertensive crises are usually dramatic (Table 28-17) . However, some patients may be relatively asymptomatic despite markedly elevated pressure and extensive organ damage. Young black men are particularly prone to hypertensive crisis with severe renal insufficiency but little obvious prior distress. When the blood pressure is sufficiently high to induce encephalopathy or accelerated-malignant hypertension, the following clinical features are frequently present:

1. Renal insufficiency with protein and red cells in the urine and azotemia; acute oliguric renal failure may also develop.
2. Elevated levels of plasma renin from the diffuse intrarenal ischemia resulting in secondary aldosteronism, often manifested by hypokalemia. Although not causal, the secondarily elevated renin and aldosterone levels most likely exacerbate the hypertensive process.
3. Microangiopathic hemolytic anemia with red cell fragmentation and intravascular coagulation.
4. Cardiac size and function may *not* be abnormal in those in whom malignant hypertension suddenly develops.

If left untreated, patients die quickly of brain damage or more gradually of renal damage. Before effective therapy was available, less than 25 percent of patients with malignant hypertension survived 1 year and only 1 percent survived 5 years.[253] With therapy including renal dialysis, over 90 percent survive 1 year and about 80 percent survive 5 years. Death in patients with severe hypertension is usually

TABLE 28-18 -- CONDITIONS TO BE DIFFERENTIATED FROM A HYPERTENSIVE CRISIS

Acute left ventricular failure
Uremia from any cause, particularly with volume overload
Cerebrovascular accident
Subarachnoid hemorrhage
Brain tumor
Head injury
Epilepsy (postictal)
Collagen diseases, particularly lupus, with cerebral vasculitis
Encephalitis
Overdose and withdrawal from narcotics, amphetamines, etc.
Hypercalcemia
Acute anxiety with hyperventilation syndrome

from stroke or renal failure if it occurs in the first few years after onset. If therapy keeps patients alive for longer than 5 years, death will usually be due to coronary artery disease, in which case factors other than the high pressure per se are probably also involved.

DIFFERENTIAL DIAGNOSIS.

The presence of hypertensive encephalopathy or accelerated-malignant hypertension demands immediate, aggressive therapy to lower blood pressure effectively, often before the specific cause is known. However, certain serious diseases, as well as psychogenic problems, i.e., acute anxiety with hyperventilation or panic attacks, can mimic a hypertensive crisis (Table 28-18) and management of these conditions obviously requires different diagnostic and therapeutic approaches. In particular, blood pressure should not be lowered too abruptly in a patient with a stroke.[254] Specific therapy for hypertensive crises is described in the next chapter (p. 991).

Chapter 29 - Systemic Hypertension: Therapy

NORMAN M. KAPLAN

As noted at the beginning of Chapter 28 , the number of patients being treated for hypertension has expanded markedly during the past 25 years so that it is now the leading reason for office visits to physicians. Nonetheless, in various developed countries--from the United Kingdom and Canada, which have national health schemes that cover everyone, to the United States, with its sporadic coverage--only 15 to 30 percent of hypertensive patients have their disease under good control.[1] This apparent paradox of expanded coverage but continued poor control is not the consequence of either the ineffectiveness of available therapy or an unwillingness of physicians to provide it. In controlled trials, most patients with the most prevalent form of hypertension, previously called "mild" but now referred to as grade 1, i.e., diastolic blood pressure (DBP) between 90 and 100 mm Hg, achieve excellent control with one of many drugs.[2] Relatively few patients are truly resistant to therapy.[3]

The problem derives from the inherent nature of hypertension: induced by common but unhealthy life styles, asymptomatic and persistent, with overt consequences delayed by 10 to 30 years so that the costs of therapy, both in money and in adverse effects, seem on the surface to outweigh benefits to be derived from adherence to the regimen. Furthermore, behind the inherent nature of the disease that often interferes with patients' adherence to their physician's requests, there lurks yet another disquieting feature of the therapy of most hypertension: It may not benefit the majority of patients who adhere faithfully to their treatment.[4] Even among such elderly patients as enrolled in the Systolic Hypertension in the Elderly Program (SHEP) trial, 111 would need to be treated for 5 years to prevent one cardiovascular death and 19 treated to prevent one cardiovascular event.[5] Because of the costs and side effects of therapy, caution is needed in the use of medication as a preventive measure.[6]

Yet another element, the issue of cost-effectiveness, has been introduced into the debate about the value of treating all patients with any degree of hypertension.[7] As the escalating costs of health care consume a greater share of society's resources, two opposing forces have risen: one, the need for less expensive illness care, and the other, the relatively large cost of prevention when indiscriminately applied to low-risk subjects. Therefore, it is likely that the calls for more selective and targeted antihypertensive therapy will be more widely listened to in the future.

We examine the evidence for benefits of therapy and then apply this evidence to the criteria for the initiation of therapy for individual patients.

BENEFITS OF THERAPY

The treatment of hypertension is aimed not at simple reduction of blood pressure but at prevention of the cardiovascular complications that are known to accompany the high pressure. During the past 30 years, many randomized, controlled trials (RCTs) have tested the ability of antihypertensive drugs--primarily diuretics and adrenergic inhibitors--to prevent strokes and heart attacks. Although such RCTs have limited ability to aid in clinical decisions about individual patients,[8] few other aspects of clinical practice have as strong an evidence base as does the treatment of hypertension.

A series of meta-analyses have portrayed the effects of therapy in a progressively enlarging number of completed trials.[9] [10] [11] They have shown a uniform and persistent reduction in morbidity and mortality from stroke averaging 40 percent, a reduction that exactly fits what was predicted from epidemiological evidence if the attributable risk had been completely reversed.[12] On the other hand, the impact on coronary artery disease reported in 1990 was only 14 percent,[9] below the 20 to 25 percent predicted if the risk attributed to blood pressure had been completely reversed.[12] By 1997, however, data from three reported trials enrolling elderly patients[5] [13] [14] brought the overall impact on coronary events to a 16 percent reduction, with confidence limits of 8 to 23 percent, which overlap the excess 20 to 25 percent risk predicted from epidemiological evidence (Fig. 29-1) . The protection against stroke has been shown to apply even to patients older than 80 years.[11] In the six trials that included 1670 patients older than 80 years, the half who were treated with either diuretics or dihydropyridine calcium antagonists had a 36 percent reduction in stroke, a 39 percent reduction in heart failure, and a statistically significant 22 percent reduction in major coronary events.[11]

The explanation for the progressively better results in the RCTs likely reflects the inclusion of higher-risk subjects. As shown in Figure 29-2 , absolute benefit in stroke prevention is progressively greater, the higher the stroke rate event in the placebo group.[15] In a like manner, benefits of treatment were first documented for patients with severe hypertension,[16] then for those with moderate disease, and only later for those with lesser degrees of hypertension.[17]

The difficulty in showing clear benefits of treatment in the larger part of the hypertensive population, those with stage 1 or blood pressures from 140/90 to 160/100 mm Hg (see Table 28-2) must be reconciled with the fact that even though their individual risk is relatively low, their sheer

Figure 29-1 Meta-analysis of randomized, placebo-controlled clinical trials in hypertension according to first-line treatment strategy. Trials indicate number of trials with at least one endpoint of interest. For these comparisons, the numbers of participants randomized to active treatment and placebo, respectively, were 7768 and 12,075 for high-dose diuretic therapy, 4305 and 5116 for low-dose diuretic therapy, and 6736 and 12,147 for beta-blocker therapy. Because the Medical Research Council trials included two active arms, the placebo group is included twice in these totals (for diuretic comparison and for beta-blocker comparison). The total numbers of participants randomized to active and control therapy were 24,294 and 23,926, respectively. RR = relative risk; CI = confidence interval; HDFP = Hypertension Detection and Follow-up Program. (Data from Psaty BM, Smith NL, Siscovick DS, et al: Health outcomes associated with antihypertensive therapies used as first-line agents. JAMA 277:739, 1997.)

number causes them to make a major contribution to the overall population risk from hypertension, as shown in Figure 28-2 . This fact has given rise to two important guidelines for clinical practice: first, the critical need for prevention of hypertension by population-wide life style modifications[18] ; second, the rationale for considering blood pressure in the larger context of overall cardiovascular risk.

THRESHOLD FOR THERAPY

The value of life style modifications is documented in the next section of this chapter. The rationale for a broader look at risk beyond blood pressure was first formalized by a group of investigators from New Zealand[19] and has now been incorporated into both the 1997 report of the U.S. Joint National Committee (JNC-6)[20] and the 1999 World Health Organization-International Society of Hypertension (WHO-ISH) guidelines.[1] The basis for risk assessment and stratification provided in JNC-6 are shown in Tables 28-8 and 28-9 (pp. 950 , 951). The somewhat more detailed list of factors influencing risk in the 1999 WHO-ISH report is shown in Table 29-1 . The stratification in both reports is similar, with a fourth "very high" risk group having associated clinical conditions added in the WHO-ISH report, as are the

recommendations for management: Low-risk patients with blood pressures as high as 159/99 mm Hg should be given life style modification; high-risk patients with blood pressures as low as 130/85 mm Hg should be immediately started on drug therapy (see Table 28-9) . The WHO-ISH report provides additional data on the absolute effects of treatment on cardiovascular risk (Table 29-2) . As shown, relatively small benefits have been seen in RCTs of about 5 years' duration in low-risk patients, although with more intensive therapy to lower blood pressure by 20/10 mm Hg, they too can achieve more impressive protection.

All in all, these recommendations have placed the decision to treat individual patients with different levels of blood pressure and degrees of overall cardiovascular risk into a much more rational framework. Lest practitioners be concerned about the recommendation to withhold drug therapy from low-risk patients with blood pressure as high as 159/99 mm Hg, recall the experience of the placebo-treated half of the patients in the Australian trial[21] : Over 4 years, the average DBP fell below 95 mm Hg in 47.5 percent of patients with baseline DBP of 95 to 109 mm Hg, and increased morbidity and mortality were seen only in those whose average DBP remained above 100 mm Hg.

If drug therapy is not given, close surveillance of all patients must be provided, because from 10 to 17 percent of the placebo-treated patients in various trials had progression of their blood pressure to a level above that considered an indication for active treatment. Moreover, all patients should be strongly advised to use the appropriate life style modifications described beginning on page 975 .

Systolic Pressure in the Elderly

The New Zealand recommendations are that therapy be given to the elderly at lower levels of pressure because they "generally have a higher absolute risk of cardiovascular disease and therefore derive greater benefit from treatment."[19] The elderly achieved even greater protection from coronary disease in three trials. Furthermore, protection from congestive heart failure was even more impressive, therapy reducing the incidence by over 50 percent.[5] [13] Moreover,

TABLE 29-1 -- FACTORS INFLUENCING PROGNOSIS

Risk Factors for Cardiovascular Diseases	Target-Organ Damage	Associated Clinical Conditions
Used for Risk Stratification	Left ventricular hypertrophy (electrocardiogram, echocardiogram, or radiograph)	Cerebrovascular disease
Levels of systolic and diastolic blood pressure (grades 1-3)	Proteinuria and/or slight elevation of plasma creatinine concentration (1.2-2.0 mg/dl)	Ischemic stroke
Men >55 yr	Ultrasound or radiological evidence of atherosclerotic plaque (carotid, ilac, and femoral arteries, aorta)	Cerebral hemorrhage
Women >65 yr	Generalized or focal narrowing of the retinal arteries	Transient ischemic attack
Smoking		Heart disease
Total cholesterol level >6.5 mol/liter (250 mg/dl)		Myocardial infarction
Diabetes		Angina
Family history of premature cardiovascular diseaes		Coronary revascularization
		Congestive heart failure
		Renal disease

Figure 29-2 Comparison of proportionate or relative *(top)* and absolute *(bottom)* benefit from reduction in the incidence of stroke in the six trials in the elderly, as well as in one other with similar design but in which the absolute risk of stroke was much lower. Event rates are for fatal and nonfatal stroke combined. Aust = Australian study; EWPHE = European Working Party on High Blood Pressure in the Elderly trial; Coope = Cooper and Warrender; MRC = Medical Research Council trials; SHEP = Systolic Hypertension in the Elderly Program trial; STOP = Swedish Trial in Old Patients with Hypertension. (From Lever AF, Ramsay LE: Treatment of hypertension in the elderly. J Hypertens 13:571-579, 1995.)

TABLE 29-2 -- ABSOLUTE EFFECTS OF TREATMENT ON CARDIOVASCULAR RISK

From the results of randomized, controlled trials, it appears that each reduction of 10 to 14 mm Hg in systolic blood pressure and 5 to 6 mm Hg in diastolic blood pressure confers about two-fifths less stroke, one-sixth less coronary heart disease, and, in Western populations, one-third fewer major cardiovascular events overall.

In patients with grade I hypertension, monotherapy with most agents produces reductions in blood pressure of about 10/5 mm Hg. In patients with higher grades of hypertension, it is possible to achieve sustained blood pressure reductions of 20/10 mm Hg or more, particularly if combination drug therapy is used.

The estimated absolute effects of such blood pressure reductions on cardiovascular disease (CVD) risk (fatal plus nonfatal stroke or myocardial infarction) are as follows:

		Absolute Treatment Effects (CVD Events Prevented per 1000 Patients-Years)	
Patient Group	**Absolute Risk (CVD Events over 10yr)(%)**	***10/5 mm Hg***	***20/10 mm Hg***
Low risk	<15	<5	<9
Medium risk	15-20	5-7	8-11
High risk	20-30	7-10	11-17
Very high risk	>30	>10	>17

Between these strata, the estimated absolute treatment benefits range from less than five events prevented per thousand patient-years of treatment (low risk) to more than 17 events prevented per thousand patient-years of treatment (very high risk).

The absolute benefits for stroke and coronary artery disease will be augmented by smaller absolute benefits for congestive heart failure and renal disease.

These estimates of benefit are based on relative risk reductions observed in trials of about 5 years' duration. Longer-term treatment over decades could produce larger risk reductions.

From Guidelines Subcommittee: 1999 World Health Organization-International Society of Hypertension guidelines for the management of hypertension. J Hyperten 17:151, 1999.

not included in Figure 29-1 are the results of the Syst-Eur trial, in which a long-acting dihydropyridine calcium antagonist, nitrendipine, was found to provide significant reductions in stroke and coronary events[22] and dementia[23] and particularly impressive protection against all endpoints among the diabetic patients enrolled in the trial.[24] Similar protection against stroke and coronary mortality has been shown in a similar trial of elderly Chinese with systolic hypertension.[25] Based on the four trials in the elderly patients with pure systolic hypertension, the need to consider systolic levels in the decision to treat is obvious. In fact, the difference between the typically elevated systolic levels and the usually lower diastolic levels, i.e., a widened pulse pressure in the elderly is most predictive of future cardiovascular risk.[26]

USE OF SURROGATE ENDPOINTS.

All of the preceding discourse on the benefits of therapy and the threshold for treatment has involved "hard" endpoints: morbidity and mortality. Some argue that softer endpoints should also be taken into account, using as surrogates one or another sign of cardiovascular damage that may be easier to assess and quicker to appear. These include regression of left ventricular hypertrophy or carotid artery stenosis and reduction of proteinuria. Most, however, hold to the need for the hard endpoints.

GOAL OF THERAPY

Once having decided to treat, the clinician must consider the goal of therapy. In the past, most physicians assumed that the effects of reduction of blood pressure on cardiovascular risk would fit a straight line downward (line A in Fig. 29-3) , [27] justifying the opinion "the lower, the better." However, as noted, data from large trials indicated a more gradual decline in risk when pressures were reduced to moderate levels (line B in Fig. 29-3) , DBP approximately 95 mm Hg in the IPPPSH trial.[28] Subsequently, Cruickshank[29] called attention to a J curve (line C in Fig. 29-3) , reflecting a progressive fall in risk as pressure is lowered, but only to a certain level; below that level, the risk for coronary ischemic events rises again.

Additional evidence for the J curve has been added to the six retrospective studies analyzed by Cruickshank, including two prospective studies of sizable numbers of patients.[30] [31] The apparent propensity to induce myocardial ischemia when pressures are lowered below a certain critical threshold may not apply to other vital organs. Therefore, maximal protection against stroke or renal damage may require greater reductions in pressure than the coronary circulation can safely handle.

Because the presence of a J curve could reflect lower blood pressures as a consequence of coronary disease rather than a cause, the Hypertension Optimal Treatment (HOT) trial was performed.[32] Almost 19,000 patients with initial mean blood pressure of 170/105 mm Hg were randomly allocated to one of three target diastolic pressures: 90, 85, or 80 mm Hg. Treatment was based on a long-acting dihydropyridine calcium antagonist, felodipine, with additional drugs added to achieve the desired goal. Diastolic pressures were significantly reduced by more than 20 mm Hg in all three groups, but at the end, only 4 mm Hg separated them, so it was not possible to prove or disprove a J curve. The least cardiovascular mortality was seen at a blood pressure of 139/86 mm Hg; the least morbidity, at 138/83 mm Hg (Fig. 29-4) . In the absence of a placebo group, the absolute degree of protection could not be ascertained, but most of the benefit was noted in the 1500 diabetic patients who had a 51 percent reduction in major cardiovascular events in those in the below 80 mm Hg target group compared with the below 90 mm Hg target group.

Even though a J curve is suggested in the left portion of the lowest panel, the major positive result of this massive trial is that the safest blood pressure for most patients is less than 140/85 mm Hg, a level that only a small minority of patients are now achieving. As noted in JNC-6 and WHO-ISH guidelines, the goal must be less than 140/90 mm Hg for most patients, including the elderly, and less than 130/85 mm Hg for those at high risk, including all diabetic persons.

Figure 29-3 Three models representing hypothetical relationships between levels of blood pressure and risk of cardiovascular disease. (From Epstein FH: Proceedings of the XVth International Congress of Therapeutics, September 5-9, 1979. Brussels, Excerpta Medica, 1980.)

Even though the current guidelines have clarified the questions of whom to treat with drugs for mild hypertension and how much the pressure should be reduced, each patient must be considered separately, taking various factors into account. The foregoing discussion should indicate the wisdom of withholding drug therapy from many of these patients, at least until the effects of time and life style modifications have been given a chance, thereby avoiding too fast and too great reductions in pressure.

Once good control of blood pressure in a patient has been achieved, it may be possible to reduce or withdraw drug therapy. Perhaps one fourth of patients who have initially mild hypertension and who achieve good control with therapy will remain normotensive for at least 1 year after their therapy is stopped.[33] However, such patients need to remain under observation.

LIFE STYLE MODIFICATIONS

Interest in the use of various nondrug therapies, better called life style modifications, for the treatment of hypertension has risen markedly in the past few years, yet many practitioners either do not use them or use them in a casual, perfunctory manner. This hesitant attitude can be attributed both to the sparseness of firm evidence indicating that these therapies succeed and to the difficulty many have faced in convincing patients to adhere to them. This situation is likely to change: Evidence for the effectiveness of these approaches in lowering blood pressure is growing,[34] [35] techniques for improving adherence are being popularized, and patients seem increasingly willing to adopt changes in life style. These changes come at a propitious time, when many more individuals are being identified as hypertensive and are considered in need of lowering of

Figure 29-4 Estimated incidence with 95 percent confidence intervals of cardiovascular events *(top three panels)* and mortality *(bottom panel)* blood pressure in the 18,790 hypertensive patients treated in the Hypertension Optimal Treatment (HOT) trial. (From Hansson L, Zanchetti A, Carruthers SG, et al: Effects of intensive blood-pressure lowering and low-dose aspirin in patients with hypertension: Principal results of the Hypertension Optimal Treatment [HOT] randomised trial. Lancet 351:1755, 1998.)

blood pressure. Although most have turned first to drugs, the evidence presented in the previous section suggests that these can be safely withheld from many hypertensive individuals to allow life style modifications a chance to be effective. The need for strong and immediately effective therapy was clear when the majority of patients had fairly severe hypertension; however, as a larger number of patients with mild hypertension have entered the picture, a more gradual approach to their treatment seems more appropriate. In addition, increasing awareness of the need to address other risk factors, such as dyslipidemia and glucose intolerance, along with hypertension has given additional emphasis to the value of life style modifications that can favorably affect them as well.

Just as the increased awareness of the problem of patients' frequent poor adherence to drug therapy has led to attempts to improve the situation, similar attention toward adherence to life style modifications is likely to improve their effectiveness. These measures should be introduced gradually and gently. Too many and too drastic changes in life style may discourage patients from accepting them. Eventually, however, all hypertensive patients should benefit from moderate restriction of dietary salt, reduction of excess body weight, regular exercise, and moderation of alcohol intake.[20] The ability of these life style modifications to prevent hypertension has not been documented, although fewer subjects with high-normal pressures proceed into hypertension over 3 to 7 years while they practice these modalities.[36] [37] Because hypertension slowly develops over 20 to 40 years and normotensive persons have little if any decline in blood pressure even with potent antihypertensive drugs, the failure to lower blood pressure or prevent hypertension in a few years should not be taken as proof that these life style changes will not work over longer

intervals.

AVOIDANCE OF TOBACCO.

The major pressor effect of tobacco is easily missed because patients are not allowed to smoke in places where blood pressures are recorded. With automatic monitoring, the effect is easy to demonstrate[38] (Fig. 29-5) , and blood pressure immediately falls when smokers quit.[39] Patients who smoke or dip snuff should be strongly and repeatedly told to stop. Failing that, they should be advised to monitor their blood pressure while they smoke because such pressures are at least partially responsible for increased risks for cardiovascular disease and should be the target of antihypertensive therapy.

WEIGHT REDUCTION.

Relatively small increases in body weight increase the incidence of hypertension,[40] and even small decreases in excess weight lower blood pressure.[34] In a review of adequately controlled intervention studies, a

Figure 29-5 Changes in systolic blood pressure (SBP) over 15 minutes after smoking the first cigarette of the day within the first 5 minutes (solid circles), during no activity (open-circles), and during sham smoking (triangles) in normotensive smokers. (From Groppelli A, Giorgi DMA, Omboni S, et al: Blood pressure and heart rate response to repeated smoking before and after beta blockade and selective alpha$_1$ -inhibition. J Hypertens 10:495, 1992.)

1.0-kg decrease in body weight was accompanied by an average reduction of 1.6/1.3 mm Hg in blood pressure.[41] The fall in blood pressure may reflect many effects including improvements in insulin sensitivity, amelioration of sleep apnea, and decreased sensitivity to sodium. Although the rate of recidivism among obese persons is high, an attempt at weight reduction in all obese hypertensive patients should be made, using whatever level of caloric restriction a patient is able to maintain.

DIETARY SODIUM RESTRICTION.

On page 952 , evidence incriminating the typically high sodium content of the diet of persons living in developed, industrialized societies was presented as a cause of hypertension. Once hypertension is present, modest salt restriction may help lower the blood pressure. In a review by Cutler and colleagues of 32 well-controlled intervention studies in which daily intake (based on urinary sodium excretion) was reduced by a median of 77 mmol/24 hr, blood pressures fell an average of 4.8/2.5 mm Hg in the hypertensive individual.[42] There is probably a dose-response relation--the more sodium reduction, the greater the blood pressure decline. In a small but well-controlled study, the reduction in blood pressure was shown to be 8/5 mm Hg on a daily sodium intake of 100 mmol and 16/9 mm Hg on a 50 mmol/day intake.[43]

However, rigid degrees of sodium restriction are not only difficult for patients to achieve but may also be counterproductive.[44] The marked stimulation of renin-aldosterone and sympathetic nervous activity that accompanies rigid sodium restriction may prevent the blood pressure from falling and increase the amount of potassium wastage if diuretics are concomitantly used. Not all hypertensive persons respond to a moderate degree of sodium restriction to the recommended level of 100 mmol sodium, or 2.4 gm/day. Blacks and elderly patients may be more responsive to sodium restriction, perhaps because of their lower renin responsiveness.

Even if the blood pressure does not fall with moderate degrees of sodium restriction, patients may still benefit: improved beta-adrenergic responsiveness.[45] Increased antihypertensive effectiveness of other drugs[46] less diuretic-induced potassium wastage, and reduction in left ventricular hypertrophy[47] all have been reported among patients on moderate sodium restriction. Although there is no certainty that moderate sodium restriction will help, the little evidence suggesting that it will hurt[48] has been shown to be invalid.[49] In overweight persons, a lower sodium intake was associated with a reduced risk of cardiovascular disease.[49]

Therefore, I consider sodium restriction to be useful for all persons, as a preventive measure in those who are normotensive and, more certainly, as partial therapy in those who are hypertensive. The easiest way to accomplish moderate sodium restriction is to substitute natural foods for processed foods, because natural foods are low in sodium and high in potassium whereas most processed foods have had sodium added and potassium removed. It is hoped that food processors will gradually reduce the large amounts of salt they often add to processed foods, but in the meantime, patients should be asked to avoid those foods whose label indicates more than 300 mg of sodium per portion. Additional guidelines include the following:

1. Add no sodium chloride to food during cooking or at the table.
2. If a salty taste is desired, use a half sodium and half potassium chloride preparation (such as Lite Salt) or a pure potassium chloride substitute.
3. Avoid or minimize the use of "fast foods," many of which have high sodium content.
4. Recognize the sodium content of some antacids and proprietary medications. (For example, Alka-Seltzer contains more than 500 mg of sodium; Rolaids is virtually sodium free.)

POTASSIUM SUPPLEMENTATION.

Some of the advantages of a lower sodium intake may relate to its tendency to increase body potassium content, both by a coincidental increase in dietary potassium intake and by a decrease in potassium wastage if diuretics are being used. Potassium deficiency exerts many effects that may increase blood pressure, and potassium infusions increase the vasodilating effect of acetylcholine, apparently through the nitric oxide pathway.[50] Potassium supplements have been shown to reduce the blood pressure an average of 3.1/2.0 mm Hg in 33 RCTs published before July 1995.[51] Nonetheless, potassium supplements are too costly and potentially hazardous for routine use in normolcalemic hypertensive persons. Patients should be protected from potassium depletion and encouraged to increase dietary potassium intake, which may be enough to lower blood pressure.

MAGNESIUM SUPPLEMENTATION.

Only a few controlled trials find an effect on blood pressure with magnesium supplements.[52] However, those who are magnesium depleted may not be able to replete concomitant potassium deficiency.[53]

CALCIUM SUPPLEMENTATION.

An increase in free calcium concentration in vascular smooth muscle cells may be a final step in the pathogenesis of primary hypertension. Nonetheless, some hypertensive patients have a lower calcium intake and higher urinary calcium excretion than do normotensive persons.[54] In 42 mostly short-term studies of either calcium supplements (in 33) or dietary intervention (in 9) in 4560 nonpregnant adults, the blood pressure fell 1.44/0.84 mm Hg.[55] Because calcium supplements sometimes raise blood pressure and increase the risk of kidney stones, the best course is to ensure that calcium intake is not inadvertently reduced by reduction of milk and cheese consumption in an attempt to reduce saturated fat and sodium intake when supplemental calcium is not taken.

OTHER DIETARY CHANGES.

Significant reductions in blood pressure were observed in hypertensive persons who ate a diet rich in fruits and vegetables, an effect that was further accentuated when low-fat dairy foods were substituted for high-fat foods.[35] The effect was greater in hypertensive than in normotensive persons and in blacks than in whites. This fall in blood pressure, accomplished without change in sodium or caloric intake, could reflect increases in fiber, potassium, or other ingredients. Some lowering of the blood pressure has been noted in studies of a lacto-ovo-vegetarian diet,[56] high fiber intake,[57] and high doses of omega-3 fatty acids from fish oil.[58] Consumption of dried garlic powder lowered diastolic pressure in four of seven trials compared with placebo.[59]

In 11 carefully controlled trials involving 522 subjects who consumed an average of 5 cups of caffeine-containing coffee, the mean blood pressure rose 2.4/1.2 mm Hg.[60] An even greater effect was noted in elderly hypertensive individuals.[61] Even though consumption of tea has been found to be associated with a lower risk of myocardial infarction,[62] it too may raise blood pressure.[63]

MODERATION OF ALCOHOL.

Moderate alcohol consumption, less than 1 oz of ethanol per day, does not increase the prevalence of hypertension. Heavier drinking clearly exerts a pressor effect that makes *alcohol abuse the most common cause of reversible hypertension.*[64] One to two portions of alcohol-containing beverages a day, containing 0.5 to 1.0 oz of ethanol, need not be prohibited, particularly because fewer coronary events[65] and strokes[66] have been noted in those who consume that amount.

PHYSICAL EXERCISE.

Although the systolic pressure rises considerably during dynamic (aerobic) exercise, vascular compliance increases[67] and resting blood pressure usually falls[68] in hypertensive persons after regular exercise programs. Even in obese individuals, cardiorespiratory fitness is associated with lower cardiovascular disease mortality.[69] Although pure static exercise acutely raises both systolic and diastolic pressures, repetitive circuit weight training also lowers blood pressure.[70]

RELAXATION TECHNIQUES.

A review of 26 reports of various forms of relaxation--transcendental meditation, yoga, biofeedback, psychotherapy--reports that they were no more effective in lowering blood pressure than were sham controls.[71]

COMBINED THERAPIES

When several life style modifications are combined, additional antihypertensive effects may accrue. The best study is the placebo arm of the Treatment of Mild Hypertension Study (TOMHS),[2] in which 234 mildly hypertensive persons followed a 48-month regimen of moderate sodium restriction, weight loss, regular exercise, and moderation of alcohol use. Despite relatively small changes in weight (average loss of 6.6 lbs), sodium intake (reduction of 10 percent), exercise level, and alcohol consumption, these patients had an 8.6/8.6 mm Hg decline in blood pressure at the end of the 4-year program. Moreover, they experienced improvements in lipid profile and reduction in left ventricular mass.

THE POTENTIAL OF LIFE STYLE MODIFICATIONS

Part of the antihypertensive effect reported in this and other trials of life style modification may be attributable to the nonspecific reduction in blood pressure so often noted when repeated readings are taken. Such decreases may reflect a statistical regression toward the mean, a placebo effect, or relief of anxiety and stress with time. The same phenomenon is probably also responsible for much of the initial response to drug therapy, so that success may be attributed to both drugs and nondrugs when it is deserved by neither.

Nonetheless, increasingly long and strong evidence from controlled studies attests to the efficacy of multifaceted nondrug programs to reduce the blood pressure. Whether such success can be achieved by individual practitioners is uncertain. However, because help is available, including various educational materials for patients, professional assistants such as dietitians and psychologists, and groups organized for weight reduction, exercise, and relaxation therapies, the effort seems both increasingly easy and likely to be successful in lowering blood pressure.

ANTIHYPERTENSIVE DRUG THERAPY

If the life style modifications just described are not followed or prove to be ineffective, or if the level of hypertension at the onset is so high that immediate drug therapy is deemed necessary, the general guidelines listed in Table 29-3 should be helpful in improving patients' adherence to lifelong treatment.

General Guidelines

The guidelines listed in Table 29-3 are all aimed at providing effective 24-hour control of hypertension in a manner that encourages adherence to the regimen. The approach is based on known pharmacological principles and proven ways to improve adherence. It is designed for the 90 percent of patients with fairly mild hypertension, in whom a gradual approach is feasible.

Once the selection of the most appropriate agent for initial therapy has been made (by a process that is discussed further in the next section), a relatively low dose of a single drug should be started, aiming for a reduction of 5 to 10 mm Hg in blood pressure at each step. Many physicians, by nature and training, desire to control a patient's hypertension rapidly and completely. Regardless of which drugs are used, this approach often leads to undue fatigue,

TABLE 29-3 -- GENERAL GUIDELINES TO IMPROVE PATIENTS' ADHERENCE TO ANTIHYPERTENSIVE THERAPY

1. Be aware of the problem of nonadherence and be alert to signs of patients' nonadherence.
2. Establish the goal of therapy: to reduce blood pressure to normotensive levels with minimal or no side effects.
3. Educate the patient about the disease and its treatment.
   a. Involve the patient in decision-making.
   b. Encourage family support.
4. Maintain contact with the patient.
   a. Encourage visits and calls to allied health personnel.
   b. Allow the pharmacist to monitor therapy.
   c. Give feedback to the patient via home blood pressure readings.
   d. Make contact with patients who do not return.
5. Keep care inexpensive and simple.
   a. Do the least work-up needed to rule out secondary causes.
   b. Obtain follow-up laboratory data only yearly unless indicated more often.
   c. Use home blood pressure readings.
   d. Use nondrug, no-cost therapies.
   e. Use the fewest daily doses of drugs needed.
   f. If appropriate, use combination tablets.
   g. Tailor medication to daily routines.
6. Prescribe according to pharmacological principles.
   a. Add one drug at a time.
   b. Start with small doses, aiming for 5 to 10 mm Hg reductions at each step.
   c. Prevent volume overload with adequate diuretic and sodium restriction.
   d. Take medication immediately on awakening or after 4A.M. if patient awakens to void.
   e. Ensure 24-hour effectiveness by home or ambulatory monitoring.
   f. Continue to add effective and tolerated drugs, stepwise, in sufficient doses to achieve the goal of therapy.
   g. Be willing to stop unsuccessful therapy and try a different approach.
   h. Adjust therapy to ameliorate side effects that do not spontaneously disappear.

From Kaplan NM: Clinical Hypertension. 7th ed. Baltimore, Williams & Wilkins, 1998, p 188.

weakness, and postural dizziness, which many patients find intolerable, particularly when they felt well before therapy was begun. Although hypokalemia and other electrolyte abnormalities may be responsible for some of these symptoms, a more likely explanation has been provided by the studies of Strandgaard and Haunso.[72] As shown in Figure 29-6 , they demonstrated the constancy of cerebral blood flow by autoregulation over a range of mean arterial pressures from about 60 to 120 mm Hg in normal subjects and from 110 to 180 mm Hg in patients with hypertension. This shift to the right protects hypertensive patients from a surge of blood flow, which could cause cerebral edema. However, the shift also predisposes hypertensive patients to cerebral ischemia when blood pressure is lowered.

Figure 29-6 Mean cerebral blood flow autoregulation curves from normotensive, severely hypertensive, and effectively treated hypertensive patients are shown. (Modified from Strandgaard [Circulation 53:720, 1976.] From Strandgaard S, HaunsO S: Why does antihypertensive treatment prevent stroke but not myocardial infarction? Lancet 2:658, 1987. © by the Lancet Ltd.)

Figure 29-7 Theoretical therapeutic and toxic logarithmic-linear dose-response curves. The horizontal axis is a logarithmic scale with arbitrary dose units. The vertical axis is a linear scale showing percentage of maximum possible response. See text for discussion. (From Fagan TC: Remembering the lessons of basic pharmacology. Arch Intern Med 154:1430, 1994. Copyright 1994 American Medical Association.)

The lower limit of autoregulation necessary to preserve a constant cerebral blood flow in hypertensive patients is a mean of about 110 mm Hg. Thus, acutely lowering the pressure from 160/110 mm Hg (mean=127) to 140/85 mm Hg (mean=102) may induce cerebral hypoperfusion, although hypotension in the accepted sense has not been produced. This provides an explanation for what many patients experience at the start of antihypertensive therapy, i.e., manifestations of cerebral hypoperfusion, even though blood pressure levels do not seem inordinately low.

Thus, the approach to antihypertensive therapy should be gradual in order to avoid symptoms related to overly aggressive blood pressure reduction. Fortunately, as shown in the middle of Figure 29-6 , if therapy is continued for a period, the curve of cerebral autoregulation shifts back toward normal, allowing patients to tolerate greater reductions in blood pressure without experiencing symptoms.

STARTING DOSAGES.

The need to start with a fairly small dose also reflects a greater responsiveness of some patients to doses of medication that may be appropriate for the majority. All drugs exert increasing effect with increasing doses, portrayed by a log-linear dose-response curve[73] (Fig. 29-7) . However, different patients require different absolute amounts of drug for their own dose response.

As a hypothetical example, for the majority of patients, 50 mg of the beta blocker atenolol would provide a moderate response, shown as point A on the therapeutic effect curve, whereas a dose of 25 mg would provide only a minimal response. At dose A, providing the significant albeit partial response, the side effects would be minimal, as shown by point A
on the curve of toxic effect. If a starting dose of 100 mg were used, the therapeutic effect would be near maximal (point B) but the side effects would be much greater as well (point B
). Therefore, a lower starting dose is preferable for most patients.

However, the response to a given dose is not the same for all patients but rather assumes a bell-shaped curve; some patients are very sensitive to that dose and some very resistant, the majority having a moderate response. Therefore, a significant minority of patients--the very sensitive ones--would obtain a near-maximal response to the 25-mg dose and would better be started on 12.5 mg in order to achieve a moderate therapeutic effect (point A) with minimal side effects (point A
). Without knowing how individual patients will respond, the safest and easiest approach is to start at a dose that probably is not enough for most patients.

The situation was well described by Herxheimer.[74] "For a new drug to penetrate the market quickly, it should be rapidly effective in a high proportion of patients and simple to use. To achieve this, the dosage of the first prescription is therefore commonly set at about the ED_{90} level, i.e., the dose which the early clinical (phase 2) studies have been shown to be effective in 90 percent of the target population, provided that the unwanted effects at this dose are considered acceptable. In 25 percent of patients, a smaller--perhaps much smaller--dose (the ED_{25}) will be effective. The patients in this quartile are the most sensitive to the drug and are liable to receive far more than they need if they are given the ED_{90} . They are also likely to be more sensitive to the dose-related side effects of the drug."

As I have written,[75] Herxheimer goes on to recommend a logical solution: Starting doses should be less than the usual maximal effective dose. For this to be effective, however, physicians must be willing to start most patients with a dose of medication that will not be fully effective. As he states, "The disadvantage from the marketing standpoint is that for the majority of patients the dose must be titrated. That is time-consuming for doctors and patients and more difficult to explain to them. A drug requiring dose titration cannot be presented as the 'quick fix', the instant good news that marketing departments love."[74] The quick fix is inappropriate for most hypertensive patients. To allow for autoregulation of blood flow to maintain perfusion to vital organs when perfusion pressure is lowered, the decline in pressure should be relatively small and gradual.[75] More precipitous reductions in pressure, as frequently occur with larger starting doses, may induce considerable hypoperfusion that results in symptoms that are at least bothersome (fatigue, impotence) and that may be potentially hazardous (postural hypotension, coronary ischemia). It is far better to start low and go slow.[75]

DRUG COMBINATIONS.

Combinations of smaller doses of two drugs from different classes have been marketed to take advantage of the differences in the dose-response curves for therapeutic and toxic (side) effects shown in Figure 29-7 .[20] By combining two drugs, each at a dose near point A, a greater antihypertensive effect is provided (up to point B), but because the side effects are not additive for different classes of drugs, they remain at point A
. A combination of low doses of a beta blocker (bisoprolol) and a diuretic (hydrochlorothiazide) has been approved for initial therapy for hypertension, after it was shown to provide antihypertensive efficacy far beyond that of each component but with no more side effects than with each separately.[76] More low-dose combinations are likely to become available. For the 50 percent or so of patients who do not respond to their initial therapy, combinations of two, three, or four drugs are needed.[32] Many of these can be provided in single tablets, thereby reducing cost and possibly improving adherence.[77]

COMPLETE COVERAGE WITH ONCE DAILY DOSING.

A number of choices within each of the six major classes of antihypertensive drugs now available provide full 24-hour efficacy. Therefore, single daily dosing should be feasible for virtually all patients, thereby improving adherence to therapy. Moreover, the use of longer-acting agents avoids the potential of inducing too great a peak effect in order to provide an adequate effect at the end of the dosing interval (the trough). As seen in Figure 29-8 , moderate doses of various formulations of calcium antagonists provide similar peak effects but different trough effects at the end of 24 hours.[78] Moreover, because many patients occasionally skip a dose of their drugs, there is an additional value in using agents with inherently long duration of action that covers the skipped dose as well (Fig. 29-9) .

Long-acting choices are available within each class.[20] However, because patients differ not only in terms of degree of response but also in terms of the duration of effect, the prudent course is to document the patient's response at the end of the dosing interval by home or ambulatory monitoring. With this approach, the abrupt surge in blood pressure that occurs on awakening will be blunted, and, it is hoped, patients can be better protected from the increased incidence of cardiovascular catastrophes at this critical time.[79]

If short-acting medications are taken at bedtime to ensure coverage in the early morning, ischemia to vital organs might be induced by the combination of the maximal effect of the drug within the first 3 to 6 hours after intake and the usual nocturnal decline in pressure.[80] Therefore, the safest course is to take medications with 24-hour duration of action as early in the morning as possible, as early as 4 or 5 A.M. if the patient awakens to urinate.

THE INITIAL CHOICE.

The initial choice of antihypertensive therapy is perhaps the most important decision made

Figure 29-8 Trough blood pressure changes (red bars), peak blood pressure changes (pink bars), and trough-to-peak ratios (numbers) observed after treatment with various calcium antagonists. All drugs were given on a once-daily basis. V = verapamil; NT = nitrendipine; D = diltiazem extended release; N GITS = nifedipine gastrointestinal therapeutic system; A = amlodipine; SBP = systolic blood pressure; DBP = diastolic blood pressure. *P < 0.05; **P < 0.01 versus baseline (From Mancia G, Cattaneo BM, Omboni S, Grassi G: Clinical benefits of a consistent reduction in blood pressure. J

Hypertens 16 [Suppl 6]:S35, 1998.)

in the treatment process. That drug is likely to be effective in about half the patients and, if no significant overt side effects occur, may be taken for many years. If the choice is ineffective or bothersome, the patient's confidence may be shaken, postponing or preventing adequate control. Two guidelines by expert committees have been published.[1] [20] The JNC-6 recommends diuretics or beta blockers as initial therapy for the relatively small portion of patients with uncomplicated hypertension, and drugs from all of the six major classes for patients with either a compelling indication or a comorbid condition that has been shown to respond well to a particular therapy.[20] The 1999 WHO-ISH

Figure 29-9 Forty-eight-hour systolic and diastolic blood pressure profile in 24 elderly subjects with isolated systolic hypertension. The 48-hour monitoring was done at the end of a 6-month administration of amlodipine at a dose of 5 to 10 mg daily and in the pretreatment placebo period. Amlodipine was administered at the beginning of the 48-hour monitoring period while the subsequent dose to be given 24 hours later was purposely missed. (From Mancia G, Cattaneo BM, Omboni S, Grassi G: Clinical benefits of a consistent reduction in blood pressure. J Hypertens 16 [Suppl 6]:S35, 1998.)

TABLE 29-4 -- GUIDELINES FOR SELECTING DRUG TREATMENT

CLASS OF DRUG	COMPELLING INDICATIONS	POSSIBLE INDICATIONS	COMPELLING CONTRAINDICATIONS	POSSIBLE CONTRAINDICATIONS
Diuretics	Heart failure Elderly patients Systolic hypertension	Diabetes	Gout	Dyslipidemia Sexually active men
Beta blockers	Angina After myocardial infarction Tachyarrhythmias	Heart failure Pregnancy Diabetes	Asthma and COPD Heart block*[*]	Dyslipidemia Athletes and physically active patients Peripheral vascular disease
ACE inhibitors	Heart failure Left ventricular dysfunction After myocardial infarction Diabetic nephropathy		Pregnancy Hyperkalemia Bilateral renal artery stenosis	
Calcium antagonists	Angina Elderly patients Systolic hypertension	Peripheral vascular disease	Heart block	Congestive heart failure
Alpha blockers	Prostatic hypertrophy	Glucose intolerance Dyslipidemia		Orthostatic hypotension
Angiotensin II antagonists	ACE inhibitor cough	Heart failure	Pregnancy Bilateral renal artery stenosis Hyperkalemia	

COPD=chronic obstructive pulmonary disease.

*Grade 2 or 3 atrioventricular block;

grade 2 or 3 atrioventricular block with verapamil or diltiazem; verapamil or diltiazem. ACE=angiotensin-converting enzyme;

guidelines broaden the number of compelling indications (Table 29-4) but give equal weight to all classes of drugs if there are no specific reasons to use one, stating that "There is as yet no evidence that the main benefits of treating hypertension are due to any particular drug property rather than to lowering of blood pressure per se."[1]

In practice, little difference remains between these two major guidelines. Until the many additional trials comparing different types of drugs now in progress are completed,[81] these guidelines should be followed. Appropriately individualized therapy will thereby be provided, maximizing the potential for a good fit between patient need and drug potential.

SUBSTITUTION.

Even after a careful attempt to select the most appropriate drug for an individual patient, the choice may be either ineffectual in perhaps a third or unacceptable because of side effects in another 10 to 20 percent of all patients. Although the overall effectiveness of all approved drugs is about equal in the general population, individual patients show considerable variability in their response to different drugs.[82] Therefore, the physician must be willing to discontinue the initial choice and try a drug from another category. In a more structured trial-and-error approach that has been described, each patient is put through several double-blind, randomized crossover trials against placebos to determine the best drug.[83] However, this approach probably is too much trouble for most physicians and patients. Although other approaches have been recommended, including one based on the renin profile,[84] the general principles shown in Tables 29-3 and 29-4 should serve well to ensure that each patient receives a drug likely to provide good control and few side effects.

For patients with more severe hypertension, in whom the first choice can be expected to be only partially effective, the stepped-care approach is logical. A diuretic enhances the effectiveness of most other drugs used, preventing the "pseudotolerance" that develops because of the fluid retention that frequently follows the use of some adrenergic blocking drugs and vasodilators. Increasingly, an angiotensin-converting enzyme (ACE) inhibitor or calcium antagonist is being chosen as the second or third drug when triple therapy is needed.

THE GOAL OF THERAPY.

As discussed earlier, caution is advised in lowering diastolic pressure below 80 mm Hg, the apparent nadir of the J curve, particularly in patients prone to coronary disease. On the other hand, lower levels are needed in high-risk patients such as those with diabetes and nephropathy.[85] The overriding problem is not that a few patients may be endangered by too aggressive therapy but rather that even with presumably adequate current therapy, maximal protection against cardiovascular complications is not being provided.[86] Recall that twice as many hypertensive patients in the United States are being treated as are being controlled to a blood pressure of 140/90 mm Hg, providing reasonable protection to only 27 percent of patients.[20]

DIURETICS (See also Chap. 18)

Diuretics useful in the treatment of hypertension may be divided into four major groups by their primary site of action within the tubule, starting in the proximal portion and moving to the collecting duct[86A] [86B] : (1) agents acting on the proximal tubule, such as carbonic anhydrase inhibitors, which have limited antihypertensive efficacy; (2) loop diuretics; (3) thiazides and related sulfonamide compounds; and (4) potassium-sparing agents. A thiazide is the usual choice, often in combination with a potassium-sparing agent. Loop diuretics should be reserved for those patients with renal insufficiency or resistant hypertension.

MECHANISM OF ACTION.

All diuretics initally lower the blood pressure by increasing urinary sodium excretion and by reducing plasma volume, extracellular fluid volume, and cardiac output. Within 6 to 8 weeks, the lowered plasma, extracellular fluid volume, and cardiac output return toward normal. At this point and beyond, the lower blood pressure is related to a decline in peripheral resistance, thereby improving the underlying hemodynamic defect of hypertension. The mechanism responsible for the lowered

peripheral resistance may involve potassium channel activation,[87] but initial diuresis is needed because diuretics fail to lower the blood pressure when the excreted sodium is returned or when given to patients who have nonfunctioning kidneys and are undergoing long-term dialysis. With the shrinkage in blood volume and lower blood pressure, increased secretion of renin and aldosterone retards the

continued sodium diuresis. Both renin-induced vasoconstriction and aldosterone-induced sodium retention prevent continued diminution of body fluids and progressive reduction in blood pressure while diuretic therapy is continued.

CLINICAL EFFECTS.

With continuous diuretic therapy, blood pressure usually falls about 10 mm Hg, although the degree depends on various factors, including the initial height of the pressure, the quantity of sodium ingested, the adequacy of renal function, and the intensity of the counterregulatory renin-aldosterone response.[87A] The antihypertensive effect of the diuretic persists indefinitely, although it may be overwhelmed by dietary sodium intake exceeding 8 gm/day.

If other antihypertensive drugs are used, a diuretic may also be needed. Without a concomitant diuretic, antihypertensive drugs that do not block the renin-aldosterone mechanism may cause sodium retention. This mechanism probably reflects the success of the drugs in lowering the blood pressure and may involve the abnormal renal pressure-natriuresis relationship that is presumably present in primary hypertension. Just as more pressure is needed to excrete a given load of sodium in a hypertensive individual, so does a lowering of pressure toward normal incite sodium retention.

The critical need for adequate diuretic therapy to keep intravascular volume diminished has been repeatedly documented.[88] Therefore, diuretics are likely to continue to be widely used in antihypertensive therapy. Drugs that inhibit the renin-aldosterone mechanism, such as ACE inhibitors, or drugs that induce some natriuresis themselves, such as calcium antagonists, may continue to work without the need for concomitant diuretics. However, a diuretic enhances the effectiveness of all other types of drugs, including calcium antagonists.[89]

DOSAGE AND CHOICE OF AGENT.

Most patients with mild to moderate hypertension and serum creatinine concentrations less than 2.0 mg/dl respond to the lower doses of the various diuretics listed in Table 29-5 . An amount equivalent to 12.5 mg of hydrochlorothiazide is usually adequate; larger doses have some additional antihypertensive effect but at the price of additional potassium wastage and insulin resistance. For uncomplicated hypertension, a moderately long-acting thiazide is a logical choice, and a single morning dose of hydrochlorothiazide provides a 24-hour antihypertensive effect. The nonthiazide agent indapamide has special properties that make it an attractive choice; it seldom disturbs lipid or glucose levels.[90] With renal failure, manifested by a serum creatinine level exceeding 2.0 mg/dl or creatinine clearance less than 25 ml/min, thiazides are usually not effective, and repeated doses of furosemide, one or two doses of torsemide, or a single dose of metolazone is needed.

SIDE EFFECTS.

A number of biochemical changes often accompany successful diuresis, including a decrease in plasma potassium level and increases in glucose, insulin, and cholesterol levels (Fig. 29-10) . Most of these are minimized or absent with low doses of diuretic.

Hypokalemia.

The degree of potassium wastage and hypokalemia is directly related to the dose of diuretic; serum potassium level falls an average of 0.7 mmol/liter with 50 mg of hydrochlorothiazide 0.4 with 25, and little if any with 12.5.[91] Hypokalemia due to high doses of diuretic may precipitate potentially hazardous ventricular ectopic activity and increase the risk of primary cardiac arrest,[92] even in patients not known to be susceptible because of concomitant digitalis therapy or myocardial irritability.

Most patients are unaware of mild diuretic-induced hypokalemia, although it may contribute to leg cramps, polyuria, and muscle weakness, but subtle interference with antihypertensive therapy may accompany even mild hypokalemia, and correction of hypokalemia may result in a reduction in blood pressure.[93]

TABLE 29-5 -- DIURETICS AND POTASSIUM-SPARING AGENTS

AGENT	DAILY DOSE (mg)	DURATION OF ACTION (hr)
Thiazides		
Bendroflumethiazide (Naturetin)	01.25-5.0	>18
Benzthiazide (Aquatag, Exna)	12.5-50	12-18
Chlorothiazide (Diruil)	125-500	6-12
Cyclothiazide (Anhydron)	0.125-1	18-24
Hydrochlorothiazide (Esidrix, HydroDIURIL, Oretic)	6.25-50	12-18
Hydroflumethiazide (Saluron)	12.5-50	18-24
Methyclothiazide (Enduron)	2.5-5.0	>24
Polythiazide (Renese)	1-4	24-48
Trichlormethiazide (Metahydrin, Naqua)	1-4	>24
Related Sulfonamide Compounds		
Chlorthalidone (Hygroton)	12.5-50	24-72
Indapamide (Lozol)	1.25-2.5	24
Metolazone (Mykrox, Zaroxolyn)	0.5-10	24
Quinethazone (Hydromox)	25-100	18-24
Loop Diuretics		
Bumetanide (Bumex)	0.5-5	4-6
Ethacrynic acid (Edecrin)	25-100	12
Furosemide (Lasix)	40-480	4-6
Torsemide (Demadex)	5-40	12
Potassium-Sparing Agents		
Amiloride (Midamor)	5-10	24
Spironolactone (Aldactone)	25-100	8-12
Triamterene (Dyrenium)	50-100	12

From Kaplan NM: Clinical Hypertension. 7th ed. Baltimore, Williams & Wilkins, 1998, p 190.

Prevention of hypokalemia is preferable to correction of potassium deficiency. The following maneuvers should help prevent diuretic-induced hypokalemia:

Use the smallest dose of diuretic needed.

Use a moderately long-acting (12- to 18-hour) diuretic, such as hydrocholorothiazide, because longer-acting drugs (e.g., chlorthalidone) may increase potassium loss.

Restrict sodium intake to less than 100 mmol/day (i.e., 2.4 gm sodium).

Increase dietary potassium intake.

Restrict concomitant use of laxatives.

Use a combination of a thiazide with a potassium-sparing agent except in patients with renal insufficiency or in association with an ACE inhibitor or angiotensin II-receptor blocker.

Concomitant use of a beta blocker or an ACE inhibitor diminishes potassium loss by blunting the diuretic-induced rise in renin-aldosterone.

If hypokalemia is to be treated, these principles should be followed, along with some form of supplemental potassium. Potassium chloride is preferred for correction of the associated alkalosis. If tolerated, granular potassium chloride can be given as a salt substitute; extra potassium will thereby be provided while sodium intake is reduced. Caution is necessary when supplemental potassium chloride is given to older patients with borderline renal function, in whom hyperkalemia may be induced.

HYPOMAGNESEMIA.

In some patients, concomitant diuretic-induced magnesium deficiency prevents restoration of intracellular deficits of potassium[94] so that hypomagnesemia should be corrected. Magnesium

Figure 29-10 The mechanisms by which chronic diuretic therapy may lead to various complications. The mechanism for hypercholesterolemia remains in question, although it is shown as arising via hypokalemia. Cl = Clearance; PRA = plasma renin activity; GFR = glomerular filtration rate. (From Kaplan NM: Clinical Hypertension. 7th ed. Baltimore, Williams & Wilkins, 1998, p 193.)

deficiency may also be responsible for some of the arrhythmias ascribed to hypokalemia.

HYPERURICEMIA.

The serum uric acid level is elevated in as many as one-third of untreated hypertensive patients. With long-term high-dose diuretic therapy, hyperuricemia appears in another third of patients, probably as a consequence of increased proximal tubular reabsorption accompanying volume contraction. Diuretic-induced hyperuricemia may precipitate acute gout, most frequently in those who are obese and consume large amounts of alcohol.[95] Because asymptomatic hyperuricemia does not cause urate deposition, most investigators agree that it need not be treated. If therapy is used, a uricosuric drug such as probenecid should be given.

HYPERLIPIDEMIA.

Serum cholesterol levels often rise after diuretic therapy, but after 1 year, no adverse effects were noted in those who responded to smaller doses.[96]

HYPERGLYCEMIA AND INSULIN RESISTANCE.

High doses of diuretics may impair glucose tolerance and precipitate diabetes mellitus, probably because they increase insulin resistance and hyperinsulinemia.[97] The manner by which diuretics increase insulin resistance is uncertain, but in view of the many potential pressor actions of hyperinsulinemia (see Chap. 28) , this could be a significant problem.

HYPERCALCEMIA.

A slight rise in serum calcium levels, less than 0.5 mg/dl, is frequent with thiazide diuretic therapy, at least in part because increased calcium reabsorption accompanies the increased sodium reabsorption in the proximal tubule induced by contraction of extracellular fluid volume.[98] The rise is of little concern except in patients with previously unrecognized hyperparathyroidism, who may experience a much more marked rise. On the other hand, the diuretic-induced positive calcium balance is associated with a reduction in the incidence of osteoporosis in the elderly.[99]

IMPOTENCE.

An increase in the incidence of impotence was noted among men who took 15 mg of chlorthalidone, the diuretic being the only one of five classes of agents attended by this effect.[100]

RENAL CELL CARCINOMA.

A significant increase in renal cell carcinoma among diuretic users was found in a search of nine case control and three cohort studies.[101] Methodological problems are inherent in this type of analysis,[102] and the overall positive effects of diuretic use far outweigh their hazard, a situation similar to oral contraceptive use.

LOOP DIURETICS.

Loop diuretics are usually needed in the treatment of hypertensive patients with renal failure, defined here as a serum creatinine level exceeding approximately 2.0 mg/dl. Furosemide has been most widely used, although either torsemide or metolazone may be as effective, and each requires only a single daily dose. Many physicians use furosemide in the management of uncomplicated hypertension, but this drug provides less antihypertensive action when given once or twice a day than do longer-acting diuretics, which maintain a slight volume contraction.

POTASSIUM-SPARING AGENTS.

These drugs are normally used in combination with a thiazide diuretic. Of the three currently available, one (spironolactone) is an aldosterone antagonist; the other two (triamterene and amiloride) are direct inhibitors of potassium secretion. In combination with a thiazide diuretic, they diminish the amount of potassium wasting. Although they are more expensive than thiazides alone, they may decrease the total cost of therapy by reducing the need to monitor and treat potassium depletion. Moreover, low doses of spironolactone may prevent myocardial fibrosis and reduce mortality in patients with heart failure.[103]

An Overview of Diuretics in Hypertension

Diuretics have been effective for the treatment of millions of hypertensive patients during the past 40 years. They reduce DBP and maintain it below 90 mm Hg in about half of all hypertensive patients, providing the same degree of effectiveness as most other antihypertensive drugs. In two groups that constitute a rather large portion of the hypertensive population, the elderly and blacks, diuretics may be particularly effective.[104] One-half of a diuretic tablet per day is usually all that is needed, minimizing cost and maximizing adherence to therapy. Even lower doses, i.e., 6.25 mg of hydrochlorothiazide, may be adequate when combined with other drugs.[76]

The side effects of high-dose diuretic therapy are usually not overly bothersome, but the hypokalemia, hypercholesterolemia, hyperinsulinemia, and worsening of

glucose tolerance that often accompany prolonged high-dose diuretic therapy gave rise to concerns about their long-term benignity. However, lower doses are usually just as potent as higher doses in lowering the blood pressure and less likely to induce metabolic mischief.[91] Therefore, the advocacy of low-dose diuretic therapy in the 1997 JNC-6 report[20] and the 1999 WHO-ISH report[1] is appropriate.

ADRENERGIC INHIBITORS

A number of drugs that inhibit the adrenergic nervous system are available, including some that act centrally on vasomotor center activity, peripherally on neuronal catecholamine

TABLE 29-6 -- ADRENERGIC INHIBITORS USED IN TREATMENT OF HYPERTENSION

Peripheral Neuronal Inhibitors
Reserpine
Guanethidine (Ismelin)
Guanadrel (Hylorel)
Bethanidine (Tenathan)
Central Adrenergic Inhibitors
Methyldopa (Aldomet)
Clonidine (Catapres)
Guanabenz (Wytensin)
Guanfacine (Tenex)
Alpha-Receptor Blockers
$Alpha_1$ and $alpha_2$ receptor
Phenoxybenzamine (Dibenzyline)
Phentolamine (Regitine)
$Alpha_1$ receptor
Doxazosin (Cardura)
Prazosin (Minipress)
Terazosin (Hytrin)
Beta-Receptor Blocker
Acebutolol (Sectral)
Atenolol (Tenormin)
Betaxolol (Kerlone)
Bisoprolol (Zebeta)
Carteolol (Cartrol)
Metoprolol (Lopressor, Toprol)
Nadolol (Corgard)
Penbutolol (Levatol)
Pindolol (Visken)
Propranolol (Inderal)
Timolol (Blocadren)
Alpha- and Beta-Receptor Blocker
Labetalol (Normodyne, Trandate)
Carvedilol (Coreg)

discharge, or by blocking alpha- and/or beta-adrenergic receptors (Table 29-6) ; some act at numerous sites. Figure 29-11 , a schematic view of the ending of an adrenergic nerve and the effector cell with its receptors, depicts how some of these drugs act. When the nerve is stimulated, norepinephrine, which is synthesized intraneuronally and stored in granules, is released into the synaptic

Figure 29-11 Simplified schematic view of the adrenergic nerve ending showing that norepinephrine (NE) is released from its storage granules when the nerve is stimulated and enters the synaptic cleft to bind to $alpha_1$ and beta receptors on the effector cell (postsynaptic). In addition, a short feedback loop exists, in which NE binds to $alpha_2$ and beta receptors on the neuron (presynaptic), to inhibit or to stimulate further release, respectively.

cleft. It binds to postsynaptic alpha- and beta-adrenergic receptors and thereby initiates various intracellular processes. In vascular smooth muscle, alpha stimulation causes constriction and beta stimulation causes relaxation. In the central vasomotor centers, sympathetic outflow is inhibited by alpha stimulation; the effect of central beta stimulation is unknown.

An important aspect of sympathetic activity involves the feedback of norepinephrine to alpha- and beta-adrenergic receptors located on the neuronal surface, i.e., presynaptic receptors. Presynaptic alpha-adrenergic receptor activation inhibits release, whereas presynaptic beta activation stimulates further norepinephrine release. The presynaptic receptors probably has a role in the action of some of the drugs to be discussed.

Elucidation and quantification of the various actions of these drugs remain incomplete. The listing in Table 29-6 is based on the predominant site of action according to currently available data. The action of beta-adrenergic receptor blockers involves a peripheral effect, but they almost certainly also act on central vasomotor mechanisms.

Drugs That Act Within the Neuron

Reserpine, guanethidine, and related compounds act differently to inhibit the release of norepinephrine from peripheral adrenergic neurons.

RESERPINE.

Reserpine, the most active and widely used of the derivatives of the rauwolfia alkaloids, depletes the postganglionic adrenergic neurons of norepinephrine by inhibiting its uptake into storage vesicles, exposing it to degradation by cytoplasmic monoamine oxidase. The peripheral effect is predominant, although the drug enters the brain and depletes central catecholamine stores as well. This probably accounts for the sedation and depression accompanying reserpine use. The drug has certain advantages. Only one dose a day is needed; in combination with a diuretic, the antihypertensive effect is significant, greater than that noted with nitrendipine in one comparative study[105] ; little postural hypotension is noted; and many patients experience no side effects. The drug has a relatively flat dose-response curve, so that a dose of only 0.05 mg/day gives almost as much antihypertensive effect as 0.125 or 0.25 mg/day but fewer side effects. Although it remains popular in some places and is recommended as an inexpensive choice where resources are limited,[1] reserpine has progressively declined in use because it has no commercial sponsor.

GUANETHIDINE.

This agent and a series of related guanidine compounds, including guanadrel, bethanidine, and debrisoquine, act by inhibiting the release of norepinephrine from the adrenergic neurons, perhaps by a local anesthetic-like effect on the neuronal membrane. In order to act, the drug must be transported actively into the nerve through

an amine pump.

Their low lipid solubility prevents guanidine compounds from entering the brain, so that sedation, depression, and other side effects involving the central nervous system do not occur. The initial predominant hemodynamic effect is decreased cardiac output: after continued use, peripheral resistance declines. Blood pressure is reduced further when the patient is upright, owing to gravitational pooling of blood in the legs, because compensatory sympathetic nervous system-mediated vasoconstriction is blocked. This results in the most common side effect, postural hypotension. Unlike reserpine, guanethidine has a steep dose-response curve, so that it can be successfully used in treating hypertension of any degree in daily doses of 10 to 300 mg. Like reserpine, it has a long biological half-life and may be given once daily. As other drugs have become available, guanethidine and related compounds have been relegated mainly to the treatment of severe hypertension unresponsive to all other agents.

Drugs That Act on Receptors

Predominantly Central Alpha Agonists

Until the mid-1980's, methyldopa was the most widely used of the adrenergic receptor blockers, but its use has declined as beta blockers and other drugs have become more popular. In addition, three other drugs--clonidine, guanabenz, and guanfacine, which act similarly to methyldopa but have fewer serious side effects--have become available.

METHYLDOPA.

The primary site of action of methyldopa is within the central nervous system, where alpha-methylnorepinephrine, derived from methyldopa, is released from adrenergic neurons and stimulates central alpha-adrenergic receptors, reducing the sympathetic outflow from the central nervous system.[106] The blood pressure mainly falls as a result of a decrease in peripheral resistance with little effect on cardiac output. Renal blood flow is well maintained, and significant postural hypotension is unusual. Therefore, the drug has been used in hypertensive patients with renal failure or cerebrovascular disease and remains the most commonly used agent for pregnancy-induced hypertension (see Chaps. 28 and 65) .

Methyldopa need be given no more than twice daily, in doses ranging from 250 to 3000 mg/day.

Side effects include some that are common to centrally acting drugs that reduce sympathetic outflow: sedation, dry mouth, impotence, and galactorrhea. However, methyldopa causes some unique side effects that are probably of an autoimmune nature, because a positive antinuclear antibody test result occurs in about 10 percent of patients who take the drug, and red cell autoantibodies occur in about 20 percent. Clinically apparent hemolytic anemia is rare, probably because methyldopa also impairs reticuloendothelial function so that antibody-sensitized cells are not removed from the circulation and hemolyzed. Inflammatory disorders in various organs have been reported, most commonly involving the liver (with diffuse parenchymal injury similar to viral hepatitis).[107]

CLONIDINE.

Although of different structure, clonidine shares many features with methyldopa. It probably acts at the same central sites, has similar antihypertensive efficacy, and causes many of the same bothersome but less serious side effects (e.g., sedation, dry mouth). It does not, however, induce the autoimmune and inflammatory side effects.

As an alpha-adrenergic receptor agonist, the drug also acts on presynaptic alpha receptors and inhibits norepinephrine release, and plasma catecholamine levels fall.[108] The drug has a fairly short biological half-life, so that when it is discontinued, the inhibition of norepinephrine release disappears within about 12 to 18 hours, and plasma catecholamine levels rise. This is probably responsible for the rapid rebound of the blood pressure to pretreatment levels and the occasional appearance of withdrawal symptoms, including tachycardia, restlessness, and sweating. If the rebound requires treatment, clonidine may be reintroduced or alpha-adrenergic receptor antagonists given.

Clonidine is available in a *transdermal* preparation, which may provide smoother blood pressure control for as long as 7 days with fewer side effects. However, bothersome skin rashes preclude its use in perhaps one-fourth of patients.

GUANABENZ.

This drug differs in structure but shares many characteristics with both methyldopa and clonidine, acting primarily as a central alpha agonist. It may differ, however, in not causing fluid retention.

GUANFACINE.

This drug is also similar to clonidine but is longer acting, which enables once-a-day dosing and minimizes rebound hypertension.[109]

Alpha-Adrenergic Receptor Antagonists

Before 1977, the only alpha blockers used to treat hypertension were phenoxybenzamine (Dibenzyline) and phentolamine (Regitine). These drugs are effective in acutely lowering blood pressure, but their effects are offset by an accompanying increase in cardiac output, and side effects are frequent and bothersome. Their limited efficacy may reflect their blockade of presynaptic alpha-adrenergic receptors, which interferes with the feedback inhibition of norepinephrine release (see Fig. 29-11) . Increased catecholamine release would then blunt the action of postsynaptic alpha-adrenergic receptor blockade. Their use has largely been limited to the treatment of patients with pheochromocytomas.

PRAZOSIN.

This was the first of a group of selective antagonists of the postsynaptic $alpha_1$ receptors. By blocking alpha-mediated vasoconstriction, prazosin induces a decline in peripheral resistance with both venous and arteriolar dilation. Because the presynaptic alpha-adrenergic receptor is left unblocked, the feedback loop for the inhibition of norepinephrine release is intact, an action that is also certainly responsible for the greater antihypertensive effect of the drug and the absence of concomitant tachycardia, tolerance, and renin release. Inhibition of norepinephrine release may also account for the propensity toward greater first-dose reductions in blood pressure.

OTHER ALPHA BLOCKERS.

Two other alpha blockers, terazosin and doxazosin, have slower onset and longer duration of action, so they may be given once daily with less propensity for first-dose hypotension.

Selective alpha blockers are as effective as other first-line antihypertensives.[2] When given to patients whose condition is poorly controlled on standard triple therapy (diuretic, beta blocker, and vasodilator), they may reduce blood pressure even more than anticipated. They can be safely and effectively used by patients with renal failure. The favorable hemodynamic changes--a fall in peripheral resistance with maintenance of cardiac output--make them an attractive choice for patients who wish to remain physically active. In addition, blood lipids are not adversely altered and may actually improve with alpha blockers, unlike the adverse effects observed with diuretics and beta blockers.[110] Moreover, improved insulin sensitivity with lesser rises in plasma glucose and insulin levels after a glucose load has been observed with alpha blockers.[111] Alpha blockers decrease the smooth muscle tone of the bladder neck and prostate, relieving the obstructive symptoms of prostatism.[112] They are then an excellent choice for older men with hypertension and benign prostatic hypertrophy.

In a large, double-blind, randomized trial of older patients (>55 years) with hypertension (ALLHAT), the alpha adrenergic blocker doxazosin, when compared with the diuretic chlorthalidone, was associated with significantly higher risks for stroke and congestive heart failure.[112A]

Side effects, beyond first-dose postural hypotension, include the nonspecific effects of lower blood pressure, such as dizziness, weakness, fatigue, and headaches. Most patients, however, find the drugs easy to take, with little sedation, dry mouth, or impotence.

Beta-Adrenergic Receptor Antagonists (See also Chaps. 23 and 37)

In the 1980's, beta-adrenergic receptor blockers became the most popular form of antihypertensive therapy after diuretics, reflecting their relative effectiveness and freedom from many bothersome side effects. For the majority of patients, beta blockers are usually easy to take, because somnolence, dry mouth, and impotence are seldom encountered. Because beta blockers have been found to reduce mortality if taken either before or after acute myocardial infarction[113] (i.e., secondary prevention), it was assumed that they might offer special protection against initial coronary events, i.e., primary prevention. However, in four large clinical trials, a beta blocker provided less protection than did a low-dose diuretic (see Fig. 29-1) .[10] Nevertheless, their efficacy in treatment of congestive heart failure will likely stimulate their use.[114]

THE VARIOUS BETA BLOCKERS.

Beta blockers now available in the United States are listed in Table 29-6 , and others are available in other countries. A number of agents with additional vasodilatory effects are available elsewhere; these may be free of many of the unfavorable hemodynamic and adverse effects of currently available agents. Pharmacologically, those now available differ considerably from one another with respect to degree of absorption, protein binding, and bioavailability. However, the three most important differences affecting their clinical use are cardioselectivity, intrinsic sympathomimetic activity, and lipid solubility. Despite these differences, they all seem to be about equally as effective as antihypertensives.

Cardioselectivity.

As seen in Figure 29-12 , beta blockers can be classified by their degree of cardioselectivity relative to their blocking effect on the $beta_1$ -adrenergic receptors in the heart compared with that on the $beta_2$ receptors in the bronchi, peripheral blood vessels, and elsewhere.

Figure 29-12 Classification of beta-adrenergic receptor blockers based on cardioselectivity and intrinsic sympathomimetic activity (ISA). Those not approved for use in the United States are in italics. (From Kaplan NM: Clinical Hypertension. 7th ed. Baltimore, Williams & Wilkins, 1998, p 206.)

Such cardioselectivity can be easily shown using small doses in acute studies; with the rather high doses used to treat hypertension, much of this selectivity is lost.

Intrinsic Sympathomimetic Activity (ISA).

Some of these drugs have ISA, interacting with beta receptors to cause a measurable agonist response but at the same time blocking the greater agonist effects of endogenous catecholamines. As a result, although in usual doses they lower the blood pressure about the same degree as do other beta blockers, they cause a smaller decline in heart rate, cardiac output, and renin levels.

Lipid Solubility.

Atenolol and nadolol are among the least lipid soluble of the beta blockers. Because they do not enter the brain as readily, they may cause fewer central nervous system side effects.[115]

Mechanism of Action.

Despite these and other differences, the various beta blockers now available are approximately equipotent as antihypertensive agents. A number of possible mechanisms are likely to be involved in their antihypertensive action. In those without ISA, cardiac output falls 15 to 20 percent and renin release is reduced about 60 percent. Central nervous system beta-adrenergic receptor blockade may reduce sympathetic discharge, but similar antihypertensive effects are seen with those drugs that are more lipid soluble, and therefore in high concentration within the central nervous system, and those that are less lipid soluble.

At the same time that beta blockers lower blood pressure through various means, their blockade of peripheral beta-adrenergic receptors inhibits vasodilation, leaving alpha receptors open to catecholamine-mediated vasoconstriction. Over time, however, vascular resistance tends to return to normal, which presumably preserves the antihypertensive effect of a reduced cardiac output.[116]

Clinical Effects.

Even in small doses, beta blockers begin to lower the blood pressure within a few hours. Although progressively higher doses have usually been given, careful study has shown a near-maximal effect from smaller doses. For example, in a double-blind crossover study involving 24 patients, 40 mg of propranolol twice a day provided the same antihypertensive effects as 80, 160, or 240 mg twice a day.[116A] The degree of blood pressure reduction is at least comparable to that noted with other antihypertensive drugs.[2] Beta blockers may be particularly well suited for younger and middle-aged hypertensive patients, especially nonblacks, and for patients with myocardial ischemia and high levels of stress.[113] Because the hemodynamic responses to stress are reduced, however, they may interfere with athletic performance.[117]

SPECIAL USES FOR BETA BLOCKERS

COEXISTING ISCHEMIC HEART DISEASE.

Even without evidence that beta blockers protect patients from initial coronary events, the antiarrhythmic and antianginal effects of these drugs make them especially valuable in hypertensive patients with coexisting coronary disease.

COEXISTING HEART FAILURE.

As described elsewhere (see Chap. 18) , beta blockers have been found to reduce mortality in patients with congestive heart failure.[114]

PATIENTS WITH HYPERKINETIC HYPERTENSION.

Some hypertensive patients have increased cardiac output that may persist for many years. Beta blockers are particularly effective in such patients, but a reduction in exercise capacity may necessitate restriction of their use in young athletes.

PATIENTS WITH MARKED ANXIETY.

The somatic manifestations of anxiety--tremor, sweating, and tachycardia--can be helped, without the undesirable effects of methods commonly used to control anxiety, such as alcohol and tranquilizers.

PERIOPERATIVE STRESS.

The ultra-short-acting cardioselective agent esmolol has been successfully used to prevent postintubation tachycardia and hypertension,[118] and atenolol protects

patients with coronary disease during surgery.[119]

SIDE EFFECTS.

Most of the side effects of beta blockers relate to their major pharmacological action, the blockade of beta-adrenergic receptors. Certain concomitant problems may worsen when beta-adrenergic receptors are blocked, including peripheral vascular disease and bronchospasm.

The most common side effect is fatigue, which is probably a consequence of decreased cardiac output and the decreased cerebral blood flow that may accompany successful lowering of the blood pressure by any drug (see Fig. 29-6) . More direct effects on the central nervous system--insomnia, nightmares, and hallucinations--occur in some patients. An association with depression appears to be accounted for by various confounding variables.[120]

Diabetic patients may have additional problems with beta blockers, more so with nonselective ones. The responses to hypoglycemia, both the symptoms and the counterregulatory hormonal changes that raise blood glucose levels, are partially dependent on sympathetic nervous activity. Diabetic patients who are susceptible to hypoglycemia may not be aware of the usual warning signals and may not rebound as quickly. The majority of noninsulin-dependent diabetic patients can take these drugs without difficulty, although their diabetes may be exacerbated, probably from beta blocker interference with insulin sensitivity.[111]

When a beta blocker is discontinued, angina pectoris and myocardial infarction may occur.[121] Because patients with hypertension are more susceptible to coronary disease, they should be weaned gradually and given appropriate coronary vasodilator therapy. Perturbations of lipoprotein metabolism accompany the use of beta blockers.[122] Nonselective agents cause greater rises in triglycerides and reductions in cardioprotective high-density lipoprotein-cholesterol levels, whereas ISA agents cause less or no effect and some agents such as celiprolol may raise high-density lipoprotein cholesterol levels. Patients with renal failure may take beta blockers without additional hazard, although modest reductions in renal blood flow and glomerular filtration rate have been measured, presumably from renal vasoconstriction.

Caution is advised in the use of beta blockers in patients suspected of harboring a pheochromocytoma (Chaps. 28 and 64) , because unopposed alpha-adrenergic agonist action may precipitate a serious hypertensive crisis if this disease is present. The use of beta blockers during pregnancy has been clouded by scattered case reports of various fetal problems. Moreover, prospective studies have found that the use of beta blockers during pregnancy may lead to fetal growth retardation.[123]

AN OVERVIEW OF BETA BLOCKERS IN HYPERTENSION.

Beta blockers are specifically recommended for hypertensive patients with concomitant coronary disease, particularly after a myocardial infarction, congestive heart failure, or tachyarrhythmias[1] (see Table 29-4) . If a beta blocker is chosen, those agents that are more cardioselective and lipid insoluble offer the likelihood of fewer perturbations of lipid and carbohydrate metabolism and greater patient adherence to therapy; only one dose a day is needed, and side effects probably are minimized. In patients with heart failure, the initial dose should be very small (e.g., metoprolol 12.5 mg twice daily) and gradually increased to the maintenance dose (100 to 200 mg twice daily) (see Chap. 18) .

Alpha- and Beta-Adrenergic Receptor Antagonists

The combination of an alpha and a beta blocker in a single molecule is available in the forms of labetalol and carvedilol, the latter agent approved for treatment of heart failure as well. The fall in pressure mainly results from a decrease in peripheral resistance, with little or no decline in cardiac output.[124] The most bothersome side effects are related to postural hypotension; the most serious side effect is hepatotoxicity. Intravenous labetalol is used to treat hypertensive emergencies.

VASODILATORS

In the past, direct-acting arteriolar vasodilators were used mainly as third drugs, when combinations of a diuretic and adrenergic blocker failed to control blood pressure. However, with the availability of vasodilators of different types that can be easily tolerated when used as first or second drugs, wider and earlier application of vasodilators in therapy of hypertension has begun (Table 29-7) .

Direct Vasodilators

Hydralazine is the most widely used agent of this type. Minoxidil is more potent but is usually reserved for patients with severe, refractory hypertension associated with renal failure.[20] Nitroprusside and nitroglycerin are given intravenously for hypertensive crises and are discussed on page 991 .

HYDRALAZINE.

From the early 1970's, hydralazine, in combination with a diuretic and a beta blocker, was used frequently to treat severe hypertension. The drug acts directly to relax the smooth muscle in precapillary resistance vessels, with little or no effect on postcapillary venous capacitance vessels. As a result, blood pressure falls by a reduction in peripheral resistance, but in the process a number of compensatory processes, which are activated by the arterial baroreceptor arc, blunt the decrease in pressure and cause side effects. With concomitant use of a diuretic to overcome the tendency for fluid retention and an adrenergic inhibitor to prevent the reflex increase in sympathetic activity and rise in renin, the vasodilator is more effective and causes few, if any, side effects. Without the protection conferred by concomitant use of an adrenergic blocker, numerous side effects (tachycardia, flushing, headache, and precipitation of angina) may occur.

The drug need be given only twice a day. Its daily dose should be kept below 400 mg to prevent the lupus-like syndrome that appears in 10 to 20 percent of patients who receive more. This reaction, although uncomfortable to the patient, is almost always reversible. The reaction is uncommon with daily doses of 200 mg or less and is more common in slow acetylators of the drug.

MINOXIDIL.

This drug vasodilates by opening potassium channels in vascular smooth muscle. Its hemodynamic effects are similar to those of hydralazine, but minoxidil is even more effective and may be used once a day. It is particularly useful in patients with severe hypertension and renal failure. Even more than with hydralazine, diuretics and adrenergic receptor blockers must be used with minoxidil to prevent the reflex increase in cardiac output and fluid retention. Pericardial effusions have appeared in about 3 percent of those given minoxidil,

in some without renal or cardiac failure. The drug also causes hair to grow profusely, and the facial hirsutism precludes use of the drug in most women.

Calcium Antagonists (See also Chap. 37)

These drugs have become the most popular class of agents used in the treatment of hypertension. They differ in both their sites and modes of action (Table 29-8) , with major pharmacological differences between the various dihydropyridines.[125] Dihydropyridines have the greatest peripheral vasodilatory action,[126] with little effect on cardiac automaticity, conduction, or contractility. However, comparative trials have shown that verapamil and diltiazem, which do affect these properties, are also effective antihypertensives, and they may cause fewer side effects related to vasodilation, such as flushing and ankle edema.

Calcium antagonists are effective in hypertensive patients of all ages and races[104] and in hypertensive diabetics.[104A] In a large comparative trial, verapamil was more effective than chlorthalidone in promoting regression of carotid intima-media thickness and preventing cardiovascular events.[127] Even more impressively, therapy based on the dihydropyridine nitrendipine provided even greater protection to elderly patients with isolated systolic hypertension in the Syst-Eur trial[22] than did chlorthalidone in the SHEP trial,[5] particularly in those in the two trials with diabetes accompanying the hypertension.[24] Dihydropyridines were also the foundation of therapy in other large trials that found significant reductions in cardiovascular events.[25] [32]

Calcium antagonists may cause at least an initial natriuresis, probably by producing renal vasodilation,[128] which may obviate the need for concurrent diuretic therapy. In fact, unlike all other antihypertensive agents, they may have their effectiveness reduced rather than enhanced by concomitant dietary sodium restriction,[129] whereas most careful studies show an enhancement of their effect by concomitant diuretic therapy.[89] Their renal vasodilatory effect allows glomerular filtration rate and renal blood flow to be well maintained as they reduce systemic blood pressure.[130] Because they act primarily to dilate afferent arterioles, these agents could accelerate a decline in renal function by increasing flow within the glomeruli. Although they may not decrease proteinuria as well as ACE inhibitors, they seem to preserve renal function as well.[131]

A potentially serious adverse effect of the use of calcium antagonists to treat hypertension was described in a case-control study in which more hypertensive patients who had a myocardial infarction were taking short-acting calcium antagonists than were hypertensive patients who had not had an infarct.[132] The most likely explanation for the finding is exclusion bias, which is an inherent problem with case-control studies in which the cases are at greater risk for the complication than the controls; i.e., higher-risk patients are excluded from the control group but not from the case group. Specifically, short-acting calcium antagonists, which were not approved for the treatment of hypertension

and which were more expensive and more difficult to use because they require three doses a day compared with the other approved antihypertensive agents, were probably given to patients considered at higher risk for coronary events. Similar case-control studies claiming that the use of reserpine was associated with a threefold increase in breast cancer were subsequently shown to be erroneous because of exclusion bias.[133] The decrease in coronary events in large randomized controlled trials with *long-acting* dihydropyridines[22] [25] [32] is the best proof of the safety of these agents. Similar claims based on case-control studies that calcium anatgonists increase cancer and gastrointestinal bleeding also have not been confirmed.[134] [135]

Along with freedom from most of the side effects accompanying other classes, calcium antagonists may be unique in not having their antihypertensive efficacy blunted by nonsteroidal antiinflammatory agents (NSAIDs).[136]

Liquid nifedipine has been used effectively to reduce high levels of blood pressure quickly, but the occasional occurrence of cerebral and myocardial ischemia has prompted a call for discontinuation of the practice.[137] Intravenous nicardipine is available for hypertensive emergencies.[138]

Renin-Angiotensin Inhibitors (See also Chap. 18)

Activity of the renin-angiotensin system (see Fig. 28-13) may be inhibited in four ways (Fig. 29-13), three of which can be applied clinically. The first, use of beta-adrenergic receptor blockers to inhibit the release of renin, was discussed earlier (p. 986). The second, direct inhibition of renin activity by specific renin inhibitors, is being investigated.[139] The third, inhibition of the enzyme that converts the inactive decapeptide angiotensin I to the active octapeptide angiotensin II, is being widely used with orally effective ACE inhibitors. The fourth approach to inhibiting the renin-angiotensin system, blockade of angiotensin's actions by a competitive receptor blocker, is now the basis for the fastest growing class of antihypertensive agents.[140] The AII receptor blockers (ARBs) may offer additional benefits, but their immediate advantage is the absence of cough that often accompanies ACE inhibitors, as well as less angioedema. In the absence of outcome data, both JNC-6[20] and WHO-ISH [1] guidelines recommend their use only if an ACE inhibitor cannot be tolerated. The ARBs are considered after the ACE inhibitors.

MECHANISM OF ACTION.

The first of these ACE inhibitors, captopril, was synthesized as a specific inhibitor of the converting enzyme that, in the classical pathway shown in Figure 29-13 , breaks the peptidyldipeptide bond in angiotensin I, preventing the enzyme from attaching to and splitting the angiotensin I structure. Because angiotensin II cannot be formed and angiotensin I is inactive, the ACE inhibitor paralyzes the classical renin-angiotensin system, thereby removing the effects of most endogenous angiotensin II as both a vasoconstrictor and a stimulant to aldosterone synthesis.

Interestingly, with long-term use of ACE inhibitors, the plasma angiotensin II levels actually return to previous level while the blood pressure remains lowered[141] ; this suggests that the antihypertensive effect may involve other mechanisms. Because the same enzyme that converts angiotensin I to angiotensin II is also responsible for inactivation of the vasodilating hormone bradykinin, by inhibiting the breakdown of bradykinin, ACE inhibitors increase the concentration of a vasodilating hormone while they decrease the concentration of a vasoconstrictor hormone. The increased plasma kinin levels may contribute to the vasodilation and improvement in insulin sensitivity observed with ACE inhibitors, but they are also responsible for the most common and bothersome side effect of their use, a dry, hacking cough.[140] ACE inhibitors may also vasodilate by increasing levels of vasodilatory prostaglandins and decreasing levels of vasoconstricting endothelins.[142]

Regardless of their mechanism of action, ACE inhibitors lower blood pressure mainly by reducing peripheral resistance with little, if any, effect on heart rate, cardiac output, or body fluid volumes, likely reflecting preservation of baroreceptor reflexes.[143] Their vasodilating effect may also involve restoration of endothelium-dependent relaxation by nitric oxide.[144] As a consequence, resistance arteries become less thickened and more responsive.[145]

CLINICAL USE.

In patients with uncomplicated primary hypertension, ACE inhibitors provide antihypertensive effects that are equal to those with other classes,[146] but they are less effective in blacks,[104] perhaps because blacks tend to have lower renin levels. They are equally effective in elderly and younger hypertensive patients. In the large controlled CAPPP trial, in which captopril-based therapy was compared with conventional therapy with diuretic and beta blockers, the two approaches provided essentially identical protection against cardiovascular morbidity and mortality.[146] As a consequence of these results, the WHO-ISH guidelines include ACE inhibitors as

a choice for initial therapy.[1] In view of the impressive reduction in morbidity

Figure 29-13 The four sites of action of inhibitors of the renin-angiotensin system. J-G = Juxtaglomerular apparatus; CE = converting enzyme. (From Kaplan NM: Clinical Hypertension. 7th ed. Baltimore, Williams & Wilkins, 1998, p 223.)Risk Factors for Cardiovascular Diseases Left ventricular hypertrophy (electrocardiogram), Associated Clinical Conditions

and mortality with ramipril in the HOPE trial of high-risk patients,[146A] the use of ACE inhibitors will almost certainly increase.

The initial dose of ACE inhibitor may precipitate a rather dramatic but transient fall in blood pressure[147] that likely reflects a higher level of renin-angiotensin and that could be a harbinger of the presence of renovascular hypertension. Because the therapeutic response will be potentiated by concomitant intravascular volume contraction from a low-sodium diet or diuretics, caution should be taken in starting an ACE inhibitor in those who might be most responsive. The response to an ACE inhibitor is usually well maintained, perhaps because its suppression of aldosterone mitigates the tendency toward volume expansion that often antagonizes the effects of other antihypertensives.

These drugs have been a mixed blessing for patients with renovascular hypertension. On the one hand, the response of plasma renin level to a single dose of captopril may provide a simple diagnostic test for the disease. More importantly, they usually control the blood pressure effectively.[148] On the other hand, the removal of the high levels of angiotensin II that they produce may deprive the stenotic kidney of the hormonal drive to its blood flow, thereby causing a marked decline in renal perfusion so that patients with solitary kidneys or bilateral disease may develop acute and sometimes persistent renal failure.[149]

Patients with intraglomerular hypertension, specifically those with diabetic nephropathy or reduced renal functional mass due to other forms of renal parenchymal disease, may benefit especially from the reduction in efferent arteriolar resistance that follows reduction in angiotensin II. The clinical evidence for modulation of the progressive loss of renal function in diabetic and nondiabetic nephropathy is now unequivocal.[150] Whether this effect is quantitatively better with ACE inhibitors than that provided by other drugs is less certain. ACE inhibitors have been widely used in diabetic hypertensive patients, in part on the basis of earlier reports of their ability to improve insulin sensitivity. However, more recent data do not confirm the effect on insulin sensitivity.[151] More impressively, ACE inhibitor-based therapy was somewhat *less* effective in preventing diabetic complications than was beta-blocker therapy in the large and long United Kingdom Prospective Diabetes Study.[152] Therefore, the need for ACE inhibitors is considered as compelling for diabetic patients with nephropathy, hypertensive patients with heart failure, or systolic dysfunction after a myocardial infarction,[20] but these agents should be considered as equal to other classes in most other circumstances. Nonetheless, they may be the best tolerated antihypertensive agent[153] (along with ARBs), so their use will continue to grow.

SIDE EFFECTS.

Most patients who take an ACE inhibitor experience neither the side effects nor the biochemical changes often accompanying other drugs that may be of even more concern even though they are not so obvious; neither rises in lipids, glucose, or uric acid nor reductions in potassium levels are noted.

To be sure, ACE inhibitors may cause both specific and nonspecific adverse effects. Among the specific ones are rash, loss of taste, and leukopenia. In addition, they may cause a hypersensitivity reaction with angioneurotic edema or a cough, although often persistent, that is infrequently associated with pulmonary dysfunction.[154] The cough, affecting more than 10 percent of women and about half as many men, may not disappear for 3 weeks after the ACE inhibitor is discontinued.[155] If a cough appears in a patient who needs an ACE inhibitor, an ARB should be substituted.

There is at least a potential problem for those patients taking an ACE inhibitor and coincidentally developing volume depletion, as from gastroenteritis, because they may be unable to marshal the compensatory homeostatic responses

TABLE 29-9 -- CLINICAL PHARMACOLOGY OF AVAILABLE ANGIOTENSIN II RECEPTOR BLOCKERS

COMPOUND	ACTIVE METABOLITE	FOOD EFFECT	HALF-LIFE (hr)
Candesartan (Atacand)	Prodrug	No	9-10
Irbesartan (Avapro)	No	No	11-15
Losartan (Cozaar)	Yes	Modest	2-4
Telmisartan (Micardis)	No	No	18-24
Valsartan (Diovan)	No	Moderate	6-8

that involve increased angiotensin II and aldosterone. Finally, patients with renal insufficiency or on potassium supplements or sparing agents may not be able to excrete potassium loads and therefore may develop hyperkalemia.

ANGIOTENSIN II RECEPTOR BLOCKERS

As the number of these agents being marketed quickly increases, they will be more widely used even in the absence of many outcome data. Those now available (Table 29-9) differ little save for a longer duration of action and perhaps a greater dose-response curve with the newer ones than with the first, losartan.[155] As more outcome data become available, ARBs may become an initial choice for many hypertensive patients. However, their price may be a consideration. Moreover, considering their presumed ability to block the response to angiotensin II more completely, they may end up being used in combination with ACE inhibitors.[140]

Other Vasodilators

Various other forms of antihypertensive therapy are under investigation. These include endothelin receptor antagonists[156] and agents that inhibit both the ACE and neutral endopeptidase, thereby increasing atrial natriuretic hormone.[157] The distant future may see the application of gene therapy.[158]

SPECIAL CONSIDERATIONS IN THERAPY

RESISTANT HYPERTENSION.

There are numerous causes of resistance to therapy, usually defined as the failure of DBP to fall below 90 mm Hg despite the use of three or more drugs.[88] Patients often do not respond well because they do not take their medications. On the other hand, what appears to be a poor response based on office readings of blood pressure may be disclosed to be an adequate response when ambulatory or home readings are obtained.[159] However, a number of factors may be responsible for a poor response even if the appropriate medication is taken regularly (Table 29-10) . Most common is volume overload owing either to inadequate diuretic or to excessive dietary sodium intake. Larger doses or more potent diuretics often bring resistant hypertension under control.

Resistance is particularly common in patients with visceral obesity and associated insulin resistance.[160] A frequently overlooked cause is the interference by NSAIDs or aspirin[161] with virtually all antihypertensive drugs, with the exception of calcium antagonists and possibly ARBs.[162]

Resistance can usually be overcome by adequate doses of a diuretic, a calcium antagonist, and an ACE inhibitor.

ANESTHESIA IN HYPERTENSIVE PATIENTS.

In the absence of significant cardiac dysfunction, hypertension adds little to the cardiovascular risks of surgery.[163] If possible, however, hypertension should be well controlled by means of medications before anesthesia and surgery to reduce the

TABLE 29-10 -- CAUSES OF INADEQUATE RESPONSIVENESS TO THERAPY

Pseudoresistance
- "White coat" or office elevations
- Pseudohypertension in the elderly

Nonadherence to Therapy
- Side effects of medication
- Cost of medication
- Lack of consistent and continuous primary care
- Inconvenient and chaotic dosing schedules

Instructions not understood
- Inadequate patient education
- Organic brain syndrome (e.g., memory deficit)

Drug-Related Causes
- Doses too low
- Inappropriate combinations (e.g., two centrally acting adrenergic inhibitors)
- Rapid inactivation (e.g., hydralazine)
- Drug interactions
  - Nonsteroidal antiinflammatory drug
  - Sympathomimetics
    - Nasal decongestants
    - Appetite suppressants
    - Cocaine
    - Caffeine
  - Antidepressants (MAO inhibitors, tricyclics)
  - Oral contraceptives
  - Adrenal steroids
  - Licorice (chewing tobacco)
  - Cyclosporine
  - Erythropoietin
  - Cholestyramine
- Excessive volume contraction with stimulation of rennin-aldosterone
- Hypokalemia (usually diuretic induced)
- Rebound after clonidine withdrawal

Associated Conditions
- Smoking
- Increasing obesity
- Sleep apnea
- Insulin resistance/hyperinsulinemia
- Ethanol intake more than 1 ounce/day (>3 portions)
- Anxiety-induced hyperventilation or panic attacks
- Chronic pain
- Intense vasoconstriction (Raynaud's, arteritis)

Secondary Hypertension
- Renal insufficiency
- Renovascular hypertension
- Pheochromocytoma
- Primary aldosteronism

Volume Overload
- Excess sodium intake
- Progressive renal damage (nephrosclerosis)
- Fluid retention due to reduction of blood pressure
- Inadequate diuretic therapy

Modified from Joint National Committee, Sixth Report of the Joint National Committee on detection, evaluation, and treatment of high blood pressure (JNC VI). Arch Intern Med 157:2413, 1997. Copyright 1997 American Medical Association.

risk of myocardial ischemia.[164] Therefore, patients taking antihypertensive medications should continue these drugs, as long as the anesthesiologist is aware of their use and takes reasonable precautions to prevent wide swings in pressure. The very short-acting beta blocker esmolol has been successful in preventing surges in blood pressure during intubation,[118] and the use of atenolol protected coronary patients undergoing noncardiac surgery.[119]

Hypertension is often observed during and immediately after coronary bypass surgery (see p. 965); various intravenous agents have been successfully used to lower the pressure. Nitroprusside has been the usual choice during the postoperative period, but toxicity, often in the form of loss of consciousness and cyanide or thiocyanate toxicity, may develop in those who are critically ill and given the drug for prolonged periods. Esmolol, labetalol, or nicardipine may be a better choice.[165]

HYPERTENSIVE CHILDREN (see also p. 956 and Chap. 45) .

Almost nothing is known about the effects of various antihypertensive medications given to children over long periods. In the absence of adequate data, an approach similar to that advocated for adults is advised.[166] Emphasis should be placed on weight reduction in hypertensive children who are obese, in the hope of attempting to control hypertension without the need for drug therapy.

HYPERTENSION DURING PREGNANCY.

This topic is discussed in Chapter 65 .

HYPERTENSION IN THE ELDERLY.

As noted on page 957 , a few elderly persons may have high blood pressure as measured by the sphygmomanometer but may have less or no hypertension when direct intraarterial readings are made, i.e., pseudohypertension due to rigid arteries that do not collapse under the cuff.

If either the systolic pressure alone or both systolic and diastolic levels are elevated, careful lowering of blood pressure with either diuretics[5] or dihydropyridine calcium antagonists[22] has been unequivocally documented to reduce cardiovascular morbidity in older hypertensive patients extending to those older than 80 years.[11] Care is needed because they may have a number of problems with the medications (Table 29-11) . In view of the reduced effectiveness of the baroceptor reflex and the failure of peripheral resistance to rise appropriately with standing,[167] drugs with a propensity to cause postural hypotension should be avoided, and all drugs should be given in slowly increasing doses to prevent excessive lowering of the pressure.

For those who start with systolic pressures exceeding 160 mm Hg, the goal of therapy should be a level around 140 mm Hg with little concern about further reductions in already low diastolic levels.[167A]

PATIENTS WITH HYPERTENSION AND DIABETES.

Special attention should be given to diabetic patients with hypertension. The two commonly coexist and multiply the cardiovascular risks of each alone. Fortunately, evidence from several trials now documents the protection provided by *intensive* control of hypertension, preferably in concert with management of the diabetes and the dyslipidemia that commonly accompanies the two.[24] [32] [85] [152] Most diabetic hypertensive patients need two or more antihypertensive drugs to bring their pressure to below 130/85 mm Hg, which is likely the highest level that should be tolerated.

An ACE inhibitor should be included if proteinuria is present. A diuretic and a beta blocker are appropriate, and a long-acting dihydropyridine will likely be required.[104A] Concerns about possible adverse effects of calcium antagonists in diabetic patients[168] have been absolved by their

TABLE 29-11 -- FACTORS THAT MIGHT CONTRIBUTE TO INCREASED RISK OF PHARMACOLOGICAL TREATMENT OF HYPERTENSION IN THE ELDERLY

FACTORS	POTENTIAL COMPLICATIONS
Diminished baroreceptor activity	Orthostatic hypotension
