1. Spontaneous myocardial ischemia or myocardial ischemia provoked by minimal exertion, during recovery from infarction.
2. Before definitive therapy of a mechanical complication of infarction such as acute mitral regurgitation, ventricular septal defect, pseudoaneurysm, or left ventricular aneurysm.
3. Persistent hemodynamic instability.

Class IIa

1. When MI is suspected to have occurred by a mechanism other than thrombotic occlusion at an atherosclerotic plaque (e.g., coronary embolism, arteritis, trauma, certain metabolic or hematologic diseases or coronary spasm).
2. Survivors of acute MI with left ventricular EF
0.40, CHF, prior revascularization, or malignant ventricular arrhythmias.
3. Clinical heart failure during the acute episode, but subsequent demonstration of preserved left ventricular function (left ventricular EF > 0.40).

During the Risk-Stratification Phase (Patients With All Types of MI)

Class I

Ischemia at low levels of exercise with ECG changes (
1-mm ST segment depression or other predictors of adverse outcome) and/or imaging abnormalities.

Class IIa

1. Clinically significant CHF during the hospital course.
2. Inability to perform an exercise test with left ventricular EF
0.45.

PERIOPERATIVE EVALUATION BEFORE (OR AFTER) NONCARDIAC SURGERY

Class I: Patients with suspected or known CAD

1. Evidence for high risk of adverse outcome based on noninvasive test results.

2. Angina unresponsive to adequate medical therapy.
3. Unstable angina, particularly when facing intermediate- or high-risk noncardiac surgery.
4. Equivocal noninvasive test result in high-clinical-risk patient undergoing high-risk surgery.

Class IIa

1. Multiple-intermediate-clinical risk markers and planned vascular surgery.
2. Ischemia on noninvasive testing but without high-risk criteria.
3. Equivocal noninvasive test result in intermediate-clinical-risk patient undergoing high-risk noncardiac surgery.
4. Urgent noncardiac surgery while convalescing from acute MI.

PATIENTS WITH VALVULAR HEART DISEASE

Class I

1. Before valve surgery or balloon valvotomy in an adult with chest discomfort, ischemia by noninvasive imaging, or both.
2. Before valve surgery in an adult free of chest pain but with many risk factors for CAD.
3. Infective endocarditis with evidence of coronary embolization.

Class IIa

None.

PATIENTS WITH CONGENITAL HEART DISEASE

Class I

1. Before surgical correction of congenital heart disease when chest discomfort or noninvasive evidence is suggestive of associated CAD.
2. Before surgical correction of suspected congenital coronary anomalies such as congenital coronary artery stenosis, coronary arteriovenous fistula, and anomalous origin of the left coronary artery.
3. Forms of congenital heart disease frequently associated with coronary artery anomalies that may complicate surgical management.
4. Unexplained cardiac arrest in a young patient.

Class IIa

Before corrective open heart surgery for congenital heart disease in an adult whose risk profile increases the likelihood of coexisting CAD.

PATIENTS WITH CHF

Class I

1. CHF due to systolic dysfunction with angina or with regional wall motion abnormalities and/or scintigraphic evidence or reversible myocardial ischemia when revascularization is being considered.
2. Before cardiac transplantation.
3. CHF secondary to postinfarction ventricular aneurysm or other mechanical complications of MI.

Class IIa

1. Systolic dysfunction with unexplained cause despite noninvasive testing.
2. Normal systolic function, but episodic heart failure raises suspicion if ischemically mediated left ventricular dysfunction.

OTHER CONDITIONS

Class I

1. Diseases affecting the aorta when knowledge of the presence or extent of coronary artery involvement is necessary for management (e.g., aortic dissection or aneurysm with known CAD).
2. Hypertrophic cardiomyopathy with angina despite medical therapy when knowledge of coronary anatomy might affect therapy.
3. Hypertrophic cardiomyopathy with angina when heart surgery is planned.

Class IIa

1. High risk for CAD when other cardiac surgical procedures are planned (e.g., pericardiectomy or removal of chronic pulmonary emboli).
2. Prospective immediate cardiac transplant donors whose risk profile increases the likelihood of CAD.
3. Asymptomatic patients with Kawasaki's disease who have coronary artery aneurysms on echocardiography.
4. Before surgery for aortic aneurysm/dissection in patients without known CAD.
5. Recent blunt chest trauma and suspicion of acute MI, without evidence of preexisting CAD.

CABG = coronary artery bypass graft; CAD = coronary artery disease; CHF = congestive heart failure; ECG = electrocardiographic; EF = ejection fraction; LBBB = left bundle branch block; MI = myocardial infarction; PTCA = percutaneous transluminal coronary angioplasty.

---

coronary disease, quantification of the hemodynamic consequences of the valvular lesions (such as pulmonary hypertension), and occasionally the acute hemodynamic response to pharmacological therapy all provide useful preoperative information that fully defines the operative risk and permits a more directed surgical approach.

The current role of cardiac catheterization in certain congenital disease states is less well defined, as echocardiography, Doppler techniques, and cardiac magnetic resonance imaging have improved in accuracy and image quality (see Chaps. 7 and 10) . Because gross cardiac anatomy can generally be well defined by these methods, catheterization is required only if certain hemodynamic information (e.g., shunt size or pulmonary vascular resistance) is important in determining the indications for surgical procedures, if catheter interventional methods are contemplated, or if coronary anomalies are suspected.

COMPLICATIONS ASSOCIATED WITH CARDIAC CATHETERIZATION (Table 11-2)

Cardiac catheterization is a relatively safe procedure but has a well-defined risk of morbidity and mortality.[4] [5] [6] [7] [8] The potential risk of major complications during cardiac catheterization may be difficult to ascertain owing to the confounding aspects of comorbid disease and disparities in methods used to collect complication data. Advances including the use of low-osmolar contrast media, lower profile diagnostic catheters, and extensive operator experience all serve to reduce further the incidence of complications. Several large trials including the American Heart Association's Cooperative Study on cardiac catheterization,[4] the Society for Cardiac Angiography's Registry,[6] [8] and others[5] [6] [7] permit insight into the incidence of major events and delineate patient cohorts that are at increased risk. Two studies

TABLE 11-2 -- RISK GROUPS FOR CARDIAC CATHETERIZATION

	MORTALITY RATE (%)
Overall mortality	0.14
Age-related mortality	
Less than 1 yr	1.75
More than 60 yr	0.25
Coronary artery disease	
One-vessel disease	0.03
Three-vessel disease	0.16
Left main disease	0.86
Coronary heart failure	
NYHA functional Class I or II	0.02
NYHA functional Class III	0.12
NYHA functional Class IV	0.67
Valvular heart disease	
PATIENTS AT HIGHEST RISK FOR COMPLICATIONS AND UNSUITABLE FOR CATHETERIZATION IN AN AMBULATORY SETTING	
Coronary artery disease	
Unstable or progressive angina	
Recent myocardial infarction (<7 days)	
Pulmonary edema thought due to ischemia	
High risk for left main disease by noninvasive testing	
Congestive heart failure	
NYHA functional Class III or IV	
Severe right heart failure	
Valvular heart disease	
Suspected severe aortic stenosis	

Suspected severe aortic regurgitation (pulse pressure
80 mm Hg)
Congenital heart disease
Suspected severe pulmonary hypertension
Severe right heart failure
PATIENTS WHO REQUIRE PROLONGED MONITORING AFTER CARDIAC CATHETERIZATION AND MAY BE UNSUITABLE FOR AMBULATORY CARDIAC CATHETERIZATION
Severe peripheral vascular disease
General debility, mental confusion, or cachexia
Need for continuous anticoagulation or a bleeding diathesis
Uncontrolled systemic hypertension
Poorly controlled diabetes mellitus
Recent stroke (<1 mo)
Renal insufficiency (creatinine 2 mg/dl)

evaluating the specific risk of coronary angiography are also available--a survey of 46,904 patients[9] and the report from the Collaborative Study of Coronary Artery Surgery that included 7553 patients who were studied prospectively.[5]

Death due to diagnostic cardiac catheterization occurs in 0.14 to 0.75 percent of patients, depending on the population studied. Data from the Society for Cardiac Angiography identified subsets of patients with an increased mortality rate.[6] These include patients with greater than 50 percent stenosis of the left main coronary artery (0.94 percent), left ventricular ejection fraction less than 30 percent (0.54 percent). New York Heart Association (NYHA) functional Class III or IV heart failure (0.24 percent), age greater than 60 years (0.23 percent), aortic valvular disease (0.23 percent), and three-vessel coronary artery disease (0.13 percent).[10] In an analysis of 58,332 patients, multivariate predictors of significant complications were moribund status, advanced NYHA functional class, hypertension, shock, aortic valve disease, renal insufficiency, unstable angina, mitral valve disease, acute myocardial infarction within 24 hours, congestive heart failure, and cardiomyopathy.[8] The risk of cardiac catheterization appears to be further increased in octogenarians,[11] in whom overall mortality is approximately 0.8 percent and the risk of nonfatal major complications, which are primarily peripheral vascular, is about 5 percent.

The risk of myocardial infarction varies from 0.07 to 0.06 percent, cerebrovascular accidents from 0.03 to 0.2 percent, and significant bradyarrhythmias or tachyarrhythmias from 0.56 to 1.3 percent. Reports of the incidence of major vascular complications have varied widely, with most series suggesting a slightly higher frequency when the brachial approach is used. The incidence of major vascular complications has been reported at approximately 0.40 percent.[8] Major vascular complications include occlusion requiring arterial repair or thrombectomy, retroperitoneal bleeding, hematoma formation, pseudoaneurysm, arteriovenous fistula formation, and infection. The risk of requiring surgical repair for vascular injury is related to advanced age, congestive heart failure, and larger body surface area.[12]

Systemic complications can vary from mild vasovagal responses to severe vagal reactions that lead to cardiac arrest. Prolonged hypotension during the procedure may also occur as a result of various mechanisms that include the vasodepressor vagal response, contrast medium-induced vasodilation or osmotic diuresis, cardiac tamponade due to myocardial perforation or coronary laceration, myocardial infarction, and an acute anaphylactoid reaction to the contrast media. Minor complications occur in approximately 4 percent of patients undergoing routine cardiac catheterization.[13] The most common untoward effects are transient hypotension and brief episodes of angina lasting less than 10 minutes. With the use of low-osmolar contrast media, however, bradycardia is infrequent and usually responds to cough. Rarely, administration of intravenous atropine is necessary.

After the procedure, diuresis from the radiographic contrast load and subsequent hypotension can be common. Intravenous hydration given before and after the procedure can usually restore the intravascular volume to compensate for the anticipated diuresis. A prospective trial evaluated the effects of saline, mannitol, and furosemide in preventing acute decreases in renal function due to contrast media-induced nephrotoxicity.[14] The researchers concluded that saline alone was most effective in reducing the acute increase in serum creatinine level. The incidence of acute renal dysfunction in patients with baseline renal insufficiency was 28 and 40 percent with mannitol and furosemide, respectively, compared with 11 percent with saline hydration alone.

Controversy surrounds the use of low-osmolar nonionic or hemionic versus high-osmolar ionic contrast media for routine cardiac catheterization and angiography. Consensus about the types of patients in whom use of low-osmolar contrast agents should be considered is growing (Table 11-3) . Several reviews have suggested that contrast media-related toxicity occurs in 1.4 to 2.3 percent of patients receiving ionic contrast media.[15] [16] High-osmolar ionic contrast media produce various adverse hemodynamic and electrophysiological effects during coronary angiography. Most of these adverse events are clearly related to the osmolality, sodium content, and calcium-binding characteristics of the ionic contrast solutions. In addition, myocardial depression, peripheral vasodilation, and increased coronary blood flow occur.[17] Nonionic low-osmolar contrast agents clearly reduce acute adverse hemodynamic and electrophysiological reactions.[18] They appear to release less histamine from mast cells and potentially reduce allergic reactions.[19] Clinical studies suggest no advantage of low-osmolar contrast over ionic contrast media in the prevention of nephrotoxicity in patients with normal renal

function.[13] [20] Other data, however, indicate that the risk of contrast media-induced nephropathy is reduced in patients with baseline renal insufficiency with or without diabetes mellitus, if nonionic contrast medium is used.[21]

Baseline renal insufficiency has been consistently shown to be an independent predictor of subsequent contrast nephrotoxicity.[13] Contrast media-induced renal dysfunction can be minimized if the dose of contrast medium is kept below 30 ml for the entire study.[22] The question of some inherent thrombogenicity of nonionic low-osmolar agents has also been raised,[23] and this possibility may relate to the formation of "thin" fibrin in the thrombus.[24] A prospective multicenter trial has demonstrated that an isosmolar nonionic contrast agent produced fewer major adverse cardiac events during percutaneous transluminal coronary angioplasty (PTCA) when compared with low-osmolar ionic contrust media.[25] Because a substantial difference in costs exists between ionic and nonionic media, the controversy about the

exclusive use of nonionic contrast media for routine diagnostic cardiac catheterization is unresolved.

TECHNICAL ASPECTS OF CARDIAC CATHETERIZATION

CATHETERIZATION LABORATORY FACILITIES

Cardiac catheterization facilities have evolved to include traditional hospital-based laboratories with in-house cardiothoracic surgical programs, hospital-based laboratories without on-site surgical programs, free-standing laboratories, and mobile laboratories. The relative merits of each type of facility have been discussed in detail by a task force of the American Heart Association and the American College of Cardiology,[26] and guidelines for development of a mobile facility have been outlined by the Society for Cardiac Angiography and interventions.[27] The goals of the free-standing and mobile cardiac catheterization facilities are to reduce cost while offering services in a convenient location for low-risk patients. In one study evaluating the safety of mobile catheterization involving 1001 low-risk patients, no patient died, 0.9 percent required urgent referral for clinical instability, 0.6 percent had major complications, and 27 percent required further referral to a tertiary site for additional diagnostic or therapeutic procedures.[28] The issue of cost-saving potential of mobile and free-standing laboratories, as well as quality of patient care and ethical issues, remains unresolved. Because the majority of patients in the United States live within 30 to 60 minutes of a hospital-based facility,[26] It is generally recommended that catheterization be performed in traditional settings.

Because of cost containment considerations and the documented safety of diagnostic cardiac catheterization, there has been increasing pressure to perform catheterization on an ambulatory outpatient basis.[29] [30] Medicare data indicate that in 1986, 5 percent of total cases were performed on an outpatient basis. This rose to 23 percent in 1993.[1] Criteria for ambulatory catheterization have been reported.[26] [31] In general, patients who are not appropriate candidates for ambulatory catheterization include those with severe peripheral vascular disease, mechanical prosthetic valves, severe congestive heart failure, bleeding disorders, severe ischemia during stress testing, ischemia at rest, known or highly suspected severe left main or proximal three-vessel disease, critical aortic stenosis, and severe comorbid disease. Despite careful screening for low-risk patients, 12 percent of patients may require hospitalization.[32]

PERSONNEL

Personnel in the catheterization laboratory include the director, physicians, nurses, and radiological technologists. All members should be trained in cardiopulmonary resuscitation and preferably in advanced cardiac life support. It is desirable for facilities to be associated with a cardiothoracic surgical program. In general, high-risk diagnostic studies and all elective percutaneous interventions should be performed in laboratories with on-site surgical facilities. The American College of Cardiology/American Heart Association task force assessment of diagnostic and therapeutic cardiovascular procedures suggests that PTCA in high-risk patients with acute myocardial infarction may be performed by trained physicians without on-site surgical back-up if the patient cannot be transferred to a more traditional setting without additional risk.[32A]

In order to maintain proficiency, laboratories for adult studies should perform a minimum of 300 procedures per year, and physicians performing diagnostic catheterization should perform a minimum of 150 procedures per year.[26] [33] Regular evaluation of laboratory and physician performance is also mandatory.[34]

EQUIPMENT

The physical requirements for the catheterization facility have been described in detail elsewhere.[26] Necessary equipment includes the radiographic system, physiological data monitoring and acquisition instrumentation, sterile supplies, and an emergency cart. Also included is support equipment consisting of a power injector, cineangiographic film or digital archiving, film processors, and viewing equipment.

RADIOGRAPHIC EQUIPMENT.

High-resolution x-ray imaging is required for optimal performance of catheterization procedures. The necessary equipment includes a generator, x-ray tube, image intensifier, video system, and either digital archiving or a cinecamera.[35] Although many facilities continue to use traditional film-based cineangiography, other laboratories have made the transition to using digital technology, thus becoming "cinefilm-less" laboratories.[36] The advantages of digital acquisition and archiving include the ability to have immediate on-line review, quantitative computer analysis of high-quality images, image manipulation capabilities, and flicker-free images at very low frame rates, thereby minimizing radiation exposure. Using these technologies, transfer of images between cardiac catheterization laboratories, hospitals, and physician offices can be accomplished using a common network.[37] The development of digital imaging and communication (DICom) standards for cardiac angiography has allowed compatability among different systems. Digital image quality is improved over videotape, and increased computer storage capabilities have allowed quick access to more than 2000 cases.

PHYSIOLOGICAL MONITORS.

Continuous monitoring of blood pressure and the electrocardiogram (ECG) is required during cardiac catheterization. Systemic, pulmonary, and intracardiac pressures are generally recorded using fluid-filled catheters connected to strain-gauge pressure transducers and then transmitted to a monitor. Equipment for determination of cardiac output and blood gas determination, as well as a standard 12-lead ECG machine, are necessary.

RADIATION SAFETY

The patient and catheterization laboratory personnel must be protected from the harmful effects of radiation. Installing and maintaining optimal x-ray imaging equipment will reduce unnecessary radiation exposure. The amount of radiation exposure to the patient can be reduced by limiting fluoroscopic and image acquisition time, collimation of the beam to the anatomical region of interest, using low-intensity fluoroscopy, acquiring images at lower frame rates (i.e., 15 frames/sec), maintaining a minimum distance between the image intensifier and the x-ray tube, and using lead shielding when appropriate. Personnel in the laboratory can limit radiation exposure by minimizing acquisition and fluoroscopy times and by using low-dose fluoroscopy and 15 frames/sec acquisition rates. The most important factors are maximizing distance from the source of x-rays and using appropriate shielding (lead aprons, lead thyroid collars, lead eyeglasses, and movable leaded glass barriers). A method for measuring radiation exposure for personnel is required. The maximum allowable radiation dose per year for those working with radiation is 5 roentgen-equivalents-man (rem). A full discussion of radiation safety has been presented by the Society for Cardiac Angiography and interventions and others.[26] [38] [39]

Catheterization Laboratory Protocol

PREPARATION OF THE PATIENT FOR CARDIAC CATHETERIZATION.

Before arrival in the catheterization laboratory, the cardiologist responsible for the procedure should fully explain to patients the procedure including its risk and

benefits and answer questions that the patient and/or family may have. Precatheterization evaluation includes a patient history, physical examination, laboratory evaluation (complete blood count, platelet count, and determinations of serum creatinine, serum electrolytes, blood glucose, prothrombin time, and partial thromboplastin time), and ECG. Important components of the history that need to be addressed include possible insulin-dependent diabetes mellitus, renal insufficiency, long-term anticoagulation, and peripheral vascular disease, as well as previous contrast media reactions. Full knowledge of any prior procedures, including prior cardiac catheterizations, percutaneous interventions, and cardiac surgery, is necessary before the procedure. Patients should be fasting, and an intravenous line should be established. Oral or intravenous sedation should usually be administered (e.g., benzodizepine). Some laboratories routinely premedicate patients with antihistamines such as diphenhydramine (25 mg intravenous push) to decrease allergic reactions and prolong mild sedation.

CATHETERIZATION PROTOCOL.

Each physician should develop a routine for performing diagnostic catheterization to ensure efficient acquisition of all pertinent data. The particular technical approach and necessary procedures should be individualized for each patient so that the specific clinical questions can be addressed (Table 11-4) . In general, hemodynamic measurements and cardiac output determination should be made before angiography to reflect basal conditions most accurately and to guide angiography. When angiography is performed, the vessel or chamber with most clinical importance should be visualized first, in case an untoward reaction to the contrast media or another complication of the procedure should occur.

Controversy exists about whether right-heart catheterization should be performed in *all* patients undergoing routine coronary angiography. Some physicians believe that right-heart catheterization including screening oximetric analysis, measurement of right-heart pressures, and determination of cardiac output should be performed in every patient because the risks are limited and potential benefits exist (uncovering an unsuspected problem). A prospective study evaluated 200 patients undergoing left-heart catheterization for suspected coronary artery disease; data from right-heart catheterization were not considered necessary for clinical treatment of these patients before the procedure.[40] The right-heart catheterization took approximately 6 additional minutes of procedure time and 86 seconds of fluoroscopy time. Treatment was altered in only 1.5 percent of patients as a result of the data obtained by right-heart catheterization. Although routine right-heart catheterization does not appear necessary for patients undergoing routine coronary angiography, it is clearly indicated when the clinical question cannot be answered by isolated left-heart catheterization or when a patient has left ventricular dysfunction, congestive heart failure, complicated acute myocardial infarction, valvular disease, suspected pulmonary hypertension, a congenital anomaly, or pericardial disease.[26]

Although the use of a temporary pacemaker is not indicated for routine cardiac catheterization, operators should understand the techniques for proper insertion and setting of the pacemaker if needed (see Chap. 24) . Even in patients with isolated left bundle branch block, right-heart catheterization can generally be safely performed with balloon flotation catheters without causing additional conduction disturbance.

CATHETERS AND ASSOCIATED EQUIPMENT.

Physicians performing cardiac catheterization should be familiar with technical aspects of the equipment used during the procedure.[41] Catheters used for cardiac catheterization come in various lengths, sizes, and shapes. The widely used balloon flotation catheter (Swan-Ganz) is shown in Figure 11-1. Typical catheter lengths vary between 50 and 125 cm, with 100 cm being the most commonly used length for adult left-heart catheterization via the femoral approach. The outer diameter of the catheter is specified using French units, where one French unit (F) = 0.33 mm. The inner diameter of the catheter is smaller than the outside diameter owing to the thickness of the catheter material. Guidewires used during the procedure must be small enough to pass through the inner diameter of both the introducer needle and the catheter. Guidewires are described by their length in centimeters, diameter in inches, and tip conformation. A commonly used wire is a 150-cm, 0.035-inch J-tipped wire. The introducer sheaths are specified by the French number of the largest catheter that passes freely through the inner diameter of the sheath, rather than its outer diameter. Therefore, a 7F introducer sheath accepts a 7F catheter but has an outer diameter of more than 7F or 2.31 mm.

The choice of the size of the catheters to be used is made by balancing the need to opacify the coronary arteries and cardiac chambers adequately, to have adequate catheter

manipulation, to limit vascular complications, and to permit early ambulation. Although the larger catheters (7F and 8F) allow greater catheter manipulation and excellent visualization, the smaller catheters (5F and 6F) permit earlier ambulation after catheterization. Catheter technology has advanced such that 5F or 6F systems can be used for routine angiography without significant compromise of angiographic quality.[42] Even 4F catheters have been used from both the femoral artery and radial artery approaches. Use of the smaller catheters requires greater technical skill of manipulation to achieve adequate angiography and thus may be less appropriate for training students of catheterization. The 6F diagnostic catheter is most widely used for routine angiography because this size catheter appears to balance most appropriately the needs outlined earlier. The relationship between sheath size and vascular complications is not clear. Rather, anticoagulation status and operator experience are more important factors related to vascular complications.[43]

Techniques

Right-Heart Catheterization

Right-heart catheterization allows for measurement and analysis of right-heart, pulmonary artery, and pulmonary capillary wedge pressures; measurement of cardiac output by thermodilution; screening for intracardiac shunts; temporary ventricular pacing; assessment of arrhythmias; and pulmonary wedge angiography.[44]
Right-heart catheterization is performed antegrade through either the inferior vena cava (IVC) or superior vena cava (SVC). Percutaneous entry is achieved via the femoral, subclavian, jugular, or antecubital vein. The anatomy of the major arteries and veins used for cardiac catheterization is shown in Figures 11-2 (Figure Not Available) and 11-3 . In the cardiac catheterization laboratory, the femoral venous access is used most often because the Judkins technique of left-heart catheterization is performed concurrently.

BALLOON FLOTATION CATHETERS.

Balloon flotation catheters are the simplest and most widely used (see Fig. 11-1 . If thermodilution cardiac outputs must be determined, catheters that contain thermistors, such as Swan-Ganz catheters, should be used. These catheters have balloon tips, proximal and distal ports, and thermistors. Therefore, intracardiac pressures and oxygen saturation to evaluate intracardiac shunts can be obtained. These catheters

Figure 11-2 (Figure Not Available) Principal arteries used for access during cardiac catheterization. Only the superficial veins are shown on the forearm. (Modified from Anthony CP: Textbook of Anatomy and Physiology. 11th ed. St. Louis, CV Mosby, 1983.)

Figure 11-3 Anatomy relevant to percutaneous catheterization of the femoral artery and vein. The right femoral artery and vein pass underneath the inguinal ligament, which connects the anterior-superior iliac spine and pubic tubercle. The arterial skin nick (indicated by X) should be placed approximately 1 1/2 to 2 fingerbreaths (3 cm) below the inguinal ligament and directly over the femoral artery pulsation. The venous skin nick should be placed at the same level, but approximately 1 fingerbreadth medial. (From Baim DS, Grossman W: Percutaneous approach including transseptal and apical puncture. *In* Baim DS, Grossman W [eds]: Cardiac Catheterization, Angiography, and Intervention. 5th ed. Philadephia, Lea & Febiger, 1996.)

are both flexible and flow directed, but when the femoral approach is used, fluoroscopic guidance is almost always necessary to cannulate the pulmonary artery and to obtain pulmonary capillary wedge position. Although most right-heart catheters have a J-shaped curvature distally to facilitate passage from the SVC to the pulmonary artery, a catheter with an S-shaped distal end has been designed for femoral insertion. Although manipulation is limited, the balloon flotation catheters are the safest and most rapid method for obtaining right-heart pressures and blood samples. Other balloon flotation end-hole catheters that are stiffer and therefore allow better manipulation are available for right-heart catheterization. These lack the ability to obtain thermodilution cardiac outputs but yield better pressure fidelity owing to less catheter whip artifact and a larger end hole.

There are two methods for advancing a balloon flotation catheter from the femoral vein. On many occasions, the catheter can be advanced directly through the right atrium and across the tricuspid valve. Once in the right ventricle, the catheter is manipulated to point superiorly and directly into the right ventricular outflow tract. This can usually be achieved while the catheter is advanced with slight clockwise rotation. Once in the outflow tract, the balloon tip should allow flotation into the pulmonary artery and wedge positions. When necessary, deep inspiration or cough can facilitate this maneuver and assist in crossing the pulmonic valve. If the catheter continues to point inferiorly toward the right ventricular apex, another technique should be used, because further advancement can risk perforation of the right ventricular apex.

One such additional technique for performing right-heart catheterization with a balloon flotation catheter is shown in Figure 11-4 . A loop is formed in the right atrium, with the catheter tip directed laterally. The loop can be created by hooking the catheter tip on the hepatic vein or by advancing the catheter while it is directed laterally in the right atrium. Once the loop is formed, the catheter should be advanced farther; this directs the tip inferiorly and then medially across the tricuspid valve. Antegrade blood flow should then direct the catheter into the pulmonary artery. After the catheter is placed into the wedge position, the redundant loop should be removed by slow withdrawal. Screening blood samples for oximetric analysis should be obtained from the SVC and the pulmonary artery to evaluate for intracardiac shunts. Cardiac output can also be determined by thermodilution techniques.

NONFLOTATION CATHETERS.

When an end-hole catheter that does not have a balloon tip is used, the technique for cannulating the pulmonary artery is markedly different. Manipulation and torquing of the nonflotation catheter are necessary to advance into the pulmonary artery. The catheter should be directed inferiorly across the tricuspid valve and then superiorly into the right ventricular outflow tract. It is generally recommended that one attempt to form a loop in the right atrium before advancement into the right ventricle in order to lessen the risk of perforation. These stiffer catheters can often prolapse into the left atrium with mild pressure against the interatrial septum in patients with a probe-patent foramen ovale. Left atrial position can be verified by the pressure waveform, by blood samples demonstrating arterial saturation, or by hand contrast injection.

COMPLICATIONS.

The most common complications of right-heart catheterization are nonsustained atrial and ventricular arrhythmias. Major complications associated with right-heart catheterization are infrequent. These include pulmonary infarction, pulmonary artery or right ventricular perforation, and infection. Pulmonary artery rupture can be avoided by combined use of fluoroscopic guidance and constant evaluation of the pressure waveform. Confusion about the location of the distal end of the catheter may arise in the setting of large v waves in the pulmonary capillary wedge pressure tracing; the operator may mistake these for a pulmonary artery waveform (Fig. 11-5) . Careful attention

Figure 11-4 Technique of right-heart catheterization from the femoral approach. *A,* The catheter is advanced through the inferior vena cava. *B,* A loop is created in the catheter by hooking on the hepatic vein or lateral right arterial wall. *C,* Clockwise rotation and advancement of the catheter cross the tricuspid valve. *D,* Additional rotation and withdrawal straightens the catheter and directs it superiorly so that it may be advanced through the right ventricular outflow tract. (Copyright 1984 Mayo Foundation.)

Figure 11-5 Acute mitral regurgitation with poor left atrial compliance. The left ventricle (LV) pressure versus the pulmonary capillary wedge (PCW) is shown on left. A large regurgitant v wave is seen. This v wave is transmitted through the pulmonary bed to the pulmonary arterial (PA) tracing and is superimposed in the right panel. (From Bashore TM, Harrison JK, Davidson CJ: Cardiac catheterization, angiography, and interventional techniques in valvular and congenital heart disease. *In* Sabiston DC, Spencer FC [eds]: Surgery of the Chest. 6th ed. Philadelphia, WB Saunders, 1995.)

to the timing of the peak pulmonary artery systolic pressure and the v wave with respect to the ECG, along with the use of fluoroscopy, prevents inadvertent inflation of the balloon in the wedged position, which can cause pulmonary artery rupture.

Left-Heart Catheterization and Coronary Arteriography

THE JUDKINS TECHNIQUE.

Because of its relative ease, speed, reliability, and low complication rate,[5] the Judkins technique has become the most widely used method of left-heart catheterization and coronary arteriography in the United States. After local anesthesia with 1 percent lidocaine (Xylocaine), percutaneous entry of the femoral artery is achieved by puncturing the vessel 1 to 3 cm (or 1 to 2 fingerbreadths) below the inguinal ligament. The ligament can be palpated as it courses from the anterior superior iliac spine to the superior pubic ramus. This ligament, not the inguinal crease, should be used as the landmark; use of this crease is misleading. A transverse skin incision is made

over the femoral artery with a scapel. Using a modified Seldinger's technique (Fig. 11-6) , an 18-gauge thin-walled needle (Fig. 11-7) (Figure Not Available) is inserted at a 30- to 45-degree angle into the femoral artery, and a 0.035- or 0.038-inch J-tip Teflon-coated guidewire is advanced through the needle into the artery. The wire should pass freely up the aorta. After arterial access is obtained, a sheath at least equal in size to the coronary catheter is usually inserted into the femoral artery. It is generally recommended that the patient receive 3000 to 5000 units of heparin after access is obtained. The technique of coronary arteriography using this approach is described in Chapter 12.

Left ventricular systolic and end-diastolic pressures can be obtained by advancing a pigtail catheter into the left ventricle (Fig. 11-8) . In assessing valvular aortic stenosis, left ventricular and aortic pressures should be recorded simultaneously. In suspected mitral stenosis, left ventricular and wedge or left atrial pressures should be obtained simultaneously. Left ventriculography is performed in the 30-degree right anterior oblique and 45- to 50-degree left anterior oblique views. A pigtail catheter is most commonly used for this purpose. Power injection of 30 to 50 ml of contrast medium into the ventricle is used to assess left ventricular function and the severity of mitral regurgitation. After ventriculography, pressure measurements may be repeated and the systolic pressure should be recorded as the catheter is withdrawn from the left ventricle into the aorta. If an aortic transvalvular gradient is present, recording these pressures detects it. For measurement of suspected intraventricular gradients, a multipurpose catheter with an end hole is desirable to localize the gradient in the left ventricle. Pigtail catheters contain side holes, which obscure the capacity to define whether the gradient is intraventricular or transvalvular.

After coronary arteriography and left-heart catheterization have been completed, the catheters are removed and firm pressure is applied to the femoral area for 15 to 20 minutes, either by hand or by a mechanical clamp. The patient should be instructed to lie in bed for several hours, with the leg remaining straight to prevent hematoma formation. With 5F catheters, 2 hours of bed rest is usually sufficient, whereas use of 6F catheters usually involves at least 3 to 4 hours. Alternatively, closure devices may be used. Two types are currently available. These are collagen plugs and suture closure. Both allow for earlier ambulation of the patients. However, none has been shown to lower vascular complication rates compared with hand compression.[45]

The main advantage of the Judkins technique is the speed and ease of selective catheterization. These attributes do not, however, preclude the importance of extensive operator experience to ensure quality studies with acceptable safety. The main disadvantage of this technique is its use in patients with iliofemoral atherosclerotic disease, in whom retrograde passage of catheters through areas of extreme narrowing or tortuosity may be difficult or impossible.

BRACHIAL ARTERY TECHNIQUE--SONES TECHNIQUE.

Sones and colleagues introduced the first technique for coronary artery catheterization by means of a brachial artery cutdown. The Sones technique is still popular in many centers and is described in Chapter 12 .

PERCUTANEOUS BRACHIAL ARTERY TECHNIQUE

A modification of Sones technique is the percutaneous brachial artery technique using preformed Judkins catheters. This technique uses Seldinger's method of percutaneous brachial artery entry. A 5F or 6F sheath is placed into the brachial artery, and 3000 to 5000 units of heparin is infused into the side port. A guidewire is then advanced to the ascending aorta under fluoroscopic control. Number 5F or 6F left, right, and pigtail catheters are passed over the guidewire for routine arteriography and ventriculography. The guidewire may occasionally be necessary to direct the left coronary catheter into the left sinus of Valsalva and the ostium of the left main coronary artery.

The main advantage of the percutaneous brachial technique is that it avoids a brachial artery cutdown and repair. The main disadvantage is that manipulation of catheters can be difficult. When this technique was compared with the femoral technique, patients' comfort, hemostasis time, and time to ambulation favored the brachial

Figure 11-6 Modified Seldinger's technique for percutaneous catheter sheath introduction. *A,* Vessel punctured by needle. *B,* Flexible guidewire placed into the vessel via the needle. *C,* Needle removed, guidewire left in place, and the hole in the skin around the wire enlarged with a scalpel. *D,* Sheath and dilator placed over the guidewire. *E,* Sheath and dilator advanced over the guidewire and into the vessel. *F,* Dilator and guidewire removed while the sheath remains in the vessel. Baltimore, Williams & Wilkins, 1998, p 107.

technique, whereas procedural efficiency, time of radiation exposure, and diagnostic film quality were more favorable with the femoral approach.[46] Complication rates appear similar.

PERCUTANEOUS RADIAL ARTERY TECHNIQUE

Left-heart catheterization via the radial artery approach was developed as an alternative to the percutaneous transbrachial approach in

Figure 11-7 (Figure Not Available) Two most commonly used needle types for vascular access. On the left, a single-piece, thin-walled "front-wall needle"; on the right, a two-component, thin-walled Seldinger needle. (From MacDonald RG: Catheters, sheaths, guidewires, needles, and related equipment. *In* Pepine CJ, Hill JA, Lambert CR [eds]: Diagnostic and Therapeutic Cardiac Catheterization. 3rd ed. Baltimore, Williams & Wilkins, 1998, p 130.)

an attempt to limit vascular complications.[47] The inherent advantages of the transradial approach are that the hand has a dual arterial supply connected via the palmar arches and that there are no nerves or veins at the site of puncture. In addition, prolonged bed rest is unnecessary after the procedure, thus allowing for more efficient outpatient angiography.

The procedure requires a normal Alien's test result: After manual compression of both the radial and ulnar arteries during fist clenching, normal color returns to the opened hand within 10 seconds after releasing pressure over the ulnar artery, and significant reactive hyperemia is absent on releasing pressure over the radial artery.[48]

The arm is abducted, and the wrist hyperextended over a gauze roll. Routine skin anesthesia is used, a small incision is made just proximal to the styloid process of the radius, and the subcutaneous tissue is tunneled using forceps. An 18-gauge needle is introduced at a 45-degree angle and an exchange-length 0.035- or 0.038-inch J-tip guidewire is inserted. A 23-cm long 4F or 5F sheath is then introduced. Heparin, 5000 units, is administered through the side arm of the sheath. Coronary catheters are then advanced over the exchange wire into the ascending aorta. The left coronary artery is intubated using a left 4-cm tip Judkins (JL 4.0), a left Amplatz, or a brachial Castillo type II catheter. The right coronary artery is intubated using a 4-cm right Judkins (JR 4.0), a left Amplatz, or a multipurpose catheter. Left ventriculography can be performed using a multipurpose catheter with side holes or a pigtail catheter. Exchanges are best performed over the guidewire. Hemostasis is obtained at the end of the procedure after sheath removal using direct pressure. It is recommended that the arterial puncture site be allowed to bleed for several beats before maintaining direct pressure. The radial pulse should be monitored regularly for several hours after the procedure.

The potential limitations of this procedure include the inability to cannulate the radial artery owing to its smaller size and propensity to develop spasm, poor visualization of the coronary arteries resulting from the small caliber catheters with limited manipulation potential, and risk of arterial occlusion caused by dissection or thrombus formation, in addition, when right-heart catheterization is required, other approaches are necessary. Although there is little debate that the femoral approach is the simplest and probably the safest technique for left-heart catheterization, the transradial approach for left-heart catheterization has gained in popularity with refinements in technique and equipment.

Figure 11-8 Technique for retrograde crossing of an aortic valve using a pigtail catheter. The upper row shows the technique for crossing a normal aortic valve. In the bottom row, the use of a straight guidewire and pigtail catheter in combination is shown. Increasing the length of protruding guidewire straightens the catheter curve and causes the wire to point more toward the right coronary ostium; reducing the length of protruding wire restores the pigtail contour and deflects the guidewire tip toward the left coronary artery. Once the correct length of wire and the correct rotational orientation of the catheter have been found, repeated advancement and withdrawal of catheter and guidewire together will allow retrograde passage across the valve. In a dilated aortic root, the angled pigtail catheter is preferable. In a small aortic root (*bottom row, right*), a right coronary Judkins catheter may have advantages. (From Baim DS, Grossman W: Percutaneous approach including transseptal and apical

puncture. *In* Baim DS, Grossman W [eds]: Cardiac Catheterization, Angiography, and Intervention. 5th ed. Philadelphia, Lea & Febiger, 1996.)

Transseptal Catheterization

This procedure has received renewed interest with the growth of percutaneous balloon mitral commissurotomy as a viable option to surgical commissurotomy (see Chap. 46) , with electrophysiologic procedures requiring access to pulmonary veins, and with increasing use of disc valves in the aortic position (Fig. 11-9) . These mechanical prosthetic valves cannot be crossed safely and prohibit retrograde left-heart catheterization.

The original technique of transseptal heart catheterization has been well described,[49] and various techniques currently exist. The transseptal catheter is a short, curved catheter with a tapered tip and side holes. One commonly used approach is to place a 0.032-inch guidewire via the femoral vein through the right atrium and into the SVC. A Mullins transseptal sheath and dilator are then advanced over the wire into the SVC. The guidewire is removed and replaced with a Brokenbrough's needle, and the distal port is connected to a pressure manifold. With the needle tip just proximal to the Mullins sheath tip, the entire catheter system is withdrawn. The catheter is simultaneously rotated from a 12 o'clock to a 5 o'clock position. The operator experiences two abrupt rightward movements of the catheter. The first occurs as the catheter descends from the SVC to the right atrium. The second occurs as the Mullins dilator tip passes over the limbic edge into the fossa ovalis. The curve of the sheath and needle should be oriented slightly anteriorly. The dilator and needle can then be advanced gently as a unit. Steady pressure often is adequate to advance the system into the left atrium. If not, the needle should be advanced across the interatrial septum while holding the Mullins sheath in place.

Left atrial position can be confirmed by the increase in pressure with left atrial a and v waveforms, hand injection of contrast medium, or measurement of arterial oxygen saturation. Once position is confirmed, the dilator and sheath can be safely advanced 2 to 3 cm into the left atrium. The sheath is held firmly, and the dilator and needle are removed. Left atrial pressure measurements may then be repeated. If measurement of left ventricular pressure and/or left ventriculography is necessary, the catheter can usually be advanced easily into the left ventricle after slight counterclockwise rotation. The risk of major morbidity with skilled operators should be less than 2 percent.[50] The major risk of transseptal catheterization lies in inadvertent puncture of atrial structures, such as the atrial free wall or coronary

Figure 11-9 Transseptal catheters. *A,* Distal catheter. *B,* Proximal catheter. *Left,* Mullins transseptal sheath. *Middle,* Introducer (dilator) that is placed inside sheath to add stiffness to the catheter. *Right,* Brockenbrough transseptal needle that is placed inside the sheath and is used to penetrate the septum.

sinus, or entry into the aortic root or pulmonary artery.

DIRECT TRANSTHORACIC LEFT VENTRICULAR PUNCTURE

The sole indication for direct left ventricular puncture is to measure left ventricular pressure and to perform ventriculography in patients with mechanical prosthetic valves in both the mitral and aortic positions, thus preventing retrograde arterial and transseptal catheterization. Crossing tilting disc valves with catheters should be avoided because this may result in catheter entrapment, occlusion of the valve, or possible dislodgement of the disc with embolization.

The procedure is performed after localizing the left ventricular apex via palpation or preferably using echocardiography.[51]

After local anesthesia is administered, a 3 1/2-inch-long 18-gauge needle is inserted at the upper rib margin and directed slightly posteriorly and toward the right shoulder. An 0.035-inch J-tip guidewire is introduced into the ventricle under fluoroscopic guidance, followed by a 4F dilator and then a 4F pigtail catheter.[52]

The risks of this procedure include cardiac tamponade, hemothorax, pneumothorax, laceration of the left anterior descending coronary artery, embolism of left ventricular thrombus, vagal reactions, and ventricular arrhythmias. The risk of pericardial tamponade, however, is limited in patients who have undergone prior cardiac surgery because mediastinal fibrosis is present. With the advent of transesophageal echocardiography, this procedure is now infrequently performed.

Endomyocardial Biopsy (See also Chaps. 20 and 48)

This procedure can be performed using various bioptomes. The most common devices in use include the stiff-shaft Caves-Schulz Stanford bioptome[53] and the floppy-shaft King's bioptome.[54] Right ventricular biopsy may be performed using the internal jugular vein,[53] [55] the subclavian vein,[56] or the femoral vein.[57] Left ventricular biopsy may be performed using the femoral arterial approach.[54]

For performing right ventricular biopsy via the right internal jugular vein, a 7-9F sheath is introduced using the usual Seldinger's technique. A 7-9F bioptome is advanced under fluoroscopic guidance to the lateral wall of the right atrium. Using counterclockwise rotation, the device is advanced across the tricuspid valve and toward the interventricular septum. Position of the bioptome against the interventricular septum is confirmed using 30-degree right anterior oblique and 60-degree left anterior oblique fluoroscopic projections. Alternatively, two-dimensional echocardiography has been used to guide the position of the bioptome with good results.[58] Contact with the myocardium is confirmed by the presence of premature ventricular contractions, lack of further advancement, and transmission of ventricular impulse to the operator. The bioptome is then slightly withdrawn from the septum, the forceps jaws are opened, the bioptome is readvanced to contact the myocardium, and the forceps closed. A slight tug is felt on removal of the device. Approximately four to six samples of myocardium are required for adequate pathological analysis. Consultation with a pathologist should be obtained to ensure appropriate specimen collection and processing.

Right or left ventricular biopsy from the femoral vein or artery requires insertion of a long 6F or 7F sheath directed toward the portion of the ventricle to be sampled. The sheath used for right ventricular biopsy has a 45-degree angle on its distal end to allow for easier access to the right ventricle. An angled pigtail catheter and long guidewire system are used to enter the right ventricle. The sheath is then advanced over the pigtail catheter into the right ventricle, the catheter is withdrawn, the sheath is flushed, and pressure is measured. The bioptome is advanced through the sheath. Samples of myocardium are taken in a manner similar to that described earlier. If left ventricular biopsy is to be performed, the biopsy sheath is generally positioned over a multipurpose or pigtail catheter that has been positioned in the ventricle. The sheath is advanced below the mitral apparatus and away from the posterobasal wall. The catheter is then withdrawn, and either a long King's bioptome or the Stanford left ventricular bioptome is inserted. Care must be taken when left ventricular biopsy is performed to prevent air embolism while introducing the bioptome into the sheath. A constant infusion of flush solution through the sheath minimizes the risk of air or thrombus embolism.

Complications of endomyocardial biopsy include cardiac perforation with cardiac tamponade (see Chap. 50) , emboli (air, tissue, or thromboembolus), arrhythmias, electrical conduction disturbances, injury to heart valves, vasovagal reactions, and pneumothorax.[59] The overall complication rate is between 1 and 2 percent, with the risk of cardiac perforation with tamponade generally reported in less than 0.05 percent.[60] Systemic embolization and ventricular arrhythmias are more common with left ventricular biopsy. Left ventricular biopsy should generally be avoided in patients with right bundle branch block because of the potential for developing complete atrioventricular block, as well as in patients with known left ventricular thrombus.

The indications for endomyocardial biopsy remain controversial.[61] [62] [63] Generally agreed is that endomyocardial biopsy is indicated to monitor cardiac allograft rejection and that it may also be useful to monitor for anthracycline cardiotoxicity.[61] However, considerable persistent controversy surrounds the use of endomyocardial biopsy to evaluate the cause of dilated cardiomopathy.[61] [64] Other possible indications for endomyocardial biopsy include differentiation between restrictive and constrictive myopathies,[65] [66] determination of whether myocarditis is the cause of ventricular arrhythmias,[61] [63] and assessment of patients with left ventricular dysfunction associated with human immunodeficiency virus infection.[67] [68]

Percutaneous Intraaortic Balloon Pump (IABP) Insertion (See also p. 159)

The intraaortic balloon counterpulsation devices available for adult use are positioned in the descending thoracic aorta. They have a balloon volume of 30 to 50 ml, use helium as the inflation gas, and are timed to inflate during diastole and deflate during systole. Details of the technique of balloon insertion have been well described.[69] Briefly, the device is inserted via the femoral artery using the standard Seldinger's technique. The device is placed such that the tip is just below the level of the left subclavian artery. Optimal positioning requires fluoroscopic guidance. Timing of the balloon is adjusted during 1:2 pumping such that inflation of the balloon occurs at the aortic dicrotic notch and deflation occurs immediately before systole to ensure maximal augmentation of diastolic flow and maximal systolic unloading.

Favorable hemodynamic effects include reduction in left ventricular afterload and improvement in myocardial oxygenation.[70] [71] Therefore, IABP insertion is indicated for patients with angina refractory to medical therapy, cardiogenic shock, or mechanical complications of myocardial infarction (see Chap. 35) (including severe mitral regurgitation, ventricular septal defect) or for those who have severe left main coronary artery stenosis and who will be undergoing cardiac surgery. IABP may also be

valuable in patients undergoing high-risk angioplasty and after primary angioplasty in the setting of acute myocardial infarction.[72] [73] IABP insertion is contraindicated in patients with moderate or severe aortic regurgitation, aortic dissection, aortic aneurysm, patent ductus arteriosus, severe peripheral vascular disease, bleeding disorders, or sepsis.

Complications of IABP insertion include limb ischemia requiring early balloon removal or vascular surgery, balloon rupture, balloon entrapment, hematomas, and sepsis.[74] [75] The incidence of vascular complications ranges from 12 percent to greater than 40 percent.[74] Most patients who develop limb ischemia after insertion of a balloon pump device have resolution of the ischemia on balloon removal and do not require surgical intervention (thrombectomy, vascular repair, fasciotomy, or amputation). The risk of limb ischemia is heightened in patients with diabetes or peripheral vascular disease, in women, and in patients with a postinsertion ankle-brachial index of less than 0.8.[74] With the development of smaller catheters (8.5F to 9.5F) and the advent of the sheathless insertion techniques, vascular complications have been reduced.[75] [76]

HEMODYNAMIC DATA

The hemodynamic component of the cardiac catheterization procedure focuses on pressure measurements, the measurement of flow (cardiac output, shunt flows, flow across a stenotic orifice, regurgitant flows, coronary blood flow, and so on), and the determination of vascular resistances. Simply stated, flow through a blood vessel is determined by the pressure difference within the vessel and the vascular resistance as described by Ohm's law: Q = DeltaP/R.

Pressure Measurements

Accurate recording of pressure waveforms and correct interpretation of physiological data derived from these waveforms are major goals of cardiac catheterization. A pressure wave is the cyclical force generated by cardiac muscle contraction, and its amplitude and duration are influenced by various mechanical and physiological parameters. The pressure waveform from a particular cardiac chamber is influenced by the force of the contracting chamber and its surrounding structures including the contiguous chambers of the heart, the pericardium, the lungs, and the vasculature. Physiological variables of heart rate and the respiratory cycle also influence the pressure waveform. An understanding of the components of the cardiac cycle is essential to the correct interpretation of hemodynamic data obtained in the catheterization laboratory (see Fig. 14-22) .

PRESSURE MEASUREMENT SYSTEMS.

Intravascular pressures are typically measured using a fluid-filled catheter that is attached to a pressure transducer. The pressure wave is transmitted from the catheter tip to the transducer by the fluid column within the catheter. The majority of pressure transducers used currently are disposable electrical strain gauges. The pressure wave distorts the diaphragm or wire within the transducer. This energy is then converted to an electrical signal proportional to the pressure being applied using the principle of the Wheatstone bridge. This signal is then amplified and recorded as an analog signal.[77]

There are a number of sources of error when pressures are measured using a fluid-filled catheter/transducer system[78] (see Fig. 15-4) . Distortion of the output signal occurs as a result of the frequency response characteristics and damping characteristics of the system. The frequency response of the system is the ratio of the output amplitude to input amplitude over a range of frequencies of the input pressure wave. The natural frequency is the frequency that the system oscillates when it is shock excited in the absence of friction. If the energy of the system is dissipated, such as by friction, this is called *damping.* To ensure a high-frequency response range, the pressure measurement system should have the highest possible natural frequency and optimal damping. Optimal damping dissipates the energy gradually, thus maintaining the frequency response curve as close as possible to an output/input ratio of 1 as it approaches the system's natural frequency. This is achieved by using a short, wide-bore, noncompliant catheter/tubing system that is directly connected to the transducer using a low-density liquid from which all air bubbles have been removed.[77]

The pressure transducer must be calibrated against a known pressure, and the establishment of a zero reference must be undertaken at the start of the catheterization procedure. To "zero" the transducer, the tranducer is placed at the level of the heart, which is approximately midchest. If the transducer is attached to the manifold and is therefore at variable positions during the procedure, a second fluid-filled catheter system should be attached to the transducer and positioned at the level of the heart. All transducers being used during the procedure should be zeroed and calibrated simultaneously.

Other sources of error include catheter whip artifact (motion of the tip of the catheter within the measured chamber), end pressure artifact (an end-hole catheter measures an artificially elevated pressure on account of streaming or high velocity of the pressure wave), catheter impact artifact (when the catheter is impacted by the walls or valves of the cardiac chambers), and catheter tip obstruction within small vessels or valvular orifices occurring because of the size of the catheter itself. The operator must be aware of the many sources of potential error, and when there is a discrepancy between the observed data and the clinical scenario, the system should be examined for errors or artifacts.

MICROMANOMETER CATHETERS.

The use of these catheters, which have the pressure transducer mounted at their tip, greatly reduces many of these errors in measurement. However, their utility is limited by the additional cost and time needed for properly calibrating and using the system. These catheters have higher natural frequencies and more optimal damping characteristics because the interposing fluid column is eliminated. In addition, there is a decrease in catheter whip artifact. The pressure waveform is less distorted and is without the 30- to 40-msec delay seen in the fluid-filled catheter/transducer system. Commercially available high-fidelity micromanometer systems (Millar Instruments, Houston, TX) have both an end hole and side holes to allow for an over-the-wire insertion into the circulation while also permitting angiography. Catheters that have two transducers separated by a short distance are useful for accurate measurement of gradients across valvular structures and within ventricular chambers. The micromanometer system has been used for research purposes to measure the rate of ventricular pressure rise (dP/dt), wall stress, the rate of ventricular pressure decay (-dP/dt), and the time constant of relaxation, and to determine ventricular pressure-volume relationships.[79]

The micromanometer catheter systems have several disadvantages, including their expense, fragility, added procedural time, and the need for sterilization between uses. In addition, the zero level of these systems may drift after the pressure is zeroed to the fluid-filled lumen within the catheter.

Normal Pressure Waveforms

An understanding of the normal pressure waveform morphologies is necessary to comprehend the abnormalities that characterize certain pathological conditions. Normal pressures in the cardiac chambers and great vessels are listed in Table 11-5 . Simply stated, whenever fluid is added to a chamber or compressed within a chamber, the pressure usually rises; conversely, whenever fluid exits from a chamber or the chamber relaxes, the pressure usually falls. One exception to this rule is the early phase of ventricular diastolic filling, when ventricular volume increases after mitral valve opening but ventricular pressure continues to decrease because of active relaxation.[80] Examples of normal pressure waveforms are shown in Figure 11-10) (Figure Not Available) .

ATRIAL PRESSURE.

The *right atrial pressure waveform* has three positive deflections, the a, c, and v waves. The a wave is due to atrial systole and follows the P wave of the ECG. The height of the a wave depends on atrial contractility and the resistance to right ventricular filling. The *x* descent follows the a wave and represents relaxation of the atrium and downward pulling of the tricuspid annulus by right ventricular contraction. The *x* descent is interrupted

TABLE 11-5 -- NORMAL PRESSURES AND VASCULAR RESISTANCES

PRESSURES	AVERAGE (mm Hg)	RANGE (mm Hg)
Right atrium		
a wave	6	2-7

v wave	5	2-7
mean	3	1-5
Right ventricle		
peak systolic	25	15-30
end-diastolic	4	1-7
Pulmonary artery		
peak systolic	25	15-30
end-diastolic	9	4-12
mean	15	9-19
Pulmonary capillary wedge		
mean	9	4-12
Left atrium		
a wave	10	4-16
v wave	12	6-21
mean	8	2-12
Left ventricle		
peak systolic	130	90-140
end-diastolic	8	5-12
Central aorta		
peak systolic	130	90-140
end-diastolic	70	60-90
mean	85	70-105
VASCULAR RESISTANCES	**MEAN (dyne-sec^{-1} cm^{-5})**	**RANGE (dyne-sec^{-1} cm^{-5})**
Systemic vascular resistance	1100	700-1600
Total pulmonary resistance	200	100-300
Pulmonary vascular resistance	70	20-130

by the c wave, which is a small positive deflection due to protrusion of the closed tricuspid valve into the right atrium. Pressure in the atrium rises after the *x* descent owing to passive atrial filling. The atrial pressure then peaks as the v wave, which represents right ventricular systole. The height of the v wave is related to atrial compliance and the amount of blood returning to the atrium from the periphery. The right atrial v wave is generally smaller than the a wave. The *y* descent occurs after the v wave and reflects tricuspid valve opening and right atrial emptying into the right ventricle. During spontaneous respiration, right atrial pressure declines during inhalation as intrathoracic pressure falls. Right atrial pressure rises during exhalation as intrathoracic pressures increase. The opposite effect is seen when patients are mechanically ventilated.

The *left atrial pressure waveform* is similar to that of the right atrium, although normal left atrial pressure is higher, reflecting the high pressure system of the left side of the heart. In the left atrium, as opposed to the right atrium, the v wave is generally higher than the a wave. This occurs because the left atrium is constrained posteriorly by the pulmonary veins, whereas the right atrium can easily decompress throughout the IVC and SVC. The height of the left atrial v wave most accurately reflects left atrial compliance.

PULMONARY CAPILLARY WEDGE PRESSURE.

The pulmonary capillary wedge pressure waveform is similar to the left atrial pressure waveform but is slightly damped and delayed as a result of transmission through the lungs. The a and v waves with both *x* and *y* descents are visible, but c waves may not be seen. In the normal state, the pulmonary artery diastolic pressure is similar to the mean pulmonary capillary wedge pressure because the pulmonary circulation has low resistance. In certain disease states that are associated with elevated pulmonary vascular resistance (hypoxemia, pulmonary embolism, and chronic pulmonary hypertension), and occasionally after mitral valve surgery, the pulmonary capillary wedge pressure may overestimate true left atrial pressure, and in this circumstance accurate measurement of mitral valve gradient may require obtaining direct left atrial pressure.

VENTRICULAR PRESSURE.

Right and left ventricular waveforms are similar in morphology. They differ mainly with respect to their magnitudes. The durations of systole and isovolumic contraction and relaxation are longer, and the ejection period shorter in the left than in the right ventricle. There may be a small (
5 mm Hg) systolic gradient between the right ventricle and the pulmonary artery. Ventricular diastolic pressure is characterized by an early rapid filling wave during which most of the ventricle fills, a slow filling phase and the a wave denoting atrial systolic activity. End-diastolic pressure is generally measured at the C-point, which is the rise in ventricular pressure at the onset of isovolumic contraction (see Fig. 14-22) . When the C-point is not well seen, a line is drawn from the R wave on the simultaneous ECG to the ventricular pressure waveform, and this is used as the end-diastolic pressure.

GREAT VESSEL PRESSURES.

The contour of the *central aortic pressure* and the *pulmonary artery pressure* tracing consists of a systolic wave, the incisura (indicating closure of the semilunar valves), and a gradual decline in pressure until the following systole. The pulse pressure reflects the stroke volume and compliance of the arterial system. The mean aortic pressure more accurately reflects peripheral resistance. As the systemic pressure wave is transmitted through the length of the aorta, the systolic wave increases in amplitude and becomes more triangular, while the diastolic wave decreases until it reaches the midthoracic aorta and then increases. The mean aortic pressures, however, are usually similar, with the mean *peripheral arterial pressure* typically equal to or less than 5 mm Hg lower than the mean central aortic pressure. The difference in systolic pressures between the central aorta and the periphery (femoral, brachial, or radial arteries) is greatest in younger patients owing to their increased vascular compliance. These

Figure 11-10 (Figure Not Available) Normal right- and left-heart pressure recorded from fluid-filled catheter systems in a human. (From Pepine C, Hill JA, Lambert CR [eds]: Diagnostic and Therapeutic Cardiac Catheterization. 3rd ed. Baltimore, Williams & Wilkins, 1998.)

potential differences between proximal aorta and peripheral artery must be considered in order to measure and interpret the peak systolic pressure gradient between the left ventricle and systemic arterial system in patients with suspected aortic stenosis.

ABNORMAL PRESSURE CHARACTERISTICS.

Abnormal pressure waveforms may be diagnostic of specific pathological conditions. Although these conditions are discussed in greater detail elsewhere in this book, Table 11-6 summarizes the more commonly encountered waveforms.

TABLE 11-6 -- PATHOLOGICAL WAVEFORMS

I. Right atrial pressure waveforms

A. Low mean atrial pressure
1. Hypovolemia
2. Improper zeroing of the transducer
B. Elevated mean atrial pressure
1. Intravascular volume overload states
2. Right ventricular failure due to valvular disease (tricuspid or pulmonic stenosis or regurgitation)
3. Right ventricular failure due to myocardial disease (right ventricular ischemia, cardiomyopathy)
4. Right ventricular failure due to left heart failure (mitral stenosis/regurgitation, aortic stenosis/regurgitation, cardiomyopathy, ischemia)
5. Right ventricular failure due to increased pulmonary vascular resistance (pulmonary embolism, chronic obstructive pulmonary disease, primary pulmonary hypertension)
6. Pericardial effusion with tamponade physiology
7. Obstructive atrial myxoma
C. Elevated a wave (any increase to ventricular filling)
1. Tricuspid stenosis
2. Decreased ventricular compliance due to ventricular failure, pulmonic valve stenosis, or pulmonary hypertension
D. Cannon a wave
1. Atrial-ventricular asynchrony (atria contract against a closed tricuspid valve, as during complete heart block, following premature ventricular contraction, during ventricular tachycardia, with ventricular pacemaker)
E. Absent a wave
1. Atrial fibrillation or atrial standstill
2. Atrial flutter
F. Elevated v wave
1. Tricuspid regurgitation
2. Right ventricular heart failure
3. Reduced atrial compliance (restrictive myopathy)
G. a wave equal to v wave
1. Tamponade
2. Constrictive pericardial disease
3. Hypervolemia
H. Prominent *x* descent
1. Tamponade
2. Subacute constriction and possibly chronic constriction
3. Right ventricular ischemia with preservation of atrial contractility
I. Prominent *y* descent
1. Constrictive pericarditis
2. Restrictive myopathies
3. Tricuspid regurgitation
J. Blunted *x* descent
1. Atrial fibrillation
2. Right atrial ischemia
K. Blunted *y* descent
1. Tamponade
2. Right ventricular ischemia
3. Tricuspid stenosis
L. Miscellaneous abnormalities
1. Kussmaul's sign (inspiratory rise or lack of decline in right atrial pressure): constrictive pericarditis, right ventricular ischemia
2. Equalization (
5 mm Hg) of mean right atrial ventricular diastolic, pulmonary artery diastolic, pulmonary capillary wedge, and pericardial pressures in tamponade
3. M or W patterns: right ventricular ischemia, pericardial constriction, congestive heart failure
4. Ventricularization of the right atrial pressure: severe tricuspid regurgitation
5. Sawtooth pattern: atrial flutter
6. Dissociation between pressure recording and intracardiac electrocardiogram: Ebstein's anomaly

II. Left atrial pressure/pulmonary capillary wedge pressure waveforms
A. Low mean pressure
1. Hypovolemia
2. Improper zeroing of the transducer
B. Elevated mean pressure
1. Intravascular volume overload states
2. Left ventricular failure due to valvular disease (mitral or aortic stenosis or regurgitation)
3. Left ventricular failure due to myocardial disease (ischemia or cardiomyopathy)
4. Left ventricular failure due to systemic hypertension
5. Pericardial effusion with tamponade physiology
6. Obstructive atrial myxoma
C. Elevated a wave (any increase to ventricular filling)
1. Mitral stenosis
2. Decreased ventricular compliance due to ventricular failure, aortic valve stenosis, or systemic hypertension
D. Cannon a wave
1. Atrial-ventricular asynchrony (atria contract against a closed mitral valve, as during complete heart block, following premature ventricular contraction, during ventricular tachycardia, with ventricular pacemaker)
E. Absent a wave
1. Atrial fibrillation or atrial standstill
2. Atrial flutter
F. Elevated v wave
1. Mitral regurgitation
2. Left ventricular heart failure
3. Ventricular septal defect
G. a wave equal to v wave
1. Tamponade
2. Constrictive pericardial disease
3. Hypervolemia
H. Prominent *x* descent
1. Tamponade
2. Subacute constriction and possibly chronic constriction
I. Prominent *y* descent
1. Constrictive pericarditis
2. Restrictive myopathies
3. Mitral regurgitation
J. Blunted*x* descent
1. Atrial fibrillation
2. Atrial ischemia K. Blunted *y* descent
1. Tamponade
2. Ventricular ischemia
3. Mitral stenosis
L. Pulmonary capillary wedge pressure not equal to left ventricular end-diastolic pressure
1. Mitral stenosis
2. Left atrial myxoma
3. Cor triatriatum
4. Pulmonary venous obstruction
5. Decreased ventricular compliance
6. Increased pleural pressure7. Placement of catheter in a nondependent zone of lung

III. Pulmonary artery pressure waveforms
A. Elevated systolic pressure
1. Primary pulmonary hypertension
2. Mitral stenosis or regurgitation
3. Congestive heart failure
4. Restrictive myopathies
5. Significant left-to-right shunt
6. Pulmonary disease (pulmonary embolism, hypoxemia, chronic obstructive pulmonary disease)
B. Reduced systolic pressure
1. Hypovolemia
2. Pulmonary artery stenosis
3. Subvalvular or supravalvular stenosis
4. Ebstein's anomaly
5. Tricuspid stenosis
6. Tricuspid atresia
C. Reduced pulse pressure
1. Right heart ischemia
2. Right ventricular infarction
3. Pulmonary embolism
4. Tamponade
D. Bifid pulmonary artery waveform
1. Large left atrial v wave transmitted backward (i.e. MR)
E. Pulmonary artery diastolic pressure greater than pulmonary capillary wedge pressure
1. Pulmonary disease
2. Pulmonary embolus
3. Tachycardia
IV. Ventricular pressure waveforms
A. Systolic pressure elevated
1. Pulmonary or systemic hypertension
2. Pulmonary valve or aortic valve stenosis
3. Ventricular outflow tract obstruction
4. Supravalvular obstruction
5. Right ventricular pressure elevation with significant:
a. Atrial septal defect
b. Ventricular septal defect
6. Right ventricular pressure elevation due to factors that increase pulmonary vascular resistance (see factors that increase right atrial pressure)
B. Systolic pressure reduced
1. Hypovolemia
2. Cardiogenic shock
3. Tamponade
C. End-diastolic pressure elevated
1. Hypervolemia
2. Congestive heart failure
3. Diminished compliance
4. Hypertrophy
5. Tamponade
6. Regurgitant valvular disease
7. Pericardial constrictoin
D. End-diastolic pressure reduced
1. Hypovolemia
2. Tricuspid or mitral stenosis
E. Diminished or absent a wave
1. Atrial fibrillation or flutter
2. Tricuspid or mitral stenosis
3. Tricuspid or mitral regurgitation when ventricular compliance is increased
F. Dip and plateau in diastolic pressure wave
1. Constrictive pericarditis
2. Restrictive myopathies
3. Right ventricular ischemia
4. Acute dilatation associated with:
a. Tricuspid regurgitation
b. Mitral regurgitation
G. Left ventricular end-diastolic pressure > right ventricular end-diastolic pressure
1. Restrictive myopathies
V. Aortic pressure waveforms
A. Systolic pressure elevated
1. Systemic hypertension
2. Arteriosclerosis
3. Aortic insufficiency
B. Systolic pressure reduced
1. Aortic stenosis
2. Heart failure
3. Hypovolemia
C. Widened pulse pressure
1. Systemic hypertension
2. Aortic insufficiency
3. Significant patent ductus arteriosus
4. Significant ruptures sinus of Valsalva aneurysm
D. Reduced pulse pressure
1. Tamponade
2. Congestive heart failure
3. Cardiogenic shock
4. Aortic stenosis
E. Pulsus bisferiens
1. Aortic insufficiency
2. Obstructive hypertrophic cardiomyopathy
F. Pulsus paradoxus
1. Tamponade
2. Chronic obstructive airway disease
3. Pulmonary embolism
G. Pulsus alternans
1. Congestive heart failure
2. Cardiomyopathy
H. Pulsus parvus et tardus
1. Aortic stenosis

3. Pulmonary embolism
G. Pulsus alternans
1. Congestive heart failure
2. Cardiomyopathy
H. Pulsus parvus et tardus
1. Aortic stenosis
I. Spike-and-dome configuration
1. Obstructive hypertrophic cardiomyopathy

Cardiac Output Measurements

There is no totally accurate method of measuring cardiac output, but it can be estimated on the basis of various assumptions. The two most commonly used methods are the Fick method and thermodilution method. For comparison among patients, cardiac output is often corrected for the patient's size based on the body surface area and expressed as cardiac index.

INDICATOR-DILUTION TECHNIQUES.

The indicator-dilution method has been used to measure cardiac output since its introduction by Stewart in 1897 and subsequent modification by Hamilton and associates in 1932. The basic equation, commonly referred to as the Stewart-Hamilton equation, follows:

The assumption is made that after the injection of a certain quantity of an indicator into the circulation, the indicator appears and disappears from any downstream point in a manner commensurate with the cardiac output. For example, if the indicator rapidly appears at a specific location downstream and then washes out quickly, the assumption is that the cardiac output is high. Although variation can occur, the site of injection is usually a systemic vein or the right side of the heart, and the sampling site is generally a systemic artery. The normal curve itself has an initial rapid upstroke followed by a slower downstroke and eventual appearance of recirculation of the tracer (Fig. 11-11) . In practice, this recirculation creates some uncertainty on the tail of the curve, and assumptions are required to correct for this distortion. Because the indicator concentration declines exponentially in the absence of recirculation, the initial data points from the descending limb are used to extrapolate the remainder of the descending limb. The area under both the ascending and descending limbs is then determined along with the total curve duration. The area of the curve is assumed to be a function of the mean indicator concentration. Both variables can be substituted in the Stewart-Hamilton equation to calculate the cardiac output.

There are several sources of error in this determination. Because the dye is unstable over time and can be affected by light, fresh preparations of indocyanine green dye are necessary.`The exact amount of dye must be accurately measured, as it is crucial to the performance of the study. It is generally administered through a tuberculin syringe and injected rapidly as a single bolus. After injection, the indicator must mix well before reaching the sampling site, and the dilution curve must have an exponential decay over time so that extrapolation can be performed. If, for example, there is severe valvular regurgitation or a low cardiac output state in which the washout

---

Figure 11-11 Thermodilution Cardiac Output Curves. A normal curve has a sharp upstroke following an injection of saline. A smooth curve with mildly prolonged downslope occurs until back to baseline. The area under curve is inversely related to the cardiac output. At low cardiac output, a prolonged period is required to return to baseline. Therefore, there is a larger area under the curve. In a high cardiac output state, the cooler saline injectate moves faster through the right side of the heart and temperature returns to baseline more quickly. The area under curve is smaller and the output is higher.

of the indicator is prolonged and recirculation begins well before an adequate decline in the indicator curve occurs, determinations will be erroneous. Intracardiac shunts may also greatly affect the shape of the curve.

THERMODILUTION TECHNIQUES.

Because of the rather tedious and time-consuming nature of the indicator-dilution method, it has been replaced by thermodilution techniques in many laboratories. The development of balloon flotation (e.g., Swan-Ganz) catheters with a proximal port and distal thermistor (see Fig. 11-1) has greatly expanded the ability to obtain thermodilution cardiac outputs in many clinical settings.

The thermodilution procedure requires injection of a bolus of liquid (saline or dextrose) into the proximal port of the catheter. The resultant change in temperature in the liquid is measured by a thermistor mounted in the distal end of the catheter. The change in temperature versus time can be plotted in a manner similar to the dye-dilution method described earlier (in which the indicator is now the cooler liquid). The cardiac output is then calculated using an equation that considers the temperature and specific gravity of the injectate and the temperature and specific gravity of the blood, along with the injectate volume. A calibration factor is also used. The cardiac output is inversely related to the area under a thermodilution curve, plotted as a function of temperature versus time, with a smaller area indicative of a higher cardiac output.

The thermodilution method has several advantages. It obviates the need for withdrawal of blood from an arterial site and is less affected by recirculation. Perhaps its greatest advantage is the rapid display of results using computerized methods (see Fig. 11-11) . Computers use the washout rate represented by the downslope of the curve to obtain a decay constant to correct the descending limb and compute the cardiac output.

Thermodilution cardiac output measurements are susceptible to pitfalls similar to those encountered with indicator-dilution methods using indocyanine green. Because the data represent right-sided heart output, tricuspid regurgitation can be a particular problem as the bolus of saline is subsequently broken up. The thermodilution method tends to overestimate cardiac output in low-output states, because the dissipation of the cooler temperature to the surrounding cardiac structures results in reduction in the total area under the curve, causing a falsely elevated cardiac output value. Other difficulties include fluctuations in blood temperature during respiratory or cardiac cycles and the warming of the temperature of the injectate before its injection into the catheter. Because of these possible limitations, the general practice is to calculate the average of several (usually three to five) cardiac output determinations.

From a practical viewpoint, thermodilution cardiac output measurements have become standard practice. Their variability can be relatively large; thus, small changes should not be overinterpreted. Practically, cardiac output data can be defined only to within a 15 percent range.[81]

FICK TECHNIQUE.

The Fick principle, first described by Adolph Fick in 1870, assumes that the rate at which oxygen is consumed is a function of the rate of blood flow times the rate of oxygen pick-up by the red blood cells. The basic assumption is that the flow of blood in a given period is equal to the amount of substance entering the stream of flow in the same period divided by the difference between the concentrations of the substance in the blood upstream and downstream from its point of entry into the circulation[82] (Fig. 11-12) . The same number of red blood cells that enter the lung must leave the lung, if no intracardiac shunt is present. Thus, if certain parameters were known (the number of oxygen molecules that were attached to the red blood cells entering the lung, the number of oxygen molecules that were attached to the red blood cells leaving the lung, and the number of oxygen molecules consumed during travel through the lung), then the rate of flow of these red blood cells as they pass through the lung could be determined. This can be expressed in the following terms:

Measurements must be made in steady state. Automated methods can accurately determine the oxygen content within the blood samples. Thus, the greatest source of measurement variability is that of the oxygen consumption. In traditional Fick determinations, expiratory gas samples

Figure 11-12 Schematic illustration of flow measurement using the Fick principle. Fluid containing a known concentration of an indicator (C_{in}) enters a system at flow rate, Q. As the fluid passes through the system, indicator is continuously added at rate V, raising the concentration in the outflow to C_{out}. In a steady state, the rate of indicator leaving the system (QC_{out}) must equal the rate at which it enters (QC_{in}) plus the rate at which it is added (V). When oxygen is used as the indicator, cardiac output can be determined by measuring oxygen consumption (VO_2), arterial oxygen content ($C_A O_2$), and mixed venous oxygen content ($C_v O_2$). (From Winniford MD, Kern MJ, Lambert CR [eds]: Blood flow measurement. *In* Pepine CJ, Hill JA, Lambert CR [eds]: Diagnostic and Therapeutic

were collected in a large bag over a specified period. By measuring the expiratory oxygen concentration and by knowing the concentration of oxygen in room air, the quantity of oxygen consumed over time could be determined. In newer techniques that allow for measurement of expired oxygen, concentration is quantified by using a polarigraph. This device can be connected to the patient by use of a plastic hood or by a mouthpiece and tubing.

The advantage of the Fick method is that it is the most accurate method in patients with low cardiac output and thus is preferred over the thermodilution method in these circumstances. It is also independent of the factors that affect curve shape and cause errors in thermodilution cardiac output. The Fick method suffers primarily from the difficulty in obtaining accurate oxygen consumption measurements and the inability to obtain a steady state under certain conditions. Because the method assumes mean flow over a period of time, it is not suitable during rapid change in flow. It requires considerable time and effort on the part of the catheterization laboratory to obtain the appropriate data. Many laboratories use an "assumed" Fick method in which oxygen consumption index is assumed on the basis of the patient's age, gender, and body surface area or an estimate made (125 ml/m^2) on the basis of body surface area. The inaccuracy of oxygen consumption measurements results in up to 10 percent variability in the calculated cardiac output, which may be even greater when assumed oxygen consumption, rather than measured oxygen consumption, is used.

ANGIOGRAPHIC CARDIAC OUTPUT.

Angiographic stroke volume can be calculated from tracing the end-diastolic and end-systolic images. Stroke volume is the quantity of blood ejected with each beat. End-diastolic volume is the maximum left ventricular volume and occurs immediately before the onset of systole. This occurs immediately after atrial contraction in patients in sinus rhythm. End-systolic volume is the minimum volume during the cardiac cycle. Calibration of the images with calibrated grids or ventricular phantoms is necessary to obtain accurate ventricular volumes. Angiographic cardiac output and stroke volume are derived from the following equations:

where EDV = end-diastolic volume and ESV = end-systolic volume. The inherent inaccuracies of calibrating angiographic volumes often make this method of measurement unreliable. In cases of valvular regurgitation or atrial fibrillation, angiographic cardiac output does not accurately measure true systemic outputs. However, the angiographic cardiac output is preferred over the Fick or thermodilution output for calculation of stenotic valve areas in patients with significant aortic or mitral regurgitation.

DETERMINATION OF VASCULAR RESISTANCE.

Vascular resistance calculations are based on hydraulic principles of fluid flow, in which resistance is defined as the ratio of the decrease in pressure between two points in a vascular segment and the blood flow through the segment. Although this straightforward analogy to Ohm's law represents an oversimplification of the complex behavior of pulsatile flow in dynamic and diverse vascular beds, the calculation of vascular resistance based on these principles has proved to be of value in a number of clinical settings.

Determination of the resistance in a vascular bed requires measurement of the mean pressure of the proximal and distal ends of the vascular bed and accurate measurement of cardiac output. For this purpose, measurement of cardiac output by the Fick, the indicator-dilution, or the thermodilution method is preferred. Vascular resistance (R) is usually defined in absolute units (dyne-sec cm^{-5}) and is defined as R = [mean pressure gradient (dyne/cm^2)]/[mean flow (cm^3 /sec)]. Hybrid units (Wood units) are less often used.[83]

Systemic vascular resistance in absolute units is calculated using the following equation:

where A_{Om} and RA_m are the mean pressures (in mm Hg) in the aorta and right atrium, respectively, and Q_s is the systemic cardiac output (in liters/min). The constant 80 is used to convert units from mm Hg/liters/min (Wood units) to the absolute resistance units dyne-sec cm^{-5} . If the right atrial pressure is not known, the term RA_m can be dropped, and the resulting value is called the *total peripheral resistance* (TPR).

Similarly, the pulmonary vascular resistance is derived from the following equation:

where PA_m and LA_m are the pulmonary artery and left atrial pressures, respectively, and Q_p is the pulmonary blood flow. Mean pulmonary capillary wedge pressure is commonly substituted for mean left atrial pressure if the latter has not been measured directly.[84] In the absence of an intracardiac shunt, Q_p is equal to the systemic cardiac output.

Normal values are listed in Table 11-5 .

Elevated resistances in the systemic and pulmonary circuits may represent reversible abnormalities or may be fixed owing to irreversible anatomical changes. In several clinical situations, such as congestive heart failure, valvular heart disease, primary pulmonary hypertension, and congenital heart disease with intracardiac shunting, determination of whether elevated systemic or pulmonary vascular resistance can be lowered transiently in the catheterization laboratory may provide important insights into potential management strategies. Interventions that may be used in the laboratory for this purpose include administration of vasodilating drugs (e.g., sodium nitroprusside), exercise, and (in patients with pulmonary hypertension) oxygen inhalation.

Vascular impedance measurements account for blood viscosity, pulsatile flow, reflected waves, and arterial compliance. Hence, vascular impedance has the potential to describe the dynamic relation between pressure and flow more comprehensively than is possible using the simpler calculations of vascular resistance. However, because the simultaneous pressure and flow data required for the calculation of impedance are complex and difficult to obtain, the concept of impedance has failed to gain widespread acceptance, and vascular impedance has not been adopted as a routine clinical index in most laboratories.

Evaluation of Valvular Stenosis (See also Chap. 46)

Determining the severity of valvular stenosis on the basis of the pressure gradient and flow across the valve is one of the most important aspects of evaluating patients with valvular heart disease. In most patients, the magnitude of the

pressure gradient alone is sufficient to distinguish clinically significant from insignificant valvular stenosis.

DETERMINATION OF PRESSURE GRADIENTS.

In patients with *aortic stenosis,* the transvalvular pressure gradient should be measured, whenever possible, with a catheter in the left ventricle and another in the proximal aorta. Although it is convenient to measure the gradient between the left ventricle and the femoral artery, downstream augmentation of the pressure signal and delay in pressure transmission between the proximal aorta and femoral artery may alter the pressure waveform substantially and introduce errors into the measured gradient.[85]

Left ventricular-femoral artery pressure gradients may suffice in many patients as an estimate of the severity of aortic stenosis to confirm the presence of a severely stenotic valve. If the side port of the arterial introducing sheath is used to monitor femoral pressure, the inner diameter of the sheath should be 1F size larger than the outer diameter of the catheter being used. The left ventricular-femoral artery pressure gradient may not always be relied on in the calculation of valve orifice area in

patients with equivocal valve gradients. A careful single catheter pull-back from left ventricle to aorta is often preferable to simultaneous measurement of left ventricular and femoral artery pressures. Alternatively, a single catheter with distal and proximal lumina or a micromanometer catheter with distal and proximal transducers may be used for simultaneous measurement of left ventricular pressure and central aortic pressure. Another method is to place two catheters, one in the aorta and the second in the left ventricle. However, this requires two punctures of the femoral artery and is rarely used.

In patients with very severe aortic stenosis, the left ventricular catheter itself may reduce the effective orifice area, resulting in an artifactual increase in the measured pressure gradient.[86] This overestimation of the severity of aortic stenosis is rarely an important issue, because the diagnosis of severe aortic stenosis is usually already apparent in such patients.

The mean pressure gradient across the aortic valve is determined by planimetry of the area separating the left ventricular and aortic pressures using multiple beats (Fig. 11-13) , and it is this gradient that is applied to calculation

Figure 11-13 Various methods of describing an aortic transvalvular gradient. The peak-to-peak gradient (47 mm Hg) is the difference between the maximal pressure in the aorta (Ao) and the maximal left ventricle (LV) pressure. The peak instantaneous gradient (100 mm Hg) is the maximal pressure difference between the Ao and LV when the pressures are measured in the same moment (usually during early systole). The mean gradient (shaded area) is the integral of the pressure difference between the LV and Ao during systole (60 mm Hg). (From Bashore TM: Invasive Cardiology: Principles and Techniques. Philadelphia, BC Decker, 1990.)

Figure 11-14 Pressure gradient in a patient with mitral stenosis. The pressure in the left atrium (LA) exceeds the pressure in the left ventricle (LV) during diastole, producing a diastolic pressure gradient (shaded area). (From Bashore TM: Invasive Cardiology: Principles and Techniques. Philadelphia, BC Decker, 1990.)

of the valve orifice area. The peak-to-peak gradient, measured as the difference between peak left ventricular pressure and peak aortic pressure, is commonly used to quantify the valve gradient, because this measurement is rapidly obtained and can be estimated visually. There is no physiological basis for the peak-to-peak gradient, however, because the maximum left ventricular and aortic pressures rarely occur simultaneously. The peak-to-peak gradient measured in the catheterization laboratory is generally lower than the peak instantaneous gradient measured in the echocardiography laboratory. This is because the peak instantaneous gradient represents the maximum pressure difference between the left ventricle and aorta when measured simultaneously. This occurs on the upslope of the aortic pressure tracing (Fig. 11-13) . Mean aortic transvalvular gradient and aortic valve area are well correlated with both techniques (r = 0.86 - 0.90 and r = 0.88 - 0.95, respectively).[87]

In patients with *mitral stenosis,* the most accurate means of determining mitral valve gradient is measurement of left atrial pressure using the transseptal technique with simultaneous measurement of left ventricular pressure and with planimetry of the area bounded by the left ventricular and left atrial pressures in diastole using several cardiac cycles (Fig. 11-14) . In most laboratories, the pulmonary capillary wedge pressure is substituted for the left atrial pressure, as the pulmonary wedge pressure is more readily obtained. The pulmonary wedge pressure tracing must be realigned with the left ventricular tracing for accurate mean gradient determination. Although it has been generally accepted that pulmonary capillary wedge pressure is a satisfactory estimate of left atrial pressure,[84] some studies indicate that the pulmonary wedge pressure may systematically overestimate the left atrial pressure by 2 to 3 mm Hg, thereby increasing

the measured mitral valve gradient.[88] In addition, accurate wedge tracings may be difficult to obtain in patients with mitral stenosis because of pulmonary hypertension or dilated right-sided heart chambers. Improperly wedged catheters, resulting in damped pulmonary artery pressure recordings, further overestimate the severity of mitral stenosis. If there is doubt about the accurate position of the catheter in the wedge position, the position can be confirmed by slow withdrawal of blood for oximetric analysis. An oxygen saturation equal to that of the systemic circulation confirms the wedge position.

In *pulmonic stenosis,* the valve gradient is usually obtained by a catheter pull-back from the pulmonary artery to the right ventricle, although multilumen catheters are available for simultaneous pressure recordings. *Tricuspid valve gradients* should be assessed with simultaneous recording of right atrial and right ventricular pressures.

CALCULATION OF STENOTIC VALVE ORIFICE AREAS.

The stenotic orifice area is determined from the pressure gradient and cardiac output using the formula developed by Gorlin and Gorlin from the fundamental hydraulic relationships linking the area of an orifice to the flow and pressure drop across the orifice.[89] Flow (F) and orifice area (A) are related by the fundamental formula

where V is velocity of flow and c is a constant accounting for central streaming of fluid through an orifice which tends to reduce the effective orifice size. Hence,

Velocity is related to the pressure gradient through the relation V=k sqrt(2gDeltaP), where k is a constant accounting for frictional energy loss, g is the acceleration due to gravity (980 cm/sec^2) and DeltaP is the mean pressure gradient (mm Hg). Substituting for V in the orifice area equation and combining c and k into one constant C,

Gorlin and Gorlin determined the value of the constant C by comparing the calculated valve area with actual valve area measured at autopsy or at surgery in 11 mitral valves. The maximal discrepancy between the actual mitral valve area and calculated values was only 0.2 cm^2 when the constant 0.85 was used. No data were obtained for aortic valves, a limitation noted by the Gorlins, and a constant of 1.0 was assumed. Because flow across the aortic valve occurs only in systole, the flow value for calculating aortic valve area (cm^2) is the cardiac output in ml/min divided by the systolic ejection period (SEP) in seconds/beat times the heart rate (HR) in beats/min. The systolic ejection period is defined from aortic valve opening to closure. Hence, the aortic valve area is calculated from the Gorlin formula using the following equation:

Similarly, as mitral flow occurs only in diastole, the cardiac output is corrected for the diastolic filling period (DFP) in seconds/beat in the equation for mitral valve area, where the diastolic filling period is defined from mitral valve opening to mitral valve closure:

The normal aortic valve area is 2.6 to 3.5 cm^2 in adults. Valve areas of 0.8 cm^2 or less represent severe aortic stenosis. The normal mitral valve area is 4 to 6 cm^2 , and severe mitral stenosis is present with valve areas less than 1.3 cm^2 .

The calculated valve area often is crucial in management decisions in patients with aortic stenosis or mitral stenosis. Hence, it is essential that accurate and simultaneous pressure gradient and cardiac output determinations be made, especially in patients with borderline or low pressure gradients.

LIMITATIONS OF THE ORIFICE AREA FORMULA.

As the square root of the mean gradient is used in the Gorlin formula, the valve area calculation is more strongly influenced by the cardiac output than the pressure gradient. Thus, errors in measuring cardiac output may have profound effects on the calculated valve area, particularly in patients with low cardiac outputs, in whom the calculated valve area is often of greatest importance.

The Fick method of determining cardiac output is the most accurate for assessing cardiac output, especially in low-output states. As noted previously, both the dye-dilution technique and the thermodilution technique may provide inaccurate cardiac output data when cardiac output is reduced or when concomitant aortic, mitral, or tricuspid regurgitation is present. In patients with mixed valvular disease (stenosis and regurgitation) of the same valve, the use of forward flow as determined by the Fick method or thermodilution technique overestimates the severity of the valvular stenosis. This is because the Gorlin formula depends on total forward flow across the stenotic valve, not net forward flow. If valvular regurgitation is present, the angiographic cardiac output is the most appropriate measure of flow. If both aortic and

mitral regurgitation are present, flow across a single valve cannot be determined and neither aortic valve area nor mitral valve area can be assessed accurately.

Other potential errors and limitations are inherent in the use of the Gorlin formula,[90] [91] related both to inaccuracies in measurement of valve gradients and to more fundamental issues regarding the validity of the assumptions underlying the formula. In low-output states, the Gorlin formula may systematically predict smaller valve areas than are actually present. Several lines of evidence indicate that the aortic valve area by the Gorlin formula increases with increases in cardiac output.[92] [93] [94] Although this may represent an actual greater opening of stenotic valves by the higher proximal opening pressures that result from increases in transvalvular flow, the flow dependence of the calculated valve area may also reflect inherent errors in the assumptions underlying the Gorlin formula, particularly with respect to the aortic valve.[90] [95]

A study was performed to compare simultaneous aortic valve area determinations by transesophageal echocardiographic planimetry and the Gorlin formula.[96] This demonstrated that with increases in transvalvular flow, the Gorlin valve area also increased. This was not associated with alterations in direct planimetry of the aortic valve area. These results suggest that flow-related variation in the Gorlin aortic valve area is due to disproportional flow depedence of the formula and not a true change in the valve area.

Cannon and colleagues[93] demonstrated in valves of fixed orifice size that the constant in the Gorlin formula is actually not constant but varies with the square root of the mean pressure gradient (C=k sqrt(mean gradient)). This concept would transform the Gorlin formula such that the square root disappears and the valve area varies inversely with the mean gradient:

This concept has particular implications in aortic stenosis, in which the higher valve gradients have a greater effect on the Gorlin constant than the considerably smaller gradients encountered in mitral stenosis. The constant h was added to correct for a small offset between predicted and measured valve areas. The values of the new constants K and h have not been fully validated, and the complete independence of these constants from transvalvular flow has not been well investigated.

Other alternative formulas for determining valve areas have been proposed. Hakki[97] observed empirically that the effects of the systolic ejection period and the diastolic filling period were relatively constant at normal heart rates and proposed eliminating this term from the equation. This assumes that (HR × SEP × 44.3) 1000 in most circumstances. In this modified and simplified approach, the aortic valve area would be determined by the following formula:

Angel and colleagues[98] tested this approach at various heart rates and proposed adding an empirical constant for heart rates less than 75 beats/min for mitral stenosis and more than 90 beats/min for aor

tic stenosis. As is the case with Cannon's modification of the Gorlin formula, this alternate approach to determining valve area has not been fully validated.

One approach to patients with a low aortic transvalvular gradient and low cardiac output is to calculate the aortic valve resistance using the following formula:

where HR is heart rate, SEP is systolic ejection period, and valve resistance is expressed in dyne-sec cm^{-5} . [94] [99] The limited data available using aortic valve resistance suggest that this measure may be a helpful adjunct in distinguishing those patients with borderline aortic valve areas (0.6 to 0.8 cm^{2}) who have severe versus mild aortic stenosis.

Measurement of Intraventricular Pressure Gradients

The demonstration of an intracavitary pressure gradient is among the most interesting and challenging aspects of diagnostic catheterization. Simultaneous pressure measurements are usually obtained in the central aorta and from within the ventricular cavity. Pull-back of the catheter from the ventricular apex to a posterior position just beneath the aortic valve demonstrates an intracavitary gradient. An erroneous intracavitary gradient may be seen if the catheter becomes entrapped by the myocardium.

The intracavitary gradient is distinguished from aortic valvular stenosis due to the loss of the aortic-left ventricular gradient when the catheter is still within the left ventricle yet proximal to the myocardial obstruction (see Fig. 48-12) (Figure Not Available) . In addition, careful analysis of the upstroke of the aortic pressure waveform will distinguish a valvular from a subvalvular stenosis, as the aortic pressure waveform demonstrates a slow upstroke in aortic stenosis. Other methods to localize intracavitary gradients include the use of a dual-lumen catheter or a double-sensor romanometer catheter, or placement of an end-hole catheter in the left ventricular outflow tract while a transseptal catheter is advanced into the left ventricle, with pressure measured simultaneously. An intracavitary gradient may be increased by various provocative maneuvers including the Valsalva maneuver, inhalation of amyl nitrate, introduction of a premature ventricular beat, or isoproterenol infusion (see Physiological and Pharmacological Maneuvers).

Assessment of Valvular Regurgitation

VISUAL ASSESSMENT OF REGURGITATION.

Valvular regurgitation may be assessed visually by determining the relative amount of radiographic contrast medium that opacifies the chamber proximal to its injection. The estimation of regurgitation depends on the regurgitant volume as well as the size and contractility of the proximal chamber. The original classification scheme devised by Sellers and colleagues remains the standard in most catheterization laboratories:[100]

++++

Minimal regurgitant jet seen. Clears rapidly from proximal chamber with each beat

++++

Moderate opacification of proximal chamber, clearing with subsequent beats

++++

Intense opacification of proximal chamber, becoming equal to that of the distal chamber

++++

Intense opacification of proximal chamber, becoming more dense than that of the distal chamber. Opacification often persists over the entire series of images obtained

REGURGITANT FRACTION.

A gross estimate of the degree of valvular regurgitation may be obtained by determining the regurgitant fraction (RF). The difference between the angiographic stroke volume and the forward stroke volume can be defined as the regurgitant stroke volume. The RF is that portion of the angiographic stroke volume that does not contribute to the net cardiac output.

Forward stroke volume is the cardiac output determined by the Fick or thermodilution method divided by the heart rate. Thermodilution cardiac output cannot be used if there is significant concomitant tricuspid regurgitation.

As detected visually, 1+regurgitation is roughly equivalent to an RF less than or equal to 20 percent; 2+ regurgitation to an RF of 21 to 40 percent; 3+41 to 60 percent; and 4+ to more than 60 percent.

The assumption underlying the determination of RF is that the angiographic and forward cardiac outputs are accurate and comparable, a state requiring similar heart rates, stable hemodynamic states between measurements, and only a single regurgitant valve. Given these conditions, the equation yields only a gross approximation of regurgitant flow.

Shunt Determinations

Normally, pulmonary blood flow and systemic blood flow are equal. With an abnormal communication between intracardiac chambers or great vessels, blood flow is shunted either from the systemic circulation to the pulmonary circulation (left-to-right shunt), from the pulmonary circulation to the systemic circulation (right-to-left shunt), or in both directions (bidirectional shunt). Although many shunts are suspected before cardiac catheterization, physicians performing the procedure should be vigilant in determining the cause of unexpected findings. For example, an unexplained pulmonary artery oxygen saturation exceeding 80 percent should raise the operator's suspicion of a left-to-right shunt, whereas unexplained arterial desaturation (<93 percent) may indicate a right-to-left shunt.[101] Arterial desaturation commonly results from alveolar hypoventilation and associated "physiological shunting," the causes of which include oversedation from premedication, pulmonary disease, pulmonary venous congestion, pulmonary edema, and cardiogenic shock. If arterial desaturation persists after the patient takes several deep breaths or coughs or after administration of 100 percent oxygen, a right-to-left shunt must be highly suspected.

Several noninvasive and invasive methods are available for detection of intracardiac shunts. Noninvasive methods include echocardiographic, radionuclide, and magnetic resonance imaging techniques. The most commonly used method in the cardiac catheterization laboratory is the oximetric method.

OXIMETRIC METHOD.

The oximetric method is based on blood sampling from various cardiac chambers for the determination of oxygen saturation. A left-to-right shunt is detected when a significant increase in blood oxygen saturation is found between two right-sided vessels or chambers.[102]

A screening oxygen saturation measurement for any left-to-right shunt should be performed with right heart catheterization by sampling blood in the SVC and the pulmonary artery. If the difference in oxygen saturation between these

samples is 8 percent or more, a left-to-right shunt may be present, and a full oximetry "run" should be performed.[101] This includes obtaining blood samples from all right-sided locations including the SVC, IVC, right atrium, right ventricle, and pulmonary artery. In cases of interatrial or interventricular shunts, it may be helpful to obtain multiple samples from the high, middle, and low right atrium or the right ventricular inflow tract, apex, and outflow tract in order to localize the level of the shunt. One may miss a small left-to-right shunt using the right atrium for screening purposes rather than the SVC because of incomplete mixing of blood in the right atrium, which receives blood from the IVC, SVC, and coronary sinus. Oxygen saturation in the IVC is higher than in the SVC because the kidneys use less oxygen relative to their blood flow than do other organs, whereas coronary sinus blood has very low oxygen saturation. Mixed venous saturation is most accurately measured in the pulmonary artery after complete mixing has occurred.

A full saturation run involves obtaining samples from the high and low IVC; high and low SVC; high, mid, and low right atrium; right ventricular inflow and outflow tracts and midcavity; main pulmonary artery; left or right pulmonary artery; pulmonary vein and left atrium if possible; left ventricle; and distal aorta. When a right-to-left shunt must be localized, oxygen saturation samples must be taken from the pulmonary veins, left atrium, left ventricle, and aorta. Although the major weakness of the oxygen step-up method is its lack of sensitivity, clinically significant shunts are generally detected by this technique. Another method of oximetric determination of intracardiac shunts uses a balloon-tipped fiberoptic catheter that allows for continuous registration of oxygen saturation as it is withdrawn from the pulmonary artery through the right heart chambers into the SVC and IVC.

SHUNT QUANTIFICATION.

The principles used to determine Fick cardiac output are also used to quantify intracardiac shunts. To determine the size of a left-to-right shunt, pulmonary blood flow (PBF) and systemic blood flow (SBF) determinations are required. PBF is simply oxygen consumption divided by the difference in oxygen content across the pulmonary bed, whereas SBF is oxygen consumption divided by the difference in oxygen content across the systemic bed. The effective blood flow (EBF) is the fraction of mixed venous return received by the lungs without contamination by the shunt flow. In the *absence* of a shunt, PBF, SBF, and EBF all are equal. These equations are shown below:

where P bar(v)O_2 , PaO_2 , SaO_2 , and M bar(v)O_2 are the oxygen contents (in milliliters of oxygen per liter of blood) of pulmonary venous, pulmonary arterial, systemic arterial, and mixed venous bloods, respectively. The oxygen content is determined as outlined in the section on Fick cardiac output.

If a pulmonary vein is not sampled, systemic arterial oxygen content may be substituted, assuming systemic arterial saturation is 95 percent or more. As discussed earlier, if systemic arterial saturation is less than 95 percent, a right-to-left shunt may be present. If arterial desaturation is present but not secondary to a right-to-left shunt, systemic arterial oxygen content is used. If a right-to-left shunt is present, pulmonary venous oxygen content is calculated as 98 percent of the oxygen capacity.

The mixed venous oxygen content is the average oxygen content of the blood in the chamber proximal to the shunt. When assessing a left-to-right shunt at the level of the right atrium, one must calculate mixed venous oxygen content on the basis of the contributing blood flow from the IVC, SVC, and coronary sinus. The most common formula used is Flamm's formula.[103]

Assuming conservation of mass, the size of a left-to-right shunt, when there is no associated right-to-left shunt, is simply

When there is evidence of a right-to-left shunt in addition to a left-to-right shunt, the approximate left-to-right shunt size is

while the approximate right-to-left shunt size is

The flow ratio PBF/SBF (or QP/QS) is used clinically to determine the significance of the shunt. A ratio of less than 1.5 indicates a small left-to-right shunt; a ratio of 1.5 to 2.0, a moderate-sized shunt. A ratio of 2.0 or more indicates a large left-to-right shunt and generally requires repair to prevent future pulmonary and/or right ventricular complications. A flow ratio of less than 1.0 indicates a net right-to-left shunt. If oxygen consumption is not measured, the pulmonic/systemic blood flow ratio may be calculated as follows:

where Sa_{O_2} , M bar(v)$_{O_2}$, P bar(v)$_{O_2}$, and Pa_{O_2} are systemic arterial, mixed venous, pulmonary venous, and pulmonary arterial blood oxygen saturations, respectively.

INDICATOR-DILUTION METHOD

Although the indicator-dilution method is more sensitive than the oximetric method in detection of small shunts, it cannot be used to localize the level of a left-to-right shunt (Fig. 11-15) . An indicator such as indocyanine green dye is injected into a proximal chamber while a sample is taken from a distal chamber using a densitometer, and the density of dye is displayed over time. To detect a left-to-right shunt, dye is injected into the pulmonary artery and sampling is performed in a systemic artery. Presence of a shunt is indicated by early recirculation of the dye on the downslope of the curve.[104] The presence of aortic or mitral regurgitation may distort the downslope of the curve, thereby yielding a false-positive result. In adults, the indocyanine green method provides estimates of shunt magnitude that are somewhat smaller than those of the oximetric method, although they are in general agreement with one another concerning the PBF/SBF.[105] [106] To detect a right-to-left shunt, dye is injected into the right heart proximal to the presumed shunt and sampling is performed in a systemic artery. If there is a right-to-left shunt, a distinct early peak is seen on the upslope of the curve.[107] The level of the right-to-left shunt may be localized by injecting more distally until the early peak disappears. Shunts may also be quantified using this technique.

MISCELLANEOUS TECHNIQUES

A sensitive method for detection and localization of a left-to-right shunt is to check systematically within the various right heart chambers for the early appearance of an indicator that is injected distal to the presumed shunt. Indicators that have been used for this purpose include indocyanine green dye, inhaled hydrogen, hydrogen dissolved

Figure 11-15 Left-to-right shunt (increased pulmonic flow). Indicator is not cleared rapidly but recirculates through the central circulation via a defect. Based on magnitude of shunt, a constant fraction leaves the central pool with each circulation. Maximal deflection is reduced, and the disappearance is prolonged as a result of slow clearance. Right-to-left shunt (decreased pulmonic flow). A portion of the indicator passes directly to the arterial circulation via the defect without passing through the lungs and arrives at the arterial sampling site before the portion that did traverse the pulmonary circulation. (From Kern MJ, Deligonul U, Donohue T, et al: Hemodynamic data. *In* Kern MI [ed]: The Cardiac Catheterization Handbook. 2nd ed. St. Louis, Mosby-Year Book, 1995, p 142.)

in saline, and ascorbic acid. Platinum-tipped electrodes are used for detection when hydrogen and ascorbic acid are used. These techniques may also be used to detect small right-to-left shunts by altering the sites of injection and sampling.

Selective injection of radiographic contrast (angiocardiography) can detect both left-to-right and right-to-left shunts, although these cannot be quantified. Angiocardiography is a useful adjunct to transesophageal echocardiography as part of a preoperative evaluation. It is also useful in detecting pulmonary arteriovenous fistulas that may not be detected by other methods.

Physiological and Pharmacological Maneuvers

Potentially significant cardiac abnormalities may be absent in the resting condition but may be unmasked by stress. Therefore, if the cause of a patient's symptoms cannot be assessed at rest, various physiological and pharmacological maneuvers can be considered.

DYNAMIC EXERCISE.

Dynamic exercise in the catheterization laboratory is most commonly performed using supine bicycle ergometry, although straight leg raises or arm or upright bicycle exercise may be used. Upright treadmill exercise may also be performed outside the catheterization laboratory, using a balloon flotation catheter inserted through an antecubital vein to measure pulmonary artery and wedge pressure and cardiac output. The associated changes in the heart rate, cardiac output, oxygen consumption, and intracardiac pressures are monitored at steady state during progressive stages of exercise. Normally, the increased oxygen requirements of exercise are met by an increase in cardiac output and an increase in oxygen extraction from arterial blood.[108] Patients with cardiac dysfunction are unable to increase their cardiac output appropriately in response to exercise and must meet the demands of the exercising muscle groups by increasing the extraction of oxygen from arterial blood, thereby increasing the arteriovenous oxygen difference. Dexter and colleagues found that the relationship between cardiac output and oxygen consumption was linear and that a regression formula may be used to calculate the predicted cardiac index at a given level of oxygen consumption.[109] The actual cardiac index divided by the predicted cardiac index is defined as the *exercise index.* A value of 0.8 or more indicates a normal cardiac output response to exercise.[108] The *exercise factor* is another method of describing the same relationship between the cardiac output and oxygen consumption. The exercise factor is the increase in cardiac output divided by the increase in oxygen consumption. Normally, for every 100 ml/min increase in oxygen consumption with exercise, the cardiac output should increase by at least 600 ml/min. Therefore, a normal exercise factor should be 0.6 or more.[108]

Supine exercise normally causes a rise in mean arterial and pulmonary pressures. There is a proportionately greater decrease in systemic vascular resistance compared with pulmonary vascular resistance and an increase in heart rate. Myocardial contractility increases owing to both increased sympathetic tone and the increase in heart rate. Left ventricular ejection fraction rises. During early levels of exercise, increased venous return augments left ventricular end-diastolic volume, leading to an increase in stroke volume.[110] At progressively higher levels of exercise, both left ventricular end-systolic and end-diastolic volumes decrease such that there is a negligible rise in stroke volume. Thus, the augmentation in cardiac output during peak supine exercise in the catheterization laboratory is generally caused by an increase in heart rate. For this reason, all agents that may impair the chronotropic response should be discontinued before catheterization if exercise is contemplated during the procedure.

Exercise may provoke symptoms in a patient who had been found to have valvular disease of borderline significance in the resting state. Exercise increases the gradient across the mitral valve in mitral stenosis and may provoke symptoms not experienced at rest. The hemodynamic response to exercise is also useful in evaluating regurgitant valvular lesions. Clinically important valvular regurgitation exists if an increase occurs in left ventricular end-diastolic pressure, pulmonary capillary wedge pressure, and systemic vascular resistance, in conjunction with a reduced exercise index and abnormal exercise factor. Simultaneous echocardiographic data may also be useful in equivocal cases. Patients with myocardial disease, ischemic or otherwise,

may have pronounced increases in left ventricular end-diastolic pressure with exercise.[111]

ISOMETRIC EXERCISE.

Isometric handgrip exercise causes an increase in heart rate, mean arterial pressure, and cardiac output. Because the systemic vascular resistance does not increase, the elevation in arterial pressure is due to the rise in cardiac output rather than a vasoconstrictor response. Patients with left ventricular dysfunction respond abnormally to isometric exercise (i.e., significant increase in left ventricular end-diastolic pressure, a failure to increase stroke work appropriately, and a blunted rise in left ventricular peak dP/dT).[108]

PACING TACHYCARDIA.

Rapid atrial or ventricular pacing increases myocardial oxygen consumption and myocardial blood flow.[112] In distinction to dynamic or isometric exercise, left ventricular enddiastolic volume decreases with pacing and there is little change in cardiac output.[113] This method may be used to determine the significance of coronary artery disease or valvular abnormalities. For example, the gradient across the mitral valve increases with rapid atrial pacing owing to the increase in heart rate. Pacing has the advantage of allowing for greater control and rapid termination of the induced stress.

PHYSIOLOGICAL STRESS.

Various physiological stresses alter the severity of obstruction in hypertrophic cardiomyopathy (see Chap. 48) . The *Valsalva maneuver* (forced expiration against a closed glottis) increases the systolic subaortic pressure gradient in the strain phase, during which there is a decrease in venous return and decreased left ventricular

volume. This maneuver is often abnormal in patients with heart failure.[114] *Mueller's maneuver* (forced inspiration against a closed glottis) causes the opposite effect. Another useful maneuver in patients with hypertrophic obstructive cardiomyopathy is the introduction of a *premature ventricular beat* (Brockenbrough's maneuver). Premature ventricular contractions normally increase the pulse pressure of the subsequent ventricular beat. In obstructive hypertrophic cardiomyopathy, the outflow gradient is increased during the postpremature beat with a decrease in the pulse pressure of the aortic contour. A premature ventricular beat may also accentuate the spike-and-dome configuration of the aortic pressure waveform.

Rapid volume loading may reveal occult pericardial constriction, when atrial and ventricular filling pressures are relatively normal under baseline conditions owing to hypovolemia,[115] and may help distinguish pericardial constriction from myocardial restriction. *Kussmaul's sign* occurs in pericardial constriction (see Chap. 50) . This is demonstrated when, with inspiration, right atrial pressure fails to decrease or actually increases in relation to impaired right ventricular filling. *Cold pressor testing,* in which a patient's forearm is exposed to ice water, may induce coronary vasoconstriction in patients with coronary artery disease.[116]

PHARMACOLOGICAL MANEUVERS.

Isoproterenol infusion may be used to simulate supine dynamic exercise, although untoward side effects may limit its applicability. This drug's positive inotropic and chronotropic effects may increase the gradients in obstructive hypertrophic cardiomyopathy and mitral stenosis. *Nitroglycerin* and *amyl nitrate* decrease preload and accentuate the systolic gradient in patients with obstructive hypertrophic cardiomyopathy. Amyl nitrate is generally inhaled, and its onset of action is very rapid. Agents that increase systemic vascular resistance, such as *phenylephrine,* reduce the gradient in obstructive hypertrophic cardiomyopathy. Infusion of *sodium nitroprusside* may improve the cardiac output and filling pressures in patients with dilated cardiomyopathies and in patients with mitral regurgitation by lowering systemic and pulmonary vascular resistances. A favorable response to sodium nitroprusside infusion may predict a good clinical outcome.

Methylergonovine maleate has replaced ergonovine as a safer and more specific provocation test for coronary artery spasm (see Chap. 37) . Small intracoronary increments of 5 to 10 mug are given. Total dose should not exceed 50 mug. Intracoronary acetylcholine is also as effective and safe as methylergonovine.[119]

CORONARY BLOOD FLOW DETERMINATIONS

Five methods are available for measuring human coronary blood flow in the cardiac catheterization laboratory: thermodilution, digital subtraction angiography, electromagnetic flow meters, Doppler velocity probes, and pressure wires. Although most current methods measure relative changes in coronary blood flow, useful information about the physiological significance of stenosis,[120] cardiac hypertrophy, [121] and pharmacological interventions[122] can be obtained from these measurements.

Ganz and colleagues[123] introduced thermodilution methods for measuring coronary sinus flow (Fig. 11-16) . This inexpensive, widely available technique is the most frequently applied method for measuring global coronary blood flow in humans.[124] By injecting iced saline in the distal end of the catheter placed in the coronary sinus and measuring the temperature change from a proximal thermistor, the rate of change in temperature can be used to define coronary flow. The frequency response of this system is sufficient to measure flow changes that occur in 2 to 3 seconds and exceed 30 percent.[123] This technique has several limitations, however.[124] Although the method has been validated in vitro with the thermodilution catheter attached to the coronary sinus,[123] weaker correlations have been shown when the thermodilution catheter is allowed to move within the coronary sinus.[125] No studies have clearly demonstrated the accuracy of this method in patients with severe coronary artery disease or myocardial infarction. Other limitations include the fact that (1) rapid changes in flow cannot be assessed because of the slow time constant of the technique, (2) right atrial and ventricular perfusion cannot be evaluated because the venous drainage does not occur via the coronary sinus, and (3) regional flow and specifically transmural coronary flow cannot be assessed.

To measure coronary flow with digital subtraction angiography, contrast medium is power injected into a coronary artery at a rate sufficient to replace blood within the artery completely. It is assumed that the contrast bolus is undiluted until the peak concentration has been imaged distally in the arterial segment. Regional flow reserve can be calculated in a number of ways, including the use of downstream appearance time and maximal contrast concentration before and during reactive hyperemia.[126] The assumption is that transit time within a region is inversely proportional to coronary blood flow in that region. This is true if the volume of distribution is constant. The technique is limited by a slow time constant and the inability to measure absolute flow. Evaluation of coronary flow reserve

Figure 11-16 Schematic illustration of venous thermodilution method for measurement of coronary blood flow. The thermal indicator (injectate) at temperature T_1 is infused at a constant rate (e.g., 15 ml/min). Turbulence causes mixing of the injectate with coronary venous blood at temperature T_B , resulting in a blood-injectate mixture at temperature. T_M . The catheter tip thermistor monitor T_B and T_M , while an internal thermistor monitors T_1 , and these are recorded continuously on a uniform temperature scale *(lower left)*. Because heat loss by blood is gained by injectate, coronary venous flow is calculated using the measured temperatures, the rate of indicator injection, and the constant derived from the specific heats of blood and injectate. (From Bradley AB, Baim DS: Measurement of coronary blood flow in man: Methods and implications for clinical practice. Cardiovasc Clin 14:67, 1984.)

by this method has been validated in dogs by comparing digital flow ratio estimates with electromagnetic flow ratio measurements.[127] In humans, flow reserve has been shown to be abnormal in stenosed coronary arteries and bypass grafts and after coronary angioplasty.[128] Further validation in humans is necessary.

The electromagnetic flow meter is based on Faraday's induction law, which states that a conductor moving in an electric field produces current. A major advantage of electromagnetic flow meters is the high-frequency response.[121] Although these flow meters have been used to measure aortic blood flow velocity in humans,[129] they have not been developed to the point at which they are useful for measuring coronary blood flow at catheterization, in part because most methods require placement directly around the coronary artery. Electromagnetic flow meters are still in occasional use intraoperatively to evaluate flow in aortocoronary bypass grafts.

The Doppler flow meter is based on the principle of the Doppler effect (Fig. 11-17) (see also Chap. 7) . It is the most widely applied technique for measurement of coronary flow in humans. High-frequency sound waves are reflected from moving red blood cells and undergo a shift in sound frequency that is proportional to the velocity of the blood flow. In pulsed-wave Doppler methods, a single piezoelectric crystal can both transmit and receive high-frequency sound waves. These methods have been applied successfully in humans by using miniaturized crystals fixed to the tip of catheters. Technological developments have further miniaturized steerable 12-mHz Doppler guidewires to 0.014inch in diameter. Therefore, flow can be assessed distal and proximal to a stenosis. The Doppler guidewire measures phasic flow velocity patterns and tracks linearly with flow rates in small, straight coronary arteries.[130] It has been advocated for use in determining the severity of intermediate stenosis (40 to 60 percent) and in evaluating whether normal blood flow has been restored after PTCA. Validation studies have been performed to compare Doppler flow probes with labeled microspheres[131] and electromagnetic flow probes. [132] This method has been validated both in vitro and in vivo.[133] The use of this technique for assessment of lesion severity has been reported.[134] It has the advantage of permitting repeated sampling and at high frequency, thus allowing measurements after physiological or pharmacological interventions. The use of smaller Doppler catheters allows selective coronary artery flow velocity to be measured. By noting the increase in flow velocity following a strong coronary vasodilator, such as papaverine,

Figure 11-17 Schematic diagram of the distal portion of a 3F intracoronary Doppler catheter with side-mounted piezoelectric crystal. The copper wires attached to the crystal exit from the proximal end of the catheter and are connected to a 20-mHz pulsed Doppler velocimeter. The catheter is advanced into the coronary artery over an 0.014-inch angioplasty guidewire. O.D. = outer diameter. (Modified from Wilson RF, Laughlin DE, Ackell PH, et al: Transluminal, subselective measurement of coronary artery blood flow velocity and vasodilator reserve in man. Circulation 72:82, 1985. Copyright 1985 American Heart Association.)

the coronary flow reserve (CFR) can be defined. CFR provides an index of the functional significance of coronary lesions that obviates some of the ambiguity of anatomical description.[134]

Animal data indicate that stenosis exceeding 50 percent is associated with a reduction in absolute flow reserve (see Chap. 34) . It has been suggested that stenosis flow reserve (SFR) is a more reliable method of evaluating functional severity.[135] For a fixed arterial dimension and stenosis geometry, directly measured arterial CFR can be zero if no aortic perfusion is present or may change with other physiological conditions. Thus, CFR can be broken into its component parts of SFR (i.e., the flow reserve of the proximal arterial stenosis) and myocardial perfusion reserve (MPR), the flow reserve of the distal vascular bed. SFR is defined by geometric quantitative coronary dimensions using standard physiological conditions. MPR is directly or indirectly measured and is affected by geometric as well as physiological variables. The equation relating pressure change across a lesion and flow is

where DeltaP is the translesional gradient, Pc is distal coronary pressure, Pa is aortic pressure, Q and Qrest are flow and rest flow, and A and B are related to lesion

geometry. A and B are defined by lesion length, minimal cross-sectional area of the lesion and reference segment, and blood viscosity.

The limitation of the current Doppler probe method is that only changes in flow velocity, rather than absolute velocity or volumetric flow, are measurable. The change in flow velocity is directly proportional to changes in volumetric flow only when vessel dimensions are constant at the site of the sample volume. Other factors including left ventricular hypertrophy and myocardial scar can also affect CFR.[126] Furthermore, a concern is that changes in luminal diameter and arterial cross-sectional area during interventions are not reflected in measurements of flow velocity, thus potentially causing underestimation of the true volume flow.[126]

The measurement of pressure gradients across coronary stenoses was originally advocated to assess the results of coronary angioplasty. Owing to the large profile of catheters used, this technique was never widely applied. However, new technology using small (0.018-inch) guidewires to assess pressure gradients across stenoses has been introduced.[136] [137] [138] Myocardial fractional flow reserve (FFR) has been used as an index of functional severity of coronary artery stenosis.

Pressure gradients are determined by measuring the ratio of the mean pressure distal to a coronary stenosis compared with that proximal to the stenosis. The proximal stenosis is measured through the tip of the guiding catheter, and distal pressure is measured through the tip of the guidewire. Maximal vasodilatation is induced by intracoronary administration of either adenosine or papaverine. FFR is calculated from the ratio of the mean pressure distal to a coronary stenosis to the mean aortic pressure during maximal hyperemia. If the FFR is less than 0.75, there is at least 80 percent sensitivity and 85 percent specificity for an abnormal exercise test result. Pressure wire measurement has been less well validated than Doppler flow reserve measurement. However, early studies indicate improved clinical utility owing to the ease of use and reproducibility of re

sults.[139]

LEFT VENTRICULAR ELECTROMECHANICAL MAPPING

Advances in catheter design and navigational technology have resulted in catheter-based three-dimensional mapping systems for evaluating regional and global left ventricular function. By integrating measurements of local endocardial electrical activity and wall motion during the cardiac cycle, the electromechanical mapping system provides information about myocardial ischemia and viability (Fig. 11-18) . The ability of the electromechanical left ventricular maps to distinguish viable from nonviable myocardium and ischemic from nonischemic myocardium has been validated in animal models of myocardial ischemia and infarction.[140] [141] [142] The clinical experience with this system is limited at this time. However, the preliminary data from these studies indicate that the mapping system has promise in differentiating normal myocardium from myocardial fibrosis[142] and may also distinguish ischemic from infarcted myocardium.[143] In addition to identifying infarcted myocardium and zones of viable but ischemic myocardium, this technology has the potential to guide accurate, direct transendocardial administration of drug or gene therapies targeted at specific myocardial regions identified during the mapping process.

Chapter 12 - Coronary Angiography and Intravascular Ultrasonography

JEFFREY J. POPMA
JOHN BITTL

GLOSSARY

ACC/AHA=American College of Cardiology/American Heart Association
AP=anteroposterior
CABG=coronary artery bypass graft surgery
CAD=coronary artery disease
CCS=Canadian Cardiovascular Society
EKG=electrocardiogram
Fr=French size
GEO=gastroepiploic artery
IMA=internal mammary artery
LMCA=left main coronary artery
LAD=left anterior descending artery
LAO=left anterior oblique
LCA=left coronary artery
LCx=left circumflex coronary artery
MI=myocardial infarction
PCI=percutaneous coronary intervention
RAO=right anterior oblique
RCA=right coronary artery
SVG=saphenous vein bypass graft

Coronary arteriography remains the "gold standard" for identifying the presence or absence of stenoses due to coronary artery disease (CAD) and provides the most reliable anatomical information for determining the appropriateness of medical therapy, percutaneous coronary intervention (PCI), or coronary artery bypass graft (CABG) surgery in patients with ischemic CAD. First performed by Sones in 1959,[1] coronary arteriography has subsequently become one of the most widely used invasive procedures in cardiovascular medicine. It is performed by directly injecting radiopaque contrast material into the coronary arteries and recording radiographic images on 35-mm cinefilm or digital recordings.[2] More than 2 million patients will undergo coronary arteriography in the United States this year alone. Coronary arteriography is now performed in 25 percent of acute care hospitals in this country.

The methods used to perform coronary arteriography have evolved substantially since 1959. Smaller (5-6 French), high-flow injection catheters have replaced larger (8 Fr), thick-walled catheters, and the reduced sheath size has allowed same-day coronary arteriography, ambulation, and discharge. Complication rates associated with coronary arteriography have been reduced with a better understanding of the periprocedural management of patients undergoing cardiac catheterization. The number of "filmless" digital laboratories increases steadily, based on recent advances in digital image acquisition, storage, and data transfer. New adjunct imaging modalities performed at the time of coronary arteriography, such as intravascular ultrasonography (IVUS), have also been developed to give the clinician more precise characterization of the vessel wall and extent of atherosclerosis.

In this chapter we review the indications and techniques of coronary arteriography, the cineangiographic x-ray imaging and digital storage systems, the normal coronary anatomy and pathological coronary variants, the qualitative and quantitative angiography techniques for the assessment of stenoses severity and risk stratification, and the advantages and limitations of IVUS for the diagnosis and treatment of CAD.

INDICATIONS FOR CORONARY ARTERIOGRAPHY

Coronary arteriography is used to establish the presence or absence of coronary stenoses, define therapeutic options, and determine prognosis in patients with symptoms or signs of ischemic CAD.[2] Coronary arteriography can also be used as a research tool to evaluate serial changes that occur after PCI or pharmacological therapy or assess dynamic changes in arterial tone based on evaluations of endothelial tone. The American College of Cardiology/American Heart Association (ACC/AHA) Task Force has established indications for coronary arteriography in patients with known or suspected CAD (Table 12-1) .[2]

Patients with suspected CAD who are asymptomatic or have stable angina should undergo coronary arteriography if their angina is severe (Canadian Cardiovascular Society [CCS] Class III-IV) or there are "high-risk" criteria for adverse outcome on noninvasive testing. High-risk features include severe resting left ventricular dysfunction (left ventricular ejection fraction [LVEF]<35 percent) or a standard exercise treadmill test demonstrating hypotension or 1 to 2 mm or more ST segment depression associated with decreased exercise capacity[3] or an exercise-induced LVEF less

TABLE 12-1 -- INDICATIONS FOR CORONARY ARTERIOGRAPHY

CLASS I	CLASS IIA	CLASS IIB	CLASS III
Asymptomatic or Stable Angina			

CCS Class III and IV on medical therapy High-risk criteria on noninvasive testing irrespective of angina Successfully resuscitated from sudden cardiac death with sustained monomorphic VT or nonsustained polymorphic VT	CCS Class III or IV that improves to Class I or II with medical therapy Worsening noninvasive testing Patients with angina and severe illness that precludes risk stratification CCS Class I or II angina with intolerance to medical therapy Individuals whose occupation affects the safety of others	CCS Class I or II angina with demonstrable ischemia but no high-risk criteria on noninvasive testing Asymptomatic men or postmenopausal women with >2 major clinical risks with low-risk noninvasive testing and no CAD Asymptomatic patients with prior MI, normal LV function, and not-high-risk noninvasive testing	Angina in patients who prefer to avoid revascularization Angina in patients who are not candidates for revascularization or in whom it will not improve QOL As a screening test for CAD After CABG when there is no evidence of ischemic on noninvasive testing Coronary calcification on fluoroscopy or EBCT
Unstable Angina			
High or intermediate for adverse outcome in patients refractory to medical therapy High or intermediate risk that stabilizes after initial treatment Initially low short-term risk that is high risk on noninvasive testing Suspected Prinzmetal variant angina	None	Low short-term-risk unstable angina without high-risk criteria on noninvasive testing	Recurrent chest discomfort suggestive of unstable angina, but without objective signs of ischemia and with a normal coronary angiogram within the past 5 years Unstable angina in patients who are not candidates for revascularization
Post-Revascularization Ischemia			
Suspected abrupt closure or subacute stent thrombosis after PCI Recurrent angina and high-risk criteria on noninvasive evaluation within 9 months of PCI	Recurrent symptomatic ischemia within 12 months of CABG Noninvasive evidence of high-risk criteria occurring at any time post CABG Recurrent angina inadequately controlled by medications	Asymptomatic post-PCI patient suspected of having restenosis with the first months after PCI because of an abnormal but not high-risk noninvasive test Recurrent angina without high-risk criteria on noninvasive testing occurring >1 year postoperatively Asymptomatic post-CABG in whom a deteriorating noninvasive test is found	Symptoms in a post-CABG patient who is not a candidate for revascularization Routine angiography after PCI or CABG unless part of an approved research protocol
After QWMI or NQWMI			
Spontaneous myocardial ischemia or ischemia provoked with minimal exertion Before surgical therapy for acute MR, VSD, true or pseudoaneurysm Persistent hemodynamic instability	Suspected MI due to coronary embolism, arteritis, trauma, certain metabolic diseases, or coronary spasm Survivors of acute MI with LVEF<0.40, CHF, prior PCI or CABG, or malignant ventricular arrhythmias	For a suspected persistant occlusion of the IRA to perform delayed PCI Coronary arteriography performed without risk stratification to identify the presence of left main or three-vessel CAD All patients after NQWMI Recurrent ventricular tachycardia despite antiarrhythmic therapy without ongoing ischemia	Patients who are not a candidate for or refuse revascularization
Nonspecific Chest Pain			
High risk features on noninvasive testing	None	Patients with recurrent hospitalizations for chest pain who have abnormal or equivocal findings on noninvasive testing	All other patients with nonspecific chest pain

Class I: conditions for which there is agreement that the procedure is useful and effective; Class IIa: weight of the evidence is in favor of usefulness and efficacy; Class IIb: weight of the evidence is less well established by evidence and opinion; Class III: conditions for which there is general agreement that the procedure is not useful and effective and in some cases may be harmful.

CABG=coronary artery bypass graft surgery; CAD=coronary artery disease; CCS=Canadian Cardiovascular Society; CHF=congestive heart failure; EBCT=electron beam computed tomography; IRA=infarct-related artery; LV=left ventricular; MI=myocardial infarction; MR=mitral regurgitation; NQWMI=non-Q-wave MI; PCI=percutaneous coronary intervention; QOL=quality of life; VSD=ventricular septal defect; VT=ventricular tachycardia.

than 35 percent.[2] Stress imaging that demonstrates a large perfusion defect (particularly in the anterior wall), multiple defects, a large fixed perfusion defect with left ventricular dilatation or increased thallium-201 lung uptake, or extensive stress or dobutamine-induced wall motion abnormalities also indicate high risk for an adverse outcome.[2] [4] Patients resuscitated from sudden cardiac death, particularly those with residual ventricular arrhythmias, are also candidates for coronary arteriography, given the favorable outcomes associated with revascularization in these patients.[2]

Patients with unstable angina who develop recurrent symptoms despite medical therapy or are at "intermediate" or "high" risk of subsequent death or myocardial infarction (MI) are also candidates for coronary arteriography.[2] [5] [6] High-risk features include prolonged ongoing (>20 minutes) chest pain, pulmonary edema, or worsening mitral regurgitation, dynamic ST segment depression of 1 mm or more, or hypotension.[2] Intermediate-risk features include angina at rest (>20 minutes) relieved with rest or sublingual nitroglycerin, angina associated with dynamic electrocardiographic changes, recent-onset angina with a high likelihood of CAD, pathological Q waves or ST segment depression less than 1 mm in multiple leads, or age older than 65 years.[2]

Patients with Q-wave or non-Q-wave MI who develop spontaneous ischemia or with ischemia at a minimal workload or who have MI complicated by congestive heart failure (CHF), hemodynamic instability, cardiac arrest, mitral regurgitation, or ventricular septal rupture should undergo coronary arteriography. Patients with angina or provocable ischemia after MI should also undergo coronary arteriography, because revascularization may reduce the high risk of reinfarction in these patients.[7]

Patients presenting with chest pain of unclear etiology, particularly those who have high-risk criteria on noninvasive testing, may benefit from coronary arteriography to diagnose or exclude the presence of significant CAD.[2] Patients who have undergone prior revascularization should undergo coronary arteriography if there is suspicion of abrupt vessel closure or when recurrent angina develops with high-risk noninvasive criteria in patients who have undergone PCI within the past 9 months.

Coronary arteriography should be performed in patients scheduled to undergo noncardiac surgery who develop high-risk criteria on noninvasive testing, have angina unresponsive to medical therapy, develop unstable angina, or who have equivocal noninvasive test results and are scheduled to undergo high-risk surgery. Coronary arteriography is also recommended for patients scheduled to undergo surgery for valvular heart disease or congenital heart disease, particularly those with multiple

cardiac risk factors and those with infective endocarditis and evidence of coronary embolization.[2]

Coronary arteriography should be performed annually in patients after cardiac transplantation in the absence of clinical symptoms because of the diffuse and asymptomatic nature of graft atherosclerosis.[8] Coronary arteriography is useful in potential donors for cardiac transplantation whose age or cardiac risk profile increases the likelihood of CAD. The arteriogram often provides important diagnostic information about the presence of CAD in patients with intractable arrhythmias before electrophysiological testing or in patients who present with a dilated cardiomyopathy of unknown etiology.

CONTRAINDICATIONS.

There are no absolute contraindications for coronary arteriography.[2] Relative contraindications include unexplained fever, untreated infection, severe anemia with hemoglobin less than 8 g/dl, severe electrolyte imbalance, severe active bleeding, uncontrolled systemic hypertension, digitalis toxicity, previous contrast allergy but no pretreatment with corticosteroids, and ongoing stroke. Other relative contraindications include acute renal

TABLE 12-2 -- PATIENTS AT INCREASED RISK FOR COMPLICATIONS AFTER CORONARY ARTERIOGRAPHY

Increased General Medical Risk
Age>70 years
Complex congenital heart disease
Morbid obesity
General debility or cachexia
Uncontrolled glucose intolerance
Arterial oxygen desaturation
Severe chronic obstructive lung disease
Renal insufficiency with creatinine greater than 1.5 mg/dl
Increased Cardiac Risk
Three-vessel coronary artery disease
Left main coronary artery disease
Functional Class IV
Significant mitral or aortic valve disease or mechanical prosthesis
Low ejection fraction less than 35 percent
High-risk exercise treadmill testing (hypotension or severe ischemia)
Pulmonary hypertension
Pulmonary artery wedge pressure greater than 25 mm Hg
Increased Vascular Risk
Anticoagulation or bleeding diathesis
Uncontrolled systemic hypertension
Severe peripheral vascular disease
Recent stroke
Severe aortic insufficiency

failure, decompensated CHF, severe coagulopathy, and active endocarditis.[2] Risk factors for significant complications after catheterization include advanced age, as well as several general medical, vascular, and cardiac characteristics (Table 12-2) . Patients with these characteristics should be monitored closely for a minimum of 18 to 24 hours after coronary arteriography. Coronary arteriography performed under emergency conditions is associated with a higher risk of procedural complications. Careful discussion of the risks and benefits of the procedure, and its alternatives, should be reviewed with the patient and family in all circumstances before coronary arteriography is performed.

TECHNIQUE OF CORONARY ARTERIOGRAPHY

PREPARATION OF THE PATIENT.

Elective coronary arteriography should be performed, alone or in conjunction with right-sided heart catheterization or contrast medium-enhanced left ventriculography (see Chap. 11) , when comorbid conditions, such as CHF, diabetes mellitus, or renal insufficiency, are stable. A baseline electrocardiogram (ECG), electrolyte and renal function tests, complete blood cell count, and coagulation parameters should be reviewed before coronary arteriography. Patients who may undergo PCI should receive aspirin, 80 to 325 mg, at least 2 hours before the procedure. Warfarin sodium should be discontinued 2 days before elective coronary arteriography, and the international normalized ratio (INR) should be less than 2.0 before arterial puncture. Patients at increased risk for systemic thromboembolism on withdrawal of warfarin, such as those with atrial fibrillation, mitral valve disease, or a prior history of systemic thromboembolism, may be treated with intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin in the periprocedural period.

VASCULAR ACCESS.

A variety of vascular approaches are available for coronary arteriography. The selection of the vascular access will depend on operator and patient preferences, anticoagulation status, and presence of peripheral vascular disease.

Femoral Artery Approach.

The right or left femoral arteries are the most commonly used access sites for coronary arteriography. The anterior wall of the common femoral artery should be punctured several centimeters below the inguinal ligament but proximal to the bifurcation of the superficial femoral and profunda arterial branches. The common femoral artery courses across the junction between the middle and medial thirds of the femoral head and can be localized by fluoroscopy before arterial puncture. If the puncture site is proximal to the inguinal ligament, hemostasis after the procedure may be difficult with manual compression, leading to an increased risk of retroperitoneal hemorrhage. If the puncture site is at or distal to the femoral bifurcation, there is a higher risk of pseudoaneurysm formation after sheath removal.

Brachial and Radial Artery Approaches.

Access to the brachial and radial arteries is obtained percutaneously in most cases, although access to the brachial artery can also be obtained using a "cutdown" with blunt dissection and direct visualization. These approaches are preferred in the presence of severe peripheral vascular disease. Whereas saphenous vein grafts (SVGs) can be engaged using either brachial artery, cannulation of the internal mammary artery (IMA) is best performed from the ipsilateral brachial or radial artery. Contralateral catheterization of the left internal mammary artery from the right brachial or radial artery is technically challenging and may require the use of a "headhunter" catheter for selective entry into the left subclavian artery. The brachial artery will easily accommodate an 8-Fr (1 Fr=0.33 mm in diameter) sheath, whereas the radial artery is smaller and generally limited to 6-Fr catheters. Before radial artery access is attempted, an Allen test should be carried out to ensure that the ulnar artery is patent in the event of radial artery occlusion.

CATHETERS.

A number of injection catheters have been developed to perform coronary arteriography from the femoral, brachial, and radial approaches. These catheters are generally constructed of polyethylene or polyurethane with

Figure 12-1 Right (R) and left (L) Judkins catheters. The primary (straight arrow) and secondary (curved arrow) curves of the left Judkins catheter are shown. (Courtesy of Cordis Corporation.)

a fine wire braid within the wall to allow advancement and directional control (torque ability) and prevent kinking. The outer diameter size of the catheters ranges from 4 to 8 Fr, but 5 and 6 Fr catheters are used most commonly for diagnostic arteriography.

Judkins Catheters.

The left Judkins catheter is preshaped to allow entry into the left coronary ostia from the femoral approach with minimal catheter manipulation (Figs. 12-1 and 12-2) . A preformed left Judkins catheter

Figure 12-2 Tip configurations for several catheters useful in coronary arteriography. (Courtesy of Cordis Corporation.)

can also be used from the left brachial or radial artery, but a catheter with 0.5 cm less curvature than required for the femoral approach is generally needed. The right Judkins catheter is shaped to permit entry into the RCA with a small amount of rotational catheter manipulation from any vascular approach.

Selection of Judkins catheter shape is based on the body habitus of the patient and size of the aortic root. The left coronary artery (LCA) is easily engaged with the Judkins left 4.0 catheter from the femoral approach in most patients, whereas patients with a dilated ascending aorta (e.g., in the setting of congenital aortic stenosis and post-stenotic dilatation) may require the use of a Judkins left 5.0 or 6.0 catheter. Patients with large ascending aortic aneurysms may require arteriography with heat-modified catheters to achieve Judkins left 7.0 to 10.0 shapes. Use of a Judkins shape that is too small for the ascending aorta often leads to folding of the catheter within the aortic root. The best technique for removing a folded Judkins left catheter from the body involves withdrawing the folded catheter into the descending aorta and advancing a guidewire anterograde in the contralateral common iliac artery. On withdrawal of the catheter and guidewire together, the catheter will straighten and can be removed safely from the body without disrupting the arterial access site.

Amplatz Catheters.

Amplatz catheters can be used for the femoral or brachial approach to coronary arteriography (Fig. 12-3) . [9] The Amplatz catheters are an excellent alternative in cases in which the Judkins catheter is not appropriately shaped to enter the coronary arteries. The Amplatz L-1 or L-2 catheter may be used for coronary angiography from the right brachial or radial approaches.

Other Catheters.

Other catheters used for coronary arteriography include the Sones catheter and a variety of catheter shapes for engagement of SVGs, including the multipurpose catheter (Fig. 12-4) and Hockey stick catheters, among others**.** Specially designed catheters for engagement of the coronary arteries from the radial artery have been developed.

Drugs Used During Coronary Arteriography

ANALGESICS.

The goal of analgesic use is to achieve a state of conscious sedation, defined by a minimally depressed level of consciousness that allows a patient to respond appropriately to verbal commands and to maintain a patent airway.[10] Several different sedation regimens are recommended, but depending on patient comorbid conditions, most use diazepam, 2.5 to 10 mg orally, and diphenhydramine,

Figure 12-3 Right (R) and left (L) Amplatz catheters. (Courtesy of Cordis Corporation.)

Figure 12-4 Multipurpose A, B, and C type catheters. (Courtesy of Cordis Corporation.)

25 to 50 mg orally, 1 hour before the procedure. Intravenous midazolam, 0.5 to 2 mg, and fentanyl, 25 to 50 mug, are useful agents to provide sedation during the procedure. Patients undergoing conscious sedation should have continuous hemodynamic, ECG, and oximetry monitoring and access to oxygen and suction ports and a resuscitation cart.[11]

ANTICOAGULANTS.

Intravenous unfractionated heparin is no longer required during routine coronary arteriography.[12] Patients at increased risk for thromboembolic complications, including those with severe aortic stenosis, critical peripheral arterial disease, or arterial atheroembolic disease, or those undergoing procedures in which there is a need for prolonged (>1 to 2 minutes) use of guidewires in the central circulation, may be given intravenous heparin, 3000 to 5000 units. Patients undergoing brachial or radial artery catheterization may also be given intraarterial unfractionated heparin, 2000 to 5000 units. Frequent (every 30-60 seconds) flushing of catheters with contrast medium or heparinized saline will avoid the formation of microthrombi within the catheter tip.

The anticoagulant effect of unfractionated heparin can be reversed with protamine, 1 mg for every 100 units of heparin. Protamine may cause anaphylaxis or serious hypotensive episodes in approximately 2 percent of patients. Protamine should not be administered to patients with prior exposure to NPH insulin, owing to an excess risk of adverse effects, or in patients with a history of unstable angina or high-risk coronary anatomy or those patients who have undergone coronary arteriography by means of the brachial or radial arteries. Femoral sheaths can be removed after the anticoagulant effect of heparin has dissipated (activated clotting time<150-180 seconds).

TREATMENT OF PERIPROCEDURAL ISCHEMIA.

Patients may develop angina during coronary arteriography, owing to ischemia induced by tachycardia, hypertension, contrast agents, microembolization, coronary spasm or enhanced vasomotor tone, or dynamic platelet aggregation. Sublingual (0.3 mg), intracoronary (50 to 200 mug), or intravenous (25 mug/min) nitroglycerin can be given in patients with a systolic blood pressure greater than 100 mm Hg. Patients without contraindications to beta blockers, such as bradycardia, bronchospasm, or left ventricular dysfunction, can be given

TABLE 12-3 -- CHARACTERISTICS OF RADIOCONTRAST AGENTS

COMPOUND	BRAND NAME	OSMOLALITY mOsm/kg H_2O	VISCOSITY AT 37° C	IODINE (mg/ml)	SODIUM (mEq/liter)	ADDITIVES
Ionic Agents						
Sodium diatrizoate	Hypaque	1690	9.0	370	160	Calcium disodium EDTA

intravenous metoprolol, 2.5 to 5.0 mg, or propranolol, 1 to 4 mg. Intraaortic balloon counterpulsation is also a useful adjunct in patients with coronary ischemia and left main coronary artery disease, cardiogenic shock, or refractory pulmonary edema.

Contrast Agents

All radiographic contrast agents contain iodine, which effectively absorbs x-rays in the energy range of clinical imaging systems.[13] Radiographic contrast agents currently used for coronary arteriography produce a number of adverse hemodynamic, electrophysiological, and renal effects. These agents differ in their ionic content, osmolality, viscosity, side-effect profile, and cost (Table 12-3) .

IONIC CONTRAST AGENTS.

Monomeric ionic contrast agents used historically for coronary arteriography were the high-osmolar meglumine and sodium salts of diatrizoic acid. These substances dissociate into cations and iodine-containing anions,[14] resulting in a serum osmolality greater than 1500 mOsm/kg H_2O (vs. 300 mOsm/kg H_2O in human plasma). The hypertonicity of these compounds produced sinus bradycardia, heart block, QT interval and QRS prolongation, ST segment depression, giant T wave inversion, decreased left ventricular contractility, decreased systolic pressure, and increased left ventricular end-diastolic pressure, owing, in part, to the calcium-chelating properties of these agents. Ventricular tachycardia and fibrillation occur in 0.5 percent of cases and may develop more often when ionic contrast agents are injected into a damped coronary catheter or are given too rapidly or in too great a volume.

NONIONIC AND LOW OSMOLAR CONTRAST AGENTS.

Nonionic agents do not ionize in solution and provide more iodine-containing particles than ionic agents per milliliter of contrast.[13] Their osmolality is substantially reduced (<850 mOsm/kg H_2O) because these agents go into solution as single neutral molecules and do not contain calcium-chelating agents, potentially leading to fewer side effects. It is estimated that nonionic agents are used in 60 to 70 percent of current coronary arteriographic procedures.[15]

SIDE EFFECTS.

Toxic reactions may also occur after radiocontrast use, relating, in part, to the hyperosmolality of these agents[13] (Table 12-4) . Toxic reactions include hot flushing, nausea, vomiting, and arrhythmia. When hypotension occurs after contrast medium administration, it may be due to an anaphylactoid reaction, a direct toxic effect, or a vasovagal reaction.[13] Whereas ionic radiocontrast agents inhibit clot formation when mixed with blood, nonionic agents exhibit less of this inhibitory effect, and clots may form when low ionic contrast agents and blood are in direct contact with one another. The clinical effects of this finding are not known.[15A] Low-osmolality ionic dimer methylglucamine-sodium ioxaglate retains most of the anticoagulant properties of diatrizoate sodium.[14] [16] [17] [18] [163A]

Nephrotoxicity may occur after contrast agent administration, particularly in those patients with prior renal insufficiency, diabetes mellitus, dehydration before the procedure, CHF, larger volumes of contrast, and those with recent (<48 hour) contrast agent administration.[19] [20] Oliguria generally occurs within the first 24 hours after contrast exposure and generally lasts for 2 to 4 days after the procedure.[13] The creatinine reaches its peak 3 to 5 days after contrast agent administration and returns to baseline in the majority of cases.[13] In patients with baseline renal insufficiency (creatinine > 1.5 mg/dl), use of nonionic contrast agents is associated with a lower incidence of contrast nephropathy.[21] [21A]

TABLE 12-4 -- TOXICITIES ASSOCIATED WITH RADIOCONTRAST AGENTS

Hypersensitivity (Anaphylactoid) Reactions

Grade I: Single episode of emesis, nausea, sneezing, or vertigo
Grade II: Hives, multiple episodes of emesis, fevers, or chills
Grade III: Clinical shock, bronchospasm, laryngospasm or edema, loss of consciousness, hypotension, hypertension, cardiac arrhythmias, angioedema, or pulmonary edema

Cardiovascular Toxicity

Electrophysiological

Bradycardia (asystole, heart block)

Tachycardia (sinus, ventricular)

Ventricular fibrillation

Hemodynamic

Hypotension (cardiac depression, vasodilatation)
Heart failure (cardiac depression, increased intravascular volume)

Nephrotoxicity
Discomfort

Nausea, vomiting

Heat and flushing

Hyperthyroidism

Adequate fluid hydration before the procedure was the only method shown to reduce the frequency of contrast medium-induced nephropathy in a randomized study.[22]

CONTRAST REACTION PROPHYLAXIS.

Allergic reactions to radiocontrast agents can classified as mild (grade I: single episode of emesis, nausea, sneezing, or vertigo), moderate (grade II: hives, multiple episodes of emesis, fevers, or chills), or severe (grade III: clinical shock, bronchospasm, laryngospasm or edema, loss of consciousness, hypotension, hypertension, cardiac arrhythmias, angioedema, or pulmonary edema).[23] Although mild or moderate reactions occur in approximately 9.0 percent of patients, severe reactions are uncommon (0.15-0.7 percent).[19] [20] Contrast reactions may be more difficult to manage in patients receiving beta-blocker therapy. Recurrence rates may approach 50 percent on reexposure to contrast agents, and prophylactic use of H_1 and H_2 histamine blocking agents and aspirin therapy has been advocated.[13] Patients treated with corticosteroids (methylprednisolone, 32 mg) 12 hours and 2 hours before contrast agent exposure had a lower (6.4 percent) incidence of allergic reactions than patients treated with a single dose of methylprednisolone 2 hours before contrast agent exposure (9.4 percent) or placebo (9.0 percent) ($p<0.001$). [23] Based on these findings, patients with a prior history of radiocontrast allergy should be treated with two doses of prednisone, 60 mg (or its equivalent), on the night before and 2 hours

before the procedure. Diphenhydramine, 50 mg, and cimetidine, 300 mg, may also be given before the procedure.[13]

CONTRAST AGENT SELECTION.

A number of randomized studies have shown that side effects occur less often with nonionic contrast agent use than with conventional ionic agents.[13] The major drawback of the nonionic contrast agents was their 10- to 20-fold increase in cost relative to the ionic agents. Although these differences have been narrowed with the availability of lower cost nonionic agents, nonionic or low osmolar agents may be particularly useful in patients with severe bradycardia (<55 to 60 beats/min), diabetes mellitus, baseline renal insufficiency, hypotension, unstable angina, acute MI, renal failure, age older than 65 to 70 years, CHF, valvular heart disease, internal mammary injection, or a previous reaction to contrast agents.[13] When ionic agents are selected, additional precautions are needed to avoid complications. Patients should be "coached" about coughing before the first selective coronary arteriogram is performed, and use of the minimal amount of contrast agent to fill the entire coronary artery for two cardiac cycles and allow brief reflux of contrast agent into the aortic root is needed.

CINEANGIOGRAPHIC IMAGE TECHNOLOGY

The basic principle of radiographic coronary imaging is that radiation produced by the x-ray tube is attenuated as it passes through the body and is detected by the image intensifier. Iodinated contrast medium injected into the coronary arteries enhances the absorption of x-rays and produces a sharp contrast with the surrounding cardiac tissue.[24] The x-ray shadow is then converted to a visible light image by an image detector, then displayed on fluoroscopic monitors, and stored on 35-mm cinefilm or digital storage systems.[24]

Cineangiographic Equipment

There are several important parts of the x-ray imaging system that are required for image generation, review, and storage (Fig. 12-5) .

X-RAY GENERATOR.

The x-ray generator produces the power that accelerates electrons within the x-ray tube.[24] Constant-potential and multipulse generators are both suitable for coronary imaging. X-ray generators should provide a voltage range between 40 and 150 kVp, a

Figure 12-5 Cineangiographic equipment. The major components include a generator, x-ray tube, image intensifier attached to a positioner such as a C-arm, optical system, cine camera, video camera, videocassette recorder (VCR), analog-to-digital converter (ADC), and television monitors. The x-ray tube is the source of the x-ray beam, which passes superiorly through the patient.

current that reaches a maximum of 600 mA, a cine pulse system that provides individual exposure times ranging from 5 to 8 milliseconds to optimize image quality, and power output that is 100 kW at 80 kVp.[24] Longer exposures times are associated with motion artifact, whereas shorter exposure times may require increased voltage, which results in decreased image resolution. Automatic exposure control maintains the optimal brightness level of the image intensifier by varying voltage, current, and exposure duration.

X-RAY TUBE.

The x-ray tube is responsible for the conversion of electrical energy to x-radiation. Newer ceramic and graphite tubes are more expensive than conventional tubes but provide a longer half-life and higher heat load capacity. Focal spots should vary between 0.5 mm and 1.0 mm. Smaller (0.2-0.3) focal spots increase image resolution at the expense of more heat production. X-ray pulsing using carbon grid switching is more efficient compared with secondary electronic switching methods that have long radiation decay and more radiation scatter.

IMAGE INTENSIFIER.

The image intensifier converts an x-ray image into a visible light image. The image intensifier is generally a bell-shaped glass tube that contains an input and output phosphor.[24] X-ray photons that have passed through the patient produce visible light photons by interacting with the input phosphor.[24] An electronic image is produced by the interaction of the light photons with the photocathode tube.[24] These electrons are then accelerated toward the output phosphor, where they create a bright replica of the x-ray pattern. A dual- or triple-mode cesium iodide image intensifier with a resolution capability of approximately 5 line pairs per millimeter, a contrast ratio of greater than 15:1, and a conversion factor of greater than 50 for the small mode is recommended for coronary arteriography.[24] The intensifier should have at least two modes, with the large mode approximating 9 inches to be able to image large ventricles and a small mode (magnified mode) of 6 inches or less for coronary imaging.[24]

OPTICAL SYSTEM.

The objective and the camera lenses gather light generated in the image intensifier and focus it onto the image detector.[24] The output screen of the image intensifier is located at the focal spot of the objective lens, which then emits parallel light rays from the image intensifier.[24] The camera lens then collects the parallel light rays and forms an image at its focal plane.[24] The focal length of the camera lens should allow the proper degree of overframing, which is used to increase the image magnification.[24] Apertures ranging from f-20 to f-75 are generally used for cardiac imaging.

VIDEO SYSTEMS.

Permanent recording of angiographic images historically utilized 35-mm film, using a cine camera capable of operating at 15 to 60 frames per second with low vibration levels. A partially-silvered mirror splits the image and diverts 10 percent of the light to a television system that allows real-time viewing. The television system must have excellent image clarity and minimal lag. A high-quality 525-line or 1023-line television camera and monitor with a signal-to-noise ratio of at least 45 dB is suggested.[11] The 1023-line television system results in reduced raster line artifact.

Image Recording and Storage

While 35-mm cine film has been the preferred medium for recording and storage of coronary arteriograms or Digital Imaging and COMmunication standard (DICOM3) compatible digital storage has become a prevalent alternative. Despite its relative expense, 35-mm cinefilm currently meets the desirable criteria of exchangeability,

adherence to a standard format, a medium with high resolution, the need for a permanent record, and suitability for quantitative analysis. With adequate quality control in film development, no other recording medium can compete with the spatial resolution or the dynamic contrast range of 35-mm cinefilm. Optimal radiographic imaging is critical to the success of coronary arteriography. Under ideal circumstances, modern radiographic imaging techniques provide spatial resolution of 5 line pairs per millimeter, a level of resolution that must be considered of borderline adequacy for imaging coronary vessels as small as 1 millimeter.

Use of 35-mm cinefilm does have certain drawbacks, including cost, delay in access, and inability for processing of data directly on film. Digital imaging and storage modalities are now available as possible replacements for cinefilm.[25] Because spatial resolution is lost in the transfer of digital to analog images, the earlier practice of using Super-VHS videotapes as the storage medium, analog videotape cannot be recommended as a replacement for cinefilm at the current time.[26] [27]

Digital Imaging

The American College of Cardiology, American College of Radiology, and the National Electronic Manufacturer's Association (NEMA) have recommended that interinstitutional transfer of digital images be performed using the DICOM3 standard as the exchange medium. Long-term storage can be performed using 2:1 JPEG lossless compression onto DLT tapes or magnetooptical disc for storage without loss of information. Requirements for storage are substantial (approximately 400

megabytes-1 gigabyte per study).[26]

ANATOMY AND VARIATIONS OF THE CORONARY ARTERIES

The major epicardial branches and their second and third order branches are visualized using coronary arteriography. The networks of smaller intramyocardial branches are generally not visualized because of their size, cardiac motion, and limitations in resolution of cineangiographic systems. These "resistance" vessels play a major role in autoregulation of coronary blood flow, may limit myocardial perfusion during stress, and contribute to ischemia in patients with left ventricular hypertrophy or systemic hypertension.

ARTERIAL NOMENCLATURE AND EXTENT OF DISEASE.

The Coronary Artery Surgery Study (CASS) Investigators established the most commonly used nomenclature to describe the coronary anatomy, defining 27 segments in three major coronary arteries (Table 12-5) .[28] The Bypass Angioplasty Revascularization Investigators modified these criteria by addition of two segments for the ramus intermedius and the third diagonal branch.[29] In this system, the three major coronary arteries include the left anterior descending (LAD), left circumflex (LCx), and right coronary arteries (RCA) with a right-dominant, balanced, or left dominant circulation (see later). CAD is defined as a more than 50 percent diameter stenosis in one or more of these vessels, although it is clear that stenoses of less than 50 percent have major prognostic implications because these lesions most commonly lead to plaque rupture and acute myocardial infarction. Subcritical stenoses of less than 50 percent are best characterized as nonobstructive CAD. CAD is classified as one-, two-, or three-vessel disease.

A number of "jeopardy scores" have been used to quantitate plaque burden and predict patient-based clinical outcomes[30] and to identify risk factors for the presence of atherosclerosis and its progression.[31] The Califf scoring system divided the coronary circulation into 6 segments with 2 points allotted for each coronary stenosis of 75 percent or more (score range: 0-12).[32] The Gensini scoring system used an ordinal ranking based on stenosis severity in 11 coronary segments (score range: 0-72).[33] The Candell-Riera scoring system used an ordinal ranking (from 1 to 5) of 13 coronary segments (score range: 0-65).[34] One comparative study found that 80 percent of the prognostic information in one jeopardy index was obtained with other indices using subtly different methodologies.[30] In the Coronary Artery Surgery Study (CASS), the major determinants of 6-year outcome included the number of diseased vessels, the number of diseased proximal segments, and the global left ventricular function; these three factors alone accounted for 80 percent of the prognostic information obtained in this study.[30]

ANGIOGRAPHIC PROJECTIONS.

The major coronary arteries traverse the interventricular and atrioventricular grooves, aligned with the long and short axes of the heart, respectively. Because the heart is oriented obliquely in the thoracic cavity, the coronary circulation is generally visualized in the right anterior oblique (RAO) and left anterior oblique (LAO) projections (Figs. 12-6 and 12-7) , but these views are limited by vessel foreshortening and superimposition of branches.[35] [36] Simultaneous rotation of the x-ray beam in the sagittal plane provides a better view of the major coronary arteries and their branches. A simple nomenclature has evolved for the description of these sagittal views, which characterizes the relationship between the image intensifier and the patient. Assuming that the x-ray tube is under the patient table and the image intensifier is over the patient table, the projection is referred to as the "cranial" view if the image intensifier is tilted toward the head of the patient. The projection is referred to as "caudal" if the image intensifier is tilted down toward the feet of the patient.

It is difficult to predict which angulated views will be most useful in any given patient, because the "optimal" angiographic projection depends largely on body habitus, variation in the coronary anatomy, and location of lesions. It is recommended that the coronary arteries be visualized in both the LAO and RAO projections using both cranial and caudal angulation.

TABLE 12-5 -- CLASSIFICATION SYSTEM FOR CORONARY SEGMENTS

NUMBER	MAP LOCATION	NUMBER	MAP LOCATION	NUMBER	MAP LOCATION
	Right Coronary Artery		**Left Main Coronary Artery**		**Left Circumflex**

Coronary Artery Surgery Study: National Heart, Lung, and Blood Institute Coronary Artery Surgery Study: A multicenter comparison of the effects of randomized medical and surgical treatment of mildly symptomatic patients with coronary artery disease and a registry of consecutive patients undergoing coronary arteriography. Circulation 63 (Suppl I): I81, 1981. Copyright 1981, American Heart Association.

Figure 12-6 Angiographic views of the left coronary artery. The approximate position of the x-ray tube and image intensifier are shown for each of the commonly used angiographic views. The 60-degree left anterior oblique view with 20 degrees of cranial angulation (LAO cranial) shows the ostium and distal portion of the left main coronary artery (LMCA), the middle and distal portions of the left anterior descending artery (LAD), septal perforators (S), diagonal branches (D), and the proximal left circumflex (LCx) and superior obtuse marginal branch (OMB). The 60-degree left anterior oblique view with 25 degrees of caudal angulation (LAO caudal) shows the proximal LMCA and the proximal segments of the LAD and LCx. The anteroposterior projection with 20 degrees of caudal angulation (AP caudal) shows the distal LMCA and proximal segments of the LAD and LCx. The anteroposterior projection with 20 degrees of cranial angulation (AP cranial) also shows the midportion of the LAD and its septal (S) branches. The 30-degree right anterior oblique projection with 20 degrees of cranial angulation (RAO cranial) shows the course of the LAD and its septal (S) and diagonal branches. The 30-degree right anterior oblique projection with 25 degrees of caudal angulation (RAO caudal) shows the LCx and obtuse marginal branches (OMB).

Figure 12-7 Angiographic views of the right coronary artery. The approximate position of the x-ray tube and image intensifier are shown for each of the commonly used angiographic views. The 60-degree left anterior oblique view (LAO) shows the proximal and midportions of the right coronary artery (RCA) as well as the acute marginal branches (AMB) and termination of the RCA in the posterior left ventricular branches (PLV). The 60-degree left anterior oblique view with 25 degrees of cranial angulation (LAO cranial) shows the midportion of the RCA and the origin and course of the posterior descending artery (PDA). The 30-degree right anterior oblique view (RAO) shows the midportion of the RCA, the conus branch, and the course of the PDA.

Left Coronary Artery

CANNULATION.

The Judkins left coronary catheter is used most often to engage the LCA (Fig. 12-8) . If the catheter begins to turn out of profile (so that one or both curves of the catheter are no longer visualized *en face*), it can be rotated very slightly and advanced slowly to enter the left sinus of Valsalva, permitting the catheter tip to engage the ostium of the LCA. In conditions of a large ascending aorta, advancement of the Judkins left coronary catheter is associated with the formation of an acute

secondary angle. Further advancement should be avoided, because this would distort the catheter shape and prevent catheterization of the LCA. In the presence of a mildly dilated ascending aorta, the guidewire can be temporarily reinserted into the catheter to straighten the secondary bend and permit the catheter to be advanced to the left sinus of Valsalva. If the ascending aorta is significantly dilated, the catheter should be exchanged for a larger size (e.g., Judkins left 5.0 or 6.0). If the tip of the Judkins left catheter advances beyond the ostium of the LCA without engagement, the primary bend of the catheter can be reshaped within the patient's body by further careful advancement and prompt withdrawal of the catheter, allowing the tip to "pop into" the ostium of the LCA. This maneuver, along with gentle clockwise or counterclockwise rotation, frequently permits selective engagement of the LCA when the initial attempt has failed.

To cannulate the LCA with the Amplatz catheter, the broad secondary curve of the appropriately sized left Amplatz catheter is positioned so that it rests on the right aortic cusp with its tip pointing toward the left aortic cusp. Alternating advancement and retraction of the catheter with slight clockwise or counterclockwise rotation allows the catheter tip to enter the left coronary ostium. Once the tip enters the ostium, the position of the catheter can usually be stabilized with slight retraction. After the left coronary ostium has been cannulated, the pressure at the tip of the catheter should be checked immediately to ensure that there is no damping or "ventricularization" of the pressure contour. If a damped or ventricularized pressure tracing is obtained, the catheter should be removed immediately from the LCA and an attempt at repositioning should be made. If abnormal pressure recording persists, the catheter should be withdrawn from the coronary artery and a nonselective injection

Figure 12-8 Push-pull technique for catheterizing the left coronary artery with the Judkins left catheter. In the left anterior oblique view, the coronary catheter is positioned in the ascending aorta over a guidewire and the guidewire is removed. The catheter is advanced so that the tip enters the left sinus of Valsalva. If the catheter does not selectively engage the ostium of the left coronary artery, further slow advancement into the left sinus of Valsalva imparts a temporary acute angle at the catheter. Prompt withdrawal of the catheter allows easy entry into the left coronary artery.

of contrast medium into the LCA should be performed in the anteroposterior (AP) view to evaluate the left main coronary artery (LMCA). If the pressure measured at the catheter tip is normal, and a test injection of contrast agent suggests the absence of LMCA disease, left coronary arteriography is then performed using standard techniques.

LEFT MAIN CORONARY ARTERY.

The LMCA arises from the superior portion of the left aortic sinus, just below the sinotubular ridge of the aorta, which defines the border separating the left sinus of Valsalva from the smooth (tubular) portion of the aorta. The LMCA ranges from 3 to 6 mm in diameter and 0 to 10 mm in length. The LMCA courses behind the right ventricular outflow tract and usually bifurcates into the LAD artery and LCx branches. The LMCA is best visualized in the AP projection with slight (0-20°) caudal angulation, but it should be viewed in several projections with the vessel off the spine to exclude LMCA stenosis (Figs. 12-9 and 12-10) .[37]

LEFT ANTERIOR DESCENDING ARTERY.

The LAD courses along the epicardial surface of the anterior interventricular groove toward the cardiac apex. In the RAO projection, it extends along the anterior aspect of the heart; and in the LAO projection, it passes down the cardiac midline, between the right and left ventricles (see Fig. 12-6) .

The major branches of the LAD are the septal and diagonal branches. The septal branches arise from the LAD at approximately 90-degree angles and pass into the interventricular septum, varying in size, number, and distribution. In some cases there is a large first septal branch that is vertically oriented and divides into a number of secondary "pitchforking" branches that ramify throughout the septum. In other cases a more horizontally oriented, large first septal branch is present that passes parallel to the LAD itself within the myocardium. In still other cases a number of septal arteries are roughly comparable in size. These septal branches interconnect with similar septal branches passing upward from the posterior descending branch of the RCA to produce a network of potential collateral channels. The interventricular septum is the most densely vascularized area of the heart.

The diagonal branches of the LAD pass over the anterolateral aspect of the heart. Although virtually all patients have a single LAD in the anterior interventricular groove, there is wide variability in the number and size of diagonal branches. Most (90 percent) patients have one to three diagonal branches,[38] and acquired atherosclerotic occlusion of the diagonal branches should be suspected if no diagonal branches are seen, particularly if there are unexplained contraction abnormalities of the anterolateral left ventricle. Visualization of the origin of the diagonal branches often requires very steep (50-60 degrees) LAO and angulated cranial (20-40 degrees) skews.

In some (37 percent) patients the LMCA trifurcates into the LAD, LCx, and ramus intermedius.[38] In these cases the ramus intermedius arises between the LAD and LCx arteries. This vessel is analogous to either a diagonal branch or an obtuse marginal branch, depending on its anterior or posterior course along the lateral aspect of the left ventricle. In most (78 percent) patients the LAD courses around the left ventricular apex and terminates along the diaphragmatic aspect of the left ventricle. In the remaining (22 percent) patients the LAD fails to reach the diaphragmatic surface, terminating instead either at or before the cardiac apex.[39] In these cases the posterior descending branch (PDA) of the RCA is larger and longer than usual and supplies the apical portion of the ventricle.

The best angiographic projections for viewing the course of the LAD are the cranially angulated LAO, AP, and RAO views. The LAO cranial view displays the midportion of the LAD and separates the

Figure 12-9 Missed left main coronary artery (LMCA) stenosis. *A-C,* Left coronary arteriography in the standard right anterior oblique, left anterior oblique, and right anterior oblique caudal views fails to demonstrate significant stenoses of the LMCA or left anterior descending (LAD) artery. *D,* Left anterior oblique cranial view shows severe stenosis (curved arrow) for the LAD (L) immediately beyond the origin of the diagonal branch. *E,* Right anterior oblique cranial view shows the LAD stenosis (curved arrow) but also shows a severe stenosis of the LMCA (straight arrow) at its bifurcation.

Figure 12-10 Difficulty in detecting ostial left main coronary artery (LMCA) stenosis. *A,* Shallow right anterior oblique views of the left anterior descending artery with the catheter not well seated in the vessel results in poor visualization of the ostial stenosis of the LMCA. *B,* Left anterior oblique cranial view shows the catheter tip selectively positioned in the LMCA without reflux of contrast medium around the tip.

diagonal and septal branches. The RAO cranial view displays the proximal, mid, and distal segment of the LAD and allows separation of the diagonal branches superiorly and the septal branches inferiorly. The AP view requiring cranial (20 to 40 degrees) skew will often project the midportion of the LAD, separating the vessel from its diagonal and septal branches. The LAO caudal view will also display the origin of the LAD in a horizontally oriented heart, and the AP caudal or shallow RAO caudal view will visualize the proximal LAD as it arises from the LMCA. The RAD caudal projection is also useful for visualizing the distal LAD and its apical termination.

Some patients have no LMCA but separate ostia for the LAD and LCx. In general, the LAD has a more anterior origin than the LCx. The LAD can be engaged with the left Judkins catheter in this setting with paradoxical counterclockwise rotation, which rotates the secondary bend of the catheter to a posterior position in the aorta and turns the primary bend and tip of the catheter to an anterior position. The opposite maneuver may be used to engage the LCx selectively in the setting of separate LAD and LCx ostia. A Judkins catheter, such as Judkins left 5.0 with a larger curve, will selectively engage the downward coursing LCx, and a catheter with shorter curve, such as a Judkins left 3.5, will tend to selectively engage the more anterior and superior LAD.

LEFT CIRCUMFLEX ARTERY.

The LCx artery originates from the LMCA and courses within the posterior (left) atrioventricular groove toward the inferior interventricular groove (see Fig. 12-6). The LCx artery is the dominant vessel in 15 percent of patients, supplying the left PDA from the distal continuation of the LCx. In the remaining vessels, the distal LCx varies in its size and length, depending on the number of posterolateral branches supplied by the distal RCA. The LCx usually gives off one to three large obtuse marginal branches as it passes down the atrioventricular groove. These are the principal branches of the LCx, because they supply the lateral free wall of the left ventricle. Beyond the origins of the obtuse marginal branches, the distal LCx tends to be small. The actual position of the LCx can be determined on the late phase of a

left coronary injection, when the coronary sinus becomes opacified with diluted contrast material.

The RAO caudal and LAO caudal projections are best for visualizing the proximal and mid LCX and obtuse marginal branches. The AP (or 5- to 15-degree RAO) caudal projections also show the origins of the obtuse marginal branches. More severe rightward angulation often superimposes the origins of the obtuse marginal branches on the LCx. If the LCA is dominant, the optimal projection for the left PDA is the LAO cranial view. The LCx also gives rise to one or two left atrial circumflex branches. These branches supply the lateral and posterior aspects of the left atrium.

Right Coronary Artery

Cannulation of the origin of the RCA is also performed in the LAO position but requires different maneuvers than cannulation of the LCA. Whereas the left Judkins catheter naturally seeks the ostium of the LCA, the right coronary catheter must be rotated to engage the vessel. This usually is accomplished by first passing the catheter to a point just superior to the aortic valve in the left sinus of Valsalva and then rotating the catheter clockwise, which forces the tip to move anteriorly from the left sinus of Valsalva to the right sinus of Valsalva along the sinotubular ridge. Sudden rightward and downward movement of the catheter tip signifies the entry into the right coronary ostium. If the ostium of the RCA is not easily located, the most common reason is that the ostium has a more superior and anterior origin than anticipated. Repeat attempts to engage the RCA should be made at a level slightly more distal to the aortic valve. Nonselective contrast agents injections in the right sinus of Valsalva may reveal the site of the origin of the RCA. Positioning an Amplatz catheter in the ostium of the RCA requires a technique similar to that used with the right Judkins catheter. If a gentle attempt to withdraw the Amplatz catheter results in paradoxical deep entry into the coronary artery, removal of the catheter can be achieved by clockwise or counterclockwise rotation and advancement to prolapse the catheter into the aortic sinus.

An abnormal pressure tracing showing dampening or ventricularization may suggest the presence of an ostial stenosis or spasm, selective engagement of the conus branch, or deep intubation of the right coronary artery. If an abnormal pressure tracing has been encountered, the catheter tip should be gently rotated counterclockwise and withdrawn slightly in an effort to free the tip of the catheter. If persistent damping occurs, a very small amount of contrast medium (<1 ml) can be injected carefully and the catheter immediately withdrawn in a "shoot-and-run" maneuver, which may allow the cause of damping to be identified. If the pressure tracing is normal on entry into the RCA, the vessel should be imaged in at least two projections. The

initial injection should be gentle, because of the possibility that forceful injection through a catheter whose tip is immediately adjacent to the vessel wall may lead to dissection.

ANGIOGRAPHIC PROJECTIONS.

The ideal angiographic projections for evaluating the RCA are the LAO cranial, AP cranial, and RAO views. The ostium of the RCA is best evaluated in the LAO view, with or without cranial angulation. The origin of the PDA is evaluated in the LAO cranial view, whereas the midportion of the RCA occasionally requires the left lateral view. The ostium of the RCA is best viewed in the LAO projection, occasionally with caudal angulation.

The RCA originates from the right anterior aortic sinus somewhat inferior to the origin of the LCA (see Fig. 12-7). It passes along the right atrioventricular groove toward the crux (a point on the diaphragmatic surface of the heart where the anterior [right] atrioventricular, the posterior [left] atrioventricular groove, and the inferior interventricular groove coalesce). The first branch of the RCA is generally the conus artery, which arises at the right coronary ostium or within the first few millimeters of the RCA in 50 percent of patients. The Judkins right coronary catheter may engage the conus artery subselectively, producing a damped or ventricularized pressure tracing. Gentle withdrawal and further clockwise rotation may allow the catheter to enter the true RCA. In the remaining patients, the conus artery arises from a separate ostium in the right aortic sinus just above the right coronary ostium.[40] The second branch of the RCA usually is the sinoatrial node artery. It has been found that this vessel arises from the RCA in 59 percent of patients, from the LCx in 38 percent, and from both arteries with a dual blood supply in 3 percent.[41] The midportion of the RCA usually gives rise to one or several medium-sized acute marginal branches. These branches supply the anterior wall of the right ventricle and may provide collateral circulation in patients with LAD occlusion.

RCA DOMINANCE.

The RCA is dominant in 85 percent of patients, supplying the PDA and at least one posterolateral branch (right dominant) (Figs. 12-11 , 12-12 , and 12-13). The PDA courses in the inferior interventricular groove and gives rise to a number of small inferior septal branches, which pass upward to supply the lower portion of the interventricular septum and interdigitate with superior septal branches passing down from the LAD. After giving rise to the PDA, the dominant RCA continues beyond the crux as the right posterior atrioventricular branch along the distal portion of the posterior (left) atrioventricular groove, terminating in one or several posterolateral branches that supply the diaphragmatic surface of the left ventricle. The RCA is nondominant in 15 percent of patients. One half of these patients have a left PDA and left posterolateral branches that are provided by the distal LCx artery (left dominant circulation). In these cases, the RCA is very small, terminates before reaching the crux, and does not supply any blood to the left ventricular myocardium. The remaining patients have a RCA that gives rise to the PDA with the

Figure 12-11 Strongly dominant right coronary artery (RCA). *A* and *B,* Left anterior oblique and right anterior oblique views of the RCA show that the distal segment (arrows) extends to the left atrioventricular groove. After giving rise to the posterior descending artery, the RCA gives rise to multiple posterior left ventricular branches. *C,* A variation in the origin of the posterior descending artery, which originates early from the RCA, runs parallel to it and enters the posterior interventricular groove. *D,* Right anterior oblique right coronary arteriogram showing the posterior descending artery (P) arising from a right ventricular branch of the RCA. E, Left anterior oblique right coronary arteriogram showing duplicated posterior descending arteries (arrows). (From Levin DC, Baltaxe HA: Angiographic demonstration of important anatomic variations of the posterior descending artery. AJR Am J Roentgenol 116:41, 1972.)

Figure 12-12 Weakly dominant right coronary artery (RCA). *A* and *B,* Left anterior oblique and right anterior oblique views of the RCA. Both the conus and sinoatrial node artery arise from the RCA. The distal portion of the RCA beyond the origin of the posterior descending artery is short and gives rise to a single small posterior left ventricular branch. *C-E,* Left coronary artery in the right anterior oblique, left anterior oblique, and left lateral projections. Note that the circumflex artery gives rise to four obtuse marginal branches, the most distal of which (arrow) supplies some of the diaphragmatic surface of the left ventricle. The left anterior descending artery gives rise to two small and one medium-sized diagonal branches. C=conus branch; L=left anterior descending artery; P=posterior descending artery; S=sinoatrial nodal artery.

LCx artery providing all the posterolateral branches (balanced or codominant circulation). In about 25 percent of patients with RCA dominance, there are significant anatomical variations in the origin of the PDA. These variations include partial supply of the PDA territory by acute marginal branches, double PDA, and early origin of the PDA proximal to the crux. At or near the crux, the dominant artery gives rise to a small atrioventricular node artery, which passes upward to supply the atrioventricular node.

CORONARY BYPASS GRAFTS.

Selective cannulation of bypass grafts may be more challenging than cannulation of the native coronary arteries because the locations of graft ostia are more variable, even when surgical clips or ostia markers are used. Knowledge of the number, course, and type of bypass grafts obtained from the operative report is invaluable for the identification of the location of the bypass grafts during arteriography.

SAPHENOUS VEIN GRAFTS.

SVGs from the aorta to the distal RCA or PDA originate from the right anterolateral aspect of the aorta approximately 5 cm superior to the sinotubular ridge. SVGs to the LAD originate from the anterior portion of the aorta about 7 cm above the superior to the sinotubular ridge. SVGs to the obtuse marginal branches arise from the left anterolateral aspect of the aorta 9 to 10 cm superior to the sinotubular ridge. In most patients, all SVGs can be engaged with a single catheter, such as a Judkins right 4.0 (JR-4.0) or a modified Amplatz right 2.0 (AR-2.0). Other catheters useful for engaging SVGs include the right and left bypass graft catheters. Amplatz left 1.0 to 2.0 catheters are useful for superiorly oriented SVGs (see Fig. 12-3) . A multipurpose catheter may also be useful for the cannulation of the SVG to the RCA or PDA.

Viewed in the LAO projection, the JR-4.0 or AR-2.0 catheters will rotate anteriorly from the leftward position as the catheter is rotated in a clockwise direction at the

level of the femoral artery or manifold. The relation between the movement of catheter shaft at the femoral artery and the response of catheter tip on fluoroscopy immediately indicates whether the catheter tip is anteriorly positioned in the aorta and likely to enter an SVG ostium or posteriorly positioned and unlikely to engage a SVG. Steady advancement and withdrawal of the catheter tip proximal and distal in the ascending aorta, 5 to 10 cm above the sinotubular ridge, with varying degrees of rotation, usually results in entry into the SVG. Entry into the SVG is associated with abrupt outward motion of the tip of the catheter. When this occurs, a small test injection of contrast material verifies that the catheter is in the SVG. A well-circumscribed "stump" is almost always present if the SVG is occluded. Each SVG or stump must be viewed in nearly orthogonal views. The

Figure 12-13 Dominant left coronary system. *A,* The left anterior oblique projection shows that the right coronary artery is small and terminates before reaching the crux. *B-D,* The right anterior oblique, left anterior oblique, and left lateral projections show that the left circumflex artery is large and gives rise to the posterior descending artery at the crux of the heart and to several posterior descending arteries.

relation between the origin of the SVGs and surgical clips confirms whether all targeted SVGs have been visualized. If neither a patent SVG nor stump can be located, it may be necessary to perform an ascending aortogram (preferably in biplane) in an attempt to visualize all SVGs and their course to the coronary arteries.

The goal of SVG angiography is to provide an assessment of the ostium of the SVG, its entire course, and the distal insertion site at the anastomosis between the bypass SVG and the native coronary vessel. The ostium of a SVG must be evaluated by achieving a coaxial engagement of the catheter tip and the origin of the SVG. The midportion (body) of the SVG must be evaluated with complete contrast filling of the SVG, because inadequate opacification produces an angiographic artifact suggestive of friable filling defects. It is critical to assess the SVG insertion or anastomotic site in full profile without any overlap of the distal SVG or the native vessel. Angiographic assessment of the native vessels beyond SVG anastomotic sites requires views that are conventionally used for the native segments themselves.

INTERNAL MAMMARY ARTERY.

The left IMA arises inferiorly from the left subclavian artery approximately 10 cm from its origin. Catheterization of the left IMA is performed with a specially designed J-tip IMA catheter (see Fig. 12-2, bottom row). The catheter is advanced into the aortic arch distal to the origin of the left subclavian artery in the LAO projection, and the catheter is rotated counterclockwise and is gently withdrawn with the tip pointing in a cranial direction, allowing entry into the left subclavian artery (Fig. 12-14). A 0.035 "J" or angled Terumo guidewire is advanced to the left subclavian artery under fluoroscopy, and the catheter is advanced into the subclavian artery. The RAO or AP projections can then be used to selectively cannulate the IMA by withdrawing and slightly rotating the catheter anteriorly (counterclockwise) with tip down. The right IMA can also be cannulated with the IMA catheter. The innominate artery is entered in the LAO projection, and the guidewire is advanced cautiously to avoid entry into the right common carotid artery. Once the guidewire is positioned in the distal right subclavian artery, the IMA catheter is advanced to a point distal to the expected origin of the right

Figure 12-14 Catheterization of the left internal mammary artery. The internal mammary catheter is positioned in the aortic arch and visualized in the left anterior oblique position. The catheter tip is rotated so that it engages the origin of the left subclavian artery immediately subjacent to the head of the clavicle *(A).* This is followed by gentle advancement of the guidewire into the left subclavian artery to a point distal to the origin of the left internal mammary artery. After the guidewire is removed, the left subclavian artery is visualized in the right anterior oblique projection, the catheter is withdrawn, and the catheter tip engages the ostium of the left internal mammary artery selectively *(B).* (From Judkins MW: Coronary arteriography. *In* Douglas JS Jr, King SB III [eds]: Coronary Arteriography and Intervention. New York, McGraw-Hill, 1985, p 231.)

IMA. The catheter is withdrawn in the LAO view and rotated to cannulate the right IMA. Selective catheterization of the IMAs may be difficult due to tortuosity of the subclavian arteries. In this circumstance, the Headhunter catheter may be used to enter the left subclavian or the innominate artery.

The IMA itself is rarely affected by atherosclerosis, which may be attributable to preserved endothelial properties of anticoagulation, vasodilatation, and growth inhibition, as compared with SVGs and native coronary arteries.[42] Angiographic studies of the IMAs should assess not only the patency of the graft itself but also the distal anastomosis, where most of IMA graft compromise occurs.[43] Whereas the LAO cranial view may be limited in demonstrating the anastomosis of the IMA with the LAD because of overlap, the left lateral or AP cranial project may be useful in visualizing the anastomotic site. The risk of catheter-induced dissection of the origin of the IMA can be reduced by careful manipulation of the catheter tip and avoidance of forceful advancement without the protection of the guidewire. If the IMA cannot be selectively engaged because of tortuosity of the subclavian artery, nonselective arteriography can be enhanced by placing a blood pressure cuff on the ipsilateral arm and inflating it to a pressure above systolic arterial pressure. The occurrence of IMA spasm can be treated with 50 to 200 mug of intraarterial nitroglycerin or 50 to 100 mug of intraarterial verapamil.

GASTROEPIPLOIC ARTERY.

The right gastroepiploic artery (GEA) is the largest terminal artery of the gastroduodenal artery. The other terminal branch of the gastroduodenal artery is the superior pancreaticoduodenal artery. The gastroduodenal artery arises from the common hepatic artery in 75 percent of cases, but it may also arise from the right or left hepatic artery or the celiac trunk. Catheterization of the right GEA is carried out by first entering the common hepatic artery with a Cobra catheter (Fig. 12-15) . A torquable, hydrophilic-coated guidewire is advanced to the gastroduodenal artery and then to the right GEA. The Cobra catheter is then exchanged for a multipurpose or Judkins right coronary catheter, which will then permit selective arteriography of the right GEA.

STANDARDIZED PROJECTION ACQUISITION.

General recommendations about routine views can be made for most patients, although tailored views may be needed to accommodate variations in patient anatomy. Each coronary artery should be visualized in multiple projections (Figs. 12-16 , 12-17 , and 12-18). During coronary arteriography, an AP view with shallow caudal angulation is often performed first to evaluate the possibility of LMCA disease. Other important views include the LAO view with cranial angulation to evaluate the LAD. This view should have sufficient leftward positioning of the image intensifier to allow separation of the LAD, diagonal, and septal branches. This is followed by the LAO caudal view to evaluate the proximal segment of the LCx, RAO view with caudal angulation to assess the LCx and marginal branches, and shallow RAO or AP cranial view to evaluate the midportion of the LAD.

Complications of Coronary Arteriography

Major complications are uncommon (<2 percent) after coronary arteriography (Table 12-6) . [44] In two large registries of patients undergoing femoral artery catheterization, death occurred in 0.10 to 0.14 percent, MI in 0.06 to 0.07 percent, cerebral ischemia or neurological complications in 0.07 to 0.14 percent, contrast agent reactions in 0.23 percent, and local vascular complications in 0.24 to 0.46 percent.[45] [46] Complications occurred more often in patients whose brachial artery was treated.[45] [47]

The incidence of death during coronary arteriography is higher in the presence of LMCA disease (0.55 percent), with a left ventricular ejection fraction less than 30 percent (0.30 percent), and with New York Heart Association functional Class IV disease (0.29 percent). More recent registries have identified equivalent complication rates despite increasing age and acuity of illness.[47] The risk of clinically significant coronary air embolus during diagnostic coronary arteriography is low, occurring in less than 0.1 percent of cases. If the syndrome of coronary air embolus and air lock does occur, 100 percent oxygen should be administered, which allows resorption of smaller amounts of air within 2 to 4 minutes. Morphine sulfate may be given for pain relief. Ventricular arrhythmias associated with air embolus can be treated with lidocaine and direct current cardioversion.

Figure 12-15 Catheterization of the right gastroepiploic artery (GEA) graft. The celiac trunk (CT) is selectively engaged with a cobra catheter, and a guidewire is gently advanced to the gastroduodenal artery (GDU) and the GEA. The catheter is advanced over the guidewire for selective arteriography of the GEA graft. CHA=common hepatic artery; RCA=right coronary artery; SA=splenic artery.

Figure 12-16 Importance of orthogonal projections. Each vascular segment of the coronary artery must be recorded in two orthogonal or nearly orthogonal views to avoid missing important diagnostic information about eccentric stenoses. In plane A the image is associated with a 75 percent stenosis, but in plane B the image results in 10 percent stenosis. (Modified from Miller SW, Wilson CL: Cardiac Angiography. Boston, Little, Brown, 1984, p 87.)

Figure 12-17 Superimposition of branches. *A* and *B,* Left anterior oblique and right anterior oblique views of the left coronary arteriogram show that the left anterior descending artery (LAD) is totally occluded, although the point of occlusion is not visualized. There is a large diagonal branch (black arrows) that closely parallels the LAD in both projections and could be mistaken for the LAD. Late-phase frames from a right anterior oblique *(C)* and left anterior oblique *(D)* right coronary arteriogram show filling of the LAD (white arrows) by means of septal collaterals.

Figure 12-18 Septal branch mimicking the left anterior descending (LAD) artery. *A,* Left anterior oblique left coronary arteriogram shows an enlarged septal branch (arrowhead) occupying the expected course of the LAD. *B,* The right anterior oblique view shows that the LAD is totally occluded (white arrowhead). The septal branch (black arrowhead) runs in a course approximately parallel to the LAD but below it and within the interventricular septum. CONGENITAL ANOMALIES OF THE CORONARY CIRCULATION

Anomalies that Cause Myocardial Ischemia

CORONARY ARTERY FISTULAE.

Coronary artery fistulae are the most common abnormality of the coronary arteries that are hemodynamically significant.[48] Although half the patients with a coronary artery fistula remain asymptomatic, the other half develop CHF, infective endocarditis, myocardial ischemia, or rupture of an aneurysm.[48] Fistulae arise from the RCA or its branches in about 50 percent of cases; the remaining fistulae arise from the LAD or LCx arteries or their branches, or they have multiple origins (Fig. 12-19). Drainage occurs into the right ventricle in 41 percent, right atrium in 26 percent, pulmonary artery in 17 percent, left ventricle in 3 percent, and superior vena cava in 1 percent.[48] A left-to-right shunt exists in more than 90 percent. Coronary arteriography is the best method of demonstrating the origin of these fistulae.

ORIGIN OF THE LEFT CORONARY ARTERY FROM THE PULMONARY ARTERY.

Most patients with the origin of the LCA from the main pulmonary artery manifest congestive heart failure and myocardial ischemia in the first 4 months of life.[48] About 25 percent survive to adolescence or adulthood

TABLE 12-6 -- RISK OF CARDIAC CATHETERIZATION

	SCAI REGISTRY (%)
Mortality	0.11
Myocardial infarction	0.05
Cerebrovascular accident	0.07
Arrhythmias	0.38
Vascular complications	0.43
Contrast reaction	0.37
Hemodynamic complications	0.26
Perforation of heart chamber	0.03
Other complications	0.28
Total of major complications	1.70

but develop mitral regurgitation, angina, or CHF.[49] Aortography typically shows a large RCA with absence of a left coronary ostium in the left aortic sinus. During the late phase of the aortogram, patulous LAD and LCx branches fill by means of collateral circulation from RCA branches. Still later in the filming sequence, retrograde flow from the LAD and LCx opacifies the LMCA and its origin from the main pulmonary artery (Fig. 12-20) . The clinical course of the patient tends to be more favorable if extensive collateral circulation exists. In rare instances, the RCA rather than the LCA may arise from the pulmonary artery.

CONGENITAL CORONARY STENOSIS OR ATRESIA.

Congenital stenosis or atresia of a coronary artery can occur as an isolated lesion or in association with other congenital diseases, such as calcific coronary sclerosis, supravalvular aortic stenosis, homocystinuria, Friedreich's ataxia, Hurler's syndrome, progeria, and rubella syndrome.[48] In these cases, the atretic vessel usually fills by means of collateral circulation from the contralateral side.

ANOMALOUS ORIGIN OF EITHER CORONARY ARTERY FROM THE CONTRALATERAL SINUS.

Origin of the LCA from the proximal RCA or the right aortic sinus with subsequent passage between the aorta and the right ventricular outflow tract has been associated with sudden death during or shortly after exercise in young persons[50] [51] [52] [53] [54] (Fig. 12-21) . The increased risk of sudden death may be due to a slitlike ostium with acute takeoff angles of the aberrant coronary arteries or possible compression between the pulmonary trunk and aorta. After its aberrant origin, the LCA takes an abrupt leftward turn and tunnels between the aorta and the right ventricular outflow tract. Sudden death is thought to result from transient occlusion of the anomalous LCA, caused by an increase in blood flow through the aorta and pulmonary artery that occurs during exercise and creates either a kink at the sharp leftward bend or a pinchcock mechanism in the tunnel. Origin of the RCA from the LCA or left aortic sinus with passage between the aorta and the right ventricular outflow tract is somewhat less dangerous. This anomaly, however, has also been associated with myocardial ischemia or sudden death, presumably through the same mechanism.[52] [53] [55] In rare cases of anomalous origin of the LCA from the right aortic sinus, myocardial ischemia may occur even if the LCA passes anterior to the right ventricular outflow tract or posterior to the aorta (i.e., not through a tunnel between the two great vessels).[56]

The course of the anomalous coronary arteries is easily assessed by angiography in the RAO view (Fig. 12-22) . There are four common courses for the anomalously arising LCA from the right sinus of Valsalva, one common course for the anomalous RCA arising from left sinus of Valsalva, and one common course for the anomalous LCx arising from the right sinus of Valsalva. The anomalous LCA arising from the right sinus of Valsalva may take either a septal, anterior,

Figure 12-19 Congenital fistula. *A,* Right anterior oblique cranial view of the left coronary arteriogram shows a congenital fistula (arrow) arising from branches of both the left anterior descending and

left circumflex arteries and draining into the left ventricle. *B,* Left anterior oblique view of the left coronary arteriogram shows the fistula (arrow).

Figure 12-20 Anomalous origin of the left coronary artery (LCA) from the pulmonary artery. *A-C,* The thoracic aortogram shows a large right coronary artery (RCA) and no antegrade filling of the LCA. The LCA fills primarily through extensive collaterals from the RCA to the LAD (white arrows). The anomalous origin of the LCA from the pulmonary artery is demonstrated in late phases of the aortogram (*C,* curved arrow).

Figure 12-21 Anomalous origin of the right coronary artery (RCA). Right anterior oblique coronary arteriogram shows an anomalous RCA arising from left sinus of Valsalva. The origin of the aberrantly arising artery, which is engaged with a left Judkins catheter, arises immediately anterior to the origin of the left coronary artery (not shown in the arteriogram). The anomalous right coronary follows an interarterial course opposite but analogous to that for the anomalous left coronary artery arising from the right sinus of Valsalva.

Figure 12-22 Anomalous origin of the left coronary artery from the right sinus of Valsalva. Each panel includes a caudocranial cross-sectional schematic representation at the level of the semilunar valves, showing the course of the anomalous coronary. The right anterior oblique angiograms and bitmaps show examples of each of the four most common courses of the anomalous left coronary artery aberrantly arising from the right sinus of Valsalva: posterior (retroaortic), interarterial, anterior, and septal (subpulmonic) courses.

interarterial, or posterior course.[57] The posterior course of the anomalous LCA arising from the left sinus of Valsalva is similar to the course of the anomalous LCx arising from the right sinus of Valsalva (Fig. 12-23) , whereas the common interarterial course of the anomalous RCA from the left sinus of Valsalva is similar to the interarterial course of the anomalous LCA arising from the right sinus of Valsalva.

When either the LCA or the LAD arises anomalously from the right aortic sinus, another angiographic method to identify the course of the anomalous vessel is to first pass a catheter into the main pulmonary artery and then perform an arteriogram of the aberrant coronary artery in the steep AP caudal projection. This places the aberrant coronary artery, the rightward and anterior pulmonary valve, and the

Figure 12-23 Anomalous origin of the left circumflex. The caudocranial cross-sectional view at the level of the semilunar valves shows the common course of the left circumflex coronary artery aberrantly arising from the right sinus of Valsalva. The left circumflex artery passes behind the aortic root and runs to the left atrioventricular groove following an initial course identical to that for the anomalous left coronary artery arising from the right sinus of Valsalva that follows a posterior, retroaortic course.

leftward and posterior aortic valve all in one plane (see Fig. 12-22) . From this "laid-back aortogram," which can be used even in mapping the course of anomalous coronary arteries in transposition of the great vessels, it is usually possible to confirm whether the course of the aberrant coronary artery is between the great vessels. Although angiography is useful for establishing the presence of anomalous coronary arteries, transesophageal echocardiography may also be an important adjunctive diagnostic tool for establishing the course of the vessels.[58]

SINGLE CORONARY ARTERY.

Although there are numerous variations of this anomaly,[59] it assumes hemodynamic significance when a major branch passes between the aorta and the right ventricular outflow tract.

Anomalies Not Causing Myocardial Ischemia

In this category of anomalies, the coronary arteries originate from the aorta, but their origins are in unusual locations. Although myocardial perfusion is normal, cannulation of the origin of these vessels may be problematic. These anomalies occur in about 0.5 to 1.0 percent of adult patients undergoing coronary arteriography.[60]

ORIGIN OF THE LEFT CIRCUMFLEX ARTERY FROM THE RIGHT AORTIC SINUS.

Anomalous origin of the circumflex artery from the right aortic sinus is the most common of these anomalies (see Fig. 12-23). In a series of nearly 3000 patients, this anomaly was found in 0.67 percent.[61] The anomalous LCx generally arises posterior to the right coronary artery and courses inferiorly and posteriorly to the aorta to enter the left atrioventricular groove. An interarterial course for an anomalous LCx originating from the right sinus of Valsalva is extremely uncommon.

ORIGIN OF ALL THREE CORONARY ARTERIES FROM EITHER RIGHT OR LEFT AORTIC SINUSES VIA MULTIPLE SEPARATE OSTIA.

This rare anomaly is similar to single coronary artery. There is absence of a coronary ostium in either the left or right aortic sinus. The missing vessels arise in the contralateral aortic sinus, but instead of arising as a single coronary artery they arise through two or even three separate ostia.

HIGH ANTERIOR ORIGIN OF THE RIGHT CORONARY ARTERY.

This anomaly is commonly encountered but of no hemodynamic significance. The inability to engage the ostium of the RCA selectively from conventional catheter manipulation raises the question of this superior origin of the RCA above the sinotubular ridge. Forceful, nonselective injection contrast medium into the right sinus of Valsalva may reveal the anomalous take-off of the RCA, which can then be selectively engaged with a Judkins right 5.0 catheter or Amplatz left 1.0 or 1.5 catheter.

CORONARY ARTERY SPASM (See also Chap. 37.)

In 1959, Prinzmetal and colleagues[62] described an unusual or variant form of angina in which the onset of chest pain was not provoked by the usual factors, such as exercise, emotional upset, cold, or ingestion of a meal. Patients considered to have variant angina are those in whom chest pain commences at rest or both at rest and during exertion,[63] occurs in a cyclical pattern at the same time every day, and is accompanied by ST segment elevation if an ECG is recorded. Although the ST segment elevation often is striking, it rapidly reverts to normal when the pain disappears spontaneously or is terminated by the administration of nitroglycerin and may be accompanied by atrioventricular block, ventricular ectopic activity, ventricular tachycardia, or ventricular fibrillation.[62]

Coronary arteriography plays an important role in understanding the pathophysiology and clinical consequences of coronary artery spasm.[64] Angiographic studies have shown that although spasm usually was superimposed on areas of fixed stenosis, it often occurred in segments of coronary arteries that appeared angiographically normal. Intravenous ergonovine maleate was used in the late 1970s to provoke spasm in patients with suspected variant angina who were undergoing coronary arteriography.[64] In a series of 1089 consecutive patients undergoing coronary arteriography for chest pain, coronary artery spasm was found in 12 percent of patients after ergonovine provocation.[65] Coronary spasm occurred with angiographic evidence of a coronary stenosis in 59 percent and in the absence of a demonstrable coronary lesion in 41 percent. Although ergonovine-induced spasm occurred rarely (<5 percent) in patients with atypical chest pain and exertional angina, it occurred in 14 percent of patients with symptoms of both exertional and resting angina. Ergonovine-induced coronary spasm was seen in 85 percent of patients with primarily rest angina who were observed to have episodes of ST segment elevation. Coronary angiography is also useful in these patients to exclude the diagnosis of fixed CAD. Accordingly, the diagnosis of coronary artery spasm must rely instead on clinical features and response to treatment with nitrates and calcium channel blockers.

MORPHOLOGY OF ATHEROSCLEROTIC LESIONS

Characterization of lesion morphology based on the coronary arteriogram has been used to assess the chance of success and risk for complications associated with

PCI.[66] [67] Criteria established by a joint ACC/AHA task force (Table 12-7) [68] were prospectively tested in a series of 350 patients undergoing multivessel PCI, which found that procedural success and complication rates were 92 percent and 2 percent, respectively, for type A lesions; 76 percent and 10 percent, respectively, for type B lesions; and 61 percent and 21 percent, respectively, for type C lesions. Lesions with two or more type B lesion characteristics (modified ACC/AHA B2) had an intermediate risk between lesions with one type B characteristic (modified ACC/AHA B1) and type C lesions.[66] Certain lesion characteristics were associated

TABLE 12-7 -- CHARACTERISTICS OF TYPE A, B, AND C CORONARY LESIONS

Type A Lesions (high success, >85%; low risk)	
Discrete (<10 mm)	Little or no calcium
Concentric	Less than totally occlusive
Readily accessible	Not ostial in locations
Nonangulated segment, <45 degrees	No major sidebranch involvement
Smooth contour	Absence of thrombus
Type B Lesions (moderate success, 60-85%; moderate risk)	
Tubular (10 to 20 mm length)	Moderate to heavy calcification
Eccentric	Total occlusions >3 months old
Moderate tortuosity of proximal segment	Ostial in location
Moderately angulated segment, 45 degrees, <90 degrees	Bifurcation lesion requiring double guidewire
Irregular contour	Some thrombus present
Type C Lesions (low success, <60%; high risk)	
Diffuse (2 cm length)	Total occlusion >3 months old
Excessive tortuosity of proximal segment	Inability to protect major sidebranches
Extremely angulated segments, 90 degrees	Degenerated vein grafts with friable lesions

From Ryan T, Faxon D, Gunnar R, et al: Guidelines for percutaneous transluminal coronary angioplasty: A report of the American College of Cardiology/American Heart Association Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures (Subcommittee on Percutaneous Transluminal Coronary Angioplasty). J Am Coll Cardiol 12:529-545, 1988.

with higher risk, including chronic total occlusions, high-grade stenoses, stenoses on a bend of 60 degrees or more, and lesions located in vessels with proximal tortuosity[66] (Fig. 12-24) .

With advances in operator experience, availability of coronary stents, and the use of glycoprotein IIb to IIIa inhibitors (see Chap. 38) , higher (>90 percent) procedural success rates have been reported with complex type B and C lesions.[69] It is now recognized that the ACC/AHA classification system is limited by the subjectivity of the criteria,[66] [66A] [70] variable risk with the individual criteria,[71] and the demonstration that some criteria are associated with a risk for failure but low risk for complications, whereas others are associated with a higher risk for both failure and complications.[69]

Specific Lesion Characteristics

Estimation of procedural risk may be more useful based on the presence of one or more specific adverse morphological features rather than use of a composite scoring system (see Chap. 38) (Table 12-8).

IRREGULAR LESIONS.

Lesion irregularity, including those lesions with ulceration, aneurysm formation, a "sawtooth" pattern, or an intimal flap, suggests a friable surface, correlating pathologically with plaque fissuring, rupture, and platelet and fibrin aggregation.[72] Complex, irregular plaques have been associated with unstable coronary syndromes[72] and progression to total occlusion,[73] whereas smooth lumen contours are more suggestive of stable angina.[72] Other surface morphology features associated with unstable angina and infarction include lesions with sharply angulated leading or trailing borders, multiple serpiginous channels, and discrete intraluminal filling defects.[74]

Semiquantitative measurements of lesion irregularity have obtained in patients with unstable coronary syndromes.[75] By using curvature analysis of the arterial contour in one study, lesion irregularity was quantified by measuring the number and magnitude of the peaks and

Figure 12-24 Examples of the ACC/AHA lesion complexity score. A concentric stenosis (arrow) is identified in the proximal segment of the proximal right coronary artery (type A lesion, *A*). A calcified, ostial lesion of the left anterior descending artery (arrow) is shown (type B2 lesion, *B*). A long (35 mm) diffuse narrowing (arrow) in the midsegment of the left anterior descending artery is demonstrated (type C lesion, *C*).

TABLE 12-8 -- DEFINITIONS OF PREPROCEDURAL LESION MORPHOLOGY*

FEATURE	FREQUENCY (%)	DEFINITION
Eccentricity	48.0	Stenosis that is noted to have one of its luminal edges in the outer one fourth of the apparent normal lumen.
Irregularity	17.9	Characterized by lesion ulceration, intimal flap, aneurysm, or "sawtooth" pattern
Ulceration	12.1	Lesions with a small crater consisting of a discrete luminal widening in the area of the stenosis
Intimal flap	3.22	A mobile, radiolucent extension of the vessel wall into the arterial lumen

Aneurysm	5.49	Segment of arterial dilatation larger than the dimensions of the normal arterial segment
"Sawtooth"	0.84	Multiple, sequential stenosis irregularities
Length		Measured "shoulder-to-shoulder" in an unforeshortened view
Discrete	55.0	Lesion length <10 mm
Tubular	34.8	Lesion length 10-20 mm
Diffuse	10.2	Lesion length >20 mm
Ostial location	10.0	Origin of the lesion within 3 mm of the vessel origin
Angulation		Vessel angle formed by the center line through the lumen proximal and distal to the stenosis
Moderate	15.3	Lesion angulation 45 degrees
Severe	0.93	Lesion angulation 90 degrees
Bifurcation stenosis	6.05	Stenosis involving the parent and daughter branch if a medium or large branch (>1.5 mm) originates within the stenosis and if the side branch is completely surrounded by stenotic portions of the lesion to be dilated
Proximal tortuosity		
Moderate	15.3	Lesion is distal to two bends 75 degrees
Severe	NR	Lesion is distal to three bends 75 degrees
Degenerated SVG	7.1	Graft characterized by luminal irregularities or ectasia comprising >50% of the graft length
Calcification	34.3	Readily apparent densities noted within the apparent vascular wall at the site of the stenosis
Total occlusion	6.4	TIMI 0 or 1 flow
Thrombus	3.4	Discrete, intraluminal filling defect is noted with defined borders and is largely separated from the adjacent wall. Contrast staining may or may not be present.

SVG=saphenous vein graft; NR=not reported.

troughs of the lumen contour. The number of peaks per centimeter, summed maximum errors per centimeter, integrated errors per centimeter, and features per centimeter were higher in patients with unstable angina than in those with stable angina.[75] Clinical application of this technique has been limited owing to the sophisticated software and time required for its routine use.

LESION LENGTH.

Estimates of axial lesion length have been obtained using a number of methods, including the measurement of the "shoulder-to-shoulder" extent of atherosclerotic narrowing more than 20 percent or by the lesion length with a more than 50 percent visual diameter stenosis.[76] In clinical practice, the lesion length is often estimated by the distance between the proximal and distal angiographically "normal" segments. The ACC/AHA criteria categorize lesions as discrete (<10 mm), tubular (10-20 mm), and diffuse (> 20 mm). Diffuse lesions are associated with reduced procedural success.[77] Lesion length is also an important predictor of restenosis after PCI,[67] [69] potentially relating to the more extensive plaque burden in long lesions.

OSTIAL LOCATION.

Ostial lesions are defined as those arising within 3 mm of origin of the vessel or branch. Balloon PTCA of aortoostial lesions and ostial lesions of LAD or LCx coronary arteries has been associated with a reduced procedural success and high recurrence rates,[78] [79] potentially owing to smooth muscle and eccentric intimal proliferation noted pathologically in ostial lesions. Technical factors may also account for the suboptimal success rates, such as difficulty with guide catheter support, lesion inelasticity precluding maximal balloon inflation, and the need for multiple balloon exchanges. Although directional and rotational atherectomy improve the procedural success rates in patients with ostial lesions, late clinical recurrence remains high.[80] [81] [82] Coronary stents have improved the late recurrence rates by reducing the degree of arterial recoil.

ANGULATED LESIONS.

Balloon PTCA of highly angulated (
45 degrees) lesions carries an increased risk of procedural complications (13 percent versus 3.5 percent in nonangulated stenoses; $p<0.001$). [83] Complications are most often due to coronary dissection, with the risk of dissection related to the severity of the angulation.[66] Vessel curvature should be measured in the most unforeshortened projection using a length of curvature that approximates the balloon or stent length used for coronary dilatation. Those devices that are relatively rigid (e.g., directional atherectomy) are less useful in angulated lesions. Coil stents appear better able to conform to an angulated segment than tubular slotted or multicellular designs.

BIFURCATION LESIONS.

The risk of sidebranch occlusion ranges from 14 to 27 percent in bifurcation lesions, relating to the extent of atherosclerotic involvement within the origin of the sidebranch.[67] [84] The risk of sidebranch compromise has been reduced using advanced angioplasty methods, including guidewire protection, "kissing balloon" techniques, branch vessel stent placement,[85] and lesion angulation, but calcification or vessel size may preclude adequate sidebranch protection in some cases. Sidebranch occlusion during PCI is a frequent cause of periprocedural cardiac enzyme elevation.

DEGENERATED SVGs.

The procedural success rate after balloon angioplasty of SVG lesions ranges from 84 to 92 percent,[86] [87] [88] depending, in part, on the presence of SVG friability or degeneration, lesion location, and SVG age of 36 months or more.[86] Few criteria have been proposed for classifying the degree of SVG degeneration, although such a definition should include an estimate of the percentage of SVG irregularity and ectasia, friability, presence of thrombus,

Figure 12-25 Intracoronary thrombus in acute myocardial infarction. In the setting of acute MI, this right anterior oblique caudal left coronary arteriography shows an eccentric lesion (arrowhead) in the proximal left anterior descending artery, immediately followed by a globular filling defect (arrow) surrounded by contrast media on all sides.

and number of discrete or diffuse lesions (>50 percent stenosis) located within the SVG. The major periprocedural risk for PCI is the occurrence of distal embolization of thrombus and plaque contents.

LESION CALCIFICATION.

Coronary artery calcium is an important marker for coronary atherosclerosis. With IVUS as a reference standard, conventional angiography is moderately sensitive for the detection of extensive lesion calcium (sensitivity, 60 percent and 85 percent for three- and four-quadrant calcium, respectively) but is less sensitive for the presence

of milder degrees of lesion calcification.[89]

The presence of angiographic coronary artery calcium has also been related to reduce procedural success rates after balloon PTCA and DCA.[67] [90] Higher (90 percent) procedural success rates have been reported after rotational atherectomy in heavily calcified lesions.[91]

Figure 12-26 Intracoronary thrombus in unstable angina. This left anterior oblique right coronary arteriogram shows a severe stenosis in the midportion of the right coronary artery (arrowhead), followed by a large filling defect surrounded by contrast medium on all sides (arrows).

Figure 12-27 Total occlusion with blunt appearance. The left anterior oblique right coronary arteriogram shows a blunt total occlusion (arrow) of the midportion of the right coronary artery associated with a sidebranch. The blunt appearance and the presence of the sidebranch are characteristics that angioplasty may be unsuccessful.

THROMBUS.

Conventional angiography is a relatively insensitive method to detect coronary thrombus,[92] although complex lesion morphology has been associated with clinical findings of "high-risk" unstable angina.[93] When it is present, angiographic thrombus, defined as discrete, intraluminal filling defects within the arterial lumen, has also been associated with a variably higher (range: 6-73 percent) incidence of ischemic complications after PCI[94] [95] (Figs. 12-25 and 12-26). Large, intracoronary thrombi may be treated with a combination of pharmacological agents (e.g., glycoprotein IIb-IIIa inhibitors) and mechanical devices (e.g., rheolytic thrombectomy) (see Chap. 38) .

Figure 12-28 Total occlusion with taper. The left anterior oblique right coronary arteriogram shows a total occlusion (arrow) of the midportion of the right coronary artery, but the smoothly tapering appearance of the site of total occlusion suggests that attempt with angioplasty may be successful.

TABLE 12-9 -- THROMBOLYSIS IN MI (TIMI) FLOW

Grade 3 (complete reperfusion)	Anterograde flow into the terminal coronary artery segment through a stenosis is as prompt as anterograde flow into a comparable segment proximal to the stenosis. Contrast material clears as rapidly from the distal segment as from an uninvolved, more proximal segment.
Grade 2 (partial reperfusion)	Contrast material flows through the stenosis to opacity the terminial artery segment. However, contrast material enters the terminal segment perceptibly more slowly than more proximal segments. Alternatively, contrast material clears from a segment distal to a stenosis, noticeably more slowly than from a comparable segment not preceded by a significant stenosis.
Grade 1 (penetration with minimal perfusion)	A small amount of contrast flows through the stenosis but fails to fully opacify the artery beyond.
Grade 0 (no perfusion)	No contrast flow through the stenosis.

Modified from Sheehan F, Braunwald E, Canner P, et al: The effect of intravenous thrombolytic therapy on left ventricular function: A report on tissue-type plasminogen activator and streptokinase from the Thrombolysis in Myocardial Infarction (TIMI) Phase I trial. Circulation 72:817-829, 1987. Copyright 1987, American Heart Association.

TOTAL OCCLUSION.

Total coronary occlusion is identified on the cineangiogram as an abrupt termination of the epicardial vessel; anterograde and retrograde collaterals may be present and are helpful in quantifying the length of the totally occluded segment (Fig. 12-27). Primary success rates for balloon angioplasty of total occlusions remains suboptimal (66-83 percent),[67] [69] [96] lower than the 94.2 percent primary success rates for subtotal occlusions.[69] The risk of an unsuccessful procedure depends on the duration of the occlusion[69] and certain lesion morphological features, such as bridging collaterals, occlusion length greater than 15 mm, and the absence of a "nipple" to guidewire advancement (Fig. 12-28) .

CORONARY PERFUSION.

Perfusion distal to a coronary stenosis can occur anterograde by means of the native vessel, retrograde through collaterals, or through a coronary bypass graft.[29] The rate of anterograde coronary flow is influenced by both the severity and complexity of the stenosis and the status of the microvasculature. The Thrombolysis in Myocardial Infarction (TIMI) study group established criteria to assess the degree of anterograde coronary reperfusion in patients with acute MI[97] (Table 12-9) . Successful reperfusion was present with TIMI flow 2 or 3, whereas TIMI 0 or 1 flow was deemed failed reperfusion. It is now clear that TIMI 2 flow may also be insufficient for myocardial perfusion, associated with increased mortality in patients with acute MI compared with those with normal TIMI 3 perfusion.[98] [99] The TIMI frame count was subsequently introduced to quantifying the coronary artery perfusion rates in patients with acute MI.[100] With this method, the number of cinefilm frames required for opacification of the involved vessel are counted by means of an automated frame counter, which is present on most cine projectors. Flow delayed more than 60 frames (approximately two cardiac cycles at 30 frames/second) and 90 frames (approximately three cardiac cycles at 30 frames/second) may be associated with increased risks for cardiac morbidity.[100]

Coronary Collateral Circulation

In the normal human heart, networks of tiny anastomotic branches interconnect the major coronary arteries and are precursors for the collateral circulation.[101] These anastomotic arteries cannot be visualized in patients with normal or mildly diseased coronary arteries because they carry only minimal flow and their small (<200 mum) caliber is well beyond the spatial resolution capabilities of cine imaging systems. As a coronary artery obstruction forms, a pressure gradient develops within anastomotic vessels connecting the distal hypoperfused segment with the proximal artery or the adjacent anastomotic channels of other vessels. The trans-stenosis pressure gradient facilitates blood flow through the anastomotic vessels, which progressively dilate and eventually become angiographically visible as collateral channels.

Although it is not entirely clear why some patients develop effective collateral vessels distal to a severe stenosis and others do not, a gradual rate of obstruction formation may allow enlargement of preexisting channels or growth of new ones by angiogenesis. This may allow the development of a "protected" region of myocardial perfusion. Coronary collaterals are usually not visualized until the coronary obstruction is larger than 90 percent.[101] [102] The temporal sequence of collateral development has been studied in patients who show persistent occlusion of the IRA after acute MI.[103] Among patients studied within 6 hours of infarction, about half demonstrated angiographically visible collateral vessels. Among those studied more than 24 hours after infarction, virtually all had visible collaterals. This suggests that collateral flow may develop more rapidly than previously recognized and may potentially develop within hours after total occlusion. It thus appears that collateral circulation does not represent the formation of new vessels but rather the utilization of vessels that already exist but carry little blood flow because distal perfusion was not compromised. Other factors that affect collateral development are patency of the arteries supplying the collateral and the size and vascular resistance of the segment distal to the stenosis.[104] A classification system for the grading of coronary collaterals has been proposed (Table 12-10) . A wide variety of collateral pathways exist in patients with severe CAD (Figs. 12-29 (Figure Not Available) to 12-31) .

FUNCTION OF COLLATERAL VESSELS.

Coronary collateral vessels have a number of functional roles. In patients with total occlusions, regional

TABLE 12-10 -- PERFUSION GRADES DISTAL TO A CORONARY STENOSIS

GRADE	TIMI	COLLATERAL FLOW	RENTROP COLLATERAL GRADE
3	Prompt anterograde flow and rapid clearing	Excellent	Complete perfusion. Contrast material enters and completely opacifies the target epicardial vessel.
2	Slow distal filling, but full opacification of distal vessel	Good	Partial collateral flow. Contrast material enters but fails to opacify the target epicardial vessel completely.
1	Small amount of flow, but incomplete opacification of distal vessel	Poor	Barely detectable collateral flow. Contrast medium passes through collateral channels but fails to opacify the epicardial vessel at any time.
0	No contrast flow	No visible flow	No collaterals present.

left ventricular contraction is better in segments supplied by adequate collateral circulation than in those segments supplied by inadequate or no collateral circulation.[101] In patients with acute MI undergoing emergency coronary arteriography without antecedent thrombolytic therapy, those with adequate collaterals had significantly lower left ventricular end-diastolic pressures, higher cardiac index, higher ejection fraction, and lower percentage of area dyssynergy than patients without collaterals.[105] Patients with severe coronary obstruction without collateral circulation were found to have a significantly higher incidence of thallium-201 myocardial perfusion defects than those with an intact collateral circulation.[106] With balloon inflation during PTCA, patients with well-developed collateral vessels experienced less pain, have less left ventricular asynergy, and have less summed ST segment elevation than those with poorly developed collateral vessels.[107] Distal coronary perfusion pressure during balloon inflation is higher in patients with well-developed collaterals than in those with poorly developed collateral circulation.[108] [109] [110]

Angiographic Findings After Percutaneous Coronary Intervention

A number of angiographic complications have been characterized after PCI, based on their risk for early complications and late restenosis. Pathological studies have demonstrated that plaque fracture and dissections are integral components of PCI,[111] occurring after 32 to 41 percent of balloon procedures[112] [113] [114] (Figs. 12-32 and 12-33). A scoring system for the severity of the dissection was proposed by the National Heart, Lung, and Blood Institute (NHLBI) PTCA Registry investigators (Table 12-11) . The immediate prognostic importance of a coronary dissection depends on its extent into the medial and adventitia, axial length, presence of contrast staining, and effect on coronary perfusion.[112] [115] [116] Dissections involving more than 50 percent of the vessel circumference or extending more than 10 mm in axial length are associated with a worse prognosis. [111] Plaque rupture, fissure, intimal flaps, and nonocclusive thrombus formation may also be manifest angiographically as intraluminal haziness, obscuring arterial borders and making visual and quantitative estimates of residual coronary dimensions difficult.

Embolic complications may also be identified during PCI. Distal embolization is defined as the migration of a filling defect or thrombus to distally occlude the target vessel or one of its branches. "No reflow" is defined as a reduction in anterograde flow without a demonstrable residual stenosis at the treatment site. These complications occur during 1 to 2 percent of PCI procedures.[117] [118] [119] Coronary perforation is defined as the extravasation of contrast material outside the vessel lumen and classified as localized (confined to the pericardial space immediately surrounding the artery) or nonlocalized (extending diffusely within the pericardial space). Coronary perforation may develop more often in patients treated with new devices compared with balloon PTCA.[120]

Quantitative Angiography

Quantitative angiographic methods, including automated arterial contour-detection, videodensitometry, and digital parametric algorithms, have been used to assess procedural outcome after PCI. These methods have been developed based on the recognized limitations of visual estimation of stenosis severity, which include observer variability,[121] overestimation of the stenosis severity before PCI and underestimation of the stenosis severity after PCI,[122] and provision of some visual estimates (>90 percent) that are physiologically untenable.[123] It does seem clear that once the inherent limitations of visual estimation of stenosis severity are understood that the clinician's eye can become "retrained," and one series has shown that visual estimates by experienced observers may correlate more closely with quantitative measurements.[124]

DIGITAL CALIPERS.

Digital calipers provide a more quantitative estimate of stenosis severity than visual estimates, and, when properly applied, this method appears to correlate

Figure 12-30 Common collateral pathways seen with left anterior descending artery occlusion. (See Figure 12-29 (Figure Not Available) for abbreviations.) (From Levin DC: Pathways and functional significance of the coronary collateral circulation. Circulation 50:831, 1974. Copyright 1974, American Heart Association.)

with automated-edge detection algorithms.[125] With the use of digital calipers, cineangiograms are magnified and projected onto a wall or flat surface using this method. Calibration is performed by measuring the known dimensions of the diagnostic or guiding catheter. The lumen border is measured using the caliper, and a calibration factor is obtained to determine quantitative dimensions.[29] Notably, if the caliper measurements are obtained from nonmagnified images, the correlation with automated edge-detection algorithms is less favorable (r=0.72).[126]

AUTOMATED EDGE DETECTION ALGORITHMS.

Based on early work using hand-drawn arterial contours that corrected for pincushion distortion and reconstructed a three-dimensional representation of the arterial contour,[127] computer-assisted methods for automated arterial contour detection were developed. These computer-assisted techniques have been applied to directly acquired digital images or to 35-mm cinefilm digitized using a cinevideo converter. Examples of such systems include the Cardiovascular Angiographic Analysis System (CAAS),[128] ARTREK,[129] Cardiovascular Measurement System (CMS),[130] and the Duke University Quantitative/Qualitative Evaluation System,[131] among others.[132] [133]

Quantitative angiographic analysis is divided into several distinct processes, including film digitization, image calibration, and arterial contour detection. A cine-video converter is used to digitize 35-mm cineframes into a 512×512 (or 480)×8 bit pixel matrix. Magnification of the image results in an effective pixel matrix of approximately 2458×2458.[129] The contrast agent-filled diagnostic or guiding catheter can be used as a scaling device for determining absolute vessel dimensions, yielding a calibration factor in millimeters per pixel. Catheter and arterial contours are obtained by drawing a center line through the segment of interest. Linear density profiles are then constructed perpendicular to the center line, and a weighted average of the first and second derivative function is used to define the catheter or arterial edges. Individual edge points are then connected using an automated algorithm, and outliers are discarded and the edges are smoothed. The automated algorithm is then applied to a selected arterial segment, and absolute coronary dimensions and percent diameter stenosis are obtained.

Important differences exist in the various quantitative coronary angiographic systems with respect to the calibration method, identification of the arterial edge, use of minimal cost or "smoothing" algorithms for contour construction, and identification of the normal "reference" segment. These systematic differences may affect the accuracy and precision of the quantitative coronary angiographic measurements, and system-to-system variability may be substantial.[134] For most angiographic systems, interobserver variabilities are 3.1 percent for diameter stenosis and 0.10 to 0.18 mm for minimal lesion diameter.

VIDEODENSITOMETRY.

This technique has also been used to evaluate changes in stenosis severity before and after PCI.[135] With this method, the contrast density of a selected reference segment is compared with the contrast density in the region of a stenosis. The major advantage of videodensitometry is that lesion eccentricity and irregularity, typically manifest as haziness within a single projection, can be accounted for without the need for multiple image projections. The primary limitation of videodensitometry is that vessel overlap with other anatomical structures (e.g., diaphragm, ribs) and image overpenetration make precise determination of the reference vessel area problematic in some vessels.

Figure 12-31 Common collateral pathways seen with left circumflex artery occlusion. (See Figure 12-19 for abbreviations.) (From Levin DC: Pathways and functional significance of the coronary collateral circulation. Circulation 50:831, 1974. Copyright 1974, American Heart Association.)

Figure 12-32 Moderately severe coronary dissection. This left anterior oblique cranial left coronary arteriogram shows a large intramural collection of contrast medium (arrows) at the site of angioplasty in the proximal left anterior descending artery. Although contrast medium cleared rapidly from artery itself, contrast medium persisted within the dissection, thus meeting criteria for a type C dissection.[120] [121]

The accuracy and reproducibility of quantitative angiography are dependent on a number of factors that add error to the precision of the measurements.[136] The total variance associated with the measurement of the minimal lumen and reference diameters within a study is affected by (1) the biological differences among lumen dimensions (e.g., intrinsic arterial size, vasomotor tone, thrombus); (2) inconsistencies in radiographic image acquisition parameters (e.g., quantum mottling, out-of plane magnification, foreshortening); and (3) angiographic measurement variability (e.g., frame selection, factors affecting the edge-detection algorithm) (Table 12-12) . It is essential that these factors be minimized during image acquisition, particularly in prospectively designed research protocols.[137]

Although analysis of two or more "orthogonal" projections has been recommended to allow a more accurate assessment of the physiological significance of lesion severity,[138] [139] a second, technically suitable projection may not be available in many (14-53 percent) angiographic cases, owing to vessel foreshortening, overlap, and poor image quality.[140] If orthogonal projections are not available, analyses of the "worst-view" projection may provide sufficiently accurate information.[140]

Figure 12-33 Spiral dissection. This left anterior oblique right coronary arteriogram shows evidence of a vessel dissection emanating from the site of angioplasty in the midportion of the right coronary artery (arrowhead) and extending to the distal right coronary artery (arrow), thus meeting criteria for a severe type D dissection.[112] [113]

TABLE 12-11 -- STANDARDIZED CRITERIA FOR POSTPROCEDURAL LESION MORPHOLOGY

FEATURE	DEFINITION
Abrupt closure	Obstruction of contrast flow (TIMI 0 or 1) in a dilated segment with previously documented anterograde flow
Ectasia	A lesion diameter greater than the reference diameter in one or more areas
Luminal irregularities	Arterial contour that has a "sawtooth pattern" consisting of opacification but not fulfilling the criteria for dissection or intracoronary thrombus
Intimal flap	A discrete filling defect in apparent continuity with the arterial wall
Thrombus	Discrete, mobile angiographic filling defect with or without contrast medium staining
Dissection,* A	Small radiolucent area within the lumen of the vessel
B	Linear, nonpersisting extravasation of contrast medium
C	Extraluminal, persisting extravasation of contrast medium
D	Spiral-shaped filling defect
E	Persistent lumen defect with delayed anterograde flow
F	Filling defect accompanied by total coronary occlusion
Dissection, length (in mms)	Measure end-to-end for type B through F dissections
Dissection, staining	Persistence of contrast medium within the dissection after washout of contrast medium from the remaining portion of the vessel
Perforation, localized	Extravasation of contrast medium confined to the pericardial space immediately surrounding the artery and not associated with clinical tamponade
Nonlocalized	Extravasation of contrast medium with a jet not localized to the pericardial space, potentially associated with clinical tamponade
Side branch loss	TIMI 0, 1, or 2 flow in a side branch >1.5 mm in diameter that previously had TIMI 3 flow
Distal embolization	Migration of a filling defect or thrombus to distally occlude the target vessel or one of its branches
Coronary spasm	Transient or permanent narrowing >50% when a <25% stenosis has been previously noted

Modified from Popma JJ, Lansky AJ: Qualitative and quantitative angiography. In Topol EJ (ed): Textbook of Interventional Cardiology, 3rd ed. Philadelphia, WB Saunders, 1999.

TABLE 12-12 -- CORRECTABLE SOURCES OF IMAGING ERROR DURING ACQUISITION AND ANALYSIS

SOURCE OF ERROR	POTENTIAL CORRECTIONS
Biologic Variation in Lumen Diameter	
Vasomotor tone	Nitroglycerin, 200 mug IC every 10 minutes
Variations in image acquisition	
Single Studies	
Vessel motion Cardiac	End-diastolic/end-systolic cineframe
Respiration	Breath holding
Vessel foreshortening	Obtain multiple angiographic projections
Insufficient contrast injection	Use 7-8 Fr large, high flow catheters

Branch vessel overlap	Obtain multiple angiographic projections
Pincushion distortion	Image objects in center of image
Sequential Studies	
X-ray generator (pulse width/dose/beam quality)	Repeat study in same imaging laboratory
X-ray tube (focal spot/shape/tube current)	As above
Image intensifier (magnification/resolution)	As above
Differences in angles and gantry height	Record gantry height/angle/skew on worksheet
Image calibration	Use measured catheter diameter
Errors in Image Analysis	
Electronic noise	Recursive digitization and frame averaging
Quantum noise	Spatial filtering of digital image data
Automated edge detection algorithm	Minimize observer interaction
Selection of reference positions	Interpolated or averaged normal segment
Identification of lesion length	Use of sidebranches, other landmarks
Frame selection	End-diastolic frame showing "worst" view

Pitfalls of Coronary Arteriography

A systematic approach based on a few, common-sense principles is needed to avoid pitfalls in the performance and interpretation of coronary arteriography. It should be recalled that the normal coronary artery tapers gradually from proximal to distal and has smooth walls completely free of irregularities. Several factors may affect the quality of the angiographic interpretation.

INADEQUATE OPACIFICATION.

Inadequate filling of the coronary artery with contrast medium may result in streaming of contrast medium and give the impression of ostial stenoses, missing sidebranches, or thrombus. Superselective injection of contrast medium into the LCx through short LMCA may give the impression of total occlusion of the LAD. Adequate filling of the coronary arteries and bypass grafts is required to overcome the native flow of unopacified blood and produce high-quality coronary arteriograms. Streaming of contrast medium, admixed with unopacified blood, leads to artifactual impression of filling defects and incomplete assessment of stenosis severity. The causes of incomplete filling include competition from increased native coronary blood flow in the setting of left ventricular hypertrophy associated with aortic insufficiency or anemia and inadequate placement of the diagnostic catheter with subselection of the LCx through a short LCMA. The problem of underfilling can be overcome by more forceful contrast agent injection so long as catheter tip position and pressure recording confirm the safety of such a maneuver. Under some conditions, switching to an angioplasty-guiding catheter with soft, short tip and a larger lumen than a diagnostic catheter may allow for more complete opacification of the target coronary artery or bypass graft.

ECCENTRIC STENOSES.

Coronary atherosclerosis more often leads to eccentric or slitlike atherosclerotic narrowings than concentric narrowings. If the long axis of the lumen is projected, the vessel may appear to have a normal or near-normal caliber. Only if the short axis of the stenotic lumen is projected will the narrowing be visible. For this reason, coronary arteries must be viewed in at least two projections approximately 90 degrees apart.

A related problem is that of the bandlike or membranous stenosis. Lesions such as this may be exceedingly difficult to detect. It is not clear whether these peculiar lesions represent pure atherosclerotic stenosis or are caused in some instances by congenital membranous bands. Aside from the difficulty in detecting these lesions, it is difficult to ascertain their hemodynamic significance. Measurement of the pressure gradient across the lesion through a small inner catheter inserted through the angiographic catheter may be useful in this regard.

UNRECOGNIZED OCCLUSIONS.

Flow disturbances associated with branch points predispose to the development of atherosclerosis and total occlusions of major arteries at this location. Because of this fact and the variability in the number and distribution of side branches in the normal coronary circulation, it is possible for occlusions at branch origins to escape detection. In some cases, occlusion of a branch can be recognized only by late filling of the distal segment of this branch by means of collateral circulation.

SUPERIMPOSITION OF BRANCHES.

Superimposition of major branches of the left coronary tree in the LAO and RAO projections can result in failure to detect stenoses or total occlusions of these branches. Although this problem most commonly affects the LAD and parallel diagonal branches, it is alleviated by the use of cranial and caudal angulation. Septal branches may mimic the LAD in the LAO cranial projection. When the LAD is occluded beyond the origin of the first septal branch, this branch often becomes quite enlarged in an attempt to provide collateral circulation to the vascular bed of the distal LAD.

MYOCARDIAL BRIDGING.

The major coronary arteries pass over the epicardial surface of the heart. In some cases,

however, short segments descend into the myocardium for a variable distance. This occurs in 5 to 12 percent of patients and is almost always confined to the LAD. Because a "bridge" of myocardial fibers passes over the involved segment of the LAD, each systolic contraction of these fibers can cause narrowing of the artery. Myocardial bridging has a characteristic appearance on cineangiography. The bridged segment is of normal caliber during diastole but abruptly narrows with each systole. Systolic narrowing caused by myocardial bridging should not be confused with an atherosclerotic plaque. Although bridging is not thought to have any hemodynamic significance in most cases, some have suggested that when it produces severe systolic narrowing, ischemia or infarction may result. The presence of myocardial bridging has important implications for interventional cardiovascular therapy, because bridges do not respond to balloon dilatation or other interventions.

RECANALIZATION.

Although a narrowed segment of a coronary artery seen on arteriography usually is considered a "stenosis," such lesions may actually be a segment that was once totally occluded but has recanalized. Pathological studies suggest that approximately one third of totally occluded coronary arteries ultimately recanalize. The arteriographic appearances of stenosis and recanalization may be indistinguishable. Recanalization usually results in the development of multiple tortuous channels, which are quite small and close to one another, creating an impression on cineangiography of a single, slightly irregular channel. It is unlikely that the spatial resolution of cineangiography is sufficient to demonstrate this degree of detail in most patients with recanalized total occlusions, but this has important implications for interventional cardiovascular treatments because they are unlikely to be successful in the setting of multiple microscopic channels.

INTRAVASCULAR ULTRASONOGRAPHY (See also Chap. 7.)

Contrast coronary arteriography is limited in its ability to quantitate the extent or distribution of atherosclerosis[141] or to identify changes within the vessel wall over time.[142] [143] IVUS is a safe,[144] accurate,[145] and reproducible[146] [147] method of detecting vessel wall pathology[148] and lends insight into the dynamic changes before, after, and late after PCI.[149] [150] The two-dimensional tomographic images provided by IVUS also permits 360-degree characterization of arterial lumen dimensions in

regions that are difficult to assess using conventional angiography, such as the LMCA and the ostii of the LAD, LCx, and RCA.[151]

TECHNICAL ISSUES.

IVUS has evolved substantially since the early 1990s, resulting in the commercial availability of rapid exchange, mechanical or dynamic array imaging catheters,[152] ranging in size from 2.6 to 3.2 Fr, compatible with 6- to 7-Fr guiding catheters, and yielding a 30-MHz imaging frequency for enhanced tissue characterization.[153] Longitudinal or three-dimensional display of the arterial wall is best performed using an automated pullback device,[154] [155] which uses sidebranches and other anatomical landmarks to ascertain the plaque location along the axial length of the vessel.[156]

VESSEL WALL COMPOSITION.

In nondiseased arteries, IVUS differentiates the vessel wall into three components: (1) the intimal, which is composed of endothelial cells, subintimal smooth muscle cells, and fibroblasts, is 150 to 200 mum in diameter and is partitioned from the media by the internal elastic lamina; 2) the media, which is composed of smooth muscle cells, elastin, and collagen, is 100 to 350 mum in diameter and is encircled by the external

Figure 12-34 Intravascular ultrasonographic examples of plaque morphology. A longitudinal pullback in the left anterior descending artery using intravascular ultrasonography shows concentric calcification of the left anterior descending artery with echo dropout *(A).* A normal vessel wall is demonstrated in *B.* A thick fibrous cap is shown in *C* (arrow). A soft, echolucent plaque with a rupture of the fibrous cap is shown in *D* (arrow). (Courtesy of Gary S. Mintz, MD.)

Figure 12-35 Discordance between angiographic and intravascular ultrasonographic findings. The proximal and distal regions of the right coronary artery have only minor lumen irregularities by conventional angiography (arrows, *A*). The corresponding intravascular sonogram demonstrates significant plaque burden proximal (71 percent plaque burden, *B*) and distal (63 percent plaque burden, *C*) within the vessel. (Courtesy of Gary S. Mintz, MD.)

elastic membrane (EEM); and (3) the adventitia, which contains fibrous tissue, is 300 to 500 mum in diameter and is encased by perivascular stroma and epicardial fat.[157] Differences in acoustic impedance between the cell layers generally account for the "three-layer" appearance seen in the normal vessel wall of most patients by IVUS.[158] A "two-layer" coronary artery is seen in some patients, depending on the IVUS transducer frequency (<30 MHz), intimal thickness (<160 mum), and collagen content of the media.[158]

In diseased arteries, the differentiation between vessel wall components becomes more obscure, and, depending on the cellular composition of the atherosclerotic plaque, at least three plaque types can be described.[157] Hypoechoic, or soft, plaques are echolucent compared with the EEM and indicate a high lipid content and presence of fatty pools[157] (Fig. 12-34) . Thrombus within the vessel lumen can often be mistaken for soft plaque, but it can be distinguished from soft plaque by its mobility, lobular edges, and movement away from the vessel wall during the cardiac cycle.[157] Fibrous plaques have similar brightness as the adventitia and indicate a higher content of collagen and elastin.[157] Calcified plaques are identified by their bright, echogenic components with acoustic shadowing of the underlying vascular structures.[157] A calcified plaque may be characterized as superficial or deep and quantified by its circumferential extent (from 0 to 360 degrees) and by its axial length (in millimeters)**.** [157] [159] Comparative studies with IVUS show that fluoroscopy is relatively insensitive for the detection of vessel wall calcium.[159] In one study of 110 patients undergoing PCI, IVUS detected calcium in 76 percent of target lesions, whereas fluoroscopy identified calcium in only 48 percent (p<0.001). Detection of fluoroscopic calcium increased to 74 percent in lesions with two or more quadrants of calcium by IVUS and 86 percent in lesions with calcium of 6 mm or more in length or with a circumferential arc of calcium 180 degrees or more by IVUS.[160] The presence of lesion calcification has also been correlated with the overall plaque burden.[160]

IVUS studies in patients undergoing PCI have also demonstrated that coronary atherosclerosis is more diffuse than appreciated using conventional angiography[161] (Fig. 12-35). In an IVUS series of 884 angiographically "normal" reference segments, only 6.8 percent were free of atherosclerosis; with an average 51 percent cross-sectional plaque area found proximal or distal to the target lesion.[161] IVUS studies have also confirmed an earlier pathological finding,[162] suggesting that the coronary artery undergoes "adaptive" remodeling, or vessel expansion, in most patients in the early stages of atherosclerosis, maintaining a nonobstructive coronary lumen diameter (Fig. 12-36). Once the EEM has expanded by 40 percent, further accumulation of plaque encroaches on the arterial lumen.[161] Arterial constriction has also been seen in some patients, particularly diabetics, owing to "negative" arterial remodeling.[163]

IVUS USE DURING PCI.

IVUS may be used for several purposes during PCI: (1) to characterize baseline plaque composition, vessel size, and lesion accessibility, to select the best single device, or combination of devices, for PCI; (2) to confirm (or refute) angiographic estimates of stenosis severity, particularly in regions difficult to visualize using conventional methods; and (3) to assess anatomical results and detect complications, including dissections and residual minimal cross-sectional area, after PCI.[163A] IVUS has also been used after stent placement to ensure full strut apposition against the vessel wall, symmetrical and complete stent expansion compared with the contiguous reference vessel, and absence of significant "margin" dissections adjacent to the stent. The Angiography Versus Intravascular Ultrasound-Directed (AVID) study, a randomized comparison of 759 patients assigned to angiography-guided or IVUS-guided (<10 percent area stenosis, absence of dissections, full stent apposition) stent placement, showed similar (p=0.22) rates of target lesion revascularization (TLR) in the IVUS-guided (8.7 percent) and angiography-guided (6.2

Figure 12-36 Characterization of the plaque burden using intravascular ultrasonography. A cross-section of a diseased artery is demonstrated in *A.* The external elastic membrane (EEM) cross-sectional area (CSA) is demonstrated in *B.* The lumen CSA is shown in *C.* The area between the lumen and the EEM contains the plaque and the media, comprising atherosclerotic plaque. (Courtesy of Gary S. Mintz, MD.)
from sudden cardiac death
Individuals whose occupa-
function, and not-high-risk
prefer to avoid revascular-

percent) groups, despite a larger initial lumen cross-sectional area in the IVUS-guided lesions (7.54 mm^2 versus 6.94 mm^2 in angiography-guided lesions; p<0.01).[164] For vessels less than 3.25 mm, however, the TLR rate was 7.9 percent in the IVUS-guided group and 14.6 percent in the angiography-guided group (p=0.04), suggesting a potential benefit for IVUS-guided stent placement in smaller vessels.[164]

VESSEL WALL CHANGES AFTER PCI.

IVUS provides unique insight into the dynamic changes that occur within the vessel wall after PCI.[165] [166] Sequential IVUS studies show that lumen renarrowing after balloon PTCA and atherectomy relates both to arterial remodeling and, to a lesser extent, to intimal hyperplasia.[165] The Serial Ultrasound Restenosis (SURE) Trial, a registry of 61 lesions treated with balloon PTCA or DCA, performed angiography and IVUS at baseline, after PCI, and 24 hours, 1 month, and 6 months later.[165] Lumen cross-sectional area by IVUS improved from 6.81 mm^2 after PCI to 8.22 mm^2 at 1 month (p=0.0001) but decreased to 4.88 mm^2 6 months later (p=0.0001). Vessel, or EEM, cross-sectional area enlarged from 17.32 mm^2 after PCI to 19.39 mm^2 at 1 month (p=0.0001) but decreased to 16.33 mm^2 at 6 months (p=0.0001). Intimal hyperplasia, as assessed by the plaque+media cross-sectional area, increased from 10.51 mm^2 after PCI to 10.96 mm^2 at 24 hours (p=0.001) and 11.45 mm^2 (p=0.03) 6 months later.[165] Changes in lumen cross-sectional area in each study interval correlated more closely with changes in vessel cross-sectional area than with changes in intimal hyperplasia cross-sectional area.[165] In contrast to these findings, IVUS studies have also shown that lumen renarrowing after stent implantation is virtually all due to intimal hyperplasia within the axial length of the stent or its border.[167] [168]

LIMITATIONS OF IVUS.

A number of factors have limited the widespread use of IVUS during PCI, including its cost, its cumbersome set-up for occasional IVUS users, steep "learning curve"

for "online" IVUS interpretation, and the improved outcomes associated with routine use of stents. Current catheter-based IVUS systems are also limited by their inability to assess lumen diameters less than 1.0 mm, owing to the catheter size and "ring-down artifact[26] [27] ; and the limited spatial resolution of a 30-MHz imaging transducer (theoretical spatial resolution, 80 mum; usual spatial resolution, 120-150 mum) makes IVUS detection of a "vulnerable" plaque somewhat problematic. Nevertheless, IVUS will remain useful in lesions difficult to assess using conventional angiography as these limitations are addressed with newer IVUS designs.

Chapter 13 - Relative Merits of Cardiovascular Diagnostic Techniques

GEORGE A. BELLER

THE SPECTRUM OF CARDIOVASCULAR DIAGNOSTIC PROCEDURES

A variety of noninvasive and invasive techniques can be used for the diagnostic and prognostic assessment of patients with cardiovascular disease. The technologies supporting these techniques vary widely, and all require significant training of physicians who supervise and interpret test results. The confidence of requesting physicians who order these tests relates predominantly to their experience regarding the accuracy of test results in their patient populations from the laboratories to which such patients are referred. Although one test modality may have higher specificity for the detection of disease than a competing test aimed at identifying the same pathophysiology as reported from specialized centers of excellence, the specificity advantage may not apply in other settings because of local differences in quality control and/or experience of the test interpreter. Therefore, it is always difficult to definitively declare superiority of one diagnostic test over another since local equipment and expertise can influence their results substantially.

Most of the diagnostic tests presently available to cardiovascular specialists are based on assessment of regional and global function (echocardiography [see Chap. 7], radionuclide angiography [see Chap. 9], magnetic resonance imaging [MRI] [see Chap. 10]), myocardial perfusion (myocardial scintigraphy, contrast echocardiography, contrast MRI), myocardial metabolism (positron-emission tomography [PET] [see Chap. 9]), or coronary anatomy (coronary angiography [see Chap. 12]) under resting conditions, stress conditions, or both. The cardiovascular system can be stressed by either exercise or pharmacological means, such as the infusion of a vasodilator or an inotropic agent. The principle underlying all of the noninvasive stress tests that can be performed for diagnosing coronary artery disease (CAD) is uncovering abnormal flow reserve or an ischemic response in patients with physiologically significant luminal narrowing of one or more coronary arteries. The ischemic response can be identified as flow heterogeneity represented by a "defect" on a perfusion scan, abnormal regional systolic thickening or abnormal wall motion, or abnormal regional metabolism. Regional myocardial perfusion and metabolism are simultaneously assessed for the detection of myocardial viability in ischemic cardiomyopathy. Various other techniques used to distinguish viable from nonviable myocardium are inotropic reserve as assessed with dobutamine echocardiography or MRI, determination of the integrity of the microcirculation as evaluated with contrast echocardiography, or evaluation of myocardial membrane transport as determined from imaging a radiolabeled monovalent cation such as thallium-201 (^{201}Tl).

Diagnostic techniques such as electron beam computed tomography[1] and measurement of carotid intimal-medial thickness have emerged in recent years and are used for detecting asymptomatic coronary or carotid atherosclerosis, respectively. These technologies are not aimed at identifying an ischemic response but at detecting occult vascular disease in the coronary or peripheral circulation. The precise clinical role of these imaging methodologies is yet to be determined.

Sources of Bias when Evaluating and Comparing Diagnostic Techniques

The "gold standard" used for comparing the sensitivity and specificity of the various noninvasive techniques for detecting CAD remains the coronary angiogram, which can be obtained only with invasive means (see also Chap. 12) . However, the coronary angiogram can at times be misleading, and it often underestimates disease severity, particularly in segments with crescentic lumina and in the presence of diffuse disease rendering the reference diameter misleading. A high degree of intraobserver and interobserver variability in visually interpreting the degree and significance of coronary stenosis is well known. Quantitative angiography for measuring the minimal luminal diameter of a coronary lesion has greater predictive physiological significance with less intraobserver and interobserver variability. In recent years, the amount of information that can be obtained at the time of coronary angiography regarding the extent and severity of CAD has increased (see also Chap. 12) . Assessment of coronary flow reserve with Doppler-tipped

catheters in conjunction with vasodilator stress adds value to the mere assessment of coronary anatomical findings. The use of intravascular ultrasound has also provided important additional diagnostic and prognostic information in comparison with contrast angiography alone. Presently, the noninvasive techniques aimed at diagnosing CAD and assessing its functional and prognostic severity are being compared with physiological data obtained at cardiac catheterization and not with the degree of coronary anatomical narrowing alone.

Another significant limitation in determining the specificity of noninvasive techniques for detection of CAD is that most patients with normal noninvasive study findings (e.g., a normal stress perfusion scan or normal stress echocardiogram) are not referred for coronary angiography. Patients are referred for coronary angiography most often because of abnormal noninvasive test results, which leads to a posttest referral bias whereby predominantly patients with true-positive or false-positive noninvasive test results (an abnormal perfusion scan or abnormal echocardiogram and normal coronary arteries) undergo angiography. Patients with true-negative noninvasive test results are not sent to cardiac catheterization. This trend has led to use of the normalcy rate as a surrogate for specificity in evaluating the accuracy of a noninvasive test for CAD diagnosis. The normalcy rate represents the percentage of normal scans in patients who have less than a 5 percent posttest likelihood of CAD when taking into account clinical information, the resting electrocardiogram (ECG), and exercise treadmill test results. This posttest referral bias tending to lower the specificity if a normal coronary angiogram is required as the "gold standard" for a normal test result should be kept in mind when reviewing the literature, particularly with reports following the introduction of a new test.

A critical observer should bear in mind that the sensitivity and specificity of a test for detecting a cardiovascular abnormality (e.g., significant CAD, resting left ventricular [LV] dysfunction) are always very high in the first few reports that are published for a newly introduced imaging methodology. These initial good results relate to many variables, including the inclusion of a highly selected patient population that may include normal volunteers on one end of the spectrum and patients with severe disease at the other end.

When evaluating the worth of a test for diagnosing cardiovascular disease or a complication of disease, cost should now also be considered.[2] [3] One test may have a few percentage points higher sensitivity than another test to which it is being compared, but the cost may be twice as high. Thus, the cost/benefit ratio should also be weighed when comparing the worth of two or more tests that are developed for the same clinical application. A good example is the noninvasive assessment of myocardial viability with PET imaging versus resting and delayed ^{201}Tl perfusion imaging and low-dose dobutamine echocardiography. PET imaging for viability assessment may be slightly more accurate than the two competing technologies[4] but at a substantially higher cost.

Table 13-1 summarizes the major clinical indications for noninvasive and invasive testing and lists various techniques applicable to each of these clinical indications. The remainder of this chapter will sequentially address the headings provided in this table.

ASSESSMENT OF LEFT VENTRICULAR FUNCTION AT REST

Echocardiography (see also Chap. 7)

Of all the noninvasive techniques available for the assessment of regional and global LV function at rest, echocardiography

TABLE 13-1 -- CLINICAL APPLICATIONS OF NONINVASIVE AND INVASIVE TECHNIQUES IN CARDIOVASCULAR DISEASE

ASSESSMENT OF LEFT VENTRICULAR FUNCTION
Echocardiography
Radionuclide angiography
Gated SPECT
Gated MRI
Contrast ventriculography
DETECTION OF CORONARY ARTERY DISEASE AND ASSESSMENT OF PROGNOSIS
Exercise electrocardiographic stress testing
Exercise or pharmacological stress SPECT myocardial perfusion imaging
Exercise or dobutamine echocardiography
Pharmacological stress MR perfusion imaging
Dobutamine stress MRI
MR angiography
Coronary angiography, intravascular ultrasound, and measurement of flow reserve
ASSESSMENT OF MYOCARDIAL VIABILITY
Resting SPECT perfusion imaging
Low-dose dobutamine echocardiography
Positron-emission tomography
Low-dose dobutamine MRI

MRI=magnetic resonance imaging; SPECT=single-photon emission computed tomography.

is the most versatile overall, provides the most ancillary information, and has the lowest cost.[5] Two-dimensional echocardiography provides excellent images of the heart and great vessels, but it depends on obtaining satisfactory windows from the body surface to the area of interest in the heart. When good windows are obtained, echocardiography is superbly well suited for the evaluation of global and regional LV systolic function because of its high spatial and temporal resolution and its ability to define both regional wall thickening and inward endocardial excursion. When compared with all other techniques, it should be the preferred initial test to diagnose heart muscle diseases of yet unknown etiology. These disease entities include ischemic cardiomyopathy, nonischemic dilated cardiomyopathy, hypertrophic cardiomyopathy, and restrictive myocardial disease. Resting echocardiographic technology not only allows a thorough assessment of cardiac morphology and function but also permits the simultaneous assessment of valvular, pericardial, intramyocardial, and extracardiac abnormalities.

Echocardiography has an advantage over other techniques for assessing LV function in its ability to accurately assess regional myocardial thickening, which is not influenced by either cardiac translation or the center of reference used. Regional thickening is a better marker of regional function than is regional wall motion. Regional thickening abnormalities cannot be well identified by radionuclide angiography or contrast ventriculography. The only other technique that perhaps permits a more accurate assessment of regional systolic thickening is gated MRI. The latter, however, is currently more expensive than two-dimensional echocardiography and cannot be performed at the bedside in critically ill patients. The advent of small portable echocardiographic apparatus will enhance only the bedside utility of this technique. A limitation of resting echocardiography in gauging the severity of regional or global LV dysfunction is the lack of a reproducible quantitative technique to measure the LV ejection fraction. A quantitative ejection fraction is better obtained by using alternative approaches such as LV contrast angiography, radionuclide angiography, and gated single-photon emission computed tomography (SPECT) imaging.

Echocardiography is invaluable in assisting in the detection

of acute myocardial infarction and such mechanical complications as right ventricular infarction, acute mitral regurgitation from papillary muscle rupture or dysfunction, ventricular septal defect, a true or false LV aneurysm, or pericardial effusion (Chap. 35) . Thus, it is the noninvasive technique of choice for the comprehensive evaluation of regional and global LV dysfunction and associated abnormalities in the setting of acute myocardial infarction. Transesophageal echocardiography can be performed at the bedside in an acutely ill patient with shock in the intensive care unit setting to help identify the etiology of the hemodynamic disturbance. Echocardiography can also be performed in the emergency room in patients with chest pain and a possible acute ischemic syndrome. A defined regional wall motion abnormality lends support to a presumptive diagnosis that regional ischemia may be the cause of the chest pain syndrome.

Echocardiography is more sensitive than ECG for detecting LV hypertrophy[6] and is an excellent technique for estimating LV mass, which has been shown to independently predict cardiovascular morbidity and mortality.[7] [7A] The variability in LV mass measurements and the reliability of serial measurements to assess regression of hypertrophy[8] have been reduced by the substitution of linear measurements of LV wall thickness and internal dimension from the two-dimensional parasternal long-axis view whenever the two-dimensional directed M-mode beam is not ideally oriented for measuring thickness and cavity dimensions[9] (see also Chap. 7) . Further improvements in the echocardiographic measurement of LV mass may be offered by three-dimensional localization of imaging slices.[10]

Radionuclide Angiography (see Chap. 9)

First-pass radionuclide angiography and gated equilibrium blood pool radionuclide angiography are nuclear cardiology techniques that use a gamma camera and ECG gating for determining the changes in radioactivity in the left and right ventricular chambers over the cardiac cycle by generating time-activity curves. Quantitative ejection fraction measurements from both the right and left ventricles are highly accurate. Ventricular and pulmonary blood volumes and regional ventricular wall motion can also be assessed. As with echocardiography, resting radionuclide angiography is clinically useful for prognostication: the lower the resting LV ejection fraction or the more global the LV dysfunction, the worse the subsequent outcome with respect to survival. An advantage of radionuclide angiography over echocardiography is its ability to accurately quantitate the left and right ventricular ejection fractions by using a "count-based" technique and to obtain data in virtually all patients. Patients with arrhythmias can undergo radionuclide angiography since windows for cycle length can be preset and all beats falling outside the window are rejected.

Chemotherapy with anthracycline agents can result in a dose-dependent deterioration in LV function because of the toxic effects of the drug on cardiac myocytes (see also Chap. 69) . Radionuclide angiography is ideally suited to provide serial quantitative LV ejection fraction measurements in patients who have received or are receiving doxorubicin therapy. If doxorubicin administration is continued after objective evidence of reduced systolic function, significant symptomatic congestive heart failure and irreversible LV dysfunction may ensue. Resting radionuclide angiography may provide a more quantitative assessment of LV dysfunction after myocardial infarction, but it cannot provide other important information such as the extent of infarction expansion, presence of LV thrombus, development of mitral regurgitation, and extent of regional systolic thickening abnormalities.

Gated SPECT Imaging (see Chap. 9)

The emergence of technetium-99m (^{99m}Tc)-labeled myocardial perfusion agents led to the development of gated ^{99m}Tc-SPECT imaging,[11] which permits simultaneous evaluation of regional systolic thickening, global LV function, and myocardial perfusion (see also Chap. 9) . The introduction of gated ^{99m}Tc-SPECT imaging significantly enhanced the specificity of SPECT for detection of CAD in patients with chest pain,[12] [13] [14] [120A] [120B] [120C] [120D] [120E] [131A] increased the detection rate of viable myocardium by demonstration of preserved systolic thickening corresponding to preserved tracer uptake,[15] and improved the ability to risk-stratify patients by

providing information relevant to the global LV ejection fraction.[16] New techniques using technology similar to that used for gated equilibrium blood pool imaging allow for automated determination of the LV ejection fraction.[17] [18] Thus, a quantitative global ejection fraction and percent thickening in various regions of the left ventricle can be reported with results of myocardial perfusion analysis under resting and stress conditions.

Severe perfusion abnormalities can limit quantitation of the LV ejection fraction by the gated SPECT technique by interfering with detection of endocardial edges along the whole LV volume on SPECT tomograms. Manrique and colleagues found that gated SPECT underestimated the LV ejection fraction when compared with equilibrium radionuclide angiography in patients with LV dysfunction and large perfusion defects.[19] Others have reported accurate LV ejection fraction measurements by gated SPECT in the presence of large perfusion defects.[20] Count-based techniques for assessing regional systolic thickening are not as adversely influenced by low regional radioactive counts in areas of severe defects.[17] Gated ^{99m} Tc-tetrofosmin SPECT imaging compared favorably with cine-MRI with respect to grading regional wall motion abnormalities in patients with an acute myocardial infarction.[21] Exact agreement in wall motion scores between gated SPECT and MRI was 92 percent (kappa=0.82). Gated ^{99m} Tc-sestamibi SPECT assessment of regional function also correlates well with echocardiography.[22]

Gated SPECT can also be performed with ^{201} Tl. He and associates[20] reported similar LV ejection fraction measurements for ^{201} Tl-gated SPECT (54 ± 15 percent) and ^{99m} Tc-gated SPECT (54 ± 16 percent) in 63 patients who had LV ejection fractions also determined by first-pass radionuclide angiography (54 ± 12 percent). ^{99m} Tc-gated SPECT is preferred to ^{201} Tl-gated SPECT because of better image quality and better interobserver agreement.[23] Patient obesity significantly reduces the accuracy of quantitative SPECT ^{201} Tl perfusion imaging.[23A]

Magnetic Resonance Imaging (see Chap. 10)

MRI systems have recently become more available for cardiovascular imaging.[24] Regional and global cardiac function can be evaluated at rest and under pharmacological stress with MRI,[25] and high-speed MRI techniques allow for the simultaneous assessment of myocardial perfusion with magnetic resonance (MR) contrast agents.[26] MRI is superior to other noninvasive imaging modalities in diagnosing congenital heart disease,[27] aortic disease, anomalous coronary arteries, and right ventricular dysplasia. The role of MRI in evaluation of CAD is still in the early stages. At present, nuclear cardiology techniques and echocardiographic techniques have cost/benefit characteristics superior to those of MRI for assessing regional and global function. The major strength of MRI is its ability to provide high-resolution detail of cardiovascular anatomy. It can yield three-dimensional information on anatomy, function, and blood flow. It is accurate in determining wall thickness and may be the best technique for quantitating overall LV mass. MRI tagging is an imaging modality that uses a grid overlying the full thickness of the myocardium on tomographic slices for assessment of progressive thickening of endocardial, midwall, and epicardial layers during the cardiac cycle. This technique measures intramyocardial function, which enhances measurement of the degree of regional myocardial dysfunction. Serial assessment of LV mass and volume is important in monitoring LV remodeling after myocardial infarction, and this technique is being used in clinical trials to test certain pharmacological interventions for their effect on remodeling.

Contrast Left Ventriculography (see Chap. 15)

Left ventriculography has been available for many years for the assessment of LV function in a variety of pathological

disorders. It has been used as the "gold standard" to which noninvasive techniques have been compared. Abnormal wall motion, but not abnormal thickening, can be assessed by contrast left ventriculography and quantitative measurements of LV ejection fraction, and absolute volumes are highly reproducible and perhaps yield the most precise quantitative measurements of global function of all the noninvasive techniques discussed above. Limitations of contrast ventriculography include its invasive nature, high cost, potential nephrotoxicity of the dye, and the need to trace endocardial contours to quantitate ejection fraction and volume. LV hypertrophy and LV mass are better quantitated by echocardiography or MRI. An advantage of contrast ventriculography is its ability to simultaneously measure intracavitary pressure and other hemodynamic variables such as stroke and end-diastolic volume, as well as performance of coronary angiography during the same cardiac catheterization procedure. Differentiation between dilated and ischemic cardiomyopathy can easily be made, and associated valvular lesions such as mitral regurgitation can be simultaneously diagnosed and semiquantitated. Left-to-right shunts at the atrial and ventricular levels are most accurately quantitated by cardiac catheterization measurements, although echocardiography and MRI can precisely localize atrial and ventricular septal defects.

The Utility of Different Approaches to the Assessment of Left Ventricular Function

Overall, when all factors are considered, two-dimensional echocardiography with Doppler remains the most effective approach to assessment of resting LV function. Its major limitation is an inability to visualize all regions of the left ventricle in every patient, and poor-quality images are acquired in certain patients, such as those with severe chronic obstructive pulmonary disease. The lack of a highly accurate and reproducible method for deriving a quantitative measurement of LV ejection fraction also limits the utility of echocardiography. Contrast echocardiography improves visualization of myocardial walls and shows promise for the simultaneous assessment of regional perfusion at rest and during stress. Gated ^{99m} Tc-SPECT and gated MRI provide precise determinations of regional myocardial thickening and LV ejection fraction, and MRI also allows for simultaneous assessment of perfusion by using a contrast agent. Visualization of the coronary arterial tree is one of the ultimate goals of MRI, and progress has been made in this application, although it is not ready for clinical use. Table 13-2 summarizes the strengths and limitations of the various techniques for assessment of regional and global LV function.

DETECTION OF CORONARY ARTERY DISEASE

A number of noninvasive techniques are available to the clinician for detection of CAD in patients with chest pain. The techniques vary greatly in methodology but have as a fundamental principle the detection of myocardial ischemia or flow heterogeneity with exercise or pharmacological stress. The variables indicative of myocardial ischemia differ considerably and are specific for the test under consideration. The advent of myocardial imaging techniques using radionuclide, echocardiographic, or MRI methodology has provided enhanced accuracy for detection of CAD but at a higher cost than for the standard exercise treadmill test. The strengths and limitations of the various noninvasive techniques used for the detection of CAD are described in the sections to follow.

TABLE 13-2 -- STRENGTHS AND LIMITATIONS OF THE VARIOUS DIAGNOSTIC TECHNIQUES FOR ASSESSMENT OF LEFT VENTRICULAR FUNCTION

ECHOCARDIOGRAPHY
Strengths: Portability; immediately available; repeatability; provides ancillary structural and physiological information; high spatial and temporal resolution; accurately measures regional systolic thickening; sensitive for detecting LV hypertrophy and measuring LV mass; good for RV function assessment; excellent for detection of diastolic dysfunction; no ionizing radiation or contrast material needed; low cost
Limitations: Poor acoustic windows in some patients; lack of quantitative ejection fraction; high operator dependence
RADIONUCLIDE ANGIOGRAPHY
Strengths: Accurate measurement of LV and RV ejection fractions; reproducible; little operator dependency; serial monitoring of patients receiving cancer chemotherapy
Limitations: Regional systolic thickening not evaluated; radiation exposure; ancillary anatomical information not obtained; difficult to detect LV hypertrophy
GATED ^{99m} TC SPECT IMAGING
Strengths: Assessment of systolic thickening; global LV ejection fraction accurately measured; simultaneous evaluation of perfusion and function; viability assessment
Limitations: Decreased accuracy of LV ejection fraction assessment with large defects; lack of portability; LV hypertrophy and mass not measured; no ancillary structural information obtained; lower spatial resolution than ultrasound
MAGNETIC RESONANCE IMAGING
Strengths: Best technique for diagnosing congenital heart disease; high-resolution anatomical detail; excellent for measuring wall thickness and LV mass; provides functional images in any desired imaging plane; can accurately assess regional and global LV function; 3-dimensional information; proximal coronary arteries visualized; myocardial tagging permits analysis of subendocardial, midwall, and subepicardial function; high-speed MRI permits perfusion imaging
Limitations: Lack of portability; cannot monitor ST segments during imaging; claustrophobia in some patients; need to correct for cardiac and respiratory motion; patients with pacemakers excluded

LV=left ventricular; RV=right ventricular; SPECT=single-photon emission computed tomography.

Exercise Electrocardiography (see also Chap. 6)

A review of the literature concerning the diagnostic accuracy of the standard exercise test was published by Gibbons and colleagues[28] and used as a basis for formulating guidelines for exercise testing by the American College of Cardiology/American Heart Association Practice Guidelines Task Force. Meta-analysis showed that the sensitivity and specificity of the exercise ECG stress test for the detection of CAD were 68 and 77 percent, respectively, in 147 consecutively published reports of patients who underwent both angiography and exercise testing.[29] However, bias from the selection of patients who agreed to undergo both treadmill testing and coronary angiography at the outset led to a 45 percent sensitivity for 1.0 mm of horizontal or downward ST segment depression but an 85 percent specificity.[30] Even when studies that included patients with resting ST segment depression were excluded, the sensitivity and specificity of the exercise test were only 67 and 84 percent, respectively.[28]

SENSITIVITY.

The sensitivity of exercise ECG is very dependent on the level of exercise achieved. Sensitivity is reduced in patients who fail to achieve 85 percent of the age-adjusted maximum predicted heart rate or greater. Specificity of the ST segment depression response is markedly affected by variables such as LV hypertrophy, hyperventilation, digoxin therapy, intraventricular conduction disturbances, preexcitation syndrome, hypokalemia, severe hypertension, and resting ST segment depression from a variety of causes. Many patients are precluded from undergoing treadmill testing alone because

of nonspecific resting ST or T wave abnormalities, conduction abnormalities, or claudication. Interestingly, however, the specificity of the exercise test was only 69 percent in an analysis of 10 studies totaling 3548 patients who underwent exercise testing without digitalis therapy. Similarly, the specificity of the exercise test in studies excluding LV hypertrophy only increased to 77 percent, which was just 8 percent higher than the 69 percent specificity of the ST segment response for CAD detection when studies including LV hypertrophy were analyzed.

SPECIFICITY.

The specificity of the exercise ECG response is also suboptimal in women,[31] particularly those who are in the premenopausal age group with a low to intermediate pretest likelihood of CAD. In contrast, the negative predictive value of a normal exercise ECG response in women for excluding CAD is high. Women with a normal baseline resting ECG who achieve greater than 85 percent of the maximum predicted heart rate for age and have a normal peak stress ECG have an excellent prognosis and a low prevalence of underlying CAD. The negative predictive value of the exercise ECG response appears to be lower in men than in women, whereas the positive predictive value of the ST segment depression response is higher in men than women.[32] [33] Heart rate adjustment for the ST segment response may improve diagnostic accuracy of the exercise ECG.[34]

EXTENT OF CAD.

The extent of CAD affects the sensitivity of the exercise ECG. Its sensitivity is less than 50 percent for patients with single-vessel disease but exceeds 85 percent for patients with three-vessel disease. Horizontal or downsloping ST segment depression at low exercise heart rates has a higher positive predictive accuracy for CAD than does ST segment depression at very high heart rates or workloads. The administration of beta-blocking drugs certainly influences exercise test results since they prevent the patient from attaining the desired heart rate-blood pressure product at which ischemic ST segment depression would appear. This effect leads to an increased prevalence of false-negative responses. In addition, other antianginal drugs, such as nitrates given before testing, may prevent the appearance of abnormal ST segment changes. Slow upsloping ST segment depression has occasionally been used to increase the criteria for a positive test. Although such responses may enhance the sensitivity of the exercise ECG, specificity is lowered.[35]

In summary, although the exercise ECG is the least expensive of the noninvasive tests for detecting CAD, it has limited sensitivity and specificity in certain patient populations. Its main value may be as the initial test for excluding CAD in patients with a low pretest likelihood of CAD based on age and gender, in those who have a normal resting ECG, and in patients with nonanginal or very atypical chest pain. If such patients achieve their maximum exercise heart rates with no ST segment depression and with normal hemodynamic responses, significant stenoses would not be likely to be the cause of their atypical chest pain syndrome. However, in most other populations, the exercise ECG is limited by suboptimal sensitivity and specificity for diagnosing CAD for the reasons outlined above.

Stress Radionuclide Myocardial Perfusion Imaging (see also Chap. 9)

Exercise or pharmacological stress ^{201}Tl or ^{99m}Tc-sestamibi SPECT imaging in patients with chest pain yields a sensitivity for detecting CAD in the 85 to 90 percent range.[36] Specificity for excluding CAD is in the 90 percent range when gated SPECT imaging is used.[13] Exercise SPECT imaging and pharmacological SPECT imaging both yield sensitivities and specificities for coronary artery detection that are superior to those of exercise ECG testing alone.[37] [38] Radionuclide stress perfusion imaging has particular value when compared with exercise ECG testing alone in (1) patients with resting ECG abnormalities, such as those seen with LV hypertrophy, digitalis effect, preexcitation, and intraventricular conduction abnormalities, and (2) patients who fail to achieve greater than 85 percent of the maximum predicted heart rate and have no ST segment depression. Patients who fail to achieve a target heart rate and stop exercising at submaximal exercise levels demonstrate a higher sensitivity for CAD detection than when exercise ECG testing is performed alone[39] because myocardial perfusion abnormalities in response to stress appear earlier during the course of graded exercise stress. The ST segment depression response appears to require a higher rate-pressure product to induce flow heterogeneity, which is demonstrated as a perfusion defect on scintigraphy. Figure 13-1 shows an example of a reversible inferior wall perfusion defect on exercise ^{99m}Tc-sestamibi SPECT in a patient with a normal exercise ECG.

The addition of stress perfusion imaging to the exercise ECG stress test greatly assists in differentiating true-positive from false-positive exercise ST segment depression responses. In patients with a low to intermediate pretest likelihood of CAD, approximately 40 percent with ST segment depression have no evidence of CAD (false-positive findings). Quantitative analysis of SPECT has resulted in a higher sensitivity and specificity than merely visual evaluation of SPECT images. The single-vessel disease detection rate with stress SPECT imaging is approximately 25 percent higher than the rate achieved with exercise ECG testing alone. The sensitivity for detecting three-vessel disease with exercise SPECT is in the range of 95 to 100 percent.

LIMITATIONS.

The major limitation of using ^{201}Tl as a tracer for myocardial perfusion imaging is the high false-positive rate observed in many laboratories. This high rate is predominantly attributed to image attenuation artifacts that are interpreted as defects secondary to CAD. Although quantitation of ^{201}Tl images improves specificity, the false-positive rate remains higher than desirable, particularly with imaging of obese persons and women, who may demonstrate defects reflecting breast attenuation artifacts. Such artifacts are sometimes difficult to distinguish from myocardial perfusion abnormalities caused by inducible ischemia or from myocardial scarring (see also Chap. 9) . In the past decade, new ^{99m}Tc-labeled perfusion agents introduced into clinical practice have enhanced the specificity of SPECT.[14] The quality of images obtained with ^{99m}Tc-labeled radionuclides is superior to that of images obtained with ^{201}Tl because

Figure 13-1 Representative short-axis and vertical long-axis stress and rest ^{99m}Tc-sestamibi images showing a reversible inferior defect consistent with significant stenosis in the right coronary artery. The sensitivity for detecting single-vessel disease is substantially greater with stress myocardial perfusion imaging than with stress electrocardiography. This patient had a normal ST segment response to exercise stress.

of the more favorable physical characteristics of ^{99m}Tc for imaging with a gamma camera.[37] The feasibility of using ^{99m}Tc doses approximately 10 to 20 times higher than the doses used with ^{201}Tl permits the acquisition of images with higher count density, less scatter and attenuation, and fewer artifacts than seen with ^{201}Tl imaging. Perhaps most importantly, ^{99m}Tc-sestamibi or ^{99m}Tc-tetrofosmin imaging facilitates gated acquisition, thereby allowing simultaneous evaluation of regional systolic thickening, global LV ejection fraction, and myocardial perfusion.[40]

ECG-gated SPECT yields important information about regional and global LV function that could previously only be obtained with a second test, such as radionuclide

angiography, echocardiography, or contrast ventriculography. The ability to accurately measure the resting LV ejection fraction with ^{99m} Tc-sestamibi or ^{99m} Tc-tetrofosmin adds supplementary value to the detection of perfusion abnormalities alone.

Women with chest pain who are referred for exercise or pharmacological stress testing benefit most from the enhanced test accuracy of ^{99m} Tc-gated SPECT imaging. Taillefer and coworkers prospectively evaluated the diagnostic accuracy of ^{201} Tl SPECT and ^{99m} Tc-sestamibi SPECT perfusion imaging for detection of CAD in women.[13] The greater than 70 percent overall sensitivity for detecting stenoses was similar for ^{201} Tl SPECT and ^{99m} Tc SPECT; the specificity, however, was only 67 percent for ^{201} Tl SPECT but increased to 92.2 percent when gated ^{99m} Tc-sestamibi images in the same women were analyzed (Fig. 13-2) . Since soft tissue attenuation causes nonuniformity of photon activity in the myocardium that results in artifacts often perceived as perfusion defects, attempts have been made to correct for attenuation by using certain algorithms emerging from advances in gamma camera instrumentation and software development.[41] [42] Specificity for CAD detection can be improved by the use of such approaches for correction of nonuniform photon attenuation. In one multicenter study, attenuation and scatter correction of ^{99m} Tc-sestamibi SPECT increased the normalcy rate from 86 to 96 percent in patients with a low pretest likelihood of CAD.[43] Caution, however, should be exercised when using currently available attenuation correction techniques since enhanced specificity may be offset by a decrease in multivessel disease identification[42] and a decrease in the detection of left anterior descending CAD.[43]

Some patients are less than ideal candidates for treadmill testing alone, and pharmacological stress with vasodilators such as dipyridamole or adenosine or an inotropic agent such as dobutamine is an alternative to exercise for detecting physiologically significant coronary artery stenosis. The basis for vasodilator perfusion imaging relates to the concept of coronary flow reserve. When coronary blood flow is maximally increased with an intravenously administered vasodilator, an impairment in flow reserve capacity in a stenotic artery simultaneous with a large flow increase in a normal vascular bed results in relative inhomogeneity of myocardial perfusion between normal and stenotic beds. If tracers such as ^{201} Tl or ^{99m} Tc-sestamibi are injected during peak vasodilation in the presence of a hemodynamically significant coronary stenosis with reduced flow reserve, heterogeneity in tracer uptake will be observed as defects on post-stress images acquired soon after tracer injection. Sensitivity and specificity for coronary artery detection are comparable for dipyridamole and adenosine. Dobutamine stress is preferred in patients who have bronchospasm or a history of asthma or in those who have consumed caffeine before testing. Dipyridamole or adenosine administration in such patients could result in severe bronchospasm. Vasodilator imaging is the scintigraphic method of choice for detection of CAD in patients with complete left bundle branch block.[44] Such patients will be unable to undergo diagnostic exercise ECG testing alone.

Today, most laboratories use ^{99m} Tc perfusion imaging agents for detection of CAD in conjunction with exercise or pharmacological stress because of enhanced specificity for CAD detection and the ability to gate the images to the ECG

Figure 13-2 Specificity of ^{201} Tl stress single-photon emission computed tomographic (SPECT) imaging (open bars), ^{99m} Tc-sestamibi SPECT (crosshatched bars), and gated ^{99m} Tc-sestamibi SPECT (stippled bars) for detection of coronary artery disease in women. The specificities are for criteria of 50 percent or greater or 70 percent or greater stenosis representing significant coronary artery disease. Note that the specificity was only 67 percent for ^{201} Tl SPECT versus 92 percent for gated ^{99m} Tc SPECT in women evaluated for the presence of coronary artery disease when 70 percent or greater stenosis was used as the criteria. (From Taillefer R, DePuey EG, Udelson JE, et al: Comparative diagnostic accuracy of Tl-201 and Tc-99m sestamibi SPECT imaging [perfusion and ECG-gated SPECT] in detecting coronary artery disease in women. J Am Coll Cardiol 29:69, 1997. Reprinted with permission from the American College of Cardiology.)

to view regional systolic thickening. Mild nonreversible defects that represent attenuation artifacts usually show preserved systolic thickening, whereas if such areas of diminished tracer uptake represent scar, abnormal systolic thickening is observed.

Exercise and Dobutamine Stress Echocardiography (see also Chap. 7)

Stress echocardiography can be performed either with treadmill, upright bicycle, or supine bicycle exercise or by using pharmacological stressors such as dobutamine or dipyridamole. Dobutamine stress has a higher sensitivity than vasodilator stress does.[45] A pooled analysis of data in the literature pertaining to the diagnostic value of exercise or dobutamine stress echocardiography was recently published by Cheitlin and colleagues in the summary of the American College of Cardiology/American Heart Association Guidelines for Clinical Application of Echocardiography.[5] For the same reasons as outlined above for SPECT perfusion imaging, stress echocardiography is more sensitive and specific for detecting inducible ischemia than is exercise ECG testing alone. The sensitivity of exercise stress echocardiography in 21 studies gleaned from the literature averaged 84 percent (71 to 97 percent), with a specificity of 86 percent (64 to 100 percent).[5]

These published studies reveal a rather marked variation in the sensitivity of exercise and dobutamine echocardiography for detecting angiographically documented CAD.[5] [46] This large variability may be related to patient selection, including the percentage of patients in each study with previous infarction and/or multivessel disease, the definition of what constitutes a new stress-induced wall motion abnormality (a new wall motion abnormality vs. failure to demonstrate hyperkinesis), the use of beta blockers during testing, and pretest referral bias.[47] The sensitivity of exercise echocardiography may be diminished if submaximal exercise heart rates are attained. Marwick and coauthors reported that when exercise heart rates were less than 85 percent of the maximum predicted heart rate, the sensitivity of exercise echocardiographic tests was only 42 percent.[48] Also, like stress SPECT imaging, stress echocardiography is more sensitive in detecting stenoses larger than 70 percent than in detecting vessels with 50 to 70 percent narrowing. It is also more sensitive in detecting CAD in patients with multivessel disease than with single-vessel disease[46] (Fig. 13-3) .

The sensitivity of exercise echocardiography is approximately 10 percent lower in women than men, with comparable specificities. [49] This decreased sensitivity for CAD detection in women has been reported for ECG treadmill testing,[50] radionuclide perfusion imaging, radionuclide angiography, and dobutamine echocardiography.[51]

Dobutamine stress echocardiography was often found to be negative in women with single-vessel stenosis.[52] The overall sensitivity of dobutamine stress echocardiography for detecting 50 percent or greater coronary narrowing in women was 40 percent. In women with two- or three-vessel disease, the sensitivity increased to 60 percent. The sensitivity of dobutamine stress echocardiography in women without a baseline wall motion abnormality was 21 percent overall and 33.3 percent in patients with two- or three-vessel disease. The explanation for the poor overall sensitivity of dobutamine stress echocardiography in this group of women relates, in part, to the relatively low overall prevalence of severe coronary artery narrowing. This lower sensitivity for detection of single-vessel disease has been reported by most investigators and is in the 50 to 80 percent range.[53] [54] [55] [56] [57] Another reason for a lower sensitivity of dobutamine stress echocardiography in the detection of single-vessel disease or mild stenoses is premature termination of the test because of side effects. Secknus and Marwick reported premature termination of dobutamine stress echocardiography in 15 percent of 3000 patients.[58] Most of the episodes of premature test termination were due to cardiovascular side effects, including ventricular and supraventricular arrhythmias, severe hypertension, hypotension, severe ischemia by echocardiography, or severe chest pain.

To acquire images at peak stress and thus enhance the sensitivity of the test, some have proposed that supine bicycle echocardiography be the stress technique of choice for the ultrasound modality. Although treadmill exercise yields higher maximal heart rates, systolic

Figure 13-3 Sensitivity of dobutamine stress echocardiography for detection of coronary artery disease by the number of diseased vessels. (From Geleijnse ML, Fioretti PM, Roelandt JR: Methodology, feasibility, safety and diagnostic accuracy of dobutamine stress echocardiography. J Am Coll Cardiol 30:595, 1997. Reprinted with permission from the American College of Cardiology.)

blood pressure is higher with supine bicycle exercise, so a similar double product is seen with the two techniques. With respect to detection of CAD, Badruddin and colleagues reported an 82 percent sensitivity for supine bicycle exercise versus 75 percent for upright treadmill echocardiography with a somewhat lower specificity for supine bicycle exercise (80 vs. 90 percent).[59] Several other studies have shown that imaging at peak exercise is approximately 8 to 9 percent more sensitive than acquiring images after bicycle exercise.[60] [61]

Comparison of Exercise SPECT Perfusion Imaging and Exercise Echocardiography

Stress echocardiography and stress perfusion imaging share common positive features that deserve emphasis before comparing the value and limitations of each technique. First, both are associated with a higher sensitivity and specificity for CAD detection than is exercise ECG testing alone. Second, both noninvasive techniques provide *functional* information for risk stratification, assessment of the area at risk, and determination of myocardial viability that is superior to that obtained with coronary angiography (see below).

ADVANTAGES OF STRESS ECHOCARDIOGRAPHY.

When compared with radionuclide perfusion imaging, advantages of stress echocardiography include the following: (1) The technique is totally noninvasive, safe, and repeatable; (2) no radiation exposure is involved; (3) the time to complete a full examination is short; (4) the technique is portable and requires no highly sophisticated instrumentation; (5) the cost is relatively low; (6) it has the ability to identify structural abnormalities of the heart, including coexisting valvular disease, LV hypertrophy, and pericardial abnormalities; and (7) ultimately, contrast echocardiography will be used with conventional stress echocardiography to allow for simultaneous assessment of regional myocardial perfusion and regional systolic function. Contrast echocardiography performed in association with vasodilator stress is still in the preliminary phases of testing. The addition of contrast should enhance the diagnostic accuracy and value of the technique.

LIMITATIONS OF STRESS ECHOCARDIOGRAPHY.

Limitations include the following: (1) Images are difficult to acquire at peak exercise because of exertional hyperpnea and

cardiac excursion; (2) an ischemic response is required for the elucidation of regional abnormal wall motion; (3) rapid recovery of wall motion abnormalities can be seen with mild ischemia, particularly with single-vessel disease, which may lead to a false-negative test result if the images are not acquired rapidly postexercise; (4) detection of residual ischemia within an infarct zone is difficult because of resting akinesis; (5) the technique is highly operator dependent for data collection and image analysis, and considerable interindividual variability in interpreting stress echocardiograms has been reported[62] ; (6) good-quality, complete images are acquired in only 70 percent of patients. An inability to image all of the LV myocardium occurs in a substantial number of patients. In four studies involving a total of 418 patients, the echocardiography investigators determined that visualization of all myocardial segments was inadequate in 37 percent of patients[63] ; (7) a long training period is required to gain experience; and (8) quantitative assessment of inducible wall motion abnormalities and LV ejection fraction is operator dependent.

ADVANTAGES OF EXERCISE PERFUSION IMAGING.

When compared with exercise echocardiography, the following advantages of exercise myocardial perfusion imaging for detection of CAD may be listed: (1) Myocardial perfusion imaging detects abnormal flow reserve and does not require an ischemic response for a positive test result; (2) data relevant to abnormal myocardial perfusion are obtained at peak stress with treadmill exercise rather than after exercise as required for echocardiography; (3) the sensitivity for detecting CAD is slightly higher (8 to 10 percent) with exercise perfusion imaging, chiefly because the sensitivity for detecting single-vessel disease and mild stenoses of 50 to 70 percent narrowing is rather low with exercise echocardiography; (4) perfusion imaging appears to identify more ischemic regions than stress echocardiography does,[64] [65] [66] [67] perhaps because mere flow heterogeneity and not true ischemia causing systolic myocardial dysfunction produces defects on stress scintigrams[68] ; (5) infarct zone ischemia is more easily identified with perfusion imaging by demonstration of a partial reversible defect in an area that contains a mixture of scar and viable myocardium; (6) operator dependency is not nearly as much a factor with SPECT perfusion imaging for the acquisition of images as it is with echocardiography; (7) virtually 100 percent of patients can undergo adequate SPECT perfusion imaging in which all areas of the myocardium are visualized; (8) with ^{99m} Tc-sestamibi, simultaneous assessment of myocardial perfusion and function can be obtained, and recent data show that the resting LV ejection fraction can be accurately measured from gated ^{99m} Tc SPECT; and (9) vasodilator stress SPECT imaging has a significantly higher sensitivity for CAD detection than does vasodilator stress echocardiography, whereas dobutamine stress echocardiography is associated with a significantly higher sensitivity and specificity for CAD detection than is vasodilator echocardiography.

LIMITATIONS OF STRESS PERFUSION IMAGING.

When compared with stress echocardiography, the limitations of stress SPECT imaging are (1) longer imaging protocols, which may take many hours; (2) greater equipment expense and the necessity of injecting radiopharmaceuticals with exposure to radiation; (3) less than desirable specificity in many laboratories because of failure to distinguish attenuation artifacts from scarring; (4) inability to visualize the heart in a real-time approach; (5) lower spatial resolution than seen with echocardiography; and (6) higher cost to patients.

COMPARATIVE STUDIES OF STRESS ECHOCARDIOGRAPHY VERSUS PERFUSION IMAGING

In seven comparative studies,[69] the overall sensitivity of myocardial perfusion imaging was 80 percent versus 74 percent for stress echocardiography. In contrast, the specificity for stress echocardiography was higher than that of myocardial perfusion imaging (88 vs. 78 percent). When single-vessel disease detection was analyzed separately, the sensitivity of myocardial perfusion imaging was 76 percent as compared with 67 percent for stress echocardiography. Another review of the literature by O'Keefe and colleagues that involved 11 studies and 808 patients reported an overall sensitivity and specificity for stress echocardiography of 78 and 86 percent, respectively, as compared with 83 and 77 percent for myocardial perfusion imaging.[70] Thus, sensitivity is lower and specificity higher for stress echocardiography.

Fleischmann and associates reviewed 44 articles to compare the diagnostic performance of exercise echocardiography and exercise SPECT imaging for CAD detection.[71] These authors concluded that when exercise echocardiography was compared with exercise SPECT via a receiver operating characteristic model, exercise echocardiography yielded significantly better discriminatory power when adjusted for age, publication year, and a setting including known CAD than did SPECT studies. This review did not include some of the more recent studies using gated ^{99m} Tc SPECT in which the specificity for detection of CAD is higher than the specificity with ^{201} Tl.[13] Also, the posttest referral bias may have been greater in the nuclear studies examined. Both exercise echocardiography and exercise SPECT performed significantly better than exercise testing alone.

Few studies have compared multiple diagnostic techniques for CAD detection in the same patient population. In one study, 60 patients being evaluated for the first time for chest pain underwent exercise stress testing, dipyridamole and dobutamine stress echocardiography, and dipyridamole and dobutamine ^{99m} Tc-sestamibi imaging.[72] With greater than 70 percent coronary stenosis used as the criteria for CAD, the sensitivity was 58 percent for exercise ECG testing, 55 percent for dipyridamole echocardiography, 61 percent for dobutamine echocardiography, 97 percent for dipyridamole ^{99m} Tc-sestamibi, and 91 percent for dobutamine ^{99m} Tc-sestamibi. The specificities for these tests were 67, 96, 96, 89, and 81 percent, respectively. All tests yielded higher sensitivity values for multivessel disease than for single-vessel disease. Although dobutamine echocardiography had a lower sensitivity than reported by other groups, this result agrees with the observation in another study that approximately 25 percent of patients manifested dobutamine-induced perfusion abnormalities without reversible wall motion abnormalities on dobutamine echocardiography.[73]

MAGNETIC RESONANCE CORONARY ANGIOGRAPHY.

This technique is under development and can now depict the major coronary arteries.[74] [75] [76] [77] Obstacles to its clinical use include correction for cardiac and respiratory motion, need for millimeter spatial resolution, and suppression of signal from adjacent epicardial fat and myocardium.[77] Avoiding the need for breath-holding with real-time tracking of diaphragmatic motion would be advantageous. Three-dimensional navigator-gated (to compensate for respiratory motion in the foot-to-head direction) and prospectively corrected free-breathing coronary MR angiography can provide more favorable signal-to-noise ratios but is limited by poor contrast between coronary blood and myocardium. Botnar and colleagues overcame this problem by combining three-dimensional MR angiography with a T2 preparatory prepulse for myocardial suppression and a shorter acquisition window[77] (Fig. 13-4). (Figure Not Available) This maneuver improved the contrast-to-noise ratio by 123 percent and yielded better coronary edge definition, thereby permitting good agreement between x-ray angiography and MR coronary angiography regarding vessel anatomy. The proximal left anterior descending and left circumflex coronary arteries were visualized on reconstructed images.

MRI offers the advantage of potentially examining the atheromatous lesion as well as the lumen.[77A] However, traditional selective x-ray coronary angiography currently offers higher resolution (0.1 mm).

New approaches introduced into the cardiac catheterization laboratory that provide additional anatomical and functional information for assessing coronary stenoses include quantitative angiography, intravascular ultrasound, coronary flow reserve measurements with a Doppler-tipped wire, and measurement of stenosis gradients with a pressure wire (see Chaps. 12 and 34) .

ASSESSMENT OF PROGNOSIS OF PATIENTS EVALUATED FOR CORONARY ARTERY DISEASE (see also Chap. 37)

One of the chief applications of noninvasive stress testing in patients with suspected or known CAD is the identification of patients at either high or low risk for future ischemic cardiac events.[5] [28] [37] Prognostication using noninvasive stress ECG testing or stress imaging technology is based on the rationale that physiological alterations under stress conditions predict events better than does knowledge of coronary artery anatomy. Accurate risk stratification contributes

Figure 13-4 (Figure Not Available) Reconstructed magnetic resonance angiographic images that were reformatted for length quantification. The paths of the left anterior descending (LAD) and the left circumflex (LCX) coronary arteries are visualized. The left main (LM) coronary artery is also identified. (From Botnar RM, Stuber M, Danias PG, et al: Improved coronary artery definition with T2-weighted, free-breathing, three-dimensional coronary MRA. Circulation 99:3139, 1999. By permission of the American Heart Association, Inc.)

importantly to clinical decision-making. For example, patients who are identified as being at low risk for future cardiac events on the basis of noninvasive test variables can be spared unnecessary or premature referral for invasive strategies unless symptoms are not adequately alleviated by antiischemic drugs. Conversely, patients with high-risk ECG stress test and/or imaging variables may benefit from early referral for invasive strategies, including revascularization, even if symptoms are mild.

Treadmill ECG Stress Testing for Evaluation of Prognosis (see also Chap. 6)

Treadmill exercise ECG stress testing alone without the addition of an imaging procedure is useful for differentiating low- and high-risk patients with chest pain (see also Chap. 6) . The demonstration of 1.0 mm or more of horizontal or downsloping ST segment depression at low exercise heart rates or workloads is a significant predictor of an adverse outcome when using exercise ECG testing for prognostication. Perhaps the most powerful predictive variable on treadmill testing for identifying high-risk patients is functional capacity reflected by workload achieved.[78] [79] Patients who failed to achieve at least 6 metabolic equivalents (METs) of estimated work during symptom-limited exercise had a significantly higher mortality rate over the next 2.5 years than did patients who exceeded 6 METs of work[78] (Fig. 13-5) . Similarly, chronotropic incompetence, identified as an attenuated heart rate response to exercise, predicts increased mortality.[80] [81] In the latter study, chronotropic incompetence independently predicted all-cause mortality, even after considering ^{201}Tl perfusion defects. Failure to reach 85 percent of the age-predicted maximum heart rate was associated with an increased risk of death (adjusted relative risk, 1.85). Poor exercise tolerance can be observed in patients with depressed resting LV function with or without superimposed transient exercise-induced ischemia.

A treadmill score has been proposed for better separating high- and low-risk patients undergoing ECG stress testing. Perhaps the most popular of these scores, derived by the Duke University group, relies on the duration of exercise, the maximal ST segment deviation, and a treadmill angina index.[82] Data from the literature suggest that the extent of inducible hypoperfusion on poststress SPECT perfusion images provides superior stratification of patients with stable chest pain attributed to known or suspected CAD into low- and high-risk groups than does the Duke treadmill score.[83] [84] [85] [86] In a recent follow-up study from the Duke group, patients with a low-risk Duke treadmill score who were treated medically had a 3.1 percent 5-year mortality rate. Those deemed at high risk by the Duke treadmill score criteria had a 35 percent 5-year mortality rate. The low-risk group, which represented 36 percent of the cohort, had a 40 percent prevalence of any CAD and a 9 percent prevalence of severe CAD determined angiographically. The high-risk group, which represented only 9 percent of

Figure 13-5 Cumulative mortality rates for patients who failed to achieve at least 6 metabolic equivalents (METs) of estimated work during symptom-limited exercise are compared with those of patients who exceeded 6 METs of work on stress testing. (From Snader CE, Marwick TH, Pashkow FJ, et al: Importance of estimated functional capacity as a predictor of all-cause mortality among patients referred for exercise thallium single-photon emission computed tomography: Report of 3,400 patients from a single center. J Am Coll Cardiol 30:641, 1997. Reprinted with permission from the American College of Cardiology.)

the entire cohort, had a 74 percent incidence of severe CAD, and all patients had at least one or more coronary stenoses.

The practical problem with the Duke treadmill score is that a substantial proportion of patients are classified as having intermediate or moderate risk after exercise ECG treadmill testing. In a study by Shaw and associates, 55 percent of the patients were classified as having moderate risk by the Duke treadmill score, and they had a 9.5 percent 5-year mortality rate and a 31 percent prevalence of severe CAD.[83] Perfusion imaging variables are useful in further risk-stratifying patients with intermediate-risk Duke treadmill scores.[84] A substantial number of these patients can be deemed to be at low risk if they show normal perfusion or only a mild postexercise defect.

LIMITATIONS.

Exercise ECG stress tests have other important limitations in assessing prognosis. First, a strongly positive exercise ECG, which is defined as an early or low ischemic threshold, significant horizontal ST segment depression, and a prolonged ST depression recovery time, does not necessarily signify more severe CAD by either angiographic or scintigraphic criteria.[87] The extent of exercise ST segment depression poorly predicts the extent of CAD, and the maximum ST segment depression achieved at peak exercise correlated poorly with the extent of stress-induced hypoperfusion by scintigraphy. Also, a considerable portion of patients have an uninterpretable exercise ECG response.[88] Several studies have established substantial incremental prognostic value of exercise SPECT in patients with nondiagnostic or positive ECG stress tests.[88] [89] In these studies, imaging variables provided substantial supplementary prognostic information over ECG stress test variables. Patients with normal scans have an excellent outcome even if the ECG stress test is nondiagnostic or abnormal.

Exercise ECG testing alone has particular utility in the risk assessment of patients with a normal resting ECG who have nonanginal or very atypical chest pain. If these patients achieve an adequate exercise heart rate or workload without significant ST segment depression, the prognosis during follow-up is excellent. However, for improved diagnostic and prognostic value, an imaging technique should be performed in conjunction with treadmill testing in patients with an intermediate or a high pretest likelihood of CAD on the basis of age, gender, and type of chest pain.

Stress Myocardial Perfusion Imaging for Evaluation of Prognosis (see also Chap. 9)

The prognostic value of exercise and pharmacological stress myocardial perfusion imaging has been established in thousands of patients evaluated in multiple clinical studies.[90] [91] The major prognostic variables on stress perfusion images predictive of future cardiac events are (1) a large defect size (>20 percent of the left ventricle); (2) multiple perfusion abnormalities in two or more coronary supply regions suggestive of multivessel CAD; (3) defect reversibility reflective of inducible ischemia in multiple myocardial scan segments, even in the distribution of one major coronary artery; (4) a large number of nonreversible defects; (5) transient LV cavity dilation from stress to rest images; (6) increased lung ^{201}Tl uptake best assessed by quantitating the lung/heart ^{201}Tl ratio; and (7) a resting LV ejection fraction of less than 40 percent measured on gated SPECT.[40] [90] [91] [92] Perhaps one of the most valuable features of exercise or pharmacological stress perfusion imaging with either ^{201}Tl or ^{99m}Tc-sestamibi is the ability to predict a low mortality and subsequent myocardial infarction rate in patients with a totally normal scan. Patients with normal tracer uptake at peak stress have less than a 1 percent combined annual mortality and nonfatal infarction rate and are thus often spared unnecessary invasive evaluation for assessment of their symptoms.[84] [88] [93] [94] [95] With respect to experience with exercise ^{99m}Tc-sestamibi perfusion imaging, Iskander and Iskandrian analyzed 14 prognostic studies consisting of more than 12,000 patients with respect to the prognostic value of normal and abnormal SPECT images.[95] A normal ^{99m}Tc-sestamibi study was associated with an average annual hard cardiac event rate of 0.6 percent. Patients with abnormal images had a 12-fold higher event rate at 7.4 percent annually.

INCREMENTAL VALUE OF PERFUSION IMAGING OVER ECG STRESS TESTING.

Numerous studies have shown that additional prognostic information is obtained when variables from stress myocardial perfusion imaging are added to information obtained from the clinical and ECG stress test variables.[84] [85] [88] [89] [93] [94] [95] Figure 13-6 shows the incremental value of SPECT in patients with a low, intermediate, or high likelihood of CAD after exercise ECG stress testing.[88] Patients with a high postexercise ECG stress test likelihood of CAD and a normal scan had a 0 percent event rate during follow-up. Those with an abnormal scan had a 10.8 percent event rate (death or myocardial infarction). In one study, when the stepwise Cox proportional hazards model and receiver operating characteristic curve analysis were used, nuclear testing added incremental prognostic value after inclusion of the most predictive clinical and exercise ECG stress test variables.[84] In addition, some studies have shown that when clinical, ECG stress test, and scintigraphic variables are known, little incremental prognostic information is gained by the addition of coronary angiographic variables, such as the number of vessels with significant stenoses.

The greater the number of perfusion defects on postexercise SPECT perfusion images, the greater the subsequent cardiac mortality rate with medical therapy.[89] [93] Figure 13-7 shows cardiac event-free survival curves according to the extent of hypoperfused myocardium on ^{201}Tl SPECT imaging in the study of Vanzetto and colleagues.[89] The extent of hypoperfusion could be an important variable in the selection of patients whose initial management approach would be aggressive medical therapy versus revascularization. In an observational retrospective review, Hachamovitch and associates found a low annual cardiac event rate (0.8 percent per year)

in patients with mildly abnormal normal stress perfusion scans receiving medical therapy as

Figure 13-6 Incremental value of exercise ^{99m} Tc-sestamibi myocardial perfusion imaging in patients who had either a low, intermediate, or high postexercise treadmill test likelihood of coronary artery disease (POST-ETT LK CAD). Note that patients with an abnormal scan (solid bars) had a significantly higher cardiac death or nonfatal myocardial infarction rate than did patients who had normal scan (crosshatched bar) results *$p<0.05$ for all abnormal versus normal scan results. (From Berman DS, Hachamovitch R, Kiat H, et al: Incremental value of prognostic testing in patients with known or suspected ischemic heart disease: A basis for optimal utilization of exercise technetium-99m sestamibi myocardial perfusion single-photon emission computed tomography. J Am Coll Cardiol 26:639, 1995. Reprinted with permission from the American College of Cardiology.)

Figure 13-7 Cardiac event-free survival over 7 years of follow-up after exercise ^{201} Tl single-photon emission computed tomographic (SPECT) imaging according to the extent of hypoperfused myocardium. Note that patients with three or more abnormal SPECT segments had a significantly worse event-free survival rate than did patients with more mild defects and patients who had a normal perfusion scan. (From Vanzetto G, Ormezzano O, Fagret D, et al: Long-term additive prognostic value of thallium-201 myocardial perfusion imaging over clinical and exercise stress test in low to intermediate risk patients. Study in 1137 patients with 6-year follow-up. Circulation 100:1521, 1999. By permission of the American Heart Association, Inc.)

compared with an annual cardiac death rate of 0.9 percent in patients with mildly abnormal scans who were referred for initial revascularization.[93] In contrast, patients with moderately abnormal or severely abnormal scans had a better outcome with revascularization early after nuclear testing than with medical therapy.

INCREMENTAL VALUE OF FUNCTIONAL VARIABLES OVER SPECT PERFUSION IMAGING ALONE

More recent studies have demonstrated incremental prognostic value of the poststress LV ejection fraction and LV volume determined on gated ^{99m} Tc-sestamibi SPECT over perfusion variables alone.[16] The poststress ejection fraction and end-systolic volume by gated ^{99m} Tc-sestamibi SPECT had incremental prognostic value over prescan and perfusion imaging information in predicting cardiac death. For example, patients with a resting SPECT ejection fraction of 45 percent or greater had mortality rates of less than 1 percent per year despite severe perfusion abnormalities, whereas patients with an ejection

Figure 13-8 Incremental prognostic value of the left ventricular ejection fraction on gated ^{99m} Tc single-photon emission computed tomographic imaging in relation to the myocardial perfusion findings. The ejection fraction calculated on the poststress images had incremental value over perfusion imaging information for predicting cardiac death. Patients with an ejection fraction of less than 45 percent (crosshatched bars) had a significantly higher annual mortality rate than did patients with an ejection fraction of 45 percent or greater. (Adapted from Sharir T, Germano G, Kavanagh PB, et al: Incremental prognostic value of post-stress left ventricular ejection fraction and volume by gated myocardial perfusion single photon emission computed tomography. Circulation 100:1035, 1999. By permission of the American Heart Association, Inc.)

fraction of less than 45 percent had high mortality rates, even with only mild to moderate perfusion abnormalities (9.2 percent per year) (Fig. 13-8) . Good exercise tolerance on treadmill testing is associated with a favorable prognosis. Nevertheless, myocardial perfusion imaging provides additional prognostic information for subsequent cardiac death, nonfatal infarction, or revascularization in patients who reach stage IV of the Bruce protocol.[96]

COST-EFFECTIVENESS OF SPECT IMAGING.

The use of myocardial perfusion imaging as an initial evaluation in patients with stable chest pain is highly cost-effective when compared with an initial invasive strategy. A large observational study consisting of 11,372 consecutive stable angina patients referred for stress myocardial perfusion SPECT imaging or direct catheterization revealed that costs were higher for the initial invasive strategy in clinical subsets with a low, intermediate, or high pretest likelihood of disease.[97] Diagnostic and follow-up costs of care were 30 to 41 percent higher for patients undergoing direct cardiac catheterization without any reduction in mortality or infarction. The diagnostic costs were $1320, $1275, and $1229 greater for low-, intermediate-, and high-risk patients undergoing initial cardiac catheterization than for those having stress perfusion imaging as the initial test for CAD detection. The cardiac death rate and nonfatal infarction rate in the 5826 patients undergoing initial stress perfusion imaging for assessment of stable angina were both 2.8 percent as compared with 3.3 and 3.0 percent, respectively, for the 5423 patients who were referred directly for cardiac catheterization as the initial diagnostic strategy. The cost of screening women with myocardial perfusion imaging was shown in a separate analysis to be considerably lower than the cost of direct coronary angiography in a similar type of analysis[98] (Fig. 13-9) . Thus, stress myocardial perfusion imaging undertaken as the initial step in diagnosis and assessment of prognosis yields comparable outcomes at a lower cost than does direct referral for cardiac catheterization. This noninvasive strategy is "ischemia driven" and should be applicable even to patients with angiographic disease and normal scans, since this group also has an excellent prognosis.[99]

CONCLUSIONS.

Thus, taken together, data reported from the literature demonstrate that patients with normal myocardial perfusion scans have an excellent prognosis whereas patients with abnormal scans have an increased rate of cardiac death and nonfatal infarction during follow-up. The greater the extent of stress-induced hypoperfusion and reversibility, the greater the probability of an event. It is apparent from multiple studies cited above that myocardial perfusion imaging variables provide supplementary prognostic information to exercise ECG testing alone, particularly in patients who have an intermediate risk of an adverse outcome estimated by clinical variables and exercise stress testing. Stress perfusion imaging variables appear to be equal or even superior to mere knowledge of coronary anatomical variables for assessing prognosis because the extent of hypoperfusion during stress and the magnitude and extent of stress-induced ischemia better predict subsequent cardiac death than does demonstration of the presence of one-, two-, or three-vessel disease alone. In fact, patients with three-vessel disease on angiography can be further risk-stratified by myocardial perfusion imaging performed

Figure 13-9 Composite cost of diagnostic screening and follow-up cost in patients referred directly to cardiac catheterization as the initial diagnostic strategy for evaluation of chest pain in comparison to the cost of undergoing stress perfusion imaging as the initial test for coronary artery disease detection in women. Note that for patients with either a low, intermediate, or high pretest likelihood of coronary artery disease, total cost was significantly greater in patients referred directly to cardiac catheterization as the initial test for chest pain evaluation. The cardiac death or subsequent myocardial infarction rate was comparable in the two groups. (From Shaw LJ, Heller GV, Travin MI, et al: Cost analysis of diagnostic testing for coronary artery disease in women with stable chest pain. Economics of Noninvasive Diagnosis [END] study group. J Nucl Cardiol 6:559, 1999.)

after catheterization into low-, intermediate-, and high-risk groups.

Echocardiographic Assessment of Prognosis

Evaluation of LV function on the resting echocardiogram obtained before commencing the stress portion of the protocol offers considerable prognostic information by itself. A resting wall motion abnormality has proved to be most useful in predicting future cardiac events in patients who undergo dobutamine stress echocardiography.[100] The presence of a resting wall motion abnormality in combination with a positive dobutamine echocardiogram resulted in a 34 percent incidence of any cardiac event versus an incidence of 18 percent when the stress echocardiogram was negative. After it was known that resting wall motion was normal, the second best predictor of a cardiac event was the patient's age.

Reports of the relative ability of stress echocardiography to predict the extent of CAD vary widely.[51] [101] For the most part, the sensitivity of stress echocardiography for identifying patients with severe CAD is good.

Heupler and coauthors reported that detection of exercise-induced wall motion abnormalities independently predicted cardiac events in 508 women monitored for 41 ± 10 months after exercise echocardiography.[102] Evidence of ischemia by echocardiography foretold future cardiac events better than did exercise capacity or inducible ST segment depression. The prognostic data provided by the exercise echocardiogram added to that provided by clinical and exercise ECG variables in patients with both undiagnosed and known CAD. In a study from the same institution consisting of both men and women, the presence of ischemia on exercise echocardiography predicted future cardiac events well. In the multivariate model in that study, the presence of ischemia during exercise echocardiography was the strongest independent

predictor of cardiac death, myocardial infarction, or unstable angina.[103]

COMPARISON WITH PERFUSION IMAGING

Few studies in the literature have compared exercise echocardiography with exercise perfusion imaging for long-term prediction of prognosis. Olmos and colleagues compared clinical, exercise, echocardiographic, and SPECT ^{201} Tl variables in 248 patients who underwent both stress imaging modalities simultaneously.[104] The clinical models characterized by exercise echocardiography with exercise ECG testing and ECG ^{201} Tl SPECT with exercise ECG were comparable in the prediction of cardiac events. For the exercise echocardiography model, the exercise wall motion score index and induction of ischemia were the strongest predictors of events, with odds ratios of 2.63 per unit increment. For the model with exercise ^{201} Tl SPECT, the strongest predictor was the extent of the ischemic perfusion defect, with an odds ratio of 4.93. Of interest, for the prediction of ischemic events and/or cardiac death, echocardiographic and ^{201} Tl variables were the only predictive variables. Figure 13-10 shows the event-free survival for cardiac death with the use of quantitative exercise ^{201} Tl and exercise echocardiography in this study.

One reason for the failure to predict some events by stress echocardiography is the inability to attain an adequate heart rate response.[105] This limitation agrees with the finding of compromised sensitivity of stress echocardiography for detecting ischemia in the setting of inadequate heart rate responses.[48] Therefore, patients who are deemed unable to exercise adequately should undergo dobutamine stress echocardiography for both diagnosis and prognosis indications.

With respect to the comparison of dobutamine echocardiography and simultaneously performed ^{99m} Tc-sestamibi SPECT imaging, Geleijnse and coauthors reported that any abnormality or ischemia on echocardiography or scintigraphy was associated with cardiac events.[106] Dobutamine-atropine echocardiography and ^{99m} Tc-sestamibi imaging provided comparable prognostic information. With respect to the negative predictive value of a normal study, patients with normal studies had equally very low event rates (0.4 percent by echocardiography and 0.5 percent by ^{99m} Tc-sestamibi).

Although earlier studies[91] showed a higher event rate for patients with a normal stress echocardiogram than for those with a normal stress SPECT study, later studies have shown almost comparable, very low event rates for patients with a normal stress echocardiogram and normal stress SPECT.[107] [108]

In the study by Poldermans and colleagues of 1737 patients with known or suspected CAD who underwent dobutamine-atropine stress echocardiography, a normal echocardiographic study was associated with an annual event rate of cardiac death or infarction of 1.3 percent over a 5-year period.[109] In that study, the rate of cardiac death or myocardial infarction in patients with new wall motion abnormalities or extensive resting wall motion abnormalities increased 3.6- and 2.5-fold, respectively. A negative echocardiographic response to pharmacological stress in women was associated with a less than 1 percent hard cardiac event rate over 3 years of follow-up.[110] Echocardiographic evidence of ischemia was found as the only independent predictor of hard cardiac events (odds ratio, 27.5) in this study.

Few studies have directly compared vasodilator stress and inotropic stress with echocardiography for risk stratification. High-dose dipyridamole echocardiography (up to 0.84 mg/kg over a 10-minute period) with atropine (up to 1 mg over a 4-minute period) and dobutamine-atropine echocardiography yielded comparable risk stratification on the basis of the presence, severity, and extent of induced wall motion abnormalities in a prospective, multicenter study.[111] By stepwise analysis, the wall motion score index at the peak dipyridamole dose was the most important predictor (relative risk, 7.4). Most laboratories currently prefer dobutamine stress for detection of CAD and prognostication.

PREDICTION OF PERIOPERATIVE ISCHEMIC EVENTS.

A meta-analysis of 15 studies demonstrated the prognostic value of dipyridamole ^{201} Tl imaging and dobutamine echocardiography for predicting perioperative ischemic events in patients undergoing risk stratification before vascular surgery[111A] (see also Chap. 61) . For dipyridamole ^{201} Tl studies, the cardiac death rate or myocardial infarction rate was 1, 7, and 9 percent for normal results, fixed defects, and reversible defects, respectively. For patients with a dobutamine-induced new or worsening wall motion response, 23.1 percent had a perioperative ischemic event as compared with 0.37 percent of patients with a normal stress echocardiographic response. Summary odds ratios were greater for dobutamine echocardiography than for dipyridamole ^{201} Tl, but the 95 percent confidence intervals were wider with echocardiography because of a smaller sample size.

Conclusions: Stress Perfusion Imaging Versus Stress Echocardiography

In summary, both stress perfusion imaging and stress echocardiography provide prognostic information supplemental to that of clinical and exercise ECG stress test variables.

Figure 13-10 Event-free survival for ischemic events and cardiac death with the use of quantitative parameters of exercise ^{201} Tl and echocardiography. Note that for both exercise ^{201} Tl single-photon emission computed tomographic imaging and exercise echocardiography (performed in the same patients), those with a low-risk finding had a significantly better outcome than did patients demonstrating high-risk imaging variables. ExWMS=exercise wall motion score; PDS=perfusion defect size. (From Olmos LI, Dakik H, Gordon R, et al: Long-term prognostic value of exercise echocardiography compared with exercise ^{201} Tl, ECG, and clinical variables in patients evaluated for coronary artery disease. Circulation 98:2679, 1998. By permission of the American Heart Association, Inc.)

Both techniques have excellent negative predictive value for identifying low-risk patients. Such patients with either a normal perfusion study at peak stress or normal regional function have an excellent outcome with a cardiac death or infarction rate of less than 1 percent per year. The negative predictive value of a normal study is perhaps slightly better with perfusion imaging than echocardiography because of its slightly higher sensitivity for identifying mild CAD. Patients with high-risk stress imaging findings on either perfusion imaging or echocardiography have a worse outcome with medical therapy, and the greater the degree of regional abnormalities (either perfusion or function), the higher the event rate. Either technique is superior to exercise ECG test variables alone. An abnormal workload and a suboptimum heart rate response are excellent prognostic variables derived from the ECG stress test for identifying high-risk patients. Ischemia occurring at low exercise heart rates and workloads should prompt evaluation with coronary angiography. Pharmacological stress imaging provides comparable prognostic information to exercise imaging for both nuclear cardiology and echocardiographic techniques, and either can be used for preoperative risk stratification in intermediate- or high-risk patients scheduled for vascular surgical procedures. A limitation of both stress perfusion imaging and stress echocardiography is a low positive predictive value with regard to future ischemic events. That is, the percentage of patients who die or suffer a nonfatal infarction with abnormal imaging studies is fairly low. The negative predictive value of normal studies is much better and exceeds 95 percent.

Magnetic Resonance Perfusion or Function Imaging (see also Chap. 10)

MR perfusion imaging performed with gadolinium-based contrast agents and a stressor such as dipyridamole is an alternative approach to detecting CAD. The technique is still investigational, but early results appear promising. Dipyridamole MR perfusion imaging and ^{99m} Tc-sestamibi SPECT were shown to have comparable sensitivity for detecting single-vessel disease.[112] Dipyridamole stress MRI had 85 percent agreement with ^{201} Tl scintigraphy in detection of CAD and a correlation of 0.86 in sizing perfusion defects.[113] Dobutamine MRI for the detection of induced wall motion abnormalities is an alternative stress MRI approach for CAD detection. Early studies show sensitivities comparable to those of SPECT imaging.[114] [115] [116] [117]

Stress MRI with contrast may ultimately be very clinically useful in that the technique provides high spatial resolution and has the capability of imaging in any desired plane without ionizing radiation. Images can be acquired with reproducible quality that is operator independent. Since no imaging window is required, images can be obtained in virtually all patients, including those with emphysema. The endocardial border can easily be defined and separated from the cavity blood volume.

A major competing technology will be contrast echocardiography using microbubbles with dipyridamole or adenosine stress or dobutamine echocardiography. Nagel and associates reported that high-dose dobutamine stress MRI using short breath-holds and a gradient-echo technique in 208 consecutive patients had higher sensitivity (86.2 vs. 74.3 percent) and specificity (85.7 vs. 69.8 percent) than did dobutamine stress echocardiography. [117] Dobutamine stress examinations were feasible in 89.4 percent of patients with both echocardiography and MRI. Interestingly, insufficient image quality was the major reason for exclusion from dobutamine stress echocardiography, whereas claustrophobia was the major reason for exclusion from stress MRI. Other disadvantages of stress MRI techniques are an inability to image patients with pacemakers and implanted cardioverter-defibrillators and the need for prolonged breath-holding.

Table 13-3 summarizes the major strengths and limitations of the various techniques used for detection of CAD and assessment of prognosis.

TABLE 13-3 -- MAJOR STRENGTHS AND LIMITATIONS OF VARIOUS TECHNIQUES FOR DETECTING CORONARY ARTERY DISEASE AND ASSESSING PROGNOSIS

EXERCISE ECG

Strengths: Low cost; short duration; functional status evaluated; high sensitivity in 3-vessel or left main CAD; provides useful prognostic information (e.g., ischemia at low workload)

Limitations: Suboptimal sensitivity; low detection rate of 1-vessel disease; nondiagnostic with abnormal baseline ECG; poor specificity in certain patient populations (e.g., premenopausal women); need to achieve
85% of maximum heart rate for maximizing accuracy

EXERCISE/PHARMACOLOGICAL SPECT PERFUSION IMAGING

Strengths: Simultaneous evaluation of perfusion and function with gated SPECT; higher sensitivity and specificity than exercise ECG; high specificity with ^{99m} Tc-labeled agents; studies can be performed in almost all patients; significant additional prognostic value; comparable accuracy with pharmacological stress; viability and ischemia simultaneously assessed; quantitative image analysis

Limitations: Suboptimal specificity with ^{201} Tl; long procedure time with ^{99m} Tc-labeled agents; no routine correction for attenuation and scatter; higher cost than exercise ECG; radiation exposure; poor-quality images in obese patients

EXERCISE/PHARMACOLOGICAL STRESS ECHOCARDIOGRAPHY

Strengths: Higher sensitivity and specificity than exercise ECG; additional prognostic value; comparable value with dobutamine stress; time to complete examination short; identification of coexisting structural cardiac abnormalities (e.g., valvular disease); simultaneous evaluation of perfusion with contrast agents; relatively lower cost than other techniques; no radiation

Limitations: Decreased sensitivity for detection of 1-vessel disease or mild stenosis with postexercise imaging; inability to image all of the left ventricle in some patients; highly operator dependent for image analysis; no quantitative image analysis; poor acoustic window in some patients (e.g., chronic obstruction lung disease); infarct zone ischemia less well detected

CAD=coronary artery disease; ECG=electrocardiogram; SPECT=single-photon emission computed tomography.

NONINVASIVE ASSESSMENT OF MYOCARDIAL VIABILITY (see also Chap. 37)

Regional and global LV dysfunction leading to depressed LV ejection fractions in patients with CAD can result from (1) myocardial necrosis or scarring, (2) postischemic stunning, or (3) myocardial hibernation. Hibernation is defined as the state in which myocytes are chronically hypoperfused but in which flow is sufficient to sustain structural integrity. Hibernating myocardium, by definition, demonstrates improved systolic function with improved resting perfusion after coronary revascularization.

An accurate noninvasive determination of myocardial viability that is capable of distinguishing irreversible myocardial cellular injury from hibernation is critically important for the clinical decision-making process. It allows for improved selection of patients with CAD and resting LV dysfunction who will benefit most from revascularization strategies. It plays a major role in the triage of patients with severe ischemic cardiomyopathy to transplantation versus revascularization. Patients with substantial zones of myocardial viability in asynergic myocardium reflective of hibernation demonstrate better function and overall improved outcomes after revascularization than do patients with LV dysfunction predominantly caused by myocardial scarring.

Techniques Used for Myocardial Viability Assessment

Thallium-201 Imaging (see also Chap. 9)

^{201} Tl rest and delayed redistribution imaging is the most commonly used radionuclide imaging modality for the assessment of myocardial viability (see also Chap. 9) . It is used for this purpose because the initial uptake of ^{201} Tl is related to both blood flow and myocardial membrane integrity. Myocardial stunning or hibernation does not result in impaired ^{201} Tl extraction as long as the sarcolemmal membrane transport system for monovalent cations does not have irreversible ischemic damage.[118] [119] Several groups have shown that approximately 60 to 70 percent of asynergic myocardial segments showing greater than 50 percent ^{201} Tl uptake on resting ^{201} Tl scintigraphy will show improved systolic function after revascularization.[120] The most likely reason for the lack of enhanced systolic function after revascularization in zones judged to be viable before revascularization is the presence of subendocardial scar. That is, certain segments showing 20 to 30 percent subendocardial scarring may not demonstrate improved systolic thickening after revascularization, even if greater than 50 percent ^{201} Tl uptake is seen in those regions. However, such patients may benefit from revascularization by reducing stress-induced ischemic dysfunction or reinfarction.

^{99m} Technetium-Labeled Agents (see also Chap. 9)

^{99m} Tc-labeled perfusion agents do not show significant redistribution over time after being injected at rest intravenously. However, several studies have shown comparable sensitivity and specificity for viability detection between these agents and ^{201} Tl.[120a--c] It is thought that this similarity is due to high extraction of ^{99m} Tc-sestamibi or ^{99m} Tc-tetrofosmin in regions of low flow. These agents bind to the mitochondrial membrane and can identify stunned or hibernating myocardium as long as the mitochondria are not irreversibly damaged. The advantage of ^{99m} Tc-labeled agents is less attenuation or less scatter than noted with ^{201} Tl, which produces higher quality images. In addition, gated SPECT imaging can be undertaken with ^{99m} Tc-sestamibi or ^{99m} Tc-tetrofosmin to allow for simultaneous assessment of regional systolic thickening in myocardial perfusion. Demonstration of intact thickening at rest or when images are acquired during dobutamine infusion indicates viability.

Positron-Emission Tomography (see also Chap. 9)

PET is considered by many to be the standard of reference for the noninvasive detection of myocardial viability by nuclear cardiology techniques because PET imaging can simultaneously assess myocardial perfusion and metabolism.[120D] Nitrogen-13-labeled ammonia is the most often used perfusion tracer, and fluorine-18-labeled fluorodeoxyglucose (FDG) is the metabolic tracer for assessing glucose utilization. Patients with a mismatch pattern between perfusion and FDG uptake will show improved regional and global LV function after revascularization, whereas patients demonstrating a concordant reduction in perfusion and FDG uptake (a "match" pattern) have predominantly myocardial scar as the cause of asynergy, and segments showing this pattern have a significantly lower chance of improved function after revascularization. Preserved myocardial oxygen consumption estimated by carbon 11 (^{11} C)-acetate PET imaging is found in myocardial regions that are hibernating. ^{11} C-Acetate PET imaging is an alternative to FDG-PET imaging for detection of viability.

Dobutamine Echocardiography (see also Chap. 7)

Low-dose dobutamine echocardiography is another useful modality for assessment of viability. The rationale for inotropic

stress is the identification of contractile reserve in zones of severe myocardial asynergy. This technique furnishes an alternative noninvasive approach to resting SPECT perfusion imaging or PET imaging. Enhanced systolic thickening with low-dose dobutamine predicts functional recovery well. A biphasic response in which systolic thickening increases at low doses and then deteriorates at high doses indicates both viability and ischemia. It is the most sensitive criterion for improved function after revascularization. End-diastolic wall thickness is also an important marker of myocardial viability in patients with suspected hibernation and has been shown to predict recovery of function in a manner similar to that of ^{201} Tl scintigraphy after revascularization.[120E]

STRENGTHS AND WEAKNESSES OF VARIOUS MODALITIES FOR ASSESSING VIABILITY

When compared with ^{201} Tl or ^{99m} Tc-sestamibi, dobutamine echocardiography is more specific but less sensitive. The positive predictive value of inotropic reserve for predicting improved systolic function with dobutamine echocardiography after revascularization is higher than the positive predictive value for predicting improvement in regional function with ^{201} Tl scintigraphy when greater than 50 percent ^{201} Tl uptake is used as the criterion for myocardial viability. Studies that have compared ^{201} Tl SPECT imaging and dobutamine echocardiography[121] [122] [123] [124] [125] [126] have consistently demonstrated that the number of asynergic segments exhibiting preserved ^{201} Tl uptake or showing rest ^{201} Tl redistribution significantly exceed the number of segments with residual capacity for systolic thickening as determined by dobutamine infusion. Similarly, studies that have compared PET imaging using FDG with dobutamine echocardiography[127] [128] [129] [130] [131] have shown results similar to those comparing^{201} Tl SPECT and dobutamine echocardiography in that the number of severely asynergic segments with preserved FDG uptake significantly exceeds these segments with residual inotropic reserve.

The sensitivity of dobutamine echocardiography and the negative predictive value in regard to failure to improve after revascularization are lower than the sensitivity and negative predictive value of SPECT imaging because certain regions that are severely underperfused and are akinetic at rest and supplied by severely stenotic vessels but are viable may not demonstrate enhanced systolic thickening, even with the lowest doses of dobutamine. Such segments have no flow reserve with the increased oxygen demand because of inotropic stress and therefore become ischemic immediately.

The degree of residual stenosis may significantly influence the response of ischemic myocardium to dobutamine. To have improvement in systolic wall thickening with inotropic stress, myocardial oxygen delivery must increase in proportion to oxygen demand, which at any given dose of dobutamine is influenced by the amount of viable myocardium. In the absence of stenosis, regional blood flow will increase in proportion to oxygen demand, but if a limiting stenosis is present, ischemia will occur with even very low doses of dobutamine despite the presence of significant viable myocardium.

Combined Modalities for Viability Assessment

If techniques are combined, regions with preserved FDG uptake and hypoperfusion by ^{13} N-ammonia, and with inotropic reserve by dobutamine echocardiography, have limited myocardial scarring or irreversible myocardial injury and a substantial chance of improved regional and global function after revascularization. When metabolic imaging and dobutamine echocardiographic results agree regarding the lack of substantial myocardial viability, extensive myocardial scarring most likely exists, and revascularization will seldom yield any functional benefit or even survival over medical therapy. In one study in which both PET imaging and dobutamine echocardiography were performed in patients with CAD and severe LV dysfunction, the overall rates of accuracy of PET and dobutamine echocardiography for predicting postoperative improvement in function were similar.[131A] However, the strongest predictor of improvement was a preoperative increase of LV ejection fraction with low-dose dobutamine infusion. When SPECT or PET imaging indicates the presence of viable myocardium but dobutamine echocardiography shows an absence of systolic thickening, the most likely scenario is severe resting hypoperfusion with exhausted flow reserve, subendocardial fibrosis, or a combination of these factors. Recovery of resting function after revascularization would be quite unpredictable. This viability pattern has been reported to occur in about 20 to 45 percent of segments that show viability by PET imaging and contributes to the lower sensitivity and higher specificity of dobutamine echocardiography.[132] Cornel and coauthors reported that although 94 percent of myocardial asynergic segments that were nonviable on ^{201} Tl SPECT did not show contractile reserve by low-dose dobutamine echocardiography, the disagreement between SPECT and dobutamine echocardiography was caused mainly by the absence of contractile reserve in 27 percent of the segments that were viable by ^{201} Tl scintigraphy.[133]

Summary of Approaches to Assessment of Viability

Taken together, all of the techniques for the assessment of myocardial viability described have high accuracy in the noninvasive assessment of myocardial viability. All provide value in decision-making that is supplementary to clinical and coronary angiographic information alone with respect to the worth of coronary revascularization in patients with ischemic cardiomyopathy. All the techniques show that the greater the number of viable segments preoperatively, the greater the improvement in ejection fraction and exercise tolerance after revascularization. Pagley and colleagues found that the mortality rate after revascularization over a 5-year follow-up was significantly higher in patients with lesser degrees of preoperative viability as assessed by quantitative ^{201} Tl scintigraphy [134] (Fig. 13-11) . Similarly, using dobutamine echocardiography, Afridi and coworkers found that in patients with CAD and severe LV dysfunction who demonstrated myocardial viability during dobutamine echocardiography, revascularization improved survival when compared with medical therapy and when compared with revascularized patients with poor viability preoperatively.[135] Myocardial contractile reserve significantly predicts survival in patients undergoing revascularization for

Figure 13-11 Survival free of cardiac death or cardiac transplantation relative to the extent of preoperative myocardial viability assessed by resting ^{201} Tl scintigraphy in patients with coronary artery disease and a depressed left ventricular ejection fraction who underwent coronary artery bypass graft surgery. The designation of greater or lesser viability was made on the basis of a quantitative viability index determined by the extent of ^{201} Tl uptake in multiple myocardial segments. Note that patients with lesser viability had significantly worse event-free survival than did patients with greater viability. (Adapted from Pagley PR, Beller GA, Watson DD, et al: Improved outcome after coronary bypass surgery in patients with ischemic cardiomyopathy and residual myocardial viability. Circulation 96:793, 1997. By permission of the American Heart Association, Inc.)

CAD and LV dysfunction.[136] Survival was greater with revascularization than with medical therapy in patients showing substantial myocardial contractile reserve. Among patients with myocardial contractile reserve in five or more segments, the survival rate was 93 ± 6 percent at 3 years versus 49 ± 15 percent in patients treated medically. Similarly, Bax and colleagues found that in patients with substantial viability on dobutamine stress echocardiography, the LV ejection fraction and New York Heart Association functional class improved after revascularization.[137] A combination of imaging modalities appears to provide even greater accuracy in noninvasive assessment of viability than do the individual technologies.[132]

MAGNETIC RESONANCE IMAGING.

Few studies have examined the value of MRI in the assessment of myocardial viability in patients with chronic CAD and LV dysfunction.[138] [139] [140] Markers of viability on MRI include increased signal intensity, preservation of end-diastolic thickness, systolic wall thickening at rest, and contractile reserve during dobutamine infusion.[24] When end-diastolic wall thickness is 5.5 mm or greater, the probability of viability is high.[138] When PET imaging with FDG was used as the "gold standard," this criterion had a sensitivity of 72 percent and specificity of 89 percent for viability detection. Dobutamine MRI had a sensitivity of 89 percent and specificity of 94 percent for prediction of functional recovery after revascularization.[141] A lower accuracy of 80 percent for dobutamine MRI was reported by Dendale and coauthors.[142] Thus, although a promising alternative to dobutamine echocardiography for viability assessment in chronic ischemic cardiomyopathy, further studies comparing the sensitivity, specificity, and cost-effectiveness of this approach are needed. Myocardial viability can be assessed with MRI and gadolinium contrast enhancement after acute myocardial infarction. Hypoenhancement or diminished signal intensity on delayed contrast-enhanced imaging is a marker of large infarct size and a worse prognosis.[143] [144] Nonviability can also be predicted by using first-pass and delayed MRI in that myocardial regions showing hypoenhancement with contrast injection on both first-pass and delayed imaging predict a lack of functional improvement after myocardial infarction.[145] Regions showing normal signal intensity on first-pass and increased intensity on delayed imaging exhibit significant functional improvement.

Table 13-4 summarizes the strengths and limitations of the various noninvasive techniques for detection of myocardial viability. All have been shown to be clinically useful in identifying which patients with ischemic cardiomyopathy have the greatest chance of enhancement of regional and global LV function, as well as improved survival, after revascularization.

A PERSPECTIVE ON THE FUTURE OF CARDIAC IMAGING

The future appears bright for further progress in technology and clinical application of noninvasive imaging techniques. Advances in instrumentation and the emergence of new imaging agents will permit enhanced diagnostic and prognostic value of the methodologies reviewed in this chapter. With respect to nuclear cardiology, the development of transmission-emission SPECT instrumentation will provide attenuation and scatter correction reconstruction algorithms leading to fewer imaging artifacts and enhanced specificity for CAD detection. Another expected advance in instrumentation will be the capability to image PET tracers with SPECT cameras that have special collimators or specially designed coincidence detecting software. New radiopharmaceuticals on the horizon will allow molecular imaging of gene expression by using reporter gene/reporter probe systems to image the expression of endogenous or exogenous genes (see also Chap. 9) . Micro-PET and micro-SPECT systems are being designed for imaging small animals such as mice. Imaging of the various stages of the atherosclerotic

TABLE 13-4 -- STRENGTHS AND LIMITATIONS OF NONINVASIVE TECHNIQUES FOR ASSESSMENT OF MYOCARDIAL VIABILITY

SPECT IMAGING

Strengths: High sensitivity for predicting improved function after revascularization; uses quantitative objective criteria (e.g., 60% segmental uptake); FDG imaging with special collimator; LVEF quantitated on ^{99m} Tc-sestamibi or ^{99m} Tc-tetrofosmin imaging; predictive of clinical outcomes in a large number of studies

Limitations: Reduced spatial resolution and sensitivity in comparison to PET; less quantitative than PET; areas of attenuation (e.g., inferior wall on ^{99m} Tc-sestamibi scans) misconstrued as nonviability; cannot differentiate endocardial from epicardial viability; no absolute measurement of blood flow; lower specificity than dobutamine echocardiography for predicting improved function after revascularization

PET IMAGING

Strengths: Simultaneous assessment of perfusion and metabolism; more sensitive than other techniques; good specificity; no attenuation problems; absolute blood flow can be measured; predictive of outcomes

Limitations: Lower specificity than dobutamine echocardiography or MRI; cannot separate endocardial from epicardial viability; high cost and highly sophisticated technology; limited availability

DOBUTAMINE ECHOCARDIOGRAPHY

Strengths: Higher specificity than nuclear techniques; viability assessed at low doses and ischemia at higher doses; evaluation of mitral regurgitation on baseline echocardiography; good spatial resolution; predictive of clinical outcomes; widely available; lower cost than dobutamine MRI

Limitations: Poor windows in 30% of patients; lower sensitivity than nuclear techniques; viable regions with absent flow reserve will not show increased thickening during dobutamine stimulation; reliance on visual assessment of wall thickening

CONTRAST ECHOCARDIOGRAPHY

Strengths: Microcirculatory integrity evaluated as well as systolic thickening; better estimation of extent of viability than functional assessment alone; precise delineation of area of necrosis; good spatial resolution permitting endocardial vs. epicardial perfusion; viability assessed in presence of total coronary occlusion; use of very long pulsing intervals; pulse inversion, power pulse inversion, and power modulation reduce attenuation artifacts

Limitations: Difficult windows in 30% of patients; attenuation problems; scant clinical data available

DOBUTAMINE MRI

Strengths: Separately evaluate inotropic reserve in endocardium with tagging; measurement of wall thickness more accurate than with TTE; better image quality than echocardiography for assessment of contractile reserve; simultaneous assessment of perfusion using contrast enhancement; good sensitivity and specificity for viability detection; good imaging windows in all patients

Limitations: Higher cost than echocardiography; limited availability; need better, faster automated techniques; less sensitive than nuclear techniques but may be more specific; imaging information not available in real time; lack of clinical research studies; patients with pacemakers or ICDs cannot be imaged

FDG=[18] F-fluorodeoxyglucose; LVEF=left ventricular ejection fraction; MRI=magnetic resonance imaging; PET=positron-emission tomography; SPECT=single-photon emission computed tomography; TTE=transesophageal echocardiography.

process in the vascular wall is also potentially feasible, as is imaging sites of apoptosis.

With respect to contrast echocardiography, progress in microbubble contrast agents and imaging technology to enhance the microbubble signal-to-noise ratio will enable better assessment of myocardial perfusion and viability with intravenous injection of contrast. Accurate infarct sizing with second-generation contrast agents and intermittent harmonic imaging should emerge. Imaging of myocardial inflammation will be permissible since lipid microbubbles can persist in the microcirculation during injury by means of attachment to activated leukocytes.[146] Microbubbles adhere to damaged endothelial cells and may thus furnish a way to assess areas of microvascular endothelial dysfunction in vivo. Microbubbles may ultimately prove useful for local drug delivery since such bubbles can be destroyed in tissue by ultrasound in vivo. Finally, there is a potential for quantifying myocardial blood flow by using a constant venous infusion and subsequent ultrasound destruction of microbubbles, with microbubble destruction and replenishment occurring at predetermined intervals.[147]

We can expect great advances in the field of cardiac MRI in the ensuing years. With the advent of new developments such as high-speed imaging, improved surface coils, and emergence of suitable contrast agents, MR coronary angiography could become a useful screening tool for noninvasive imaging of the proximal coronary vessels. Imaging of coronary plaque by MRI and spectroscopic techniques may allow differentiation between stable and unstable plaque, which could be a great contribution to the evaluation of patients with asymptomatic CAD. Arterial remodeling in atherosclerosis might also be assessed by MRI in either native disease or after a percutaneous intervention.[148] Finally, phosphorus-31 nuclear magnetic resonance spectroscopy, which can directly measure high-energy phosphates in the myocardium, may prove useful for noninvasively identifying metabolic evidence of stress-induced ischemia.[149]

These examples illustrate how we can look forward to further advances in the field of noninvasive cardiovascular imaging as a result of progress in instrumentation, enhanced computer processing of images, and new imaging agents for new applications.

Part III - NORMAL AND ABNORMAL CARDIAC FUNCTION

Chapter 14 - Mechanisms of Cardiac Contraction and Relaxation

LIONEL H. OPIE

MICROANATOMY OF CONTRACTILE CELLS AND PROTEINS

Ultrastructure of Contractile Cells

The major function of myocardial muscle cells *(cardiomyocytes)* is in the cardiac contraction-relaxation cycle. The contractile proteins of the heart lie within these myocytes, which constitute about 75 percent of the total volume of the myocardium, although only about one third in number of all the cells. About half of each ventricular cell is occupied by myofibers and about one fourth to one third by mitochondria (Table 14-1) .[1] A *myofiber* is a group of myocytes (Fig. 14-1) (Figure Not Available) held together by surrounding collagen connective tissue. Further strands of collagen connect myofibers to each other.[2] Excess collagen, one cause of left ventricular diastolic dysfunction, may accumulate in left ventricular pressure but not volume overload.[3]

The individual contractile muscle cells that account for more than half of the heart's weight are roughly cylindrical (Fig. 14-2) . Those in the atrium are quite small, being less than 10 mum in diameter and about 20 mum in length. Relative to atrial cells, human ventricular myocytes are large, measuring 17 to 25 mum in diameter and 60 to 140 mum in length (see Table 14-1) .

When examined under the light microscope, the atrial and ventricular muscle cells have cross striations and are branched.[4] Each cell is bounded by a complex cell membrane, the *sarcolemma* (*sarco,* "flesh"; *lemma,* "thin husk") and is filled with rodlike bundles of *myofibrils* (see Fig. 14-1) (Figure Not Available) . The latter are the contractile elements. The sarcolemma of the myocyte invaginates to form an extensive tubular network (the *T tubules*) that extends the extracellular space into the interior of the cell (see Figs. 14-1 (Figure Not Available) and 14-2) . The nucleus, which contains almost all of the cell's genetic information, is often centrally located. Some myocytes have several nuclei. Interspersed between the myofibrils and immediately beneath the sarcolemma are many mitochondria, the main function of which is to generate the energy in the form of adenosine triphosphate (ATP) needed to maintain the heart's contractile function and the associated ion gradients. Of the other organelles, the *sarcoplasmic reticulum* (SR) is most important (see Fig. 14-1) (Figure Not Available) . From the SR is discharged, in response to the wave of electrical excitation, the calcium that triggers contraction; and when the calcium is once again taken up into the SR, relaxation ensues.

Anatomically, the SR is a fine network spreading throughout the myocytes, demarcated by its lipid bilayer, which is rather similar to that of the sarcolemma. Parts of

TABLE 14-1 -- CHARACTERISTICS OF CARDIAC CELLS, ORGANELLES, AND CONTRACTILE PROTEINS

MICROANATOMY OF HEART CELLS

	Ventricular Myocyte	Atrial Myocyte	Purkinje Cells
Shape	Long and narrow	Elliptical	Long and broad
Length (mum)	60-140	About 20	150-200
Diameter (mum)	About 20	5-6	35-40
Volume (mum^3)	15,000-45,000	About 500	135,000-250,000
T tubules	Plentiful	Rare or none	Absent
Intercalated disc	Prominent end-to-end transmission	Side-to-side as well as end-to-end transmission	Very prominent abundant gap junctions. Fast; end-to-end transmission
General appearance	Mitochondria and sarcomeres very abundant. Rectangular branching bundles with little interstitial collagen	Bundles of atrial tissue separated by wide areas of collagen	Fewer sarcomeres, paler

COMPOSITION AND FUNCTION OF VENTRICULAR CELL

Organelle	% of Cell Volume	Function
Myofibril	About 50-60	Interaction of thick and thin filaments during contraction cycle.
Mitochondria	16 in neonate 33 in adult rat 23 in adult man	Provide adenosine triphosphate chiefly for contraction
T system	About 1	Transmission of electrical signal from sarcolemma to cell interior
Sarcoplasmic reticulum (SR)	33 in neonate 2 in adult	Takes up and releases Ca^{2+} during contraction cycle
Terminal cisternae of SR	0.33 in adult	Site of calcium storage and release
Rest of network of SR	Rest of volume	Site of calcium uptake en route to cisternae

Sarcolemma	Very low	Control of ionic gradients; channels for ions (action potential); maintenance of cell integrity; receptors for drugs and hormones
Nucleus	About 5	Protein synthesis
Lysosomes	Very low	Intracellular digestion and proteolysis
Sarcoplasm (= cytoplasm) (+ nuclei + other structures)	About 12 in adult rat 18 in humans	Provides cytosol in which rise and fall of ionized calcium occurs; contains other ions and small molecules

the SR lie in very close apposition to the T tubules.[4] Here the tubules of the SR expand into bulbous swellings, which are still hollow and lie along the inner surface of the sarcolemma or are wrapped around the T tubules (see Fig. 14-1) (Figure Not Available) . These expanded areas of the SR have several names: *subsarcolemmal cisternae* (from the Latin and meaning "boxes or baskets") or *junctional SR*. Sometimes the cisternae occur in pairs (*dyads*) lying astride the T tubule, the whole having the appearance of *triads*. Their major function is to release calcium from the *calcium release channel* (also called the ryanodine receptor) to initiate the contractile cycle.

The second part of the SR, the *longitudinal or network SR*, consists of ramifying tubules (see Fig. 14-1) (Figure Not Available) and is concerned with the uptake of calcium that initiates relaxation. This uptake is achieved by the ATP-requiring calcium pump, also called *SERCA* (SarcoEndoplasmic Reticulum Ca^{2+} -ATPase), that increases its activity in response to beta-adrenergic stimulation. Calcium taken up into the SR is then stored at high concentration in a number of storage proteins, including *calsequestrin,* before being released again.

The *cytoplasm* is the intracellular fluid and proteins therein contained within the sarcolemma but excluding the contents of organelles such as mitochondria and the SR. The fluid component of the cytoplasm, minus the proteins, is called the *cytosol*. It is in the cytosol that the concentrations of calcium ions rise and fall to cause cardiac contraction and relaxation. The proteins of the sarcoplasm include many enzymes that act to accelerate the conversion of one chemical form to another, thereby eventually producing energy.

SUBCELLULAR COMPARTMENTATION.

Increasingly there is evidence that the cytosol is not uniform in its composition. There may be a subsarcolemmal space from where calcium ions may preferentially exchange with the extracellular space. Also, the molecular signal systems that convey messages from surface receptors to intracellular organelles may be directed to specific sites by molecules that "anchor" components of the internal messenger chain to specific organelles, as when the beta-adrenergic chain must link up with the calcium pump of the sarcoplasmic reticulum (see p. 452). Another example is the local unloading of ATP where it is needed, by the exact cellular location of the enzyme creatine kinase that converts creatine phosphate to ATP. "In the world of intracellular real estate, location, location, and location are the key determinants of in vivo function."[5]

Contractile Proteins

The major molecules involved in the contraction-relaxation cycle are the two chief contractile proteins: the thin actin filament and the thick myosin filament (Fig. 14-3). Calcium ions initiate the contraction cycle by interacting with troponin C to relieve the inhibition otherwise exerted by troponin I. Titin is a large elastic molecule that supports myosin (Fig. 14-4). During contraction, the filaments slide over each other without the individual molecules of actin or myosin actually shortening. This interaction of the myosin heads with actin filaments is called *cross-bridge cycling.* As they slide, they pull together the two ends of the fundamental contractile unit called the *sarcomere*. On electron

Figure 14-1 (Figure Not Available) Cardiac myofiber (top), detailed structure of myocyte and sarcomere (center), and contracted proteins (bottom). The crux of the contractile process lies in the changing concentrations of Ca^{2+} ions in the myocardial cytosol. Ca^{2+} ions are schematically shown as entering through the calcium channel that opens in response to the wave of depolarization that travels along the sarcolemma. These Ca^{2+} ions "trigger" the release of more calcium from the sarcoplasmic reticulum (SR) and thereby initiate a contraction-relaxation cycle. Eventually, the small amount of calcium that has entered the cell will leave predominantly by a Na^{+} /Ca^{2+} exchanger, with a lesser role for the sarcolemmal calcium pump. The varying actin-myosin overlap is shown for systole, when calcium ions arrive, and diastole, when calcium ions leave. The myosin heads, attached to the thick filaments, interact with the thin actin filaments, as shown in Figure 14-6. For the role of titin, see Figure 14-4 . The top panel shows the difference between the myocardial cell, or myocyte, and the myofiber, composed of many myocytes. (Top panel from Braunwald E, et al: Mechanisms of Contraction of the Normal and Failing Heart. 2nd ed. Boston, Little, Brown, 1976. The other panels are reprinted with permission and copyright L. H. Opie, © 2001.)

microscopy, the sarcomere is limited on either side by the *Z line* (Z, abbreviation for German *Zuckung*, "contraction") to which the actin filaments are attached (see Fig. 14-2). Conversely, the myosin filaments extend from the center of the sarcomere in either direction toward but not actually reaching the Z lines (see Fig. 14-1 (Figure Not Available)).

As the actin filaments move inward toward the center of the sarcomere, they draw the Z lines closer together, so that the sarcomere shortens (see Fig. 14-3) . The energy for this shortening is provided by the breakdown of ATP, chiefly made in the mitochondria.

TITIN.

Titin (also called *connectin*) is the largest protein molecule yet described. It is an extraordinarily long, flexible, and slender myofibrillar protein (see Fig. 14-4) . Titin acts as a third filament to provide elasticity.[6] Being between 0.6 and 1.2 mum in length, the titin molecule extends from the Z line, stopping just short of the M line (see Fig. 14-1) (Figure Not Available) . It has two distinct segments: an inextensible anchoring segment and an extensible elastic segment that stretches as sarcomere length increases.[7] Titin has two functions. It tethers the myosin molecule to the Z line, and as it stretches its elasticity explains the stress-strain relation of cardiac and skeletal muscle.[6] [7] As the sarcomere length of cardiac muscle is increased, the enfolded part of the titin molecule straightens, and beyond 2.0 mum the elastic part of the molecule is stretched. These changes explain, at least in part,

Figure 14-2 The sarcomere is the distance between the two Z lines. Note the presence of numerous mitochondria (mit) sandwiched between the myofibrils and the presence of T tubules (T), which penetrate into the muscle at the level of the Z lines. This two-dimensional picture should not disguise the fact that the Z line is really a "Z disc," as is the M line (M), also shown in Figure 14-1. (Figure Not Available) H=central clear zone containing only myosin filament bodies and the M line; A=band of actin-myosin overlap; I=band of actin filaments, titin, and Z line; g=glycogen granules. ×32,000 rat papillary muscle. (Courtesy of Dr. J. Moravec, Dijon, France.)

Figure 14-3 The major molecules of the contractile system. The contractile cycle consists of interactions between the thin actin filament and the myosin heads *(A)*. The myosin head (*B)* undergoes a series of cyclical interactions with the thin actin filament (*A*), when Ca^{2+} ions arrive at troponin C *(C).* A complex interaction between troponin C (TnC) and the other troponins moves tropomyosin to "uncover" an actin site to which a myosin head can attach (*D*). The molecular aspects are as follows. *B*, The myosin head is composed of heavy and light chains. The heavy head chain in turn has two major domains: one of 70 kDa that interacts with actin at the actin cleft and has an ATP-binding pocket; and the "neck" domain of 20 kDa, also called the "lever arm," an elongated alpha helix that extends and bends and has two light chains surrounding it as a collar. The essential light chain is part of the structure. The other regulatory light chain may respond to phosphorylation to influence the extent of the actin-myosin interaction. *A,* Details of the thin filament, showing the calcium-binding troponin (TnC); the inhibitory troponin I (TnI); and troponin T, with a newly described role in the contractile cycle. *D,* Calcium binding to TnC induces a conformational change in TnC that elongates (compare systole with diastole). TnI closes up to TnC, and the normal inhibition of TnI on actin-tropomyosin is lessened. There is a strengthening of the interaction between TnC and TnT. These changes allow repositioning of tropomyosin in relation to actin, with lessening of its normal inhibitory effects, as shown in the bottom panel. Now the contractile cycle (see Fig. 14-6) can start. (From Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001. *D* modified from Solaro RJ, Van Eyk J: Altered interactions among thin filament proteins modulate cardiac function, J Mol Cell Cardiol 28:217-230, 1999.)

Figure 14-4 Titin is the very large elongated protein with elasticity that binds myosin to the Z line. It may act as a bidirectional spring that develops passive forces in stretched sarcomeres and resting forces in shortened sarcomeres.[6] As the sarcomere is stretched to its maximum physiological diastolic length of 2.2 mum (see Fig. 14-25), titin first undergoes straightening (up to 2 mum) and then

elongation, the latter rapidly increasing the passive forces generated. At low sarcomere lengths, when sarcomeres are slack at about the diastolic limit of 1.85 mum (see Fig. 14-25), the mechanically active elastic domain is folded on top of itself. At even shorter lengths, which may not be physiological in the intact heart, there are substantial restoring forces generated. For differences between cardiac and skeletal titin, see the work of Trombitas and colleagues.[7] (Modified from Trombitas K, Jian-Ping J, Granzier H: The mechanically active domain of titin in cardiac muscle. Circ Res 77:856-861, 1995. Copyright 1995, American Heart Association; and Helmes M, Trombitas K, Granzier H: Titin develops restoring force in rat cardiac myocytes. Circ Res 79:619-626, 1996. Copyright 1996, American Heart Association.)

the development of passive forces (which contrasts to active force development by the cross bridges). Therefore, titin may be the length sensor.[8] Conversely at short sarcomere lengths, the elastic domain is folded on itself to generate restoring forces (see Fig. 14-3) . Thus, changes in titan help to explain the *series elastic element* that postulates that there is elasticity in series between the contractile elements and the ends of the muscle.

STRONG AND WEAK BINDING STATES.

Although at a molecular level the events underlying the cross-bridge cycle are exceedingly complex, one simple current hypothesis is that the cross bridges exist in either a strong or a weak binding state (Fig. 14-5) .[9] The arrival of calcium ions at the contractile proteins is a crucial link in the series of events known as *excitation-contraction coupling.* The ensuing interaction of calcium with troponin C and the deinhibition of troponin I puts the cross bridges in the strong binding state. As long as enough calcium ions are present, the strong binding state potentially dominates (Fig. 14-6) . If, however, the strong binding state were continuously present, then the contractile proteins could never relax. Thus, the proposal is that the binding of ATP to the myosin head puts the cross bridges into a weak binding state even when calcium is high.[9] Conversely, when ATP is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate (P_i), the strong binding state again predominates (see Fig. 14-5) . Thus, the ATP-induced changes in the molecular configuration of the myosin head result in corresponding variations in the physical properties (a similar concept is common in metabolic regulation). Length activation also promotes the strong binding state. Conversely, the weak binding state predominates when cytosolic calcium levels fall at the start of diastole. As the calcium ions leave troponin C, a master switch is turned off and tropomyosin again assumes the inhibitory configuration.

ACTIN AND TROPONIN COMPLEX.

Although calcium ions provide the essential switch-on signal to the cross-bridge cycle by binding to troponin C, current evidence suggests more than an "on-off" signaling process. Rather the arrival of calcium initiates a series of interactions between the troponin components of the thin filament, to allow movement of the tropomyosin molecule that in turn promotes the strong binding state (see Fig. 14-5) so that contraction takes place. To understand the role of calcium, a brief description of the molecular structure of actin and the troponin complex is first required. Thin filaments are composed of two actin units, which intertwine in a helical pattern, both being carried on a heavier tropomyosin molecule that functions as a "backbone" (see Fig. 14-3 *A*). At regular intervals of 38.5 nm along this twisting structure is a closely bound group of three regulatory proteins called

Figure 14-5 Hypothesis for cross bridge cycle based on concepts of Brenner.[11] Strong cross bridges are required for the power stroke (see Fig. 14-6) . The probability of such cross bridges forming is decreased by troponin I. When Ca^{2+} interacts with troponin C, there is a physical interaction between troponin C and troponin I (see Fig. 14-3 *D*), with de-inhibition from the influence of tropomyosin so that stronger cross bridges form more easily. Adenosine triphosphate, when attached to the myosin head, causes the strong binding state to change to the weak state and, therefore, inhibits rigor formation (see Fig. 14-6). During force generation, the molecular force generators (myosin cross bridges) cycle between weak and strong states with apparent rate constants, f and g. (Copyright L. H. Opie, © 2001.)

Figure 14-6 Cross-bridge cycling model updated by the present author from the Rayment[12] five-step model for interaction between the myosin head and the actin filament, taking into account other recent models.[14] [15] [219] The cross bridge (only one myosin head depicted) is pear shaped and consists of the catalytic motor domain that interacts with the actin molecule and an extended alpha-helical "neck region" acting as a lever-arm.[14] The nucleotide pocket receiving and binding adenosine triphosphate (ATP) is a depression near the center of the catalytic domain (see Fig. 14-3 *B*). The actin-binding cleft bisects the catalytic motor domain. During the cross-bridge cycle, the width of the actin binding cleft changes in size although details remain controversial. Starting with the rigor state *(A)* the binding of ATP to the pocket *(B)* is followed by ATP hydrolysis *(C)* that partly closes the actin-binding cleft. The cleft opens when phosphate is released (through the cleft rather than through the pocket), and the myosin head strongly attaches to actin to induce the power stroke (*D* and *E*). During the power stroke the latter rotates about a fulcrum in the region where the helix terminates within the catalytic motor domain.[14] As the head flexes, the actin filament is displaced by about 10 nm *(E)*. In the process, adenosine diphosphate is also released so that the binding pocket becomes vacant. Finally, the rigor state is reached again *(A)* when the myosin head is again ready to receive adenosine triphosphate to reinitiate the cross-bridge cycle. Throughout, the actin monomer with which the myosin head is interacting is dotted. (Professor J. C. Ruegg of Heidelberg University, Germany, is thanked for valuable comments.)

the *troponin complex*. Of these three, it is troponin C that responds to the calcium ions that are released in large amounts from the SR to start the cross-bridge cycle.

When the cytosolic calcium level is low, the tropomyosin molecule is twisted in such a way that the myosin heads cannot interact with actin (see Fig. 14-3 *D*). Therefore, most cross bridges are in the "blocked position," although some are still in the weakly bound state.[10] As calcium ions increasingly arrive and interact with troponin C, then the activated troponin C binds tightly to the inhibitory molecule, troponin I. The latter moves to a new position on the thin filament, thereby weakening the interaction between troponin T and tropomyosin (see Fig. 14-3 *D*). Ultimately, tropomyosin is repositioned on the thin filament,[10] therefore removing most of the inhibition exerted by tropomyosin on the actin-myosin interaction. Thus, weakly bound or blocked cross bridges enter the strongly bound state and the cross-bridge cycle is initiated. As the strong cross bridges form, they activate "near neighbors" and thereby spread the activation process.[10] They also promote further tropomyosin movement to cause more forceful cross-bridge interaction.[11]

MYOSIN AND MOLECULAR BASIS OF MUSCULAR CONTRACTION.

Each myosin head is the terminal part of a heavy chain. The bodies of two of these chains intertwine, and each terminates in a short "neck" that carries the elongated myosin head (see Fig. 14-3 *B*). According to the "Rayment model," it is the base of the head, also sometimes called the neck, that changes configuration in the contractile cycle.[12] Together with the "bodies" of all the other heads, the myosin thick filament is formed. Each lobe of the bilobed head has an *ATP binding pocket* (also called nucleotide-pocket) and a narrow cleft that extends from the base of this pocket to the actin-binding face.[12] ATP and its breakdown products ADP and P_i bind to the nucleotide pocket in close proximity to the myosin ATPase activity that breaks down ATP to its products (see Fig. 14-6) . Currently, there is controversy about the role in the contractile cycle of the narrow *actin binding cleft* that splits the central 50-kDa segment of the myosin head. According to the revised Rayment model,[13] this cleft responds to the binding of ATP or its breakdown products to the nucleotide pocket in such a way that the conformational changes necessary for movement of the head are produced. According to Dominguez and associates,[14] the cleft is closed in the weakly attached states before the power stroke (see Fig. 14-6 *B* and *C*) but opens when P_i is released through the cleft, whereupon the myosin head attaches strongly to actin to induce the power stroke (see Fig. 14-6 *D* and *E*).

Starting with the rigor state (see Fig. 14-6 *A*), the binding of ATP to its pocket changes the molecular configuration of the myosin head so that the head detaches from actin to terminate the rigor state (see Fig. 14-6 *B*). Next the ATPase activity of the myosin head splits ATP into ADP and P_i and the head flexes (see Fig. 14-6 *C*). As ATP is hydrolyzed, the myosin head binds to an adjacent actin

unit. Then P_i is released from the head through the cleft and there is strong binding of the myosin head to actin (see Fig. 14-6 *D*). Next, the head extends (i.e., straightens). A power stroke takes place, the actin molecule moves by about 10 nm,[14] and the myosin head is now in the rigor state. The pocket then releases ADP and is ready for acceptance of ATP and repetition of the cycle. According to the Rayment model,[12] it is straightening and not flexion of the light chain region of the head (i.e., the "neck") that produces the power stroke. According to the "swinging lever-arm hypothesis,"[15] the arm rotates so that its end moves by about 10 nm as the power stroke occurs.[14] The lever "arm" is the "neck" shown in Figure 14-6 *B*. Thus, positional changes of the essential light chain, part of the "neck," are used experimentally to monitor movement of the "arm."

Myosin ATPase activity normally responds to calcium in such a way that an increase of calcium ion concentration from 10^{-7} M to 5×10^{-5} M results in a fivefold increase in activity.[16] Similar calcium concentrations are associated with contraction in the whole heart (Fig. 14-7) .

Myosin heavy chain isoforms help regulate myosin ATPase activity. Each myosin filament consists of two heavy chains, the bodies of which are intertwined and each ending in one head, and four light chains, two in apposition to each head. The heavy chains, containing the myosin ATPase activity on the heads, occur in two

isoforms, beta and alpha of the same molecular weight but with substantially different ATPase activities. The beta-heavy chain (beta-MHC) isoform has lower ATPase activity and is the predominant form in the adult human. In small animals, the faster alpha-MHC form changes to a predominant beta-MHC pattern in experimental heart failure.

The significance of the double-headed structure of myosin has now been clarified by comparison with single-headed variants. *Double-headed myosin* is required to produce the full displacement of actin, about 10 nm, versus only 6 nm with single-headed myosin.[17]

The *myosin neck* is chiefly formed by a long alpha helix (see Fig. 14-3 *C*), surrounded by two *light chains* (four per bilobed head) that act as a cervical collar. The light chain that is more proximal to the myosin head, the *essential light chain* (MLC-1), appears to inhibit the contractile process by interaction with actin.[18] The other *regulatory light chain* (MLC-2) is a potential site for phosphorylation, for example in response to beta-adrenergic stimulation. Such phosphorylation (i.e., the gaining of a phosphate grouping) may promote cross-bridge cycling by increasing the affinity of myosin for actin.[9] [10] Mutation of this light chain in one type of human cardiomyopathy impairs the contractile response to tachycardia.[19] In vascular smooth muscle, the phosphorylation that occurs under the influence of the enzyme myosin light chain kinase (MLCK) is an obligatory step in the initiation of the contractile process.

Graded Effects of Increased Cytosolic Calcium Levels on Cross-Bridge Cycle

Calcium ions play a crucial role in linking external neurohumoral control of the heart to stimulation of the contractile process. These ions act at multiple control sites.[9] [10] [20] [21] Their interaction with troponin C is essential for cross-bridge

Figure 14-7 The proposed explanation for the Starling effect, whereby a greater end-diastolic fiber length develops a greater force. The left panel shows how the steep ascending limb of the cardiac force-length curve is explained by an interaction between sarcomere length and calcium ions. Light lines show a family of hypothetical force-length curves for increasing free Ca^{2+} concentrations each drawn on the assumption that the shape of the curve is determined solely by the degree of overlap of thin and thick filaments (see Fig. 14-1) (Figure Not Available) . It is postulated that an increase in end-diastolic fiber length (a) at any given free Ca^{2+} concentration would increase force by a small amount on the basis of the change in filament overlap. In addition, length-dependent activation explains how the sarcomere can "upgrade itself" (b) to a higher force-length curve. The middle panel proposes that the effects of Ca^{2+} and length can be explained by the properties of troponin C (TnC) and the binding of calcium to TnC. As more Ca^{2+} ions bind to TnC in a skinned fiber preparation, more force is developed. There is a steep relation, similar to that shown in the left panel. When the fiber is stretched and the sarcomere length is increased, it is postulated that for any given number of Ca^{2+} ions binding to TnC there is a greater force development. The right panel shows how the Ca^{2+} concentration influences the development of tension at long (solid black dots) and shorter (open circles) sarcomere lengths. (Left panel modified from Fuchs F: Mechanical modulation of the Ca^{2+} regulatory protein complex in cardiac muscle. NIPS 10:6-12, 1995. Middle panel modified from Solaro RJ, Wolska BM, Westfall M: Regulatory proteins and diastolic relaxation. *In* Lorell BH, Grossman W [eds]: Diastolic Relaxation of the Heart. Norwell, MA, Kluwer Academic Publishers, 1994, pp 53-53. Right panel modified from Cazorla O, Vassort G, Garnier D, LeGuennec J-Y: Length modulation of active force in rat cardiac myocytes: Is titin the sensor? J Mol Cell Cardiol 31:1215-1227, 1995.)

cycling. It has been held that the calcium concentration acts as an on-off switch to regulate the total number of cycling cross bridges. According to this proposal, the enhanced force development in response to a greater calcium ion concentration must be due to recruitment of additional cross bridges.[22] Alternatively, to explain the graded model,[21] there may be (1) a graded response of troponin C to calcium ions, including altered rates of calcium binding and release[10] ; (2) a graded response of myosin ATPase to calcium[16] ; (3) "near neighbor" self-activation whereby actin-myosin interaction activates additional cross bridges even in the absence of increased binding of calcium to the troponin C of those cross bridges[10] ; or (4) alterations in the extent of myosin light chain phosphorylation.[9] Of specific interest is the proposal that tightly bound cross bridges act to spread activation on the thin filament to near-neighbor units to achieve full activation.[10] By such mechanisms, one calcium-troponin complex could turn on as many as 14 actin molecules, in contrast to the expected number of 7.

Length-Dependent Activation

Besides the cytosolic calcium concentration, the other major factor influencing the strength of contraction is the length of the muscle fiber at the end of diastole, just before the onset of systole. Starling observed that the greater the volume of the heart in diastole, the more forceful is the contraction. The increased heart volume translates into an increased muscle length, which acts by a length-sensing mechanism (see Fig. 14-7) . Previously, this relation was ascribed to a more optimal overlap between actin and myosin. The current view is that an increased sarcomere length leads to greater sensitivity of the contractile apparatus to the prevailing cytosolic calcium.[9] [10] The mechanism for this regulatory change, although not yet clarified, may reside in the interfilament spacing.[10] As the heart muscle is stretched, the interfilament distance decreases; and, hypothetically, there is an increased rate of transition from the weak to the strong binding state (see Fig. 14-5) . Alternatively, sarcomere stretch increases the passive forces built up by titin,[8] which in turn could hypothetically influence the position of myosin heads. Another proposal, that troponin C is the length sensor, is currently less favored.[10]

Cross-Bridge Cycling Versus Cardiac ContractionRelaxation Cycle

The cardiac cycle of Wiggers (see p. 462) must be distinguished from the cross-bridge cycle. The former reflects the overall pressure changes in the left ventricle, whereas the later cycle is the repetitive interaction between myosin heads and actin. According to the 5-step model, the binding of ATP or ADP regulates in part whether the cross bridges would be weak or strong (see Figs. 14-5 and 14-6) . So long as enough calcium ions are bound to troponin C, many repetitive cycles of this nature occur. Thus, at any given moment, some myosin heads are flexing or flexed, some are extending or extended, some are attached to actin, and some are detached from actin. Numerous such cross-bridge cycles, each lasting only a few microseconds, actively move the thin actin filaments toward the central bare area of the thick myosin filaments, thereby shortening the sarcomere. The sum total of all the shortening sarcomeres leads to systole, which is the contraction phase of the cardiac cycle. When calcium ions depart from their binding sites on troponin C, cross-bridge cycling cannot occur and the diastolic phase of the cardiac cycle sets in.

Myofilament Response to Hemodynamic Demands

Solaro and Rarick[10] have hypothesized that myofilament activity is coupled to the prevailing hemodynamic demands of the circulation. Besides length-dependent activation, there are two chief mechanisms. First, there may be variable rates of calcium binding and release from troponin C (as discussed in the previous section). Second, phosphorylation and dephosphorylation of the contractile proteins may help to control the extent of activation of the myofilaments. Conflicting evidence suggests that increased beta-adrenergic dependent phosphorylation of troponin I *reduces* the myofilament sensitivity to calcium and thereby leads to an *increased* rate of relaxation during beta-adrenergic stimulation. Hypothetically, this mechanism enhances the relaxant (lusitropic) effect of increased uptake rates of calcium into the sarcoplasmic reticulum. The effects of phosphorylation of other proteins such as the myosin essential light chains and C protein, still imperfectly understood, may also be important.[10]

Contractile Proteins and Cardiomyopathy

Abnormalities of the contractile proteins, especially myosin, are known to underlie a variety of genetic-based cardiomyopathies. Hypertrophic cardiomyopathy is, in general, linked to mutant genes that cause abnormalities in the force-generating system, such as beta-myosin heavy chain (see Chap. 48) . [23] Less commonly, there may be defects in the genes encoding myosin light chain isoforms, troponin I and C isoforms, myosin-binding protein C, and alpha-tropomyosin. In contrast, dilated cardiomyopathy can be related to mutations in non-force-generating cytoskeletal proteins, such as dystrophin and actin.[24] [25] Actin abnormalities are of special interest. When the contractile part of actin is involved, then the proposal is that hypertrophic cardiomyopathy results.[26] When the non-force-generating part is involved, then the hypothesis is that dilated cardiomyopathy follows.[26] *Dystrophin* is a large protein that links intracellular

Figure 14-8 Dystrophin is a large intracellular protein that links the contractile system by means of actin to the sarcolemma and thence to the extracellular matrix. Experimentally, dystrophin is cleaved in enterovirus myocarditis. Abnormalities of dystrophin also appear to explain the cardiomyopathies of Duchenne's dystrophy and X-linked cardiomyopathy. The dystrophin-associated protein complex is represented by alpha and beta, whereas $alpha_1$ and $beta_1$ are the syntrophins.[27] (Modified from Bardoff C, Lee G-H, Lamphear BJ, et al: Enteroviral protease 2A cleaves dystrophin: Evidence of cytoskeletal disruption in an acquired cardiomyopathy. Nat Med 5:320-326, 1999.)

actin to the extracellular matrix through a sarcolemmal dystrophin-associated-protein complex (Fig. 14-8). Experimental virus myocarditis cleaves dystrophin (see Fig. 14-8), thereby causing dilated cardiomyopathy.[27]

CALCIUM ION FLUXES IN CARDIAC CONTRACTION-RELAXATION CYCLE

Calcium Movements and Excitation-Contraction Coupling

Despite the crucial role of calcium in regulating the contraction and relaxation phases of the cardiac cycle, the exact details of the associated calcium ion fluxes that link contraction to the wave of excitation (*excitation-contraction coupling*) are still not yet fully clarified. The generally accepted hypothesis is based on the crucial role of calcium release from the SR.[28] Relatively small amounts of calcium ions actually enter and leave the cell during each cardiac cycle, whereas much larger amounts move in and out of the SR (Fig. 14-9) . *Calcium-induced calcium release* explains most of the current available data.[28] The basic proposal is that the SR releases relatively large amounts of calcium ions into the cytosol in response to the much smaller amounts entering the cardiac myocyte with each wave of depolarization.[29] This process elevates by about tenfold the concentration of calcium ions in the cytosol. The result is the increasing interaction of calcium ions with troponin C to trigger the contractile process. This theory has received strong support from several sources: (1) the molecular characterization of the ryanodine receptor on the SR (see later) that releases calcium[28] ; (2) the electrophysiological evidence closely linking the duration of the action potential with the extent of Ca^{2+} release[29] ; and (3) the close proximity of the ryanodine receptors to the sarcolemmal L-type calcium channels (see Figs. 14-9 and 14-10) .[28]

The rise of cytosolic calcium that triggers contraction comes to an end as the wave of excitation passes, no more calcium ions enter, and the release of calcium from the SR ceases. The latter event could be explained by one or more of several mechanisms, namely, (1) that the cytosolic calcium ion concentration has risen high enough to inhibit the process of calcium-induced calcium release, perhaps acting through calmodulin[28] ; (2) the release of calcium from the SR is linked tightly to opening of the calcium channel, so that when the latter closes the release of calcium from the SR ceases[30] ; (3) the rising cytosolic calcium ion concentration activates the calcium uptake pump of the SR[31] ; or (4) calcium release from the SR continues only for the duration of the action potential duration.[29] The overall effect of these mechanisms is that the cytosolic calcium ion concentration starts to fall and diastole is initiated. As the cytosolic calcium decreases, binding with troponin C lessens, tropomyosin again starts to inhibit the interaction between actin and myosin, and relaxation proceeds.

To balance the small quantity of calcium ions entering the heart cell with each depolarization, a similar quantity must leave the cell by one of two processes. First, calcium can be exchanged for sodium ions entering by the Na^{+} /Ca^{2+} exchange, and, second, an ATP-consuming sarcolemmal calcium pump can transfer calcium into the extracellular space against a concentration gradient.

CALCIUM SPARKS.

Calcium sparks are the very small quantities of calcium that can be spontaneously released and locally released from the SR even in the absence of L-channel opening. Hypothetically, the spark represents the spontaneous opening of one or at the most a cluster of calcium release channels.[28] [32] There is so little calcium diffusing

Figure 14-9 Calcium fluxes in the myocardium. Crucial features are (1) entry of Ca^{2+} ions through the voltage-sensitive L-type Ca^{2+} channels, acting as a trigger to the release of Ca^{2+} ions from the sarcoplasmic reticulum (SR), as shown in Figure 14-10; (2) the effect of beta-adrenergic stimulation with adenylate cyclase forming cyclic adenosine monophosphate, the latter both helping to open the Ca^{2+} channel and to increase the rate of uptake of Ca^{2+} into the SR; and (3) exit of Ca^{2+} ions chiefly through the Na^{+} /Ca^{2+} exchange, with the sodium pump thereafter extruding the Na^{+} ions thus gained. The latter process requires adenosine triphosphate. Note the much higher extracellular (10^{-3} M) than intracellular Ca^{2+} values and a hypothetical mitochondrial value of about 10^{-6} M. The mitochondria can act as a buffer against excessive changes in the free cytosolic calcium concentration. MITO=mitochondria. (From Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

Figure 14-10 In the *myocardium* (left side of figure), calcium is released from the sarcoplasmic reticulum (SR) through the calcium release channel (part of the ryanodine receptor), chiefly in response to calcium that has entered during voltage depolarization. Calcium is taken up again by the calcium pump of the longitudinal SR to interact with the storage protein calsequestrin (CS), thence to be released again. In contrast, in *vascular smooth muscle*, stimulation of vasoconstrictor receptors, such as angiotensin II (AII), $alpha_1$ -adrenergic receptors, and endothelin (ET), leads to release of inositol triphosphate (IP_3), which acts on its receptor to release calcium from the SR. In the myocardium, IP_3 does not have a major physiological role, yet in heart failure (HF) its receptor on the SR may be upregulated. (Modified with permission from Opie LH: The Heart, Physiology, from Cell to Circulation, Lippincott-Raven, Philadelphia, 1998. Figure copyright L. H. Opie, © 2001.)

away from a spark that it fails to activate the neighboring calcium release channels and contraction is not initiated. Calcium sparks can be activated by calcium ions, so that a summation of sparks could produce a normally propagating calcium wave that triggers excitation-contraction coupling. One model predicts that the graded response in calcium release can be explained by both an increased number of channels that are opened and an increased amount of calcium released by each channel.[33] When the SR is overloaded with calcium as in pathological conditions such as catecholamine toxicity or during early reperfusion, then calcium sparks can lead to propagated calcium waves with risk of serious arrhythmias or impaired contractile activity.

Calcium Release Channels of the Sarcoplasmic Reticulum

RYANODINE RECEPTORS.

Each L-type calcium channel of the sarcolemma controls a cluster of four to ten SR release channels.[28] [34] There is a close anatomical proximity of the calcium channels on the T tubules, to the calcium release channels, situated on the SR. The calcium release channel is part of the complex structure known as the *ryanodine receptor*, so-called because it coincidentally binds the potent insecticide ryanodine.[31] Part of this receptor extends from the membrane of the SR toward the T tubule to constitute the *foot structure* or *junctional channel complex* that bridges the gap between the SR and the T tubule. After the wave of depolarization has reached the T tubule and induced the voltage-operated calcium channels to open, the calcium ions enter the cardiac myocyte to reach the foot regions of the ryanodine receptors (see Fig. 14-10) . The result is a change in the molecular configuration of the ryanodine receptor that opens the calcium release channel of the SR to discharge calcium ions, probably into the subsarcolemmal space between the foot and the T tubule and thence into the cytosol.

IP_3 -INDUCED RELEASE OF CALCIUM FROM SARCOPLASMIC RETICULUM.

A totally different calcium release signal system may also be involved. In addition to the ryanodine receptor, there is also a second receptor on the SR, that for inositol triphosphate (IP_3) (see Fig. 14-10) . This IP_3 receptor has a high degree of molecular homology with the ryanodine receptor, although it is only about half its size. IP_3 is one of the messengers of the phosphatidylinositol pathway, responding to certain agonists with vasoconstriction as their major physiological role, namely, $alpha_1$ -adrenergic stimulation, angiotensin II, and endothelin. [35] Calcium released from the SR by IP_3 may stimulate Na^{+} /Ca^{2+} exchange directly. In vascular smooth muscle, this IP_3 messenger system is of fundamental importance in regulating the release of calcium from the SR and thereby regulating arterial tone. In cardiac muscle, the function of IP_3 is still sufficiently controversial to question its role in the inotropic response. An attractive proposal is that in human heart failure the IP_3 receptor becomes upregulated in relation to the ryanodine receptor, [36] perhaps contributing to calcium overload. Upregulation of IP_3 may promote apoptosis in response to activation of the Fas pathway, again perhaps mediated by an increased cytosolic calcium.[37]

Calcium Uptake by the Calcium ATPase of the Sarcoplasmic Reticulum

Calcium ions are taken up into the SR by the activity of the calcium pump called SERCA (sarcoendoplasmic reticulum Ca^{2+} ATPase) that constitutes nearly 90 percent of the protein component of the SR.[38] [39] Its molecular weight is about 115 kDa, and it straddles the SR membrane in such a way that part of it actually protrudes into the cytosol. It exists in several isoforms, of which the dominant cardiac form is SERCA 2a.[38] [40] For each mole of ATP hydrolyzed by this enzyme, two calcium ions are taken up to accumulate within the SR (Fig. 14-11) .

Phospholamban, which means "phosphate receiver," is the major regulator of this calcium uptake pump and plays a crucial role in the beta-adrenergic response of the myocardium.[41] Phospholamban is a pentamer protein consisting of five subunits, each with a molecular weight of 6 kDa, found in a 1:1 molar ratio to the ATPase of the calcium pump. The activity of phospholamban is governed by its state of phosphorylation, a process that alters the molecular configuration of the calcium pump (see Fig. 14-11) . There are two major protein kinases involved, the one activated by calcium ions and the other by cyclic adenosine monophosphate (AMP). Phospholamban responds to beta-adrenergic stimulation of the cardiac myocyte by enhancing (de-inhibiting) the uptake of calcium by SERCA into the SR to increase

the rate of relaxation.[39] The further proposal is that the increased store of calcium in the SR is then released by the subsequent waves of depolarization with an increased rate and force of contraction. This sequence is strongly supported by the transgenic mouse model, totally deficient in phospholamban, in which rates of contraction and relaxation

Figure 14-11 Calcium uptake into the sarcoplasmic reticulum (SR) by the energy-requiring calcium pump, SERCA 2a. Phospholamban can be phosphorylated (P) to remove the inhibition exerted by its dephosphorylated form (positive charges) on the calcium pump. Thereby, calcium uptake is increased either in response to an enhanced cytosolic calcium or in response to beta-adrenergic stimulation. Thus, there are two phosphorylations activating phospholamban at two distinct sites and their effects are additive. An increased rate of uptake of calcium into the SR enhances the rate of relaxation (*lusitropic effect*). (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

are maximal and do not vary in response to added beta-adrenergic stimulation by isoproterenol.[39]

Calcium, taken up into the SR by the calcium uptake pump, is stored within the SR before further release. The highly charged storage protein, *calsequestrin*, is found in that part of the SR that lies near the T tubules. Calcium stored with calsequestrin is thought to become available for the release process as calsequestrin discharges Ca^{2+} into the inner mouth of the calcium release channel. This process replaces those calcium ions liberated from the outer mouth into the cytosol. *Calrectulin* is another Ca^{2+} -storing protein, very similar in structure to calsequestrin and probably similar in function.[31] Hypothetically, calsequestrin and two other proteins located in the SR membrane (junctin and triadin) may help regulate the properties of the ryanonide receptor.[28]

Role of Sarcoplasmic Reticulum in Heart Failure (See also Chap. 16)

In heart failure, the force of cardiac contraction is reduced and there is an abnormal delayed pattern of cardiac relaxation. There is general agreement that the rate of calcium uptake by SERCA 2a is depressed in the failing human heart,[42] but the mechanisms remain controversial. One hypothesis is that abnormal calcium handling by the SR of the failing myocardium is due to impaired expression of the genes encoding these specific SR proteins. The messenger RNAs (mRNAs) for the ryanodine receptor, the calcium uptake pump, and phospholamban are all abnormally deficient.[43] Yet other data suggest that the poor function of SERCA 2 cannot be explained by defects in protein expression but rather that the regulation of SERCA 2a is upset in the failing human heart, perhaps at the level of phosphorylation.[42]

SARCOLEMMAL CONTROL OF CALCIUM AND SODIUM IONS

Calcium Channels

All current models of excitation-contraction coupling ascribe a crucial role to the voltage-induced opening of the sarcolemmal L-type long-lasting calcium channels in the initiation of the contractile process.[29] Channels are pore-forming macromolecular proteins that span the sarcolemmal lipid bilayer to allow a highly selective pathway for ion transfer into the heart cell when the channel changes from a closed to an open state.[44] [45] Ion channels have two major properties: gating and permeation. Guarding each channel are two or more hypothetical gates that control its opening. Ions can permeate through the channel only when both gates are open. In the case of the sodium and calcium channels, which are best understood, the activation gate is shut at the normal resting membrane potential and the inactivation gate is open, so that the channels are *voltage gated.* Depolarization opens the activation gate.

MOLECULAR STRUCTURE OF L-TYPE CALCIUM CHANNELS.

There is a superfamily of voltage-gated ion channels that includes both the sodium and calcium channels and some of the potassium channels (see also Chap. 22) . [28] The potassium channels have the simpler structure, from which it is thought that the more complex sodium and calcium channels evolved. Both sodium and calcium channels contain a major alpha subunit with four transmembrane subunits or domains, very similar to each other in structure. In addition, both sodium and calcium channels include in their overall structure a number of other subunits whose function is less well understood, such as the alpha subunit. Each of the four transmembrane domains of the alpha subunit is made up of six helices and is folded in on itself, so that the four S5-S6 spans structurally combine to form the single functioning *pore* of each calcium channel (Fig. 14-12) . [46] Activation is now understood in molecular terms as the change in charge on the fourth transmembrane segment, S4, called the *voltage sensor*, of each of the four subunits of the sodium or calcium channel.[47] *Inactivation* is the process whereby the current initially elicited by depolarization decreases with time despite continuation of the original stimulus.[47] The alpha subunit acts to enhance the calcium current flow through the beta-subunit pores.[48] Channels are not simply open or closed. Rather, the open state is the last of a sequence of many molecular states, varying from a fully closed to a fully open configuration. Therefore, it is more correct to speak of the *probability of channel opening*.

CALCIUM CHANNEL PHOSPHORYLATION.

The $alpha_1$ subunit (the organ-specific subunit) of the sarcolemmal calcium channel can be phosphorylated at several sites especially in the C-terminal tail.[28] During beta-adrenergic stimulation, cyclic AMP increases within the cell and phosphate groups are transferred from ATP to the $alpha_1$ subunit. Thereby, the electrical charges near the inner mouth of the nearby pores are altered to induce changes in the molecular conformation of the pores, so that there is an increased probability of opening of the calcium channel.[45]

T- AND L-TYPE CALCIUM CHANNELS.

There are two major subpopulations of sarcolemmal calcium channels relevant to the cardiovascular system, namely, the T channels and the L channels.[49] The T (transient) channels open at a more negative voltage, have short bursts of opening, and do not interact with conventional calcium antagonist drugs.[49] The T channels presumably account for the earlier phase of the opening of the calcium channel, which may also give them a special role in the early electrical depolarization of the sinoatrial node and, hence, of initiation of the heartbeat. Although T channels are found in atrial cells, their existence in normal ventricular cells is controversial. Nonetheless, the T channel from the human heart has been cloned,[50] and presumably most of the tissue was ventricular in origin. The sarcolemmal L (long-lasting) channels are the standard calcium channels found in the myocardium. They are involved in calcium-induced calcium release, and are inhibited by calcium channel blockers such as verapamil, diltiazem, and the dihydropyridines.

Figure 14-12 Simplified model of Ca^{2+} channel showing the $alpha_1$ subunit (a_1) forming the central pore, the regulatory beta-subunit (b), and $alpha_2$ and delta subunits of unknown function. Beta-adrenergic stimulation, by means of cyclic adenosine monophosphate, promotes phosphorylation (P) and the opening probability of the Ca^{2+} channel. The proposal is that four domains, each similar to that shown in the right panel and composed of six spanning segments, combine to form the $alpha_1$ subunit. Segment S4 is thought to respond to voltage depolarization (+=positive charges) by altering the molecular configuration of the loop between S5 and S6 (part of the pore), so that there is a greater probability of Ca^{2+} ions entering (channel opens). Ion Exchangers and Pumps

Sodium-Calcium Exchanger

During relaxation the sarcoplasmic calcium uptake pump and the Na^+ /Ca^{2+} exchanger in the sarcolemma compete for the removal of cytosolic calcium, with the SR pump normally being dominant.[51] Restitution of calcium balance takes place by the activity of a series of transsarcolemmal exchangers, the chief of which is the Na^+ /Ca^{2+} exchanger (Fig. 14-13) .[52] The exchanger (molecular weight of 108 kDa) consists of 970 amino acids and does not have substantial homology to any other known protein.[52] Specific inhibitory peptides have been identified.[53] The direction of ion exchange is responsive to the membrane potential and to the concentrations of sodium and calcium ions on either side of the sarcolemma. Because sodium and calcium ions can exchange either inward or outward in response to the membrane potential, there must be a specific membrane potential, called the reversal or equilibrium potential, at which the ions are so distributed that they can move as easily the one way as the other.[52] The reversal potential may lie about halfway between the resting membrane potential and the potential of the fully depolarized state. Changing

the membrane potential from the resting value of -85 mV to +20 mV in the phase of rapid depolarization of the action potential may therefore briefly reverse the direction of Na^+ /Ca^{2+} exchange.[52] A major unsolved problem in relation to the activity and direction of the Na^+ /Ca^{2+} exchanger is the true value of the internal sodium or calcium ion concentrations, which may differ in the subsarcolemmal "*fuzzy space*" from the bulk cytosol (Fig. 14-14) .

REVERSE MODE Na^+ /Ca^{2+} EXCHANGE.

During depolarization the charge on the inner side of the sarcolemma becomes positive, which will tend to hinder the entrance of sodium ions with their positive charge. Thus, the sodium ions that have just entered during the opening of the sodium channel will tend to leave and calcium ions will tend to enter. This process, thought to occur more in larger mammals with slow heart rates and long action potential durations, contrasts to the standard "forward mode" (Na^+ in, Ca^{2+} out) (compare Figs. 14-13 and 14-14) . Such transsarcolemmal calcium entry during reversed mode exchange may participate in calcium-induced calcium release.[54] In myocytes from the failing human heart, enhanced reversed exchange contributes to the slow decline of the Ca^{2+} transient[55] that may explain delayed diastolic relaxation (see p. 470). After ischemia, and possibly in heart failure, reverse mode exchange may predispose to afterdepolarizations and arrhythmias.[37]

HEART RATE AND Na^+ /Ca^{2+} EXCHANGE.

This exchanger may participate in the force-frequency relationship (Treppe or Bowditch phenomenon).[56] According to the "sodium pump lag" hypothesis, the rapid accumulation of calcium ions during fast stimulation of the myocardium outstrips the ability of the Na^+ /Ca^{2+} exchanger and the sodium pump to achieve return to ionic normality. The result is an accumulation of calcium ions within the SR and an increased force of contraction.[57] Prolonged calcium overload, the result of this process, may contribute to the cardiomyopathy of tachycardia.

Sodium Pump (Na^+ ,K^+ -ATPase)

The sarcolemma becomes highly permeable to Na^+ only during the opening of the Na^+ channel during early depolarization. Some Na^+ will also enter during the exit of Ca^{2+} by Na^+ /Ca^{2+} exchange. Most of this influx of Na^+ across the sarcolemma must be corrected by the activity of the Na^+ /K^+ pump, also called the Na^+ /K^+ -ATPase or simply the Na^+ pump.[58] The pump is activated by internal Na^+ or external K^+ .[58] One ATP molecule is used per transport cycle. The ions are first secluded within the pump protein and then extruded to either side. Although there has been some dispute about the exact ratio of Na^+ to K^+ that are pumped, a generally accepted model is that for each three Na^+ exported, two K^+ are imported. During this process, one positive charge must leave the cell. Hence, the pump is electrogenic and is also called the electrogenic Na^+ pump.[58] The current induced by sustained activity of the pump may contribute about -10 mV to the resting membrane potential.[58] Because the pump must extrude Na^+ ions entering by either Na^+ /Ca^{2+} exchange or by the Na^+ channel, its sustained activity is essential for the maintenance of normal ion balance (see Fig. 14-13) .

RECEPTORS AND SIGNAL SYSTEMS

The autonomic nervous system can initiate signal systems that profoundly alter the fluxes of calcium and other ions and thereby the contraction and relaxation of the myocardium. The sum total of these processes converting an extracellular hormonal or neural stimulus to an intracellular

Figure 14-13 Regulation of Ca^{2+} balance within the myocardial cell, showing role of sarcoplasmic reticulum (SR) in contraction-relaxation cycle. There is a balance between the Ca^{2+} ions entering on depolarization (right) and those leaving the cell by the Na^+ /Ca^{2+} exchange mechanism. A smaller number of Ca^{2+} ions leave by an adenosine triphosphate (ATP)-dependent sarcolemmal Ca^{2+} pump. Ion gradients for Na^+ and K^+ are maintained by the operation of the sodium pump (Na^+ ,K^+ -ATPase). The Ca^{2+} in the subsarcolemmal "fuzzy space" may be different from that in the free cytosol. An increased internal Ca^{2+} concentration after Ca^{2+} release from the SR is reduced by competition among one of three routes: uptake into the sarcoplasmic reticulum (SR), Na^+ /Ca^{2+} exchange, and outward pumping by the membrane Ca^{2+} -ATPase. The dominant uptake mechanism for Ca^{2+} is into the SR, followed by the exchanger, followed by the membrane pump. (From Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

physiological change is called *signal transduction*, which typically starts with the agonist binding to a receptor site.[35] Thus, adrenergic or cholinergic stimulation of the sarcolemmal receptors inaugurates the activity of a complex system of sarcolemmal and cytosolic messengers.[59] Occupancy of the beta-adrenergic receptor is coupled by a G-protein complex (Fig. 14-15) to activation of a sarcolemmal enzyme, adenylate cyclase, that sets in motion a series of signals that terminate with activation of certain crucial proteins, such as those of the calcium channel (Fig. 14-16). Other cardiac receptors, such as the alpha-adrenergic receptor,

Figure 14-14 Proposal for "reverse mode" Na^+ /Ca^{2+} exchange in the direction of calcium entry after accumulation of sodium ions in the "fuzzy space." According to this proposal, the Na^+ /Ca^{2+} exchange may play a role in the liberation of calcium involved in the cardiac contractile cycle. (From Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

have an alternate dual messenger system involving IP_3 and diacylglycerol, with the latter activating protein kinase C (PKC).[35] [60] Such signals are of established importance in controlling calcium flux in vascular smooth muscle, thereby regulating vascular tone and indirectly the blood pressure. In the case of cardiac myocytes, it is now appreciated that receptors coupled to PKC, such as angiotensin II, may play a major role in the regulation of cardiac myocyte growth and sometimes have inotropic effects. Yet other messenger systems exist to convey different signals. For example, in blood vessels, nitric oxide formed in the inner endothelial layer stimulates the formation of cyclic guanosine monophosphate (GMP) in the smooth muscle layer, thereby causing relaxation (vasodilation).

Beta-Adrenergic Receptors and G Proteins

Cardiac beta-adrenergic receptors are chiefly the $beta_1$ subtype, whereas most noncardiac receptors are $beta_2$. About 20 percent of the total beta-receptor population is in the left ventricle and about twice as high a percentage is in the atria. These $beta_2$ receptors appear to have greater efficacy in their capacity to activate the G protein/adenylate cyclase system than do the $beta_1$ receptors.[61] The receptor site is highly stereospecific, the best fit among catecholamines being obtained with the synthetic agent isoproterenol (ISO) rather than with the naturally occurring catecholamines norepinephrine (NE) and epinephrine (E). In the case of $beta_1$ receptors, the order of agonist activity is ISO > E=NE, whereas in the case of $beta_2$ receptors, the order is ISO > E > NE. Human $beta_1$ and $beta_2$ receptors have now both been cloned. [62] The transmembrane domains are held to be the site of agonist and antagonist binding, whereas the cytoplasmic domains interact with G proteins. One of the phosphorylation sites on the terminal COOH tail may be involved in desensitization (see next section).

ADENYLATE CYCLASE.

Adenylate cyclase is a transmembrane enzyme system, also called adenylyl or adenyl cyclase,

Figure 14-15 G proteins and their role in signal transduction in response to beta-adrenergic stimulation. Steps in G_s protein cycle: (i) inactive beta-receptor, inactive G_s protein (alpha+beta+gamma); (ii) beta-receptor occupancy, guanosine triphosphate (GTP) binds to alpha subunit of G_s ($alpha_s$) to displace GDP; (iii) the G subunits dissociate. Affinity of receptor for agonist decreases. $alpha_s$ -GTP stimulates activity of adenylate cyclase with formation of cyclic adenosine monophosphate (AMP); (iv) GTPase becomes active and converts GTP to guanosine diphosphate (GDP), and $alpha_s$ -GDP re-forms. This is the end of the activation cycle. The inactive state is resumed. $alpha_s$ =stimulatory alpha subunit of G protein; beta=beta subunit of G protein; gamma=gamma subunit of G protein; G_s =stimulatory G-protein. (Modified with permission from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

that responds to input from G proteins. G_s is the stimulatory sarcolemmal G protein complex that passes on the signal from the beta receptor to adenylate cyclase.[63] In the sinus node, a similar messenger system increases the heart rate. Adenylate cyclase, stimulated by G_s , produces the second messenger, cyclic AMP, which then

acts through a further series of intracellular signals and specifically the third messenger protein kinase A, to increase cytosolic calcium transients. In contrast, cholinergic stimulation exerts inhibitory influences, largely on the heart rate, but also on atrial contraction, acting at least in part by decreasing the rate of formation of cyclic AMP.[59]

THE STIMULATORY G PROTEIN (G_s).

G proteins are a superfamily of proteins that bind guanine triphosphate (GTP) and other guanine nucleotides. G proteins are crucial in carrying the signal onward from the first messenger and its receptor, to the activity of the membrane-bound enzyme system that produces the second messenger (see Figs. 14-15 and 14-16) . [64] The triple combination of the beta receptor, the G protein complex, and adenylate cyclase is termed the *beta-adrenergic system*.[65] The G protein itself is a heterotrimer composed of G_{alpha} , G_{beta} , and G_{gamma} , which on receptor stimulation splits into the alpha subunit that is bound to GTP, and the beta-gamma subunit.[66] Either of these subunits may regulate differing effectors such as adenylate cyclase, phospholipase C, and ion channels. The activity of adenylate cyclase is controlled by two different G-protein complexes, namely G_s , which stimulates, and G_i , which inhibits.[67] The alpha subunit of G_s ($alpha_s$) combines with GTP and then separates off from the other two subunits to enhance activity of adenylate cyclase. The beta and gamma subunits (beta-gamma) appear to be linked structurally and in function.

THE INHIBITORY G PROTEIN (G_i).

In contrast, a second trimeric GTP-binding protein, G_i , is responsible for inhibition of adenylate cyclase.[66] During cholinergic signaling, the muscarinic receptor is stimulated and GTP binds to the inhibitory alpha subunit ($alpha_1$).[68] The latter then dissociates from the other two components of the G-protein complex, which are, as in the case of G_s , the combined beta-gamma subunits. Whereas the role of $alpha_i$ is not clear, the beta-gamma subunits act as follows. By stimulating the enzyme GTPase,[69] they break down the active $alpha_s$ subunit ($alpha_s$ -GTP), so that the activation of adenylate cyclase in response to $alpha_s$ stimulation becomes less. Furthermore, the beta-gamma subunit activates the K_{ACh} channel,[70] which, in turn, can inhibit the sinoatrial node to contribute to the bradycardiac effect of cholinergic stimulation. The $alpha_i$ subunit activates another potassium channel (K_{ATP}) [70] whose physiological function in the myocardium is still under discussion. Pathophysiologically, preconditioning may link to this channel (see later). In heart failure, $beta_2$ receptors may act via G_i to limit apoptosis (see later).

THE THIRD G PROTEIN (G_q).

This links a group of heptahelical (*hepta*="seven") myocardial receptors, including the alpha-adrenergic receptor and those for angiotensin II and endothelin, to another membrane-associated enzyme, phospholipase C, and thence to PKC (see later). G_q has at least four isoforms, of which two have been found in the heart. This G protein, unlike G_i , is not susceptible to inhibition by the pertussis toxin. Overexpression of Gq in mice induces a dilated cardiomyopathy;[71] which is of interest because angiotensin II and endothelin are known to be overactive in human heart failure. The initial phases may involve myocyte hypertrophy and apoptotic signaling.[72] Experimentally, increased cardiac-directed expression of adenylate cyclase counters this dilated cardiomyopathy.[71]

Role of Cyclic Adenosine Monophosphate

Adenylate cyclase is the only enzyme system producing cyclic AMP and that specifically requires low concentrations of ATP (and magnesium) as substrate. Surprisingly, the proposed molecular structure resembles that of certain channel proteins, such as the calcium channel. Most of the adenylate cyclase protein is located on the cytoplasmic side, the presumed site of interaction with the G protein. Cyclic AMP is the second messenger of beta-adrenergic receptor activity (see Fig. 14-16) , whereas another cyclic nucleotide, cyclic GMP, acts as a second messenger for some aspects of vagal cholinergic activity. In vascular smooth muscle, cyclic GMP is the second messenger of the nitric oxide messenger system. These messenger chemicals are present in the heart cell in minute concentrations, that of cyclic AMP being roughly about 10^{-9} M and that of cyclic GMP about 10^{-11} M.[73] Cyclic AMP has a very rapid turnover as a result of a constant dynamic balance between its formation by adenylate cyclase and removal by another enzyme, phosphodiesterase. In general, directional changes in

Figure 14-16 Signal systems involved in positive inotropic and lusitropic (enhanced relaxation) effects of beta-adrenergic stimulation. When the beta-adrenergic agonist interacts with the beta receptor, a series of G protein-mediated changes (see Fig. 14-15) leads to activation of adenylate cyclase and formation of cyclic adenosine monophosphate (cAMP). The latter acts by means of protein kinase A to stimulate metabolism (on left) and to phosphorylate the calcium channel protein. The result is an enhanced opening probability of the calcium channel, thereby increasing the inward movement of Ca^{2+} ions through the sarcolemma (SL) of the T tubule. These Ca^{2+} ions release more calcium from the sarcoplasmic reticulum (SR) (see Fig. 14-11) to increase cytosolic calcium and to activate troponin C. Calcium ions also increase the rate of breakdown of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and inorganic phosphate (P_i). Enhanced myosin ATPase activity explains the increased rate of contraction, with increased activation of troponin C explaining the increased peak force development. An increased rate of relaxation is explained because cyclic AMP also activates the protein phospholamban, situated on the membrane of the SR, which controls the rate of uptake of calcium into the SR (see Fig. 14-11). The latter effect explains enhanced relaxation (lusitropic effect). AKAP=A-kinase anchoring proteins. P=phosphorylation; PL=phospholamban; SL=sarcolemma; SR=sarcoplasmic reticulum; TnI=troponin I. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

the tissue content of cyclic AMP can be related to directional changes in cardiac contractile activity. For example, beta-adrenergic stimulation increases both, whereas beta blockade inhibits the increases induced by beta agonists. *Forskolin*, a direct stimulator of adenylate cyclase, increases cyclic AMP and contractile activity. Adenosine, acting through A_1 -receptors, inhibits adenylate cyclase, decreases cyclic AMP, and lessens contractile activity. A number of hormones or peptides can couple to myocardial adenylate cyclase independently of the beta-adrenergic receptor. These are glucagon, thyroid hormone, prostacyclin (PGI_2), and the calcitonin gene-related peptide.

INHIBITION OF CYCLIC AMP FORMATION.

The major physiological stimulus to G_i is thought to be vagal muscarinic receptor stimulation. In addition, adenosine, by interaction with A_1 -receptors, couples to G_i to inhibit contraction and heart rate.[74] The adenosine A_2 -receptor paradoxically increases cyclic AMP. The latter effect, only of ancillary significance in the myocardium, is of major importance in vascular smooth muscle where it induces vasorelaxation.[74] Pathologically, inhibitory G_I is increased in experimental postinfarct heart failure[75] and in donor hearts before cardiac transplantation.[76]

CYCLIC AMP-DEPENDENT PROTEIN KINASES.

It is now clear that most of the effects of cyclic AMP are ultimately mediated by the protein kinases that phosphorylate various important proteins and enzymes.[77] [78] Phosphorylation is the donation of a phosphate group to the enzyme concerned, acting as a fundamental metabolic switch that can extensively amplify the signal.

Each protein kinase is composed of two subunits: regulatory (R) and catalytic (C). When cyclic AMP interacts with the inactive protein kinase, it binds to the R subunit to liberate the active kinase that is the C subunit:

At a molecular level, this active kinase catalyzes the transfer of the terminal phosphate of ATP to serine and threonine residues of the protein substrates, leading to phosphorylation and modification of the properties of the proteins concerned, thereby promoting further key reactions. *Protein kinase A (PKA)* occurs in different cells in two isoforms: PKA-II predominates in cardiac cells.[78] The proposed anchorage of this kinase by *A-kinase anchoring proteins* (AKAPs) to specific organelles such as the SR explains the phenomenon of cyclic AMP compartmentation.[79] The G-protein system may not be evenly spread throughout the sarcolemma but localized to certain focal areas.[66] Thus, it is very likely that there is only a specific subcompartment of cyclic AMP available to increase contractile activity.[80]

Physiological $Beta_1$ -Adrenergic Effects

The probable sequence of events describing the positive inotropic effects of catecholamines is as follows (see Fig. 14-16) .
Catecholamine stimulation
beta receptor
molecular changes

binding of GTP to alpha$_s$ subunit of G protein
GTP alpha$_s$ subunit stimulates adenylate cyclase
formation of cyclic AMP from ATP
activation of cyclic AMP-dependent protein kinase, locally bound by an A-kinase anchoring protein
phosphorylation

of a sarcolemmal protein p27
increased entry of calcium ion through increased opening of the voltage-dependent L-type calcium channels
greater calcium-induced calcium release through ryanodine receptor of sarcoplasmic reticulum, coupled with phosphorylation of the ryanodine receptor
greater and more rapid rise of intracellular free calcium ion concentration
increased calcium-troponin C interaction with deinhibition of tropomyosin effect on actin-myosin interaction
increased rate and number of cross bridges interacting with increased myosin ATPase activity
increased rate and peak of force development.

The increased *lusitropic (relaxant)* effect is the consequence of increased protein kinase A-mediated phosphorylation of phospholamban (see p. 452). Also, increased phosphorylation of troponin I may help to desensitize the contractile apparatus to calcium ions (see Fig. 14-16) .

SHORT-TERM INHIBITORY MECHANISMS.

There is a potent feedback mechanism whereby the degree of postreceptor response to a given degree of beta-adrenergic receptor stimulation can be muted (Fig. 14-17) . This physiologically decreased response in which the beta-receptor signal is terminated within minutes to seconds is called *desensitization of the beta receptor* (see Fig. 14-17) . The key event is that sustained beta-agonist stimulation rapidly induces the activity of the beta-agonist receptor kinase (betaARK) that is involved in the transfer of the phosphate group to the phosphorylation site on the terminal COOH tail of the receptor.[81] Next, betaARK increases the affinity of the beta receptor for another protein family, the *arrestins.* [81] [82] Hypothetically, arrestins change the molecular configuration of the receptor in such a way that the G proteins cannot interact optimally with it. This disconnection of receptor stimulation from the activity of adenyl cyclase is called *uncoupling.* A back-up mechanism for desensitization is mediated by protein kinase A,[82] activated by cyclic AMP. This process also phosphorylates the beta receptor within minutes, providing a direct feedback mechanism to prevent adverse effects of excess cyclic AMP elevation and protein kinase A activation. *Resensitization* of the receptor occurs when the phosphate groups are split off the beta receptor by a phosphatase, so that the receptor may then again readily be linked to G_s .[83] Resensitization, like desensitization, occurs rapidly. Such short-term changes probably occur whenever there is

Figure 14-17 Mechanisms of beta-adrenergic receptor desensitization and internalization. Note newly described links of the internalized receptor complex with growth stimulation through mitogen activated protein (MAP) kinase. (Modified from Hein L, Kobilka BK: Adrenergic receptors: From molecular structures to in vivo function. Trends Cardiovasc Med 7:137-145, 1997.)

an emotional crisis or a burst of exercise, to fine tune the effects of beta-adrenergic stimulation and to prevent the risks of excess such as severe and potentially lethal arrhythmias.[84]

LONG-TERM INHIBITORY MECHANISMS.

Prolonged desensitization during sustained excess beta-adrenergic receptor stimulation, as during long infusions of sympathomimetic agents, may be explained by receptor sequestration, *internalization,* [82] and even lysosomal degradation.[85] In addition, the internalized receptor can participate in growth signaling, because arrestin forms a complex with the beta receptor and with tyrosine kinases, thereby ultimately linking to mitogen-activated protein (MAP) kinase.[86] Thus, prolonged beta-receptor stimulation may have growth as an end result while losing physiological effects such as positive inotropic and lusitropic stimulation.

The overall picture is that of a reciprocal effect of beta-adrenergic receptor stimulation by the catecholamine beta agonists, soon followed by self-desensitization of the beta receptor by the betaARK/arrestin and protein kinase A mechanisms.[87] Long-term stimulation of the beta-adrenergic receptor increases the mRNA for betaARK, whereas beta blockade decreases the expression of betaARK, to enhance receptor signaling. Also, arrestin formation and receptor internalization may promote increased cardiac growth. Although the beta-arrestin effects are best described for beta$_2$ receptor, they also occur to a lesser extent with the beta$_1$ receptor.[88] These changes in postreceptor signaling may help to explain pathological alterations in the beta-receptor signaling system in heart failure.

Comparison of Beta$_2$ -Adrenergic Effects with Beta$_1$ -Adrenergic Effects

In the normal ventricle, about 20 percent of the receptors are beta$_2$ in nature; yet in heart failure this percentage can double. Whereas the postreceptor signaling sequence of the beta$_1$ receptor is well understood, that of the cardiac beta$_2$ receptor is still not fully clarified. Although beta$_2$ receptors link efficiently by means of G_s to adenyl cyclase, they may also couple to the inhibitory G_I proteins, at least in isolated murine myocytes.[89] In whole hearts, the inhibitory path seems latent, judging by data from studies in dogs.[90] In humans, the positive inotropic response to beta$_2$ stimulation by salbutamol occurs at least in part through beta$_2$ receptors on the terminal neurones of the cardiac sympathetic nerves, thereby releasing norepinephrine, which in turn exerts dominant beta$_1$ effects.[91] Thus, the overall evidence is that beta$_2$ -receptor stimulation has similar inotropic and lusitropic effects to beta$_1$ -receptor stimulation, even though the precise mechanisms and signal systems may differ.[90]

Cholinergic Receptors

In the case of the parasympathetic system, signaling is again an extracellular first messenger (acetylcholine), a receptor system (the muscarinic receptor), and a sarcolemmal signaling system (the G-protein system). The myocardial *muscarinic receptor* (M_2) is associated specifically with the activity of the vagal nerve endings. Receptor stimulation produces a negative chronotropic response that is inhibited by atropine.

Regarding the *negative inotropic effect of vagal stimulation* (Fig. 14-18) , the mechanism is multiple, including (1) heart rate slowing (negative Treppe phenomenon); (2) an inhibition of the formation of cyclic AMP; and (3) a direct negative inotropic effect mediated by cyclic GMP. Ventricular tissue is much less responsive to muscarinic agonists than atrial tissue, although the receptor populations are similar in density.[59] Thus, there must be postreceptor differences between atrial and ventricular tissue, probably in the degree of G-protein coupling. In general, the negative inotropic effect of vagal stimulation has been best observed in the presence of beta stimulation (Table 14-2) when vagal effects counteract those of prior beta stimulation. [59] [92] The proposal is that muscarinic stimulation acting through G_i inhibits the G_s activation that results from beta-receptor occupation. Physiologically, stimulation of G_I may give better protection

Figure 14-18 Interaction between parasympathetic and sympathetic systems at a cellular level may involve two opposing cyclic nucleotides: cyclic adenosine monophosphate (AMP) and cyclic guanosine monophosphate (GMP). Many effects of vagal stimulation could best be explained by the inhibitory effect on the formation of cyclic AMP, including formation of inhibitory G protein (G_i) in response to M_2 -receptor stimulation (see Fig. 14-19) . NO=nitric oxide. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

from the arrhythmogenic than the inotropic effects of beta stimulation.[93]

Cyclic GMP acts as a second messenger to vagal stimulation just as cyclic AMP does to beta-adrenergic stimulation. Thus, the vagus may have a dual effect on second messengers, inhibiting the formation of cyclic AMP and increasing that of cyclic GMP,[94] thereby providing one of several explanations for

sympathetic-parasympathetic interaction. In the sinus node, formation of cyclic GMP may occur not only by guanyl cyclase (see Fig. 14-18) but also by a muscarinic-mediated formation of nitric oxide.[95] Cyclic GMP may in turn inhibit the activity of the L-calcium channel by a cyclic GMP-dependent kinase (Gkinase).[96] Favoring this view is the finding that cell-permeable analogs of cyclic GMP have antiadrenergic effects. The problem with this hypothesis is the inconstant increase in ventricular cyclic GMP in response to vagal stimulation. The explanation could lie in cell compartmentation of cyclic GMP, as postulated for cyclic AMP. Also the effects of cyclic GMP on contractility may be more subtle than changes in the pattern of peak force development. Rather, there may be decreased sensitivity of the myofilaments to Ca^{2+} and earlier relaxation.[97]

Yet another mechanism for parasympathetic modulation of sympathetic interaction lies at the level of the sympathetic terminal neurones, where a *presynaptic muscarinic M_2 receptor* inhibits the release of norepinephrine.[59] Additionally, both adrenergic and cholinergic stimuli exert complex and potentially important effects on ion channels that can be translated into opposing effects on cardiac function (see Table 14-2) . The presence of such multiple mechanisms for the inhibitory effects of vagal stimulation on the heart rate, the inotropic state, and arrhythmogenicity suggest that "braking" of beta-adrenergic stimulation is desirable. Otherwise, the risk may be that intense beta-adrenergic stimulation would excessively increase the heart rate or inotropic state or provoke potentially fatal arrhythmias.

Phospholipase C-Protein Kinase C

There is an important group of receptors previously thought to act chiefly on the myocardium at the presynaptic level to enhance release of norepinephrine and on postsynaptic vascular receptors to cause vasoconstriction. Such receptors include those for $alpha_1$ -adrenergic catecholamines, angiotensin II, and endothelin. They are all linked to phospholipase C by a G protein, G_q (Fig. 14-19) . Currently, two aspects of their action are under intense focus. First, the signaling system involved is clearly different from that involved in beta-adrenergic effects.[35] Second, these receptors have been identified in ventricular myocytes, posing the question of their physiological role--a problem that is still not fully clarified.[60]

PHOSPHOLIPASE C.

When any of these agonists ($alpha_1$ -adrenergic catecholamines, angiotensin I, and endothelin) occupies its receptor, then the link to phospholipase C is by one of the G-protein family, namely G_q . Phospholipase C is the "common route for the action of many hormones" in noncardiac cells.[98] The exact steps involved are not as well understood as is the coupling of the beta receptor to adenylate cyclase, but similar components of the G-protein complex appear to be involved.[99] First G_q activates phospholipase C to split the compound phosphatidyl inositol bisphosphate (PIP_2), part of the membrane phospholipid system, into two second messengers: IP_3 and 1,2-diacylglycerol (DAG). IP_3 is the natural ligand for the IP_3 receptors on the SR, stimulating the slow release of calcium and increasing calcium oscillations.[100] This calcium is unlikely to play a major role in the regulation of contraction, but it contributes to the excess calcium oscillations that underlie reperfusion arrhythmias.[101] Physiologically, calcium released by IP_3 acts on the next messenger in the system, PKC, by promoting the translocation of this enzyme from cytosol to sarcolemma.[102] Once translocated, PKC becomes activated by DAG, the other second messenger of phospholipase C activity. DAG, being highly lipophilic, stays in the cell membrane and, together with a resident serine component of the membrane lipids, stimulates PKC into activity by reducing the calcium requirement of the PKC to micromolar values.[78]

PROTEIN KINASE C.

This key kinase has multiple functions. First, it is linked to the phospholipase signaling system, of prime importance in vascular contraction, and possibly acting as an inotropic back-up system in the myocardium (see Fig. 14-19) . Second, PKC may be a key molecular switch in the "hypertrophic signal system," responding to stretch and to neurohormonal input.[103] Third, it plays a pivotal role in preconditioning, receiving stimuli from a number of G protein-linked

TABLE 14-2 -- IONIC EFFECTS OF ADRENERGIC AND CHOLINERGIC STIMULATION: RELATION TO HEART RATE AND CONTRACTILE ACTIVITY

AGONIST	IONIC CURRENT	EFFECT
Beta-adrenergic stimulation*	I_{Ca} increased	+ Inotropic

Figure 14-19 Phospholipase C (PLC) signaling system in myocardium, linked to protein kinase C (PKC), through three receptors that couple to G protein G_q, namely those for $alpha_1$ -adrenergic, angiotensin II (AII acting on the AT_1 receptor), AT_1 , and endothelin (ET). PLC splits phosphatidyl inositol bisphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG), the latter being membrane bound. IP_3 (and IP_4) release Ca^{2+} from the sarcoplasmic reticulum (SR) to activate protein kinase C (PKC) by translocating it from a cytosolic to a membrane-bound situation. Ca^{2+} released by IP_3 may also have a supportive inotropic role and be harmful in the reperfusion period.[37] PKC plays a role in growth regulation and as an effector of preconditioning (PC) that activates mitochondrial and sarcolemmal adenosine triphosphate (ATP)-sensitive potassium channels (see Fig. 14-36) (Figure Not Available) . (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

receptors and ultimately activating the mitochondrial ATP-sensitive potassium channels.[104] Such multiple functions may be mediated by different isoforms of PKC, of which there are at least ten, the functions of which are still poorly understood. The isoforms are divided into three groups: (1) the conventional (which respond to calcium in vitro), (2) the novel (which respond to diacylglycerol but not to calcium), and (3) the atypical (which respond to neither calcium nor diacylglycerol but rather to phospholipids). The conventional beta isoforms, increased in the failing human heart,[105] may be linked to enhanced growth. [103] The novel isoforms epsilon and eta play a role in preconditioning, at least in the rabbit.[106] The epsilon isoforms may also be concerned with inotropy.[107] The function of the atypical group of isoforms is still unknown.

Inhibitory Signal Systems

There are successive brakes that can limit the potentially dangerous overactivity of the beta-adrenergic system, including the self-initiated receptor shutoff and activity of the cholinergic parasympathetic system, as already described. Other inhibitory signals include nitric oxide, adenosine, and the opioids.

Nitric Oxide as Messenger with Cyclic GMP as Target

Nitric oxide (NO), the focus of the Nobel Prize awards for 1998, may be generated by an enzyme either in the vascular endothelium (eNOS) or in certain circumstances in the cardiomyocytes by the inducible enzyme (iNOS). NO, a free radical gas, can permeate from the endothelial cells to have complex dose-dependent effects on the myocardium.[108] [109] NO synthesis in endothelial cells is increased by shear stress as during an increased blood flow, by increased cardiac loading,[110] by increased heart rate,[111] or by bradykinin. [108] The standard concept is that cyclic GMP is the second messenger of NO and that cyclic GMP can, by stimulation of the appropriate protein G-kinases (PKG), result in a decreased heart rate and in a negative inotropic effect. These actions are mediated by inhibition of the calcium channel[108] and/or by decreased sensitivity of the contractile proteins to cyclic GMP.[111]

NO-mediated formation of cyclic GMP, under the influence of guanylate cyclase, is thought to occur in response to (1) cholinergic stimulation, as already discussed, and (2) NO, derived from the endothelium or from NO donors such as the nitrates (Fig. 14-20) . NO enhances the negative inotropic effect of acetylcholine and decreases the positive inotropic effects of beta stimulation.[112] Therefore, the NO system, it is proposed, may have a negative modulatory role on the cardiac effects of autonomic stimulation in keeping with the proposed formation of cyclic GMP.[108] In addition, NO also decreases mitochondrial metabolism, thereby reducing myocardial oxygen demand. Angiotensin-converting enzyme inhibitors, decreasing the breakdown of bradykinin and thereby increasing formation of NO by the endothelium, may act likewise.[113]

Unexpected positive inotropic effects of low-dose NO have also been found.[109] The explanation may be (1) release of calcium from the SR by the messenger, cyclic ADP ribose (see Fig. 14-20) , and/or (2) inhibition of a cyclic GMP-sensitive myocardial phosphodiesterase, thereby increasing cyclic AMP. Therefore, some workers regard NO as having dose-dependent bidirectional effects on the inotropic status. Likewise in heart failure, when both eNOS and iNOS are upregulated, effects may be either favorable or unfavorable.[111] Physiological concentrations of NO suppress apoptosis whereas higher levels stimulate it. Peroxynitrite ($ONOO^-$), formed from NO and superoxide, may help to explain the toxicity of the higher levels.

ADENOSINE SIGNALING.

Adenosine, like NO, is a physiological vasodilator. It is formed from the breakdown of ATP both physiologically (as during an increased heart

Figure 14-20 Nitric oxide messenger system. Proposed role in stimulating guanylate cyclase and cyclic guanosine monophosphate (cGMP) to cause vasodilation and possibly a negative inotropic effect. The physiological significance of the cyclic adenosine diphosphate (ADP) ribose path is still speculative, but it could explain the unexpected positive inotropic effect of cGMP in some experiments. RR=ryanodine receptor. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

load) and pathologically (as in ischemia). Adenosine can diffuse from myocardial cells to act on coronary arterial smooth muscle to cause vasodilation. The mechanism of the latter effect is reasonably well understood and involves the stimulation of vascular adenylate cyclase and cyclic AMP formation. A_2 receptors mediate such vasodilation. A_2 receptors have also been identified in cardiomyocytes, yet stimulation of such receptors does not have functional consequences.[114] Therefore, it is only the A_1 receptors that are coupled to adenylate cyclase by the inhibitory G protein ($alpha_i$ subunit) that are functional in the myocardium.

Other signal systems and other receptor subtypes are also involved in adenosine signaling.[115] First, A_1 receptors couple to the acetylcholine-sensitive potassium channel (current I_{kACh}) to stimulate channel opening and thereby to exert inhibitory effects on the sinus and atrioventricular nodes. The latter inhibition is the basis for the use of adenosine in the treatment of supraventricular nodal reentry arrhythmias. Second, A_1 receptors may couple to the PKC system, and thence to the ATP-sensitive potassium channel, thereby hypothetically explaining their role in preconditioning (see Intermittent Ischemia and Preconditioning). Third, A_3 receptors also precondition by means of PKC, without, however, the obvious hemodynamic effects of A_1 receptor stimulation.[116]

OPIOID RECEPTORS.

Opioids released in the central nervous system are known to participate in cardiovascular regulation, by inhibiting sympathetic and promoting parasympathetic outflow. Such endogenous opiates, called the *endorphins,* may be involved in the benefits of cardiovascular training. In congestive heart failure, opioid activity may limit adrenergic activation. In animals, stimulation of opioid receptors may help to explain the phenomenon of hibernation.[117] In addition, opioid drugs such as morphine are often used in cardiovascular medicine and may have effects beyond pain relief. Opioid effects may be mediated, in part, through local cardiovascular opioid receptors that respond to stimulation of the opioid system, in response to conditions of physiological or psychosocial stress.

There are three opioid receptors, delta, kappa, and mu, of which the former two are found in the human heart whereas the mu receptors mediate signals that dampen the pain response. In the heart, the delta receptors inhibit the adrenergic system by coupling to G_i , thereby inhibiting the activation of adenyl cyclase by beta-adrenergic stimulation.[118] In addition, by stimulation of the PKC pathway (see later) they also mediate preconditioning.

Adaptive Signal Systems

These signals include (1) the phospholipase-protein kinase C system, important both in generating cell growth in response to hormonal stimuli and in protection from ischemia by preconditioning (see p. 459); (2) the stretch receptors, which can blend acute and chronic myocardial functional and growth responses to a chronically increased wall stress; (3) tumor necrosis factor-alpha and other cytokines, which mediate the normal inflammatory response and may be either adaptive, as in protection from ischemia-reperfusion, or maladaptive, as in severe heart failure; and (4) the beta-adrenergic adaption to heart failure, both adaptive and maladaptive.

STRETCH RECEPTORS.

Both myocardial and vascular cells can respond to stretch by activation of a group of poorly understood mechanoreceptors, also called stretch receptors. Activation of these receptors is linked to a series of intracellular phosphorylations including a crucial group of enzymes in the growth cascade, namely, MAP kinases.[119] Stretch receptors may respond to conformational changes by allowing increased entry of specific ions such as calcium, which may then initiate the intracellular signals. In addition, mechanically induced cytoskeletal distortion acting through integrins and other structural proteins can activate the MAP kinase cascade.[119] Of considerable interest is the concept that an early event in the sequence leading from muscle stretch to hypertrophy is release of angiotensin II from the stretched muscle.[120] Nonetheless, the dominant factor is stretch, not angiotensin II, as shown in a mouse knockout model of the angiotensin I receptor.[121]

CYTOKINES, INCLUDING TUMOR NECROSIS FACTORALPHA (TNF-alpha).

TNF-alpha is one of the family of peptide cytokines that form part of the injury response repertoire. Such cytokines mediate local events and are distinct from circulating neurotransmitters or hormones. TNF-alpha mediates bifunctional effects.[122] Those considered as harmful include the promotion of apoptosis as may occur in heart failure. TNF-alpha may also have a beneficial effect in cardiac homeostasis, when its formation is stimulated as part of the growth response to mechanical stress or in response to myocardial ischemia-reperfusion injury.[123] Currently, it is not known why the intracellular signaling paths leading from the surface receptors for TNF-alpha sometimes lead to cell survival and other times to apoptosis. Two proposals are, first, that there are short-term adaptive and long-term maladaptive effects of TNF-alpha, and, second, that low concentrations are adaptive and high concentrations are maladaptive.[123] An important current question is whether the acute reduction of cardiac contractility induced by TNF-alpha and possibly mediated by NO is adaptive[124] and confers cardioprotection especially during ischemia-reperfusion, or maladaptive, leading to long-term malfunction.

In congestive heart failure (Fig. 14-21) there are increased levels of circulating catecholamines that result in prolonged excessive beta-adrenergic stimulation of the heart. As outlined already (see section on Physiological Switch-off, betaARK, and Arrestin), such excess stimulation causes desensitization, explained by both uncoupling and by receptor internalization. The latter change explains why the density of the $beta_1$ receptor may be decreased by as much as 50 to 70 percent,[125] a process called *downregulation.* Other changes to the $beta_1$ -adrenergic/cyclic AMP system include (1) decreased adenylate cyclase activity[126] ; (2) increased levels of inhibitory G_i proteins[75] [127] ; and (3) a decrease of the mRNA for the $beta_1$ receptor.[81] The downregulation of the $beta_1$ receptor in advanced heart failure results in relative upregulation of the cardiac $beta_2$ receptors so that the density of these receptors is increased relative to that of the $beta_1$ receptors. There is a newly recognized inhibitory link between $beta_2$ receptors and adenyl cyclase. These receptors unexpectedly also couple with the inhibitory G_i protein, thereby limiting experimental apoptosis. [127] Antiapoptosis is a new, albeit still hypothetical, therapeutic principle in heart failure. According to these concepts, $beta_1$ blockade in heart failure could leave intact this $beta_2$ G_i -mediated protective path. *Uncoupling* of both of the beta-receptor subtypes from the signaling system linked to G_s may be explained by the betaARK/arrestin mechanism, already described (see Fig. 14-17) . Thus there is decreased activity of both $beta_1$ receptor and $beta_2$ receptor G_s -linked signaling systems (see Fig. 14-21) . All these obstructions to the flow of signals from both $beta_1$ and $beta_2$ receptors result in less formation of cyclic AMP, which partially explains the poorly developed and low-amplitude calcium transients in human tissue from severe heart failure subjects.[128] Furthermore, calcium uptake into the SR is decreased by downregulation of the calcium uptake pump on the SR, SERCA 2a, in the failing human heart.[42] The response to $alpha_1$ stimulation in heart failure is also much diminished.[129] The net result is that despite the increased circulating catecholamine levels the inotropic response is diminished and contractility falls.

Figure 14-21 In advanced heart failure, there is depressed function of both the beta-adrenergic receptor signal system and the sarcoplasmic reticulum (SR). Both $beta_1$ - and $beta_2$ -adrenergic receptors are uncoupled from G_s , the stimulatory G protein. Activity of G_i , the inhibitory G protein, is increased (
) by increased activity of its messenger RNA. The overall result is that activity of adenylate cyclase (AC) also falls. Consequently, there is less formation (
) of cyclic adenosine monophosphate (cAMP) with less release of calcium ions from the SR. Uptake of calcium into the SR also drops, as a result of impaired activity of the calcium uptake pump SERCA 2a (see Fig. 14-11) . There is also decreased synthesis of this receptor ($beta_1$ AR mRNA
) and of increased synthesis of beta-adrenergic receptor kinase (betaARK mRNA
). betaARK phosphorylates the beta-adrenergic receptors so that they are uncoupled from G_s (negative sign between the adrenergic receptors and G_s). This uncoupling is further promoted by beta arrestin (see Fig. 14-17) . $Beta_2$ -adrenergic receptors may unexpectedly couple to G_i (see reference 89). M_2 =muscarinic receptor; ACh=acetylcholine. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

CONTRACTILE PERFORMANCE OF THE INTACT HEART

There are three main determinants of myocardial mechanical performance, namely, the Frank-Starling mechanism, the contractile state, and the heart rate. This section describes the cardiac cycle and then the determinants of left ventricular function.

The Cardiac Cycle

The cardiac cycle, fully assembled by Lewis [130] but first conceived by Wiggers,[131] yields important information on the temporal sequence of events in the cardiac cycle. The three basic events are (1) left ventricular contraction, (2) left ventricular relaxation, and (3) left ventricular filling (Table 14-3) . Although similar mechanical events occur in the right side of the heart, it is those on the left side that will be focused on.

LEFT VENTRICULAR CONTRACTION.

Left ventricular pressure starts to build up when the arrival of calcium ions at the contractile proteins starts to trigger actin-myosin interaction. On the electrocardiogram (ECG), the advance of the wave of depolarization is indicated by the peak of the R wave (Fig. 14-22) . Soon after, left ventricular pressure in the early contraction phase builds up and exceeds that in the left atrium (normally 10 to 15 mm Hg), followed about 20 milliseconds later by M_1 , the mitral component of the first heart sound. The exact relation of M_1 to mitral valve closure is open to dispute. Although mitral valve closure is often thought to coincide with the crossover point at which the left ventricular pressure starts to exceed the left atrial pressure,[132] in reality mitral valve closure is delayed because the valve is kept open by the inertia of the blood flow. Shortly thereafter, pressure changes in the right ventricle, similar in pattern but lesser in magnitude to those in the left ventricle, cause the tricuspid valve to close, thereby creating T_1 , which is the second component of the first heart sound. During this phase of contraction between mitral valve and aortic valve opening, the left ventricular volume is fixed (*isovolumic contraction*), because both aortic and mitral valves are shut. As more and more myofibers enter the contracted state, pressure development in the left ventricle proceeds. The interaction of actin and myosin increases, and cross-bridge cycling augments. When the pressure in the left ventricle exceeds that in the aorta, the aortic valve opens, which is usually a clinically silent event. Opening of the aortic valve is followed by the phase of *rapid ejection*. The rate of ejection is determined not only by the pressure gradient across the aortic valve but also by the elastic properties of the aorta and the arterial tree, which undergoes systolic expansion. Left ventricular pressure rises to a peak and then starts to fall.

LEFT VENTRICULAR RELAXATION.

As the cytosolic calcium ion concentration starts to decline because of uptake of calcium into the SR under the influence of activated

TABLE 14-3 -- THE CARDIAC CYCLE

Left Ventricular Contraction
Isovolumic contraction (b)
Maximal ejection (c)
Left Ventricular Relaxation
Start of relaxation and reduced ejection (d)
Isovolumic relaxation (e)
LV filling: rapid phase (f)
Slow LV filling (diastasis) (g)
Atrial systole or booster (a)

The letters a-g refer to the phases of the cardiac cycle shown in Wiggers' diagram (Fig. 14-22) . These letters are arbitrarily allocated so that atrial systole (a) coincides with the a wave and (c) with the c wave of the jugular venous pressure.

Figure 14-22 The mechanical events in the cardiac cycle were first assembled by Lewis in 1920[130] but first conceived by Wiggers in 1915.[131] Note that mitral valve closure occurs *after* the crossover point of atrial and ventricular pressures at the start of systole. The visual phases of the ventricular cycle in the bottom panel are modified from Shepherd and Vanhoutte (Shepherd JT, Vanhoutte PM: The Human Cardiovascular System. New York, Raven Press, 1979, p 68.) For explanation of phases a to g, see Table 14-3 . ECG=electrocardiogram; JVP=jugular venous pressure; M_1 =mitral component of first sound at time of mitral valve closure; T_1 =tricuspid valve closure, second component of first heart sound; AO=aortic valve opening, normally inaudible; A_2 =aortic valve closure, aortic component of second sound; P_2 =pulmonary component of second sound, pulmonary valve closure; MO=mitral valve opening, which may be audible in mitral stenosis as the opening snap. S_3 =third heart sound; S_4 =fourth heart sound; a=wave produced by right atrial contraction; c=carotid wave artifact during rapid LV ejection phase; v=venous return wave that causes pressure to rise while tricuspid valve is closed. Cycle length of 800 milliseconds for 75 beats/min. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure

phospholamban, more and more myofibers enter the state of relaxation and the rate of ejection of blood from the left ventricle into the aorta falls during the *phase of reduced ejection*. During this phase, blood flow from the left ventricle to the aorta rapidly diminishes but flow through the arterial tree is maintained by aortic recoil--the Windkessel effect.[133] The pressure in the aorta exceeds the falling pressure in the left ventricle. The aortic valve closes, creating the first component of the second sound, A_2 (the second component, P_2 , results from closure of the pulmonary valve as the pulmonary artery pressure exceeds that in the right ventricle). Thereafter, the ventricle continues to relax. Because the mitral valve is closed during this phase, the left ventricular volume cannot change (*isovolumic relaxation*). When the left ventricular pressure falls to below that in the left atrium, the mitral valve opens (normally silent) and the filling phase of the cardiac cycle restarts (see Fig. 14-22) .

LEFT VENTRICULAR FILLING PHASES.

As left ventricular pressure drops below that in the left atrium, just after mitral valve opening, the *phase of rapid or early filling* occurs to account for most of ventricular filling. [134] Active diastolic relaxation of the ventricle may also contribute to early filling. Such rapid filling may cause the physiological third heart sound (S_3), particularly when there is a hyperkinetic circulation.[135] As pressures in the atrium and ventricle equalsize, left ventricular filling virtually stops (*diastasis*, separation). Renewed filling requires that the pressure gradient from the atrium to the ventricle should increase. This is achieved by *atrial systole* (or the *left atrial booster*), which is especially important when a high cardiac output is required, as during exercise, or when the left ventricle fails to relax normally, as in left ventricular hypertrophy.[134]

DEFINITIONS OF SYSTOLE AND DIASTOLE.

In Greek, *systole* means "contraction" and *diastole* means "to send apart." The start of systole can either be regarded as (1) the beginning of isovolumic contraction when left ventricular pressure exceeds the atrial pressure or (2) mitral valve closure (M_1). These correspond reasonably well, because mitral valve closure actually occurs only about 20 milliseconds after the crossover point of the pressures. Thus, in practice, the term *isovolumic contraction* often also includes this brief period of early systolic contraction even

before the mitral valve shuts, when the heart volume does not change substantially. *Physiological systole* lasts from the start of isovolumic contraction (where left ventricular pressure crosses over atrial pressure; see Fig. 14-22) to the peak of the ejection phase, so that physiological diastole commences as the left ventricular pressure starts to fall (Table 14-4) . This concept fits well with the standard pressure-volume curve. *Physiological diastole* commences as calcium ions are taken up into the sarcoplasmic reticulum, so that myocyte relaxation dominates over contraction, and the left ventricular pressure starts to fall as shown on the pressure-volume curve. In contrast, *cardiological systole* is demarcated by the interval between the first and second heart sounds, lasting from the first heart sound (M_1) to the closure of the aortic valve (A_2). The remainder of the cardiac cycle automatically becomes *cardiological diastole*. Thus, cardiological systole, demarcated by heart sounds rather than physiological events, starts fractionally later than physiological systole and ends significantly later. For the cardiologist, *protodiastole* is the early phase of rapid filling, the time when the third heart sound (S_3) can be heard. This sound probably reflects ventricular wall vibrations during rapid filling and becomes audible with an increase in left ventricular diastolic pressure or wall stiffness or rate of filling.

In contrast stands another physiological concept, promulgated by Brutsaert and colleagues,[136] who argue that diastole starts much later, only when the whole of the contraction-relaxation cycle is over. According to this minority view, diastole would occupy only a short portion of the cardiac cycle.[136] This definition of diastole, although seldom used in cardiological practice, does give a reminder that abnormalities of left ventricular contraction often underlie defective relaxation.

Contractility Versus Loading Conditions

CONTRACTILITY.

Contractility is the inherent capacity of the myocardium to contract independently of changes in the preload or afterload. Alternate names for contractility are the *inotropic state* (*ino*, "fiber"; *tropos*, "to move") or the contractile state. At a molecular level, an increased inotropic state can be explained by enhanced interaction between calcium ions and the contractile proteins. Increased contractility means a greater rate of contraction, to reach a greater peak force. Contractility is an important regulator of the myocardial oxygen uptake. Factors that increase contractility include exercise, adrenergic stimulation, digitalis, and other inotropic agents. Often an increased contractility is associated with enhanced rates of relaxation, called the *lusitropic effect*.

PRELOAD AND AFTERLOAD.

Any change in contractility should be independent of the loading conditions. The *preload* is the load present before contraction has started, at

TABLE 14-4 -- PHYSIOLOGICAL VERSUS CARDIOLOGIC SYSTOLE AND DIASTOLE

*Note that M_1 occurs with a definite delay after the start of left ventricular contraction.

the end of diastole (the afterload is discussed later). The preload reflects the venous filling pressure that fills the left atrium, which in turn fills the left ventricle during diastole. When the preload increases, the left ventricle distends during diastole and the stroke volume rises according to Starling's law. The heart rate also increases by stimulation of the atrial mechanoreceptors that enhance the rate of discharge of the sinoatrial node. Thus, the cardiac output, the product of stroke volume and heart rate, rises.

Starling's Law of the Heart

VENOUS FILLING PRESSURE AND HEART VOLUME.

Starling, in 1918, related the venous pressure in the right atrium to the heart volume in the dog heart-lung preparation. He proposed that, within physiological limits, the larger the volume of the heart, the greater the energy of its contraction and the amount of chemical change at each contraction. Starling did not, however, measure sarcomere length. He could only relate *left ventricular volume* to cardiac output. This holds in normal, compliant hearts. One modern version of Starling's law is that stroke volume is related to the end-diastolic volume. The left ventricular volume can now be directly measured by means of a number of imaging techniques (see Chap. 15) . Yet the value found depends on a number of simplifying assumptions and often neglects the confounding influence of the complex anatomy of the left ventricle. In practice, therefore, the left ventricular volume is not often measured but rather a variety of surrogate measures, such as left ventricular end-diastolic pressure or the pulmonary capillary wedge pressure, are used instead. Yet the relation between left ventricular end-diastolic volume and pressure is curvilinear depending on the left ventricular compliance.

FRANK AND ISOVOLUMIC CONTRACTION.

If a larger heart volume increases the initial length of the muscle fiber, to increase the stroke volume and hence the cardiac output, then diastolic stretch of the left ventricle actually increases contractility. Frank, in 1895, had already reported that the greater the initial left ventricular volume, the more rapid the rate of rise, the greater the peak pressure reached, and the faster the rate of relaxation.[137] Thus, he described both a positive *inotropic effect* and an increased lusitropic effect of increased cardiac volume at the onset of contraction. These complementary findings of Frank and Starling are often combined into the *Frank-Starling law*. Between them they could account for two of the mechanisms underlying the increased stroke volume of exercise, namely, both the increased inotropic state and the increased diastolic filling.

AFTERLOAD.

This is the systolic load on the left ventricle after it has started to contract. In the nonfailing heart, the left ventricle can overcome any physiological acute increase in load. With a chronically increased afterload, as occurs in sustained arterial hypertension or significant aortic stenosis, the left ventricle must hypertrophy. In clinical practice, the arterial blood pressure is often taken to be synonymous with the afterload, while ignoring the *aortic compliance*--the extent to which the aorta can "yield" during systole. A stiff aorta, as in isolated systolic hypertension of the elderly, increases the afterload.

PRELOAD AND AFTERLOAD ARE INTERLINKED.

In general, the preload is related to the degree to which the myocardial fibers are stretched at the end of diastole and the afterload is related to the wall stress generated by those fibers during systole. The distinctions just presented between preload and afterload do not allow for those situations when the two change concurrently. By the Frank-Starling law, an increased left ventricular volume leads to increased contractility, which in turn increases the systolic blood pressure and hence the afterload.

FORCE-LENGTH RELATIONSHIPS AND CALCIUM TRANSIENTS.

Proof that there is no increase in the calcium transient as the sarcomere length increases is provided by direct measurements (Fig. 14-23) . The favored explanation for the steep length-tension relation of cardiac muscles is *length-dependent activation,* whereby an increase in calcium sensitivity is the major factor explaining the steep increase of force development as the initial sarcomere length increases. This change may be explained by stretch of the titin molecule (see Fig. 14-3) . Is the degree of overlap of actin and myosin also involved? Whereas the overlap theory explains the force-length relationship in skeletal muscle, in cardiac muscle the situation is different (Fig. 14-24). In cardiac muscle, even at 80 percent of the maximal length only 10 percent or less of the maximal force is developed. Thus, it can be predicted that cardiac sarcomeres must function near the upper limit of their maximal length (L_{max}). Rodriguez and colleagues[138] have tested this prediction by relating sarcomere length changes to volume changes of the intact heart. By implanting small radiopaque beads in only about 1 cm^3 of the left ventricular free wall and using biplane cineradiography, the motion of the markers could be tracked through various cardiac cycles, with allowances made for local myocardial deformation. Thus, the change in sarcomere length from approximately 85 percent of L_{max} to L_{max} itself is able to effect physiological left ventricular volume changes (Fig. 14-25). This estimate is remarkably close to the normal fiber shortening of 15 percent in the human heart in situ.[139]

ANREP EFFECT: ABRUPT INCREASE IN AFTERLOAD.

When the aortic pressure is elevated abruptly a positive inotropic effect follows within 1 or 2 minutes. This used to be called homeometric autoregulation (*homeo,* "the same"; *metric,* "length"), because it was apparently independent of muscle length and by definition a true inotropic effect. A reasonable speculation would be that increased left ventricular wall tension could act on myocardial stretch receptors to increase cytosolic sodium and then, by Na^+ /Ca^{2+} exchange, the cytosolic calcium. Thus, this effect would be different from that of an increase in preload (which acts by length activation).

Figure 14-23 Length-sensitization of the sarcomere. In the top panel, the sarcomere length (SL) is 1.65 mum, which gives very little force (f) development (see Fig. 14-7). In the bottom panel, at a near maximum sarcomere length (see Fig. 14-7), the same Ca^{2+} transient (c) with the same peak value and overall pattern causes a much greater force development. Therefore, there has been length-induced calcium sensitization. (Modified from Backx PH, ter Keurs HEDJ: Fluorescent properties of rat cardiac trabeculae microinjected with fura-2 salt. Am J Physiol 264:H1098-H1110, 1993.)

Figure 14-24 Schematic drawing illustrating general shape of ascending limb of *force-length relationship* in skeletal (A) and cardiac (B) muscle. Normalized force is plotted as a function of normalized length, that is, length relative to length at which maximum force is generated (L_{max}). Also shown is approximate disposition of thick and thin filaments at different points along the physiologically relevant portion of ascending limb. The maximum length (L_{max} 100%) corresponds to the situation at maximum sarcomere lengths (2.2 mum, see Fig. 14-25) or 2.15 mum (see Fig. 14-23) . (Modified from Fuchs F: Mechanical modulation of the Ca^{2+} regulatory protein complex in cardiac muscle. NIPS 10:6-12, 1995.)

Figure 14-25 Changes in sarcomere length during a typical cardiac contraction-relaxation cycle in the intact dog heart. During diastole the sarcomere length is 2.2 mum, reducing to 1.90 mum during systole. Starting at the top right, the *preload* is the maximum sarcomere length just before the onset of contraction. As ejection decreases the left ventricular volume, by somewhat more than half, sarcomere length falls from 2.20 to 1.90 mum. Then, during the rapid phase of filling (see Fig. 14-22) , the sarcomere length increases from 1.90 to 2.15 mum to be followed by the phase of constant sarcomere length (diastasis). (Modified from Rodriguez EK, Hunter WC, Royce MJ, et al: A method to reconstruct sarcomere lengths and orientations to transmural sites in beating canine hearts. Am J Physiol 263:H293-H306, 1992. Copyright 1992, American Physiological Society.)

Wall Stress

Stress develops when tension is applied to a cross-sectional area, and the units are force per unit area. According to Laplace's law (Fig. 14-26) :

This equation, although an oversimplification, emphasizes two points. First, the larger the left ventricle and the greater its radius, the greater is the wall stress. Second, at any given radius (left ventricular size), the greater the pressure developed by the left ventricle, the greater the wall stress. An increase in wall stress achieved by either of these two mechanisms (left ventricular size or intraventricular pressure) will increase myocardial oxygen uptake. This is because a greater rate of ATP use is required, as the myofibrils develop greater tension. (For more details and formulae for circumferential and meridional wall stress, see Chapter 15.)

In cardiac hypertrophy, Laplace's law explains the effects of changes in wall thickness on wall stress (see Fig. 14-26) . The increased wall thickness due to hypertrophy balances the increased pressure, and the wall stress remains unchanged during the phase of compensatory hypertrophy. In congestive heart failure, the heart dilates so that the increased radius elevates wall stress. Furthermore, because ejection of blood is inadequate, the radius stays too large throughout the contractile cycle, and both end-diastolic and end-systolic tensions are higher.

WALL STRESS, PRELOAD, AND AFTERLOAD.

Preload can now be defined more exactly as the wall stress at the end of diastole and therefore at the maximal resting length of the sarcomere (see Fig. 14-25) . Measurement of wall stress in vivo is difficult because the radius of the left ventricle (see preceding sections) neglects the confounding influence of the complex anatomy of the left ventricle. Surrogate measurements of the indices of preload include left ventricular end-diastolic pressure or dimensions (the latter being

Figure 14-26 Wall stress increases as the afterload increases. The formula shown is derived from Laplace's law. The increased left ventricular pressure in aortic stenosis is compensated for by left ventricular wall hypertrophy, which decreases the denominator on the right side of the equation. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

the major and minor axes of the heart in a two-dimensional echocardiographic view). The *afterload*, being the load on the contracting myocardium, is also the wall stress during left ventricular ejection. When afterload is elevated, an increased intraventricular pressure has to be generated first to open the aortic valve and then during the ejection phase. These increases translate into an increased myocardial wall stress, which can be measured either as an average value during systole or at end systole. *End-systolic wall stress* reflects the three major components of the afterload, namely, the peripheral resistance, the arterial compliance, and the peak intraventricular pressure. Decreased arterial compliance and increased afterload can be anticipated when there is aortic dilation, as in severe systemic hypertension or aortic stiffening in the elderly. Generally, in clinical practice, it is a sufficient approximation to take the systolic blood pressure as an indirect measure of the afterload (reflecting both peripheral resistance and peak intraventricular pressure), provided there is no significant aortic stenosis nor change in arterial compliance.

Aortic impedance (= arterial input impedance) gives another accurate measure of the afterload. The aortic impedance is the aortic pressure divided by the aortic flow at that instant, so that this index of the afterload varies at each stage of the contraction cycle. Factors reducing aortic flow, such as a high arterial blood pressure or aortic stenosis or loss of aortic compliance, will increase impedance and hence the afterload. During systole, when the aortic valve is open, an increased afterload is reflected by increasing ventricular wall stress. In left ventricular failure, aortic impedance is augmented not only by peripheral vasoconstriction but also by decreases in aortic compliance.[140] The problem with the clinical measurement of aortic impedance is that invasive instrumentation is required. An approximation can be found by using transesophageal echocardiography to determine aortic blood flow at, for example, the time of maximal increase of aortic flow just after aortic valve opening.

Heart Rate and Force-Frequency Relation

TREPPE OR BOWDITCH EFFECT.

An increased heart rate progressively enhances the force of ventricular contraction, even in an isolated papillary muscle preparation (Bowditch staircase phenomenon). Alternative names are the *treppe* (steps, German) phenomenon or positive inotropic effect of activation or force-frequency relationship (Figs. 14-27 and 14-28) (Figure Not Available) . Conversely, a decreased heart rate has a negative staircase effect. When stimulation becomes too rapid, force decreases.[141] The proposal is that during rapid stimulation, more sodium and calcium ions enter the myocardial cell than can be handled by the sodium pump and the mechanisms for calcium exit. Opposing the force-frequency effect is the negative contractile influence of the decreased duration of ventricular filling at high heart rates. The longer the filling interval, the better the ventricular filling and the stronger the subsequent contraction. This phenomenon can be shown in patients with atrial fibrillation with a variable filling interval.

Post-extrasystolic potentiation and the inotropic effect of paired pacing can be explained by the same model, again assuming an enhanced contractile state after the prolonged interval between beats. Nonetheless, the exact cellular mechanism remains to be clarified.[142]

FORCE-FREQUENCY RELATIONSHIP IN HUMANS.

Muscle strips prepared from patients with mitral regurgitation behave very differently from normal muscle in response to an increased stimulation of frequency (see Fig. 14-28). (Figure Not Available) Normally, peak contractile force at a fixed muscle length (isometric contraction) is reached at 150 to 180 stimuli/min.[141] This is the human counterpart of the treppe phenomenon.

Figure 14-27 The Bowditch or *treppe* phenomenon, whereby a faster stimulation rate (bottom panel) increases the force of contraction (top panel). The stimulus rate is shown as the action potential duration on an analog analyzer in milliseconds (ms). The tension developed by papillary muscle contraction is shown in milliNewtons (mN) in the top panel. On cessation of rapid stimulation, the contraction force gradually declines. Hypothetically, the explanation for the increased contraction during the increased stimulation is repetitive Ca^{2+} entry with each depolarization and, hence, an accumulation of cytosolic calcium. (From Noble MIM: Excitation-contraction coupling. *In* Drake-Holland AJ, Noble MIM [eds]: Cardiac Metabolism. Chichester, John Wiley, 1983, pp 49-71.)

In severe mitral regurgitation there is hardly any response to an increased stimulation frequency. In muscle strips from normal hearts, optimal force development was reached at rates of about 120-150 beats/minute,[143] whereas in patients with cardiomyopathy, an increased heart rate produced a decreased twitch tension. In addition, in tissue from severely diseased hearts, the diastolic tension may rise markedly with the stimulation frequency,[144] suggesting that there is an excess of cytosolic calcium with deficient uptake into the sarcoplasmic reticulum.

OPTIMAL HEART RATE IN SITU.

In situ, the optimal heart rate is not only the rate that would give maximal mechanical performance of an isolated muscle strip but is also determined by the need for adequate time for diastolic filling. In normal humans, it is not possible to attach exact values to the heart rate required to decrease rather than to increase cardiac output or to keep it steady. Pacing rates of

Figure 14-28 (Figure Not Available) Force-frequency relationship in humans, comparing nonfailing controls with failing mitral regurgitation hearts. Plots of average steady-state isometric twitch tension versus stimulation frequency. Each point represents the mean ± SEM of eight control or mitral regurgitation preparations at 37°C. (Data from Mulieri LA, et al: Myocardial force-frequency defect in mitral regurgitation heart failure is reversed by forskolin. Circulation 88:2700-2704, 1993. Copyright 1993, American Heart Association.)

up to 150 beats/min can be tolerated, whereas higher rates cannot because of the development of atrioventricular block. In contrast, during exercise, indices of left ventricular function still increase up to a maximum heart rate of about 170 beats/min, presumably because of enhanced contractility and peripheral vasodilation.[145] In patients with severe left ventricular hypertrophy, the critical heart rate is between 100 and 130 beats/min, with a fall-off in left ventricular function at higher rates.[144] [146]

Myocardial Oxygen Uptake (See also Chap. 34)

The myocardial oxygen demand can be increased by heart rate, preload, or afterload (Fig. 14-29) , factors that can all precipitate myocardial ischemia in the presence of coronary artery disease. The oxygen uptake can be augmented by increased contractility, as during beta-adrenergic stimulation. Because myocardial oxygen uptake ultimately reflects the rate of mitochondrial metabolism and of ATP production, any increase of ATP requirement will be reflected in an increased oxygen uptake. In general, factors increasing

Figure 14-29 Major determinants of the oxygen demand of the normal heart are heart rate, wall stress, and contractility. For use of pressure-volume area as index of oxygen uptake, see Figure 14-31. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

wall stress increase the oxygen uptake. An increased afterload causes an increased systolic wall stress which needs a greater oxygen uptake. An increased diastolic wall stress, resulting from an increased preload, will also require more oxygen because the greater stroke volume must be ejected against the afterload. In states of enhanced contractility, the rate of change of wall stress is increased. Thus, thinking in terms of wall stress provides a comprehensive approach to the problem of myocardial oxygen uptake. Because the systolic blood pressure is an important determinant of the afterload, a practical index of the oxygen uptake is systolic blood pressure times heart rate, the *double-product*. In addition, there may be a metabolic component to the oxygen uptake that is usually small but may be prominent in certain special conditions, such as the "oxygen wastage" found during abnormally high circulating free fatty acid values. The concept of wall stress in relation to oxygen uptake also explains why heart size is such an important determinant of the myocardial oxygen uptake (because the larger radius increases wall stress).

WORK OF THE HEART.

External work is done when a mass is lifted a certain distance. In terms of the heart, the cardiac output is the mass moved and the resistance against which it is moved is the blood pressure. Because volume work needs less oxygen than pressure work, it might be supposed that external work is not an important determinant of the myocardial oxygen uptake. Yet, however, three determinants of the myocardial oxygen uptake are involved: preload (because this helps determine the stroke volume), afterload (in part determined by the blood pressure), and heart rate, as can be seen from the following formula:

where SBP=systolic blood pressure and SV=stroke volume. Thus, it is not surprising that heart work is related to oxygen uptake. The *pressure-work index* takes into account both the double-product (SBP×HR) and the HR×stroke volume, that is, cardiac output. The *pressure-volume area* is another index of myocardial oxygen uptake, requiring invasive monitoring for accurate measurements. External cardiac work can account for up to 40 percent of the total myocardial oxygen uptake.

In strict terms, the work performed needs to take into account not only pressure but also kinetic components. The latter is the component required to move the blood against the afterload. Normally, kinetic work is less than 1 percent of the total. In aortic stenosis, kinetic work increases sharply as the cross-sectional area of the aortic valve narrows, whereas pressure work increases as the gradient across the aortic valve rises. Currently, noninvasive measures of peak power production are being assessed as indices of cardiac contractility.

Efficiency of work is the relation between the work performed and the myocardial oxygen uptake. Exercise increases the efficiency of external work, an improvement that offsets any metabolic cost of the increased contractility.[147] Heart failure decreases the efficiency of work (Fig. 14-30) . Certain pharmacological agents, such as dobutamine, also improve efficiency in the failing heart.[148] The subcellular basis for changes in efficiency of work are not fully understood. Because as little as 12 to 14 percent of the oxygen uptake may be converted to external work,[147] it is probably the "internal work" that becomes less demanding. Internal ion fluxes (Na^+ /K^+ /Ca^{2+}) account for 20 to 30 percent of the ATP requirement of the heart, so that most ATP is spent on actin-myosin interaction, and much of that on generation of heat rather than on external work. An increased initial muscle length is known to sensitize the contractile apparatus to calcium, thereby theoretically increasing the efficiency of contraction by diminishing the amount of calcium flux required.

Figure 14-30 Marked increase in diastolic tension during pacing of muscle strip from advanced human heart failure. Note, in bottom panel, the increased myocardial oxygen uptake (MVO_2) with increased force (measured as the force-time integral). The combination of decreased cardiac force development and increased oxygen uptake indicates decreased efficiency of cardiac work. (Modified from Meyer M, Keweloh B, Guth K, et al: Frequency-dependence of myocardial energetics in failing human myocardium as quantified by a new method for the measurement of oxygen consumption in muscle strip preparations. J Mol Cell Cardiol 30:1459-1470, 1998.)

Can Contractility Be Measured?

FORCE-VELOCITY RELATIONSHIP AND MAXIMUM CONTRACTILITY IN MUSCLE MODELS.

If contractility is truly independent of the load and the heart rate, then unloaded heart muscle stimulated at a fixed rate should have a maximum value of contractility for any given magnitude of the cytosolic calcium transient. This value, the V_{max} of muscle contraction, is defined as the *maximal velocity of contraction* when there is no load on the isolated muscle or no afterload to prevent maximal rates of cardiac ejection. Beta-adrenergic stimulation increases V_{max} , and converse changes are found in the failing myocardium. The problem with this relatively simple concept is that V_{max} cannot be measured directly but is extrapolated from the peak rates of force development in unloaded muscle obtained from the intercept on the velocity axis.[149] In another extreme condition, there is no muscle shortening at all (zero shortening), and all the energy goes into development of pressure (P_o) or force (F_o). This situation is an example of *isometric shortening* (*iso,* "the same"; *metric,* "length"). Because the peak velocity is obtained at zero load when there is no external force development, the relationship is usually termed the *force-velocity relationship*.

The concept of V_{max} has been subject to much debate over many years chiefly because of the technical difficulties in obtaining truly unloaded conditions. Braunwald and associates[150] used cat papillary muscle to define a hyperbolic force-velocity curve, with V_{max} relatively independent of the initial muscle length but increased by the addition of norepinephrine. Another preparation used to examine force-velocity relations uses single cardiac myocytes isolated by enzymatic digestion of the rat myocardium and then permeabilized with a staphylococcal toxin. Again, the force-velocity relation is hyperbolic, suggesting the existence of

intracellular *passive elastic elements* that contribute to the load on the isolated myocyte.[151] In fact, the more hyperbolic and increased curvilinear nature of the force-velocity relationship in isolated myocytes than in the papillary muscle suggests that internal passive forces such as those generated by titin (see Fig. 14-4) are greater than expected in the isolated myocytes. In the intact heart, the noncontractile components contribute relatively little to overall mechanical behavior, at least in physiological circumstances.[152] Both data from papillary muscle and from isolated sarcomeres suggest that in unloaded conditions the intrinsic contractility as assessed by V_{max} does not change with initial fiber or sarcomere length.

MECHANISM OF BETA-ADRENERGIC EFFECTS ON FORCE-VELOCITY RELATIONSHIP.

The data on papillary muscles showing that norepinephrine can increase V_{max} could be explained either by an effect of beta-adrenergic stimulation on enhancing calcium ion entry or a direct effect on the contractile proteins, or both. Strang and coworkers[153] showed that either isoproterenol (alpha-beta agonist) or protein kinase A (intracellular messenger) increased V_{max} by about 40 percent, concurrently with phosphorylation of troponin I and of C protein in an isolated ventricular myocyte preparation. The overall concept would be that beta-adrenergic stimulation mediates the major component of its inotropic effect through increasing the cytosolic calcium transient and the factors controlling it, such as the rate of entry of calcium ions through the sarcolemmal L-type channels, the rate of calcium uptake under the influence of phospholamban into the SR, and the rate of calcium release from the ryanodine receptor in response to calcium entry in association with depolarization. Of all these factors, phosphorylation of phospholamban may be the most important (see p. 453).

ISOMETRIC VERSUS ISOTONIC CONTRACTION.

Despite the similarities in the force-velocity patterns between the data obtained on papillary muscle and isolated myocytes, it should be considered that a number of different types of muscular contraction may be involved. For example, data for P_o are obtained under isometric conditions (length unchanged). When muscle is allowed to shorten against a steady load, the conditions are *isotonic* (*iso,* "same"; *tonic,* "contractile force"). Yet measurements of V_{max} have to be under totally unloaded conditions both in papillary muscles and in permeabilized myocytes.[149] Thus, the force-velocity curve may be generated by a combination of initial isometric conditions followed by isotonic contraction and then followed by abrupt and total unloading to measure V_{max} . Although an approximation of isometric conditions can be found in the whole heart during the phase of isovolumic contraction, isotonic conditions cannot prevail because the load is constantly changing during the ejection period, and complete unloading is impossible. Therefore, the application of force-velocity relations to the heart in vivo is limited.

PRESSURE-VOLUME LOOPS.

Measurements of pressure-volume loops are among the best of the current approaches to the assessment of the contractile behavior of the intact heart (see Fig. 15-2, p. 480). Major criticisms arise when it is assumed that E_s , the slope of the pressure-volume relationship (Fig. 14-31) , is necessarily linear (it may be curvilinear) or when E_s is used as an index of "absolute" contractility. Also in clinical practice, the need to change the loading conditions and the requirement for invasive monitoring lessen the usefulness of this index. Invasive measurements of the left ventricular pressure are required for the full loop, which is an indirect measure of the Starling relationship between the force (as measured by the pressure) and the muscle length (measured indirectly by the volume). During a positive inotropic intervention, the pressure-volume loop reflects a smaller end-systolic volume and a higher end-systolic pressure, so that the slope of the pressure-volume

Figure 14-31 Pressure-volume loop of left ventricle. Note the effects of beta-adrenergic catecholamines with both positive inotropic (increased slope of line E_s) and increased lusitropic (relaxant) effects. E_s =slope of pressure-volume relationship. The total pressure-volume area (for control area, see *abcd*) is closely related to the myocardial oxygen uptake. (Modified from Opie LH: The Heart,

Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

relationship (E_s) has moved upward and to the left (see Fig. 14-31) . When the positive inotropic intervention is by beta-adrenergic stimulation, then enhanced relaxation (lusitropic effect) results in a lower pressure-volume curve during ventricular filling than in controls.

CONTRACTILITY: THEORY VERSUS PRACTICE.

Despite all the precautions that can be adopted to measure true contractility in isolated preparations, the practical application needs careful appraisal of the heart rate and the loading conditions, which should ideally be unchanged. Yet these can alter cytosolic calcium, as would a primary change in contractility. An increased heart rate, acting through the sodium pump lag mechanism, gives rise to an increased cytosolic calcium that is thought to explain the Treppe phenomenon. An increased preload involves increased fiber stretch, which in turn causes length-activation, explicable by sensitization of the contractile proteins to the prevailing cytosolic calcium concentration. An increased afterload may increase cytosolic calcium through stretch-sensitive channels. Thus, at the cellular level there is a clear overlap between contractility, which should be independent of load or heart rate, and the effects of load and heart rate. Hence, changes in the inotropic state as well as in the load and/or heart rate may all converge on the cytosolic calcium as the final messenger to the contractile proteins. A clinical example of this dilemma is in humans with atrial fibrillation and a constantly varying force-frequency relationship. Contractility, as measured in situ by pressure-volume loops, constantly changes from beat to beat, and the explanation could be either a "true" change in contractility or the operation of the Frank-Starling mechanism due to varying diastolic filling times.[154]

In clinical terms, it does nonetheless remain highly desirable to separate as far as possible the effects of a primary increase of load or heart rate from a primary increase in contractility. To apply the contractility concept to humans one needs to overcome the problem of obtaining a noninvasive index that is practical to measure and relatively free of the many assumptions that must be made about the loading conditions. The following chapter describes the techniques that can be used to estimate contractility in humans.

Ventricular Relaxation and Diastolic Dysfunction

Among the many complex cellular factors influencing relaxation, four are of chief interest (Fig. 14-32). First, the cytosolic calcium level must fall to cause the relaxation phase, a process requiring ATP and phosphorylation of phospholamban for uptake of calcium into the SR (Fig. 14-33). Second, the inherent viscoelastic properties of the myocardium are of importance. In the hypertrophied heart, because of changes in these properties, relaxation occurs more slowly. Third, increased phosphorylation of troponin I enhances the rate of relaxation.[155] Fourth, the rate of relaxation varies directly with the systolic load. The history of contraction affects cross-bridge relaxation.[156] Within limits, the greater the systolic load, the faster the rate of relaxation. This complex relationship has been explored in detail by Brutsaert and coworkers,[136] but it could perhaps be simplified as follows. When the workload is high, peak cytosolic calcium is also thought to be high. A high end-systolic cytosolic calcium means that the rate of fall of calcium also can be greater, provided that the uptake mechanisms are functioning effectively. In this way the systolic pressure load and the rate of diastolic relaxation can be related. Furthermore, a greater muscle length (when the workload is high) at the end of systole should produce a more rapid rate of relaxation by the opposite of length-dependent sensitization, so that there is a more marked response to the rate of decline of calcium in early diastole. Yet, when the systolic load exceeds a certain limit, then the rate of relaxation is delayed,[156] perhaps because of too great a mechanical stress on the individual cross bridges. Thus, in congestive heart failure caused by an excess systolic load, relaxation becomes increasingly afterload dependent, so that therapeutic reduction of the systolic load should improve left ventricular relaxation.[157]

IMPAIRED RELAXATION AND CYTOSOLIC CALCIUM.

This chapter has used the *clinical* definition of diastole according to which diastole extends from aortic valve closure to the start of the first heart sound. The first phase of diastole is the isovolumic phase, which, by definition, does not contribute to ventricular filling. The second phase of rapid filling provides most of ventricular filling. The third phase of slow filling or diastasis accounts for only 5 percent of the total filling. The final atrial booster phase accounts for the remaining 15 percent.

Isovolumic relaxation is energy dependent, requiring ATP for the uptake of calcium ions by the SR (Fig. 14-32) , which is an active, not a passive, process. Impaired relaxation is an early event in the presence of myocardial ischemia. A proposed metabolic explanation is that there is impaired generation of energy, which diminishes the supply of ATP required for the early diastolic uptake of calcium by the SR. The result is that the cytosolic calcium level, which reaches a peak in systole, delays its return to normal in the early diastolic period. In other conditions, too, there is a relationship between the rate of diastolic decay of the calcium transient and diastolic relaxation, with a relation to impaired function of the SR.[158] When the rate of relaxation is prolonged by hypothyroidism, the rate of return of the systolic calcium elevation is likewise delayed, whereas opposite changes occur in hyperthyroidism. In congestive heart failure, diastolic relaxation also is delayed and irregular, as is the rate of decay of the cytosolic calcium elevation. Most patients with coronary artery disease have a variety of abnormalities of diastolic filling. Theoretically, such abnormalities of relaxation are potentially reversible because they depend on changes in patterns of calcium ion movement. Indices of the isovolumic phase and other indices of diastolic function are shown in Table 14-5 .

Figure 14-32 Factors governing the isovolumic relaxation phase of the cardiac cycle (see Fig. 14-22) . This period of the cycle extends from the aortic second sound (A_2) to the crossover point between the left ventricular and left atrial pressures. The maximum negative rate of pressure development ($-dP/dt_{max}$), which gives the isovolumic relaxation rate, is measured either invasively or by a continuous wave Doppler velocity spectrum in aortic regurgitation. Isovolumic relaxation is increased (+ sign) when the rate of calcium uptake into the sarcoplasmic reticulum (SR) is enhanced, for example during beta-adrenergic stimulation (see Fig. 14-16). Isovolumic relaxation may also be enhanced when phosphorylation of troponin I (TnI), as in response to beta-adrenergic stimulation, may decrease the affinity of the contractile system for calcium. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation, Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

IS THERE LEFT VENTRICULAR SUCTION DURING EARLY FILLING?

A left ventricular suction effect can be found by carefully comparing left atrial and left ventricular pressures, and it occurs especially in the early diastolic phase of rapid filling. The sucking effect may be of most importance in mitral stenosis when the mitral valve does not open as it otherwise should in response to diastolic suction. During catecholamine stimulation, the rate of relaxation may increase to enhance the sucking effect and to prolong the period of filling. The proposed mechanism of sucking is as follows. When the end-systolic volume is less than the equilibrium volume, the shortened muscle fibers and collagen matrix may act as a compressed spring to generate recoil forces in diastole.

TABLE 14-5 -- SOME INDICES OF DIASTOLIC FUNCTION

Diastasis
Pressure-volume relation indicates compliance
Atrial Contraction
Invasive measurement of atrial and ventricular pressures
Doppler transmitral pattern (E to A ratio)

ERNA=equilibrated radionuclide angiography; E=early filling phase, A=atrial contraction phase.

MEASUREMENT OF ISOVOLUMIC RELAXATION.

The rate of isovolumic relaxation can be measured by negative dP/dt_{max} at invasive catheterization. *Tau*, the time constant of relaxation, describes the rate of fall of left ventricular pressure during isovolumic relaxation and also requires invasive techniques for precise determination.[160] Tau is increased as the systolic left ventricular pressure rises.[156] Another index of relaxation can be obtained echocardiographically from the peak rate of wall thinning. The isovolumic relaxation time lies between aortic valve closure and mitral valve opening measured by signals of valve movements taken by Doppler echocardiography. In mitral regurgitation, the Doppler velocity profile can be used to calculate tau.[160] In each case, precise measurement is difficult and the range of normality is large.

ATRIAL FUNCTION.

The left atrium, besides its well-known function as a blood-receiving chamber, also acts as follows. First, by presystolic contraction and its function as a booster pump, it helps to complete left ventricular filling.[78] Second, it is the volume sensor of the heart, releasing atrial natriuretic peptide (ANP) in response to intermittent stretch and several other stimuli, including angiotensin II[161] and endothelin.[162] Third, the atrium contains receptors for the afferent arms of various reflexes, including mechanoreceptors that increase sinus discharge rate, thereby contributing to the tachycardia of exercise as the venous return increases *(Bainbridge reflex)*.

The atria have a number of differences in structure and function from the ventricles, having smaller myocytes with a shorter action potential duration as well as a more fetal type of myosin (both in heavy and light chains). Furthermore, the atria are more reliant on the phosphatidylinositol signal transduction pathway,[163] which may explain the relatively greater positive inotropic effect in the atria than in the ventricles in response to angiotensin II.[164] The more rapid atrial repolarization is thought to be due to increased outward potassium currents, such as I_{to} and I_{kACh} .[165] [166] In addition, some atrial cells have the capacity for spontaneous depolarization. In general, these histological and physiological changes can be related to the decreased need for the atria to generate high intrachamber pressures, rather being sensitive to volume changes, while retaining enough contractile action to help with left ventricular filling and to respond to inotropic stimuli.[78]

DIASTOLIC DYSFUNCTION AND MYOCARDIAL MECHANICAL PROPERTIES.

In hypertrophied hearts, as in chronic hypertension or severe aortic stenosis,[167] abnormalities of diastole are common and may precede systolic failure. Impaired relaxation is associated with an increase of the late (atrial) filling phase, and the E/A ratios on the mitral Doppler pattern decline (see Fig. 15-21 (Figure Not Available) , p. 496).[168]

The assessment of diastolic dysfunction is discussed in Chapter 15 .

EFFECTS OF ISCHEMIA AND REPERFUSION ON CONTRACTION AND RELAXATION

Contractile Impairment in Ischemia

HIGH-ENERGY PHOSPHATES.

Despite experimental differences, there is now widespread agreement that early contractile failure during ischemia (Fig. 14-33) can occur even when calcium transients are normal or near normal[169] [170] ; and, therefore, a metabolic cause must be sought. The latter could be either decreased sensitivity of the contractile proteins to calcium, as may be caused by acidosis, or inhibition of the cross-bridge cycle, as may be caused by the early rise in P_i . As creatine phosphate (CP) falls, the activity of the CP shuttle decreases so that "local" ATP, required for calcium movements in the contractile cycle, falls.[171] In addition, the free energy of hydrolysis of ATP decreases during ischemia.[172] The large increase in P_i , as a result of CP breakdown, decreases free energy of hydrolysis, as do the smaller decreases in ATP and increases in ADP. The fall in CP can also indirectly inhibit contractility through the accumulation of P_i , which decreases the contractile effects of any given concentration of cytosolic calcium. P_i may act by promotion of formation of weak rather than strong cross bridges.

Accumulation of neutral lactate during ischemia can promote mitochondrial damage, decrease the action potential duration, and inhibit glyceraldehyde-3-phosphate dehydrogenase. The mechanism of these lactate effects is not clear and may include extracellular acidosis with Na^+/H^+ exchange, a subsequent gain in cell Na^+ , and then Na^+/Ca^{2+} exchange with gain of harmful Ca^{2+} .

Segmental dyskinesia during ischemia may be explained by the

Figure 14-33 Can left ventricular (LV) mechanical failure during severe ischemia be explained by changes in the cytosolic calcium? These data show that when there is abrupt ischemic LV failure (LV pressure falls to zero in *C*), the calcium signal *(A)* increases before it falls. Ischemia is designated by the abrupt fall of coronary perfusion pressure to zero in this isolated rat heart preparation. During reperfusion there is also a dissociation between the cytosolic calcium oscillations, which are augmented (right hand panel of *A*) in contrast to LV contraction, which is decreased (right hand aspect of bottom panel), so that there is mechanical stunning. It is thought that excess calcium oscillations damage the contractile proteins (see Fig. 14-34) . (From Meisner A, Morgan JP: Contractile dysfunction and abnormal Ca^{2+} modulation during postischemic reperfusion in rat heart. Am J Physiol 268:H100-H111, 1995.)

effects of repetitive stretch on the poorly contractile ischemic segments, which then lose even more contractual activity.[173]

Potassium efflux. The mechanism of early potassium efflux in ischemia is not well understood, and there are three major theories. First, the ATP-inhibited potassium channel (K_{ATP}) may open as a result of cytosolic ATP deficiency. [174] Potassium channels such as those activated by sodium or by fatty acids may play a role. Second, inhibition of the sodium-potassium pump has long been suspected, but the onset of such inhibition is likely too late to explain early potassium egress, although probably contributing to the later phase of potassium loss. Third, co-ionic loss of potassium with negatively charged lactate and phosphate ions has often been proposed but the evidence for this is scanty.[175] The importance of potassium loss is that because the action potential duration is shortened, calcium influx may be diminished.[29]

Adenosine is formed during ischemia from the breakdown of ATP. It is potentially recyclable as a building block of ATP during resynthesis. Besides being the probable origin of the ischemic anginal pain,[176] adenosine has complex cardioprotective qualities. In response to stimulation of the A_1 receptor, [114] adenosine increases the inhibitory G protein (G_i), which, in turn, lessens the activity of adenylate cyclase and increases the opening probability of two types of potassium channels. The consequences include negative inotropic, chronotropic, and dromotropic effects, as well as coronary vasodilation. Adenosine may also play an important role in preconditioning.[177]

ISCHEMIC CONTRACTURE.

After 5 to 20 minutes of severe ischemia but depending on variable metabolic circumstances, including the cardiac glycogen reserve,[178] there is the gradual onset of ischemic contracture with a rise in diastolic pressure virtually without systolic activity. In general, even complete reperfusion never fully relieves ischemic contracture. The mechanisms for contracture include ATP depletion and a rise in cytosolic calcium (Fig. 14-33) . Of interest is the proposal that continued glycolysis and production of glycolytic ATP has a role in the maintenance of intracellular calcium homeostasis, probably acting indirectly by maintaining activity of the sodium pump.[179] As glycolysis is inhibited, diastolic tension increases.

New Ischemic Syndromes

The myocardium is now known to have a very diverse and flexible response to ischemia, varying from rapid contractile arrest to delayed stimulation of potentially protective synthetic pathways involving signals similar to those inducing growth. Three specific new entities recently identified constitute the *new ischemic syndromes,* namely, preconditioning, hibernation, and stunning.[180] All three have in common that they are differing responses to ischemia and reperfusion. Ischemic-reperfusion injury (Fig. 14-34) is a well-recognized experimental entity, varying from reversible damage with mild transient ischemia to irreversible cell death with severe ischemia

followed by reperfusion. Adverse effects associated with reperfusion include arrhythmias, mechanical dysfunction, degradation of contractile proteins such as troponin I, and apoptosis.[181] It has been proposed that these adverse effects are to some extent self-limited by *a repertoire of myocardial protective events resulting from activation of a variety of signaling and metabolic pathways.* At least some of these events appear to be triggered by reperfusion, whereas others result from the ischemic phase (Fig. 14-35) .

INTERMITTENT ISCHEMIA AND PRECONDITIONING.

Whereas many repetitive episodes of ischemia should produce cumulative damage, relatively few episodes or even one burst of short-lived severe ischemia followed by complete reperfusion causes preconditioning, the condition in which the myocardium is protected against a greater subsequent ischemic insult, with less threat of infarction. The overall pathways involved are complex, starting with an

Figure 14-34 The two major mechanisms causing ischemic reperfusion damage are oxygen-derived free radicals and calcium overload, probably with interactive effects. The end result shown here is a relative insensitivity of the contractile protein, troponin C (C) to calcium released from the sarcoplasmic-reticulum (SR). For role of proteolysis of troponin-I (Tn-I), see the article by Bolli and Marban.[200] (Reprinted with permission. Figure copyright © 2001 L. H. Opie.)

agonist acting on a heptahelical receptor and leading by means of PKC to activation of the MAP kinase complex (Fig. 14-36). (Figure Not Available) The latter may then lead to either (1) opening of the mitochondrial ATP-sensitive potassium channel (K_{ATP}) now thought to mediate short-term preconditioning[182] or to (2) nuclear synthesis of new growth factors and other protective proteins, including iNOS, which may explain delayed preconditioning ("second-window of protection").[183] [184] Although preconditioning can be triggered by a wide variety of events and even pharmacological stimuli, adenosine is the single agonist most consistently linked to this phenomenon. Adenosine formed during the ischemic period results in two crucial events: one is activation of PKC, which then (through unknown signals) is linked to the second major event, namely, opening of the mitochondrial K_{ATP} channel (see Fig. 14-36) (Figure Not Available) . [182] [185] The latter channel may also mediate delayed preconditioning in response to adenosine.[186]

An alternate mechanism for preconditioning is upregulation of G_i (see Fig. 14-36) (Figure Not Available) . Activation of the heptahelical receptors coupled to it, such as adenosine A_1 , muscarinic M_2 , and opioid receptors, leads to greater inhibition of adenylate cyclase and hence to an indirect antiadrenergic effect.[187] A third proposal is that ischemia activates the beta-adrenergic pathway, with receptor desensitization and attenuated accumulation of cyclic AMP during the repeat ischemia.[188] These proposals are not necessarily mutually exclusive, because of extensive postreceptor *cross talk* between the signaling pathways and because more than one pathway may be stimulated simultaneously. Preconditioning probably has clinical implications, because patients with preinfarction angina may suffer from a less severe infarct than those thought to undergo sudden coronary occlusion without the opportunity for preconditioning.[189] [190]

Figure 14-35 Two possible additive components of postischemic dysfunction: (1) reperfusion-induced pathology, which can be restored through the use of a therapeutic intervention such as an antioxidant or calcium-limiting agent given transiently at the time of reperfusion; and (2) ischemic pathology from which the heart is slowly recovering. These may be additive to each other and to any additional reperfusion-induced component that is not amenable to the chosen intervention. (Modified from Hearse DJ: Stunning: A radical review. Cardiovasc Drugs Ther 5:853-876, 1991.)

Stunning (See also Chap. 34)

The first observation was that the recovery of mechanical function after transient coronary occlusion was not instant but delayed (see Fig. 14-35) . Thereafter, Braunwald and Kloner[199] defined "the stunned myocardium" as one characterized by prolonged postischemic myocardial dysfunction with eventual return of normal contractile activity. Stunning is now thought to occur in several clinical situations,[200] including delayed recovery from effort angina, unstable angina, early thrombolytic reperfusion, ischemic cardioplegia, cardiac transplantation, cardiac arrest, and coronary angioplasty. Interactive mechanisms thought to be responsible for stunning are an increased cytosolic calcium and the formation of oxygen-derived free radicals on reperfusion.[200] [201]

INCREASED CYTOSOLIC CALCIUM DURING EARLY REPERFUSION.

An excess cytosolic calcium is present in prolonged severe ischemia,[170] and restoration of energy with reperfusion will induce excess oscillations of calcium. Second, opening of the voltage-sensitive calcium channels during early reperfusion may also be important.[202] Third, release of Ca^{2+} from the SR is also likely, probably in response to free radicals.[200] [203] Fourth, calcium may enter the reperfused cells through the process of Na^+ /Ca^{2+} exchange, consequent on Na^+ /H^+ exchange.[202] [204] The latter exchanger may be directly activated by free radicals[205] or by endothelin released during reperfusion, acting on the ET_A receptors.[206] It may be predicted that all agents stimulating the phosphatidylinositol cycle and increasing IP_3 at the time of reperfusion should worsen stunning.[102] These include angiotensin II, endothelin,[207] and alpha$_1$ -adrenergic stimulation.[37] The myocardial angiotensin I receptor is upregulated after ischemia-reperfusion. When the receptor mRNA is inhibited by antisense nucleotides, then stunning is lessened.[208] Increased calcium transients may also explain reperfusion arrhythmias.[201] [209] Decreased systolic force generation may be linked to activation of proteases that partially digest troponin I and other contractile proteins.[200]

OXYGEN-DERIVED FREE RADICALS.

Substantial evidence shows that reperfusion produces free radicals that

Figure 14-36 (Figure Not Available) Proposed role of protein kinase C and mitochondrial adenosine triphosphate (ATP)-sensitive potassium channel in ischemic preconditioning (IPC). When ischemia is repeated, there is relative protection. Pharmacological PC by a variety of agents may act on G proteins, including the inhibitory G protein (G_i) and the G protein linked to phospholipase C (G_q , see Fig. 14-19) in mediating effects of preconditioning. The stimulatory G protein (G_s) may also be involved.[188] A_1 =subtype 1 of adenosine receptor; M_2 =subtype 2 of muscarinic receptor; BK=bradykinin; mito-$K_{(ATP)}$ =mitochondrial ATP-dependent potassium current. HSP=heat shock protein. NOS=nitric oxide synthase. (Modified from Opie LH: The Heart, Physiology, from Cell to Circulation. Philadelphia, Lippincott-Raven, 1998. Figure copyright L. H. Opie, © 2001.)

can depress cardiac contraction.[200] Hypothetically, free radicals may either directly depress contraction or do so by excessively increasing cytosolic calcium, for example by stimulating sodium-hydrogen transport with subsequent sodium-calcium exchange.[205] Thus, free radicals interact with calcium ions (see Fig. 14-34) . Other adverse effects of excess free radicals include promotion of apoptosis.[210] Support for the idea that free radicals contribute to stunning comes from the observation that antioxidants improve contractile function. Direct measurements of cytosolic calcium in stunned myocardium show that antioxidants decrease cytosolic calcium levels and increase the force of contraction.[211]

TNF-alpha AND OTHER CYTOKINES.

After ischemia, production of TNF-alpha both by interstitial cells and by human cardiomyocytes increases.[212] TNF-alpha theoretically may promote stunning by several mechanisms: desensitization of the contractile proteins to calcium[124] ; induction of other cardiodepressant agents such as nitric oxide or interleukin-1[212] ; or formation of free radicals.[212]

CHRONIC STUNNING.

Although experimental stunning typically lasts for hours, full mechanical recovery can sometimes take much longer, up to weeks after thrombolysis for acute myocardial infarction. To explain this finding, a current proposal is that there is a condition of late or chronic stunning.[199] [213] Hypothetically, this condition, part of the wide "stunning syndrome,"[200] would represent the end result of the short-term changes in cytosolic calcium and in free radical generation added to long-term changes in cytokines and growth factors. These events could then trigger complex changes in protein synthesis and degradation, to which would be added the physical forces acting on the ventricle that also shape the remodeling process. In patients with early stage myocardial infarction, reperfused by percutaneous transluminal coronary angioplasty, a slow improvement in postinfarct left ventricular function occurs when an angiotensin-converting enzyme inhibitor is combined with a calcium

antagonist.[214] Chronic stunning may be the explanation for some aspects of hibernation (see later). For example, repetitive ischemia precipitated by excitement in pigs with severe coronary stenosis can cause depressed mechanical function even in the absence of any measurable reduction of coronary blood flow at rest.[195]

ATRIAL STUNNING.

After cessation of atrial fibrillation, atrial contractility may be reduced or absent for up to several weeks despite normal electrical activity. Such stunning is clinically relevant, and potentially harmful, because it predisposes to formation of atrial thrombosis with risk of stroke. Calcium overload is the proposed mechanism, because atrial stunning is reduced by verapamil but increased by a calcium channel agonist.[215]

CONCURRENT EVENTS.

Because the human heart with advanced coronary artery disease is known to suffer from intermittent ischemia, ischemic-reperfusion injury and its consequences may all be occurring simultaneously. Thus the same heart may concurrently manifest one or more component of the new ischemic syndromes, namely stunning, hibernation, and preconditioning, as well as ischemic damage. When one episode of severe ischemia is followed by clinical reperfusion, as in thrombolysis, the extent of postischemic dysfunction could be determined by a combination of ischemic and reperfusion pathology, the former depending on the length of time that the myocardium has been ischemic and the latter potentially causing a spectrum of new ischemic syndromes.

Hibernation (See also Chap. 37)

The hibernating myocardium, like the hibernating animal, is temporarily asleep and can wake up to function normally when the blood supply is fully restored (Table 14-6) . Rahimtoola's proposal is that the fall of myocardial function to a lower level copes with the reduced myocardial oxygen supply and leads to self-preservation, so that the myocardium is "exquisitely regulated" and successfully adapted to the prevailing circumstances.[191] This sequence has been shown for acute experimental hibernation, lasting only a few hours, in which there is downgrading of contractile activity that matches the decreased coronary flow.[192] An alternative point of view, gaining ground, is that hibernation can occur even when the resting coronary flow is normal despite the presence of coronary disease. There is, however, firm evidence for an impaired coronary vascular reserve,[193] so that episodes of tachycardia would precipitate ischemia. Such recurrent episodes of ischemia would then leave behind a repetitively stunned myocardium. Thus, chronic hibernation, according to this proposal, is no more than cumulative stunning.[193] [194] [195]

Chronic hibernation in humans seems to be even more complex, without a good animal model. It is the combination of reversibly depressed regional wall motion and severe coronary artery disease (see Chap. 37) . The exact limit of coronary flow that leads to hibernation is not so clearly defined but could be only 70 to 80 percent of normal coronary flow.[196] The hypocontractile segments that still have a sustained glucose extraction, as shown by positron emission tomography, have a high chance of recovery after coronary

TABLE 14-6 -- CHARACTERISTICS OF STUNNING, HIBERNATION, AND ISCHEMIA

PARAMETER	STUNNING	HIBERNATION	TRUE ISCHEMIA
Myocardial mechanical function	Reduced	Reduced	Reduced
Coronary blood flow	Post-ischemic: normal/high	Modestly reduced or low normal; intermittent ischemia-reperfusion	Most severely reduced
Myocardial energy metabolism	Normal or excessive	Reduced or low normal; in steady state with intermittent ischemia-reperfusion	Reduced; increasingly severe as ischemia proceeds
Duration	Hours to days; late stunning over weeks	Days to hours to months	Minutes to hours
Outcome	Full spontaneous recovery	Recovery if revascularized	Myocyte necrosis if severe ischemia persists
Proposed change in metabolic regulation of calcium	Cytosolic overload of calcium in early reperfusion with damage to contractile proteins	Possibly just enough glycolytic ATP to prevent contracture	Insufficient glycolytic ATP to prevent ischemic contracture and irreversibility

ATP=adenosine triphosphate.

Modified from Opie LH: The multifarious spectrum of ischemic left ventricular dysfunction: Relevance of new ischemic syndromes. J Mol Cell Cardiol 28:2403-2414, 1966.

artery bypass surgery. In contrast, those segments with a decreased glucose extraction almost uniformly fail to recover.[197] "Mismatch" refers to the increased glucose extraction of the viable myocardium that can be visibly contrasted to the poor coronary blood flow (ammonia signal on positron emission tomography). In one series, up to 27 percent of patients with ischemic cardiomyopathy could have enough viable segments to benefit by revascularization.[198] Postoperative recovery of contractile function may vary from rapid, within hours or even minutes, to long delays over weeks or even months.[193] Thus, hibernation, like stunning, is a "syndrome."

Chapter 15 - Assessment of Normal and Abnormal Cardiac Function

WILLIAM C. LITTLE

THEORETICAL CONSIDERATIONS

Reasons to Focus on the Left Ventricle

The cardiovascular system supplies the tissues with oxygen and metabolic substrates and removes carbon dioxide and other waste products. This requires the integration of all its components (venous circulation, right side of the heart, lungs and pulmonary vascular system, left side of the heart, arterial circulation, and blood). Most circulatory dysfunction of cardiac origin in adults is due to abnormalities of the left ventricle. Thus, the clinical evaluation of cardiac function predominately concerns the performance of the left ventricle.

Levels of Integration: Myocardium, Pump, Cardiac Output

The performance of the left ventricle as a pump depends on the contraction of the sarcomeres in the myocardium as well as on the organization and configuration of the left ventricular chamber, valvular function, and loading conditions. Ultimately, the interaction of the left ventricle, the other cardiac chambers, and the arterial, pulmonary, and venous circulations results in the cardiac output. Thus, cardiac function can be evaluated at several levels of integration: (1) myocardial function, (2) chamber (usually left ventricular) pump performance, and (3) integrated cardiac output. It is important to recognize at which level of integration cardiac function is being evaluated. For example, changes in cardiac output or the level of left ventricular pump function can result from many factors and do not merely reflect myocardial contractility. Thus, measurement of cardiac output alone provides a limited and insensitive assessment of ventricular function or of myocardial contractility. Furthermore, evaluation of left ventricular pump function alone cannot assess the adequacy of cardiac output or the level of myocardial contractility.

Factors Controlling Myocardial Function (See also Chap. 14)

Myocardial shortening is determined by four factors: (1) preload, (2) afterload, (3) the myocardial contractile state (contractility), and (4) heart rate and cardiac rhythm. Preload is the stretch of the myocardium before stimulation that determines the initial sarcomere length. Within the physiological range, the greater preload the stronger the contraction. Afterload is the load that the myocardium must bear to contract. The higher the afterload, the greater the pressure generated, but the less the amount of shortening. Myocardial contractility reflects the activation, formation, and cycling of the cross bridges between actin and myosin myofilaments. At constant preload and afterload, increased contractility results in a greater extent and velocity of shortening. The final determinants of cardiac function are the heart rate and rhythm. With increasing rate there is an enhancement of contractility under normal conditions (positive force-frequency relation). These factors (preload, afterload contractility, rate, and rhythm) represent a simplification of the fundamental processes because at the level of the sarcomere, load and contractility are interrelated.[1]

Left Ventricle in Pressure-Volume Plane: Transformation of Muscle to Pump Function

The transformation of myocardial function to left ventricular pump function can be understood by plotting the cardiac cycle in the pressure-volume plane.

LEFT VENTRICULAR PRESSURE-VOLUME LOOP.

The relationship between left ventricular pressure and volume in a normal ejecting beat is shown in Figure 15-1 . Contraction of the left ventricular myocardium begins at end diastole. The energy of the contraction is first used to increase ventricular pressure to the level of aortic diastolic pressure without a change in left ventricular volume as the aortic and mitral valves are closed. When left ventricular pressure exceeds aortic pressure, the aortic valve opens. Myocardial fibers shorten as blood is ejected through the open aortic valve, and ventricular volume decreases. After the contraction reaches its peak at end systole, the myocardial fibers begin to relax; and when left ventricular pressure falls below aortic pressure, the aortic valve closes and cardiac ejection stops. Ventricular pressure then declines rapidly as the ventricle relaxes. With opening of the mitral valve, left ventricular filling begins and the left ventricular pressure-volume loop is completed.

When cardiac ejection is prevented in an experimental preparation, peak isovolumetric left ventricular pressure increases as ventricular volume increases, describing a straight line in the physiological range.[2] This is the end-systolic pressure-volume relation (ESPVR). Similarly, the upper left-hand corner of the pressure-volume loops of variably

Figure 15-1 A left ventricular (LV) pressure-volume loop describing one cardiac cycle. At end diastole the mitral valve closes. The left ventricle is a closed chamber because the pressure increases without a change in volume during isovolumetric contraction. When LV pressure exceeds aortic pressure, the aortic valve opens. During LV ejection, LV volume falls. Aortic valve closure occurs near the time of end systole. After aortic valve closure, LV pressure falls without a change in LV until LV pressure falls below left atrial pressure and mitral valve opening occurs. During diastole LV volume increases, completing the cardiac cycle. End systole falls on the LV end-systolic pressure-volume relation (ESPVR). (Redrawn from Little WC, Cheng CP: Left ventricular-arterial coupling in conscious dogs. Am J Physiol 261:H70, 1991.)

loaded beats, denoted as end systole in Figure 15-1 , fall close to isovolumetric ESPVR. The slope of this line, *termed* E_{ES} *,* has units of pressure per volume and denotes the maximum stiffness or elastance of the left ventricle. The slope and position of the ESPVR respond to changes in myocardial contractile state. An increase in contractility increases the slope of the ESPVR, shifting the line toward the left in the physiological range. Conversely, the ESPVR flattens and shifts to the right when there is depressed myocardial contractile function. Thus, the position and slope of the ESPVR can be used to measure the contractile state (see later).

The effects of altering preload, afterload, and contractility on left ventricular performance are readily described in the left ventricular pressure-volume plane. In the intact circulation, alteration of any of these three determinants of left ventricular performance elicits a prompt compensatory response that modifies the other two factors and heart rate. However, it is useful to analyze the effect of a change in each of these variables assuming for illustrative purposes that the other two factors remain constant.

An acute increase in afterload results in a greater proportion of the contraction energy being used to develop pressure so there is less myocardial shortening (Fig. 15-2) . As a result, ventricular emptying is impaired, resulting in a reduced stroke volume and decreased ejection fraction. Thus, increased afterload can decrease left ventricular systolic emptying in the absence of any depression of myocardial contractility (afterload mismatch). If an increase in preload (increased end-diastolic volume) occurs without a change in end-systolic pressure, a larger stroke volume is produced as the ventricle ejects to a similar end-systolic volume. A primary increase in myocardial contractility results in a steeper ESPVR. If preload and afterload remain constant, this results in an increase in stroke volume.

PRESSURE-VOLUME AREA AND MYOCARDIAL OXYGEN CONSUMPTION.

Left ventricular energetics can also be understood in the pressure-volume plane.[3] The area contained within the left ventricular pressure-volume loop is the stroke work (SW) (Fig. 15-3) . This is the external work performed by the ventricle. The remaining area under the ESPVR is the potential energy (PE) produced by the ventricular contraction but not resulting in external work. Myocardial oxygen consumption (MV_{O_2}) is linearly related to the sum of the SW and PE or total pressure-volume area (PVA)[3] [4] [5] [40A] (see Fig. 15-3) (see Chap. 34) . The inverse of the slope of the MV_{O_2} -PVA relation indicates the contractile efficiency. The intercept reflects the energy used for basal metabolism and excitation-contraction coupling.[6] Most positive inotropic interventions shift the MV_{O_2} -PVA relation upward, indicating an increase in these energy demands.

MEASUREMENT OF KEY VARIABLES

Pressures

The intracardiac, arterial, and venous pressures are important variables used in assessing cardiac function. These pressures have been traditionally measured using fluid-filled catheters, but, as described in Chapter 11 and as illustrated in Figure 15-4 , this technique can produce artifacts.[7] Arterial pressure can be obtained noninvasively by sphygmomanometry. Catheters tipped with a micromanometer provide a flat frequency response to above 100 Hz. Thus, a micromanometer can accurately measure cardiac pressures throughout the cardiac cycle. Micromanometers

Figure 15-2 The responses of the left ventricle to increased afterload, increased preload, and increased contractility are shown in the pressure-volume plane. ESPVR=end-systolic pressure-volume relation, E_{ES} =the slope of the end-systolic pressure-volume relation. See text for discussion.

Figure 15-3 *A,* Variably loaded pressure-volume loops generated by transient caval occlusion in a conscious animal. The upper left-hand corners of the loops define the left ventricular (LV) end-systolic pressure-volume relation (ESPVR). *B,* The stroke work (SW) is the area contained within the steady-state pressure-volume loop. The potential energy (PE) is the area under the remaining portion of the ESPVR. The total pressure-volume area (PVA) is the sum of SW and PE. *C,* The myocardial oxygen consumption (MV_{O_2}) is linearly related to the PVA. Inotropic stimulation with dobutamine shifts this relation upward, increasing the oxygen cost of PVA. See text for discussion. (Redrawn from Nozawa T, Cheng CP, Noda T, Little WC: Relation between left ventricular oxygen consumption and pressure-volume area in conscious dogs. Circulation 889:810, 1994. Copyright 1994, American Heart Association.)

are required to measure left ventricular dP/dt and determine the time constant of the isovolumetric decline in left ventricular pressure. Accurate pressure measurement with a micromanometer requires careful attention to calibration, drift, zeroing, and hydrostatic pressure gradients. Recently, Doppler echocardiographic techniques have allowed noninvasive estimation of intracardiac pressures.

NONINVASIVE PRESSURE MEASUREMENT.

Cuff sphygmomanometry (see Chap. 4) accurately measures arterial systolic and diastolic pressures. The combination of computer-controlled cuff inflation gated by the electrogram with Doppler measurements of brachial arterial flow or tonometry of the radial artery provides a quantitative measure of the entire arterial waveform.[7] [8]

Doppler echocardiography (see Chap. 7) can determine the velocity (v) of the systolic regurgitant jet across the tricuspid, mitral, or aortic valves. With the use of the modified Bernoulli equation for steady-state flow ($DeltaP=4v^2$) the pressure gradient (DeltaP) responsible for the regurgitant jet can be calculated. This can be used to estimate the time course of right and left ventricular systolic pressures.[9] [10] [11]

PULMONARY CAPILLARY WEDGE PRESSURE

(See Chap. 11) . Because the pulmonary venous pressure approximates left atrial pressure in most circumstances, the mean pulmonary capillary wedge pressure provides a clinically useful estimate of mean left atrial pressure and the left ventricular filling pressure.

Ventricular Volume

Angiographic techniques, described next, provide the most widely accepted means for measuring ventricular chamber volumes and segmental wall motion. They allow calculation of the extent and velocity of wall shortening and the assessment of regional wall motion. When they are combined with measurements of intraventricular pressure and wall thickness, wall tension and ventricular stiffness can be determined. Although noninvasive techniques are now widely used in the assessment of ventricular dimensions and volumes, their application to the assessment of cardiac function is based on the earlier work using ventricular angiography, which remains a benchmark for these measurements.

QUANTITATIVE ANGIOCARDIOGRAPHY.

The left ventricle is outlined most clearly by direct injection of contrast medium into the ventricular cavity.[12] In patients with severe aortic regurgitation the contrast material may be injected into the aorta, with the resultant reflux outlining the left ventricular cavity. Digital subtraction angiography util

Figure 15-4 Recording of left ventricular pressure from a fluid-filled catheter and a micromanometer catheter. The recording from the fluid-filled catheter is delayed slightly relative to the recording with the micromanometer. During portions of the cardiac cycle when left ventricular pressure is not rapidly changing (diastasis, end diastole, end systole) the pressures recorded through the two systems are nearly identical. When pressure is rapidly increasing or decreasing, the pressure recorded through the fluid-filled catheter initially lags behind the micromanometer pressure and then overshoots. (Recording courtesy of Dr. Che-Ping Cheng, Wake Forest University School of Medicine.)

izing injections into a peripheral vein, pulmonary artery, or left ventricle also may be used to define the left ventricle.

Unless the effects of premature contractions and of the resultant postextrasystolic potentiation are to be examined, ventricular irritability should be avoided during injection of the contrast material. Contact should be avoided between the tip of the catheter and the myocardium, and a multiholed catheter should be used to diminish the impact of the jet of contrast medium striking the endocardium. If premature contractions are induced, the premature contraction itself and the postpremature beats may exhibit changes in cardiac function. The premature ventricular contraction also may induce mitral and/or tricuspid regurgitation. However, because the contrast material usually is injected over 3 or 4 seconds and filming is carried out for 5 to 8 seconds, one or two cardiac cycles usually are available for analysis, even if a single premature contraction occurs at the beginning of the injection.

Injection of the contrast agent does not begin to produce hemodynamic changes (except for premature beats) until several beats after the injection. The hyperosmolarity produced by the contrast agent increases the blood volume, which begins to increase preload and heart rate within 30 seconds of the injection, an

effect that may persist for as long as 2 hours. Conventional contrast agents (so-called ionic agents, such as meglumine diatrizoate) depress contractility directly; however, newer, nonionic agents minimize these adverse effects and may be safer for patients with marked elevations of left ventricular end-diastolic pressures (> 25 mm Hg) or depressed cardiac function.

In calculating ventricular volumes or dimensions from angiograms, it is essential to take into account and apply appropriate correction factors for magnification as well as for distortion resulting from nonparallel x-ray beams (pincushion distortion). To apply these correction factors, care must be exercised to determine with accuracy the tube-to-patient and tube-to-film distances.

THE CONDUCTANCE CATHETER.

The conductance technique provides a method to measure left ventricular volume on line in the cardiac catheterization laboratory avoiding the problems associated with multiple injections of contrast medium.[13] In this technique, a multielectrode catheter is passed across the aortic valve and the tip is advanced to the apex of the left ventricle. An electrical field is generated (20 kHz, 0.03 mA RMS current) in the left ventricle between electrodes positioned at the top of the catheter in the apex and just above the aortic valve. Sensing electrodes that are evenly distributed along the catheter are used to measure the potential produced by the current. From these measurements, the resistance (and its inverse--conductance) between electrode pairs spanning the long axis of the left ventricle are calculated. The conductances from the electrode pairs are summed and converted to volume using a signal conditioner, assuming that all the current flows through blood in the left ventricular chamber.[13] Recently, the conductance catheter has been miniaturized for use in experimental studies of transgenic mice.[14]

NONINVASIVE METHODS.

Cardiac catheterization and quantitative selective angiography are the standard tools for evaluating the function of the heart, but these invasive procedures have some risk and are not suitable for repeated application in the same patient. Therefore, a continuing search has been made for reliable noninvasive methods of assessing cardiac volume. Such methods are needed particularly for detecting serial changes in cardiac function and in evaluating both acute and chronic effects of interventions such as drug therapy and cardiac operations. Discussed elsewhere in this book are the four principal noninvasive methods for assessing cardiac performance: echocardiography (see p. 162), radionuclide angiography (see Chap. 9) , ultrafast computed tomography (see Chap. 10) , and magnetic resonance imaging[14A] (see Chap. 10) . All of these are alternatives to contrast angiography for measurement of ventricular volumes and/or dimensions and, therefore, permit the noninvasive estimation of ejection phase indices (see later). All four noninvasive imaging methods allow estimation of ventricular systolic and diastolic volumes and both global and regional ejection fraction.

LEFT VENTRICULAR VOLUME.

The normal left ventricular end-diastolic volume averages 70 ± 20 (SD) ml/m^2 (Table 15-1) .[15] Left ventricular performance ordinarily is considered to be depressed when ventricular end-diastolic volume is clearly elevated (i.e., > 110 ml/m^2 , or > 2 SDs above the normal mean) and total stroke volume and/or cardiac index and work are either reduced or within normal limits, while heart rate and arterial pressure are normal.

Left ventricular stroke volume is the quantity of blood ejected with each beat and is the difference between end-diastolic volume and end-systolic volume. The normal stroke volume is 45 ± 13 ml/m^2 (see Table 15-1) . The cardiac output is equal to the stroke volume multiplied by the heart rate. In the absence of valvular regurgitation or intracardiac shunt, the angiographic stroke volume should correlate closely with an independent measurement of stroke volume (cardiac output/heart rate) using the Fick or thermodilution methods. In the presence of valvular regurgitation or a shunt lesion, the total stroke volume, determined by angiocardiography, is greater than the effective forward stroke volume, determined by the Fick or indicator dilution method. The difference between the two represents the regurgitant (or shunt) flow per cardiac cycle.

TABLE 15-1 -- LEFT VENTRICULAR VOLUME DATA IN PATIENTS

GROUP	NO. OF PATIENTS	END-DIASTOLIC VOLUME (ml/m^2)	STROKE VOLUME (ml/m^2)	MASS (gm/m^2)	EJECTION FRACTION
Normal*		70±20.0	45±13.0	92±16.0	0.67±0.08

*Normal values from Kennedy JW, et al: Quantitative angiocardiography: The normal left ventricle in man. Circulation 34:272, 1966.

Ejection Fraction.

The ejection fraction (EF) is the ratio between stroke volume (SV) and end-diastolic volume (EDV). In the presence of valvular regurgitation, the total stroke volume ejected by the ventricle (i.e., the sum of forward and regurgitant volumes) is used in this calculation. The regurgitant fraction (RF) is the ratio of regurgitant flow per beat to the total left ventricular stroke volume:

where SV total is determined by angiography and SV forward by the Fick or indicator dilution method. When mitral and aortic regurgitation coexist, the regurgitant fraction reflects the sum of the two regurgitant volumes and does not distinguish between them. It is important to recognize that there are errors in measuring both total SV and forward SV. These errors summate in the calculation of the regurgitant volume and the regurgitant fraction. Thus, it is difficult to determine regurgitant volume.

LEFT VENTRICULAR MASS.

Left ventricular mass can be determined by M-mode or two-dimensional echocardiography using several techniques (see Chap. 7) .[16] In one of these methods, left ventricular mass is calculated as the difference between total ventricular volume (estimated from the product of the epicardial left ventricular length and the area of the left ventricle in the short axis) and the volume of the left ventricular cavity. Echocardiographically determined left ventricular mass is an important prognostic factor in patients with left ventricular hypertrophy. [17] [18] [19] Computed tomography and magnetic resonance imaging are also useful methods to accurately measure left ventricular mass (see Chap. 10) .[16] [16A]

Left ventricular wall thickness normally averages 10.9 ± 2.0 (SD) mm and left ventricular mass averages 92 ± 16 gm/m^2 (see Table 15-1) . Chronic cardiac dilatation secondary to volume overload or primary myocardial disease increases left ventricular mass, as does chronic pressure overload. Hypertrophy caused by pressure overload (such as aortic stenosis) is characterized by an increased muscle mass resulting from an augmentation of wall thickness with little change in ventricular

chamber volume (concentric hypertrophy) (see Table 15-1) . In contrast, hypertrophy caused by volume overload or by primary myocardial disease is characterized by an increased muscle mass resulting from ventricular dilatation, with only a slight increase in wall thickness (eccentric hypertrophy) (see Table 15-1) .

LEFT VENTRICULAR FORCES.

The forces acting on the myocardial fibers within the ventricular wall can be calculated from the dimensions of the left ventricular cavity, wall thickness, and intraventricular pressure. Left ventricular tension (force/cm) is the force acting on a hypothetical slit in the ventricular wall that would pull its edges apart. According to Laplace's law, tension is the product of the intraventricular pressure and radius. Wall stress (sigma) is the force or tension per unit of cross-sectional area of the ventricular wall. Wall stress may be considered to act in three directions--circumferential, meridional, and radial (Fig. 15-5) . The calculation of stress requires assumptions concerning the shape and configuration of the ventricle.[20] [21] Circumferential wall stress, the strongest force generated within the ventricular wall, can be approximated as:

where CWS=circumferential wall stress in dynes per square centimeter×10^3 ; P=left ventricular pressure in dynes per square centimeter; a and b are major and minor semiaxes (i.e., half the longest lengths), respectively, in cen

Figure 15-5 Circumferential ($sigma_c$), meridional ($sigma_m$), and radial ($sigma_r$) components of left ventricular wall stress from an ellipsoid model. The three components of wall stress are mutually perpendicular. (From Fifer MA, Grossman W: Measurement of ventricular volumes, ejection fraction, mass, and wall stress. *In* Grossman W [ed]: Cardiac Catheterization and Angiography. 5th ed. Philadelphia, Lea & Febiger, 1996, p 324.)

timeters; and h=left ventricular wall thickness in square centimeters.[22] Meridional wall stress (MWS) can be approximated as:

where r is the internal radius of the ventricle in centimeters.

Simultaneous recording of left ventricular dimensions and intraventricular pressure recorded with a high-fidelity micromanometer allows calculation of left ventricular tension and stress throughout the cardiac cycle. A simple method of analyzing the instantaneous left ventricular tension throughout the cardiac cycle consists of recording left ventricular pressure simultaneously with left ventricular diameter across the minor axis of the left ventricle determined by echocardiography. This combination of measurements provides the data necessary to calculate ventricular circumferential fiber shortening (at either the endocardium or the midwall) and midwall circumferential stress, using minor modifications of the equations presented earlier. However, the use of echocardiography, especially M mode, for these calculations is based on the assumption of uniform wall motion. This assumption is reasonable only in conditions that affect left ventricular function relatively uniformly, such as dilated cardiomyopathy or aortic or mitral regurgitation. These assumptions are not correct when there is regional left ventricular dysfunction.

During isovolumetric contraction, left ventricular wall tension and stress rise rapidly as the ventricle contracts without decreasing the chamber volume. During ejection, as the left ventricular cavity decreases in size and wall thickness increases, the stress and tension decline even though pressure is maintained.

REGIONAL VENTRICULAR WALL MOTION.

Ischemic heart disease typically produces regional abnormalities of contraction. Hyperkinesis of normal areas may compensate for impaired function of an abnormal region, leaving global left ventricular function normal or only minimally depressed. Thus, assessment of regional wall motion is more sensitive

Figure 15-6 Left ventricular angiograms in the 30-degree right anterior oblique (RAO) and 60-degree left anterior oblique (LAO) projections. End-diastolic (ED) and end-systolic (ES) frames are shown. Tracing of ED and ES images are superimposed on the far right. The images on top are from a patient with normal left ventricular contraction. The patient on the bottom has anterior-apical and septal akinesis (arrows).

in detecting ventricular dysfunction in such patients than analysis of global ventricular function.

Regional wall motion can be assessed with a variety of methods, including contrast angiography.[23] Marked focal abnormalities of contraction can be appreciated by visual inspection of ventriculograms; segments of abnormal ventricular contraction can be localized by superimposing end-diastolic and end-systolic outlines of the left ventricular cavity (Fig. 15-6). Akinesis is present when a portion of each of the two silhouettes shares a common line; dyskinesis is present when the end-systolic silhouette extends outside the end-diastolic silhouette. The abnormally contracting segments (both akinetic and dyskinetic) may be expressed simply as percentages of the total enddiastolic circumference. Hypokinesis (focal decreases in the extent of contraction) as well as asynchrony (abnormalities of timing of contraction) are less severe disturbances of contraction. Analysis of wall motion from multiple cine frames and automated border detection may be necessary for the detection of these more subtle abnormalities (Fig. 15-7) .[24]

RIGHT VENTRICULAR AND ATRIAL VOLUME.

The shape of the right ventricle is much more complex than the shape of the left ventricle. Thus, the prolate ellipsoid that is a useful model to calculate left ventricular volume is not appropriate for the right ventricle.[25] One method is to consider the right ventricle as a pyramid with a triangular base. An alternate approach is to calculate right ventricular volume using Simpson's rule.

The shape of each atria is less complex than that of the right ventricle. Thus, the atrial volumes can be calculated assuming an ellipsoidal geometry.[26]

Figure 15-7 Automated border recognition tracing of the left ventricular endocardial borders from two-dimensional echocardiograms obtained in the four-chamber *(A)* and short-axis *(B)* views. ROI=region of interest; MV=mitral valve; PM=papillary muscle. ASSESSMENT OF LEFT VENTRICULAR FUNCTION

The factors that determine myocardial function (preload, afterload, contractility, heart rate, and rhythm; see Chap. 14) can be estimated from left ventricular pressure and volume.

Preload (See also p. 464)

Left ventricular preload can be assessed from the left ventricular filling pressure, left ventricular end-diastolic volume, or left ventricular end-diastolic stress.[27] [28] The pressure distending the ventricle immediately before contraction is the end-diastolic pressure. In the absence of disease of the mitral valve this is equivalent to the pressure in the left atrium at this time (the post a wave or Z point pressure). When there is a vigorous atrial contraction, the end-diastolic pressure is substantially higher than the mean left atrial pressure. It is important to recognize that the amount of pulmonary congestion is related to the mean pulmonary capillary (or left atrial) pressure, whereas the end-diastolic volume is determined by the left ventricular end-diastolic pressure.[27] In the absence of pulmonary vascular disease, mean

pulmonary capillary wedge pressure approximates the pulmonary artery diastolic pressure. In the presence of a tall v wave, the mean atrial pressure (and mean pulmonary capillary edge pressure) may exceed the ventricular end-diastolic pressure.[29]

The left ventricular preload depends on the end-diastolic volume produced by the distending pressure of the ventricle. Because interventions that alter end-diastolic pressure may also alter the relation between end-diastolic volume and pressure, changes in end-diastolic pressure do not always represent changes in end-diastolic volume or changes in end-diastolic fiber stretch.

Afterload

After aortic valve opening the ventricle ejects into the arterial circulation. Thus, the systolic pressure in the simplest sense represents the afterload opposing left ventricular ejection. However, arterial systolic pressure is not a pure measure of left ventricular afterload. The tension in the ventricular wall that the sarcomeres must overcome to shorten is related not only to the systolic pressure but also to the cavity size through the Laplace relation. Thus, at similar systolic pressures a larger ventricle will have greater wall tension than a smaller ventricle. Furthermore, the arterial systolic pressure depends not only on the characteristics of the arterial circulation but also on the pumping performance of the left ventricle. The more vigorous the left ventricular contraction, the larger the volume ejected and the higher the systolic pressure. Thus, left ventricular systolic function and left ventricular afterload are interrelated.

The steady-state arterial load opposing left ventricular ejection can be quantified as the peripheral vascular resistance.[3] ° This is calculated as the cardiac output divided by the mean arterial pressure minus the mean venous pressure (see Chap. 11) . Because venous pressure is very low relative to mean arterial pressure, it is frequently neglected in this calculation. The peripheral vascular resistance provides only steady-state information concerning the relation between flow and pressure in the arterial system. However, the left ventricular ejection is pulsatile, and there are pulsatile elements to the arterial load that increase in importance with tachycardia, aging, and peripheral vascular disease.[31] [32]

The full relation between flow and arterial pressure can be evaluated in the frequency domain as the arterial input impedance.[33] [34] Calculation of the input impedance spectrum requires the high-fidelity measurement of aortic pressure and flow at the same point. The impedance spectrum consists of a magnitude and phase at each frequency. The magnitude of the impedance at a given frequency is the ratio of a sinusoidally varying pressure and related flow at that frequency. Because arterial pressure and flow do not vary sinusoidally, the Fourier transformation is used to mathematically describe the aortic pressure and flow as a combination of a fundamental sine wave (at the heart rate)

Figure 15-8 Recordings of ascending aortic pressure and flow *(A)* and the resulting aortic input impedance spectra *(B)* from a 56-year-old normotensive subject (
--
) and a 61-year-old subject with isolated systolic hypertension (

), with an impedance spectrum from a young (28 years) normotensive subject (

), shown for comparison. Peripheral vascular resistance (R), impedance moduli of the first harmonic (Z_i) and characteristic impedance (Z_0) were all higher in the subject with isolated systolic hypertension. Also, the impedance moduli minimum was shifted to a higher frequency in the subject with isolated systolic hypertension. Yrs=years; Freq=frequency. (From Nichols WW, Nicolini FA, Pepine CJ: Determinants of isolated systolic hypertension in the elderly. J Hypertension 10[Suppl 6]:S73, 1992.)

Figure 15-9 Left ventricular arterial coupling assessed in the pressure-volume plane. The left ventricular end-systolic pressure-volume relation (ESPVR) is used to describe left ventricular systolic performance. *Top left,* Pressure-volume loops for variably loaded beats are shown with the upper left corner of each beat falling on the ESPVR (dotted line). *Top right,* The arterial circulation is described as a relation between stroke volume and end-systolic pressure (solid line). The slope of this relation represents the effective end-systolic arterial elastance (E_A). *Bottom left,* The left ventricular ESPVR and the aortic ESPVR (A_O P_{ES} -V_{ES}) are plotted on the same axis. End systole occurs at the intersection of the two relations. Thus, description of the arterial circulation in terms of the aortic P_{ES} -SV relation allows understanding of the coupling between the left ventricle and arterial circulation. (Redrawn from Little WC, Cheng CP: Left ventricular-arterial coupling in conscious dogs. Am J Physiol 261:H70, 1991. Reproduced by permission of the American Physiological Society.) *Bottom right,* Pressure-volume loops in the same format recorded in an elderly patient without cardiac disease. (Reproduced from Chen CH, Nakayama M, Nevo E, et al: Coupled systolic-ventricular and vascular stiffening with age: Implications for pressure regulation and cardiac reserve in the elderly. J Am Coll Cardiol 32:1225, 1998.)

and a series of harmonic waves. The impedance spectrum is then calculated as the ratio of the pressure to flow at each frequency. Figure 15-8 provides an example of such an impedance spectrum. Although the impedance spectrum contains all the information concerning the linear relation between pulsatile flow and pressure in the arterial circulation, its clinical usefulness is limited by the difficulty in obtaining the appropriate measurement and the calculations.

Evaluation of the interaction of the left ventricle and the arterial system requires that they be described in similar terms. Description of the arterial system in the frequency domain does not easily allow this coupling to be assessed because the left ventricle is difficult to describe in these terms. Because the left ventricle can be evaluated in the pressure-volume plane, Sunagawa and colleagues[35] proposed that the arterial system be evaluated in an analogous manner. In this analysis, the arterial system is described by the relation between the stroke volume and end-systolic pressure (Fig. 15-9) . The higher the stroke volume, the greater the end-systolic pressure. The slope of this relation represents the effective arterial end-systolic elastance (E_A). If it is assumed that this relation passes through the origin, then E_A can be calculated as the ratio of end-systolic pressure to stroke volume. As shown in Figure 15-9 , this can be plotted on the left ventricular pressure-volume loop. End systole occurs at the intersection of the arterial and ventricular relations. The production of SW is maximum when the E_{ES} and E_A are approximately equal.[36]

Under usual conditions, E_A , the slope of the arterial end-systolic pressure stroke volume relation, can be approximated by the peripheral vascular resistance multiplied by the heart rate.[37] In older hypertensive patients, E_A may exceed the product of peripheral vascular resistance and heart rate. However, E_A can be accurately estimated over a wide range of conditions from arterial systolic (P_{SYS}) and diastolic pressures (P_{diast}) as: (2×P_{SYS} +P_{dias})/3 divided by the stroke volume.[37]

Contractile State (See also p. 464)

In experimental cardiac muscle or isolated heart preparations, loading can be readily controlled and the effects of an intervention on the strength, extent, and velocity of muscle shortening indicate its effect on the contractile

Figure 15-10 *A,* Recording of left ventricular pressure (LVP), the rate of change of left ventricular pressure (dP/dt) and left ventricular volume (LVV). The maximum value of dP/dt, (dP/dt_{max}) increases in response to dobutamine; however, dP/dt_{max} also increases when left ventricular end-diastolic volume is increased by infusing dextran. This demonstrates the sensitivity of dP/dt_{max} to both contractility and left ventricular end-diastolic volume (preload). (Data from Little WC: The left ventricular dP/dt_{max} -end-diastolic volume relation in closed chest dogs. Circ Res 56:808, 1985. ---

state. It is more difficult to make analogous measurements in patients in whom preload and afterload are interrelated and cannot be readily controlled. Many drugs that affect myocardial contractility also act on the arterial and/or venous beds, thereby altering cardiac loading. Furthermore, in patients with valvular heart disease, it is necessary to evaluate the level of myocardial contractility despite the marked alterations in loading conditions. These considerations have led to the search for methods of evaluating cardiac function that go beyond analysis of the pumping function of the ventricle and provide an assessment of contractility. A number of indices of contractility have been proposed and investigated empirically. Unfortunately, there is no absolute measure of myocardial contractility; that is, there is no gold standard with which these indices can be compared. Furthermore, at the sarcomere level, contractility and load are interrelated and, thus, not independent variables.[1]

Many indices have been proposed as measures of left ventricular contractile function[38] (Table 15-2) . These can be divided into isovolumetric phase indices, ejection phase indices, and measures derived from left ventricular pressure-volume relations.

ISOVOLUMETRIC INDICES OF CONTRACTILITY. Ventricular dP/dt.

The maximum rate of rise of ventricular pressure (dP/dt_{max}) is highly sensitive to acute changes in contractility (Fig. 15-10) .[39] Under normal conditions dP/dt_{max} occurs before aortic valve opening; thus it is not affected by steady-state alterations in aortic pressure. However, dP/dt_{max} may be delayed until after aortic valve opening in patients with severe left ventricular depression or marked arterial vasodilation with very low aortic diastolic pressures. In the absence of these conditions, dP/dt_{max} can be considered to be relatively independent of afterload. However, dP/dt_{max} is very sensitive to changes in preload. This preload sensitivity is greater in ventricles with enhanced contractility but is reduced in depressed ventricles.[39] However, a change in dP/dt_{max} without a change in preload or with an opposite change in preload indicates an alteration in contractility.

Although dP/dt_{max} correlates with basal contractility, the wide variation between individuals and the marked preload dependence decreases its usefulness for assessing basal contractility. Instead, dP/dt_{max} is more useful in assessing directional changes in contractility during acute interventions when used in combination with a measure of left ventricular preload.

V_{max} .

This is the maximum velocity of shortening of the unloaded contractile elements (CE). It was originally proposed as a measure of myocardial contractility that is independent of preload or afterload. However, there are theoretical and practical limitations to the calculation of CE V_{max} in isolated muscle, and even more so in the intact heart. Because of the theoretical problems and practical difficulties in calculating V_{max} , it is no longer used as a clinical measure of contractility.

Relation Between dP/dt and Developed Pressure.

Some of the difficulties involving the calculation of V_{max} can be partially avoided by the selection of certain points on the curve relating dP/dt to DP, the developed left ventricular pressure (i.e., left ventricular pressure minus end-diastolic pressure). The dP/dt at a DP of 40 mm Hg, a level of pressure that almost always occurs before the opening of the aortic valve, is commonly used. dP/dt at a DP of 40 mm Hg and the maximum dP/dt/DP are useful for assessing directional changes in contractility, because it is unaffected by changes in afterload and less sensitive to changes in preload than dP/dt_{max} .

EJECTION PHASE INDICES.

The extent of left ventricular ejection can be measured as the stroke volume, ejection fraction, or fractional shortening, and the rate of ejection can be quantified as the mean and peak velocity of shortening (V_{CF}).[40A] All of these measurements are influenced by both contractility and load.[40] The marked preload dependence of the stroke volume is minimized by dividing by the end-diastolic volume producing the ejection fraction. However, the ejection fraction is sensitive to changes in afterload; so it is best to consider it a measure of systolic performance, because it is not a pure measure of contractility (see later).

The afterload dependence of the ejection fraction or measures of the left ventricular shortening can be minimized using concepts derived from the myocardial force-velocity relation of isolated cardiac muscle (Fig. 15-11) . For example, the relation between ejection fraction or frac

Figure 15-11 The relation between left ventricular ejection fraction (EF) and arterial load (E_a) in patients with aortic regurgitation. EF falls with increasing arterial load, both in patients with normal contractile function (solid circles) and those with impaired contractile performance (open circles). The fall in ejection performance (EF) with load is more marked in the patients with reduced contractile performance. ---

myocardial fiber shortening and left ventricular end-systolic stress, obtained in the basal state and during pharmacologically altered afterload, provides a useful framework for assessing the basal level of left ventricular contractility.[41] [42] [43] [44] Augmentation of V_{CF} at a constant wall stress signifies an improvement of contractility. These relations are particularly useful in patients who have a reduced ejection fraction, because it distinguishes between reduced myocardial shortening due to excessive afterload and that due to depressed myocardial contractility.[45] The V_{CF} -$sigma_{ES}$ relation during a single beat is not defined by parallel straight lines; thus, it may not be accurately defined from measurements made from a single loading condition.[46]

PRESSURE-VOLUME RELATIONS.

As discussed earlier, consideration of the left ventricle in the pressure-volume plane provides a powerful method to understand left ventricular performance.[2] [47] [48] The generation of variably loaded beats allows determination of several relations that provide information concerning left ventricular contractility and systolic performance. The variably loaded beats can be produced by transient balloon occlusion of the inferior vena cava.[49] [50] An alternate approach is to generate a range of loading conditions using graded infusions of vasoactive agents, such as methoxamine and nitroprusside.[50] [51]

Left Ventricular ESPVR.

The upper left-hand corner of variably loaded pressure-volume loops defines the left ventricular ESPVR (Fig. 15-12) . In the physiological range, this relation can be approximated as a straight line. Thus, it can be described with a slope (E_{ES}) and volume axis intercept (V_0),[52] [53] that is,

The slope, which has dimensions of pressure/volume (units of mm Hg/ml), has been called the end-systolic elastance (E_{ES}). This represents the end-systolic stiffness of the left ventricle and indicates how sensitive ejection will be to increases in afterload (as reflected in the end-systolic pressure). With enhanced contractility, E_{ES} increases. The volume axis intercept (V_0) of the ESPVR has been referred to as the "dead volume" of the ventricle. This is the volume at which the left ventricle would generate no pressure. This volume intercept cannot be directly measured clinically. Instead, it must be determined by extrapolation and thus is subject to large errors.[52] [53] [54] In many clinical studies the extrapolated V_0 is negative, which is a physiological impossibility. This indicates the difficulties involved in accurately determining V_0 in clinical studies. [54]

The position of the ESPVR on the volume axis at the operating pressure (e.g., the end-systolic volume associated with an end-systolic pressure of 100 mm Hg) indicates the extent of ejection. Global increases in contractility, such as the infusion of dobutamine, both increase E_{ES} and shift the ESPVR to the left in the physiological range.[53] [54] Thus, at a constant afterload (i.e., constant left ventricular end-systolic pressure) the left ventricle with enhanced contractility ejects to a lower volume and is less sensitive to changes in systolic pressure. Global decreases in contractility produce the opposite effect. Thus, E_{ES} and the position of the ESPVR in the physiological range provide load-insensitive measures of the contractile state.[53] [54]

Regional left ventricular dysfunction resulting from coronary artery occlusion produces a parallel rightward shift of the left ventricular ESPVR in the physiological range with little change in the E_{ES} .[55] [56] A similar parallel shift of the ESPVR occurs during dysynchronous activation of the left ventricle (Fig. 15-13) . [57] [58]

An echocardiographically determined left ventricular end-systolic dimension or cross-sectional area can be used as a surrogate for left ventricular volume in the left ventricular ESPVR provided there is not a segmental wall motion abnormality.[59] Automated echocardiographic border detection makes it possible to determine pressure-area relations on-line.[60]

There are practical and theoretical difficulties in using the ESPVR as a clinical measure of left ventricular contractility. First, to accurately define the ESPVR, a wide range of loading conditions must be obtained. Such alterations in

Figure 15-12 *A,* Variably loaded pressure-volume loops produced by caval occlusion in a conscious experimental animal. End systole occurs at the upper left corner of the pressure-volume loops. The end-systolic points of the variably loaded beats fall along a single relation, the left ventricular end-systolic pressure-volume relation (LV ESPVR). Within the physiological range, this relation is approximated by a straight line. The line can be described in terms of its slope (E_{ES}) and volume axis intercept (V_0). Note that the volume axis intercept results from extrapolation of the line outside the range of end-systolic pressures in which data can be acquired. An increase in contractile state, produced by infusing dobutamine, shifts the LV ESPVR toward the left while increasing the slope. (Data from Little WC, Cheng CP, Mumma M, et al: Comparison of measures of left ventricular contractile performance derived from pressure-volume loops in conscious dogs. Circulation 80:1378, 1989. Copyright 1989, American Heart Association.) *B* and *C,* Recordings of right atrial pressure (RAP), left ventricular volume (LVV) measured with the conductance catheter, and left ventricular pressure (LVP) in a patient during transient balloon occlusion of the inferior vena cava. These variably loaded beats are shown in the pressure-volume plane on the right. The upper left corner of these loops defines the LV ESPVR (dotted line). (From Kass DA: Clinical ventricular pathophysiology: A pressure-volume view. *In* Warltier DC [ed]: Ventricular Function. Baltimore, Williams & Wilkins, 1995.)

Figure 15-13 *Top,* Left ventricular (LV) pressure-volume loops in an experimental animal during transient caval occlusions. The upper left corners of the loops define the left ventricular end-systolic pressure-volume relation (ESPVR). During atrial pacing producing normal LV activation the ESPVR is shifted leftward in a parallel fashion, compared with ventricular pacing that produces dysynchronous LV activation and contraction. (From Park RC, Little WC, O'Rourke RA: Effect of alteration of left ventricular activation sequence on the left ventricular end-systolic pressure-volume relation in closed-chest dogs. Circ Res 57:711, 1985.) *Bottom,* Steady-state left ventricular pressure-volume loop recorded using the conductance catheter in a patient with dilated cardiomyopathy and dysynchronous left ventricular activation due to left bundle branch block (LBBB). A decrease in dysynchronous contraction produced by left ventricular free wall pacing (LVFW) produced loops with greater width (stroke volume) as the end-systolic pressure-volume point shifted toward the left. (From Kass DA, Chen DH, Curry C, et al: Improved left ventricular mechanics from acute VDD pacing in patients with dilated cardiomyopathy and ventricular conduction delay. Circulation 99:1570, 1999. Copyright 1999, American Heart Association.)

load may induce reflexly mediated changes in heart rate and left ventricular contractility. In addition, arterial vasoconstriction and vasodilation produce parallel shifts of the left ventricular ESPVR.[61] [62] Thus, the interventions required to accurately define the ESPVR may themselves alter the relation, thus confounding the ability to define the ESPVR with precision in clinical studies.[63]

A second difficulty in evaluating the ESPVR is the determination of the timing of end systole. End systole is defined as the upper-left-hand corner of the pressure-volume loop. This may not exactly correspond to aortic valve closure or the time of maximum ventricular elastance. This difference may be accentuated when there is reduced impedance to left ventricular ejection, as occurs in mitral regurgitation.[64]

A third difficulty is that the slope of the ESPVR depends on the size of the ventricle; thus it is not possible to define a normal range for E_{ES} . Attempts to correct for ventricular size have not been uniformly successful. However, this does not prevent E_{ES} from differentiating patients with normal from abnormal left ventricular contractile function.[65] One method of correcting for differences in left ventricular size is to evaluate the left ventricle in the stress-strain plane.[66] In this analysis the left ventricular end-systolic stress-strain relation is analogous to the ESPVR, except that which has been normalized for wall thickness and chamber size and configuration.

If V_0 is assumed to be small, then E_{ES} can be approximated by the ratio of left ventricular systolic pressure to end-systolic volume (P_{ES} /V_{ES}).[53] [67] This approach has the advantage of avoiding the need to evaluate multiply loaded beats. However, the P_{ES} /V_{ES} ratio is subject to large errors in estimating E_{ES} when V_0 is large and is not a sensitive measure of contractile performance. E_{ES} can also be estimated from a single cardiac cycle using the time varying elastance model to predict V_0 .[68]

Despite the theoretical and practical limitations to the clinical evaluation of contractility using the ESPVR, left ventricular pressure-volume analysis provides a powerful tool to help understand the interaction of contractile state and load to produce ventricular performance (Fig. 15-14) .

Other Pressure-Volume Relations.

Two other relations can be derived from variably loaded pressure-volume loops: the dP/dt_{max} -end-diastolic volume (V_{ED}) relation and SW-V_{ED} relation (Fig. 15-15) .

During caval occlusion, dP/dt_{max} and V_{ED} are linearly related.[39] The slope of the relation (dE/dt_{max}) represents the maximum rate of change of left ventricular elastance during contraction and is very sensitive to contractile state. Thus, this resting dP/dt_{max} -V_{ED} relation accounts for the preload-dependence of dP/dt_{max} , which increases when the contractile state is augmented. Although it is very sensitive to changes in contractile state, the dP/dt_{max} -V_{ED} relation has several limitations. First, dP/dt_{max} is more variable than P_{ES} , and this relation is less stable than the ESPVR.[69] Second, the dP/dt_{max} -V_{ED} relation saturates at volumes only slightly above the operating point.[70] Thus, this relation can be defined only by preload reduction and not by pharmacologically produced increases in load.

SW is the external work performed by the left ventricle and is calculated as the area of the pressure-volume loop. It can be approximated as the product of the stroke volume and the mean arterial pressure. Thus, SW integrates the two determinants of tissue perfusion: flow and pressure. During caval occlusions, SW and V_{ED} are

linearly related. SW is insensitive to arterial load in the physiological range; thus, the SW-V_{ED} relation is afterload independent under these conditions.[36] [71] [72] In response to increase in contractile state, the slope of this relation, termed *preload recruitable stroke work* (PRSW), increases. Thus, PRSW has been proposed as a load-independent measure of contractile state.[73] However, the SW-V_{ED} relation is not only determined by contractile state, but it also can be altered by changes in the diastolic left ventricular pressure-volume relation.[69] For example, the diastolic pressure-volume relation can be altered under some circumstances without a change in the ESPVR.[74] This alters the LV SW-V_{ED} relation and PRSW. Although importantly influenced by contractility, the SW-V_{ED} relation is best considered as a measure of integrated pump function (see later).

The SW-V_{ED} relation has several important advantages.[69] First, since SW integrates pressure and volume throughout the cardiac cycle it is free of noise and is remarkably stable. Second, during reductions in preload as produced by caval occlusion, both determinants of SW (stroke volume and end-systolic pressure) decline, producing a wide range of SW values. This wide range of data increases the statistical precision with which the SW-V_{ED} relation can be defined. Finally, the slope (PRSW) has dimensions of pressure; thus, it is independent of left ventricle cavity size.

Figure 15-14 Examples of variably loaded pressure-volume loops used to define the left ventricular end-systolic pressure-volume relations in four patients: normal ventricle, hypertrophic cardiomyopathy (HCM), left ventricular hypertrophy (LVH) due to hypertension (HTN), dilated cardiomyopathy (DCM), and hypertrophic cardiomyopathy (HCM). (From Pak PH, Maughan WL, Baughman KL, Kass DA: Marked discordance between dynamic and passive diastolic pressure-volume relations in idiopathic hypertrophic cardiomyopathy. Circulation 94:57, 1996. Copyright 1996, American Heart Association.)

MAXIMUM POWER.

The power generated by the left ventricle can be calculated as the product of aortic flow and pressure. The maximum power (PWR_{max}) responds to changes in contractile state, is insensitive to changes in the arterial circulation, and is linearly related to the square of V_{ED} (V_{ED}^{2}) in the physiological range. [75] [76] Thus, PWR_{max}/V_{ED}^{2} may provide a preload independent measure of contractility. PWR_{max}/V_{ED}^{2} can be determined noninvasively using nuclear techniques or Doppler echocardiography to determine aortic flow and by measuring arterial pressure using indirect means.[77]

Clinical Evaluation of Determinants of Left Ventricular Function

Many of the complex measures just discussed are not appropriate for routine clinical use. Although left ventricular preload is most accurately determined by its end-diastolic volume, preload is usually assessed clinically by measurements of the pulmonary capillary wedge pressure (see earlier discussion). The level of left ventricular afterload can be estimated by the systolic arterial pressure (in the absence of aortic stenosis). When the systolic pressure is low, calculation of the vascular resistance can determine whether it is due to a low arterial tone (low vascular resistance) or inadequate cardiac output. Although, the left ventricular ejection fraction is a measure of left ventricular systolic performance (see later) in the absence of abnormal afterload or valvular disease, it reflects myocardial contractility. Similarly, left ventricular end-systolic volume (or dimension) when arterial systolic pressure is normal (100-140 mm Hg) indicates the operating position of the left ventricular ESPVR, reflecting systolic (and contractile) performance. Thus, echocardiographic measurements of left ventricular end-systolic dimension can be used to follow the contractile performance of patients with mitral or aortic regurgitation.[78] [79] [79A] [80]

Figure 15-15 Three relations describing left ventricular systolic performance derived from variably loaded pressure-volume loops: the left ventricular end-systolic pressure-volume relation, the relation between dP/dt_{max} and end-diastolic volume (V_{ED}), and the relation between stroke work and V_{ED}. All three relations can be approximated by a straight line within the range of data generated by transient caval occlusion. Each relation is shifted toward the left with an increase in slope in response to increase in contractile state produced by dobutamine. (From Little WC, Cheng CP, Mumma M, et al: Comparison of measures of left ventricular contractile performance derived from pressure-volume loops in conscious dogs. Circulation 80:1378, 1989. Copyright 1989, American Heart Association.)

LEFT VENTRICULAR PUMP FUNCTION (See also p. 462)

The contraction of individual sarcomeres is integrated into the myocardial shortening, which ultimately is expressed as the pumping function of the left ventricle. The left heart can be analyzed as a pump with an input (the pulmonary venous or mean left atrial pressure) and an output (which in simplest terms is the cardiac output=stroke volume×heart rate). The relationship between the input and output is the ventricular function curve or the Frank-Starling relationship (Fig. 15-16) . In this relationship, the output can be considered to be the stroke volume, cardiac output, or the SW.

A family of Frank-Starling curves reflects the response of the pump performance of the ventricle to a spectrum of contractile states, and the position of a given curve provides a description of ventricular contractility. Movement along a single curve represents the operation of the Frank-Starling principle, which indicates that stroke volume, cardiac output, or SW varies with preload. By contrast, upward or downward displacement of the curve represents a positive or negative inotropic effect, that is, an augmentation or depression of contractility, respectively (see Fig. 15-16) . However, it is important to recognize that this ventricular function curve represents a complex interaction of preload, afterload, and contractility.

The pump performance of the left ventricle depends on its ability to fill (diastolic performance) and to empty (systolic performance) (Fig. 15-17) . The forward stroke volume is equal to the end-diastolic volume multiplied by the effective ejection fraction (see later). Thus, the generation of stroke volume depends on the conversion of the filling pressure to end-diastolic volume (diastolic performance) and the generational stroke volume from the end-diastolic volume (systolic performance).[28]

Systolic Performance

Left ventricular systolic performance is reflected in the ability of the left ventricle to empty. Because myocardial contractility is an important determinant of the left ventricle's systolic performance, systolic performance and contractility are frequently considered to be interchangeable. However, they are not the same because the systolic performance of the left ventricle is also importantly influenced by load and ventricular configuration. Thus, it is possible to have abnormal systolic performance despite normal contractility when left ventricular afterload is excessive. Alternatively, left ventricular systolic performance may be nearly normal despite decreased myocardial contractility if left ventricular

Figure 15-16 Depiction of the Frank-Starling relationship. With increasing left ventricular filling pressure measured by the pulmonary capillary wedge pressure (reflecting the pulmonary venous pressure), there is an increase in cardiac output and stroke work. The positions of the curves are influenced by the contractile state of the left ventricle. An enhancement of contractile state shifts the curves upward, whereas a depression produces a downward shift.

Figure 15-17 Block diagram of left ventricular pump performance. The input is the pulmonary venous pressure, and the output is the cardiac output. These are related by the Frank-Starling relations (see Fig. 15-16) . The stroke volume depends on the end-diastolic volume (ED) and the effective left ventricular ejection fraction (EF). See text for discussion.

afterload is low, as occurs in some patients with mitral regurgitation.

Left ventricular systolic performance can be quantified as the left ventricular emptying fraction or ejection fraction. In the presence of a left-sided valvular regurgitant

lesion (mitral regurgitation or aortic regurgitation) or a shunt (ventricular septal defect or patent ductus arteriosus), the left ventricular stroke volume may be high, whereas the forward stroke volume (stroke volume minus regurgitant volume or shunt volume), which contributes to useful cardiac output, is lower. Accordingly, the *effective* ejection fraction is the forward stroke volume divided by end-diastolic volume.[38] [81] The effective ejection fraction is a useful means to quantitate systolic function because it represents the functional emptying of the left ventricle that contributes to cardiac output and is relatively independent of left ventricular end-diastolic volume over the clinically relevant range. An operational definition of systolic dysfunction is an effective ejection fraction of less than 50 percent.[81] [82] When defined in this manner, systolic left ventricular dysfunction may result from impaired myocardial function, increased left ventricular afterload, and/or structural abnormalities of the left side of the heart.

If left ventricular contractile state and arterial properties remain constant as end-diastolic volume increases, the ejection fraction stays constant or increases slightly.[40] Thus, an increase in the end-diastolic volume will allow for a normal forward stroke volume despite a reduced effective ejection fraction.

Diastolic Performance

For the left ventricle to function as a pump, it must not only empty but also fill. The left atrial (and pulmonary venous) pressure is the source pressure for left ventricular filling. Thus, normal left ventricular diastolic function can be defined as filling of the left ventricle sufficient to produce a cardiac output commensurate with the body's needs with a normal pulmonary venous pressure (less than 12 mm Hg).[27] In some instances this definition of normal integrated diastolic performance can be met despite clear abnormalities of left ventricular diastolic properties. For example, a compensated patient with a dilated cardiomyopathy may have an adequate cardiac output at rest without an elevated pulmonary venous pressure despite impaired relaxation and a very abnormal left ventricular diastolic pressure-volume curve.

A patient with systolic dysfunction (reduced effective ejection fraction) requires a larger end-diastolic volume to produce an adequate stroke volume and cardiac output. If the larger left ventricular end-diastolic volume can be achieved without an abnormally high pulmonary venous pressure, this can compensate for impaired systolic performance. However, if the larger end-diastolic volume requires an elevation of pulmonary venous pressure, the systolic dysfunction (i.e., reduced effective ejection fraction) will result in diastolic dysfunction. Thus, when defined in this manner, systolic dysfunction in symptomatic patients is usually associated with diastolic dysfunction.

However, diastolic dysfunction frequently occurs in the absence of systolic dysfunction. As defined, diastolic dysfunction may be due to an obstruction to left ventricular filling or an external compression of the left ventricle, but it is usually considered to result from left ventricular abnormalities. Such left ventricular diastolic dysfunction may result from increased myocardial stiffness or impaired relaxation. Relaxation can be slowed, decreasing early diastolic filling, or incomplete, which impairs filling throughout diastole and decreases end-diastolic distensibility. In the pressure-volume plane, reduced distensibility is represented by a leftward and upward shift of the end-diastolic pressure-volume relation (EDPVR) (Fig. 15-18) . When this occurs, significantly higher pressures are required to distend the left ventricle to achieve the same end-diastolic volume. If the shift in the EDPVR is severe enough, filling of the left ventricle to the level sufficient to produce a normal stroke volume can only be achieved with an elevated pulmonary venous pressure that will be associated with pulmonary congestion. Thus, an alteration in diastolic distensibility may produce pulmonary congestion and congestive heart failure in the absence of systolic dysfunction.[83] [84] [85]

Evaluation of Diastolic Performance

The indices of diastolic function can be organized into three groups: (1) measures of isovolumetric relaxation, (2) indices of passive left ventricular characteristics derived from the diastolic left ventricular pressure-volume relations, and (3) measurements of the pattern of left ventricular diastolic filling obtained from Doppler echocardiography or radionuclide angiography.[27] [86] [87]

ISOVOLUMETRIC RELAXATION.

Isovolumetric relaxation can be quantified by measuring its duration or by describing the time-course of the fall in left ventricular pressure. The duration of isovolumetric relaxation, or the time from aortic valve closure to mitral valve opening, can be measured by M-mode echocardiography. A similar interval, the time from aortic valve closure to the onset of mitral valve flow, can be measured by combining phonocardiography and Doppler echocardiography. The duration of isovolumetric relaxation depends not only on the rate of left ventricular relaxation but also on the difference in pressures between the aorta at the time of aortic valve closure and the left atrium at mitral valve opening.[88] Thus, the duration of isovolumetric relaxation can be increased by an elevation of aortic pressure or decreased by an increase in left atrial pressure. The time interval from minimal left ventricular volume to peak left ventricular filling rate can be measured using radionuclear angiography.[87] Because this time interval spans both isovolumetric relaxation and part of early filling, the interpretation is even more complicated than the duration of isovolumetric relaxation alone.

The time course of isovolumetric pressure decline has been quantitatively described by the peak rate of pressure fall (dP/dt_{min}) and the time constant of an exponential fit of the time course of isovolumetric pressure decline. Each of

Figure 15-18 *A,* Left ventricular end-diastolic pressure-volume relation (LV EDPVR) in a patient with normal left ventricular function. The open triangles (delta) connected by the red line indicate the exponential end-diastole pressure-volume relation. The solid circles (
) show the viscoelastic effects during the filling of a single beat. (Modified from Pak PH, Maughan L, Baughman KL, Kass DA: Marked discordance between dynamic and passive diastolic pressure-volume relations in idiopathic hypertrophic cardiomyopathy. Circulation 94:57, 1996. Copyright 1996, American Heart Association.) *B,* The slope of the LV EDPVR indicates the passive chamber stiffness. Because the relation is exponential in shape, the slope increases as the end-diastolic pressure increases (curve A). A shift of the curve from A to B indicates that a higher LV pressure will be required to distend the LV to a similar volume; thus the ventricle is less distensible. (From Little WC, Downes TR: Clinical evaluation of left ventricular diastolic performance. Prog Cardiovasc Dis 32[4]:273, 1990.)

these requires the measurement of left ventricular pressure using a micromanometer. dP/dt_{min} is strongly influenced by the pressure at the time of aortic valve closure and is not a good measure of the rate of isovolumetric relaxation.

After aortic valve closure, left ventricular pressure declines in an exponential fashion during isovolumetric relaxation (Fig. 5-19) . The rate of pressure decline can be quantified by the time-constant of the exponential decline. The time-constant (tau) is increased by processes such as ischemia or other causes of myocardial depression that slow ventricular relaxation.[89] [90] It is shortened by an acceleration of the rate of active relaxation, as caused by an increase in heart rate or sympathetic stimulation. The time-constant of isovolumetric pressure decline can also be altered by changes in loading conditions. An increase in arterial pressure or end-diastolic volume can increase the time-constant, although changes in the preload at a constant arterial pressure may have less effect.[90]

Calculation of the time constant of left ventricular isovolumetric pressure decline has several technical limitations. Data are analyzed from the time of minimum dP/dt to a pressure 5 or 10 mm Hg above end-diastolic pressure. Even if pressure is measured every 2 milliseconds, there are only a limited number of data points. This contributes to a large beat-to-beat variability of tau.[91]

If mitral inflow is prevented, left ventricular pressure will decay to subatmospheric levels. Thus it has been suggested that the data should be fit to an exponential function with an asymptote (P_B):

This is usually done by differentiating both sides and then using the linear least squares technique to fit the equation:

The normal range of values of tau calculated using this method is 37 to 67 milliseconds.[92]

The use of an asymptote to calculate tau is particularly important when the external pressure of the left ventricle may be changing.[93] However, tau calculated from a nonfilling beat in an experimental animal in which the full time course of left ventricular relaxation is available correlates most closely with tau calculated from a normal beat without the use of an asymptote.[94] To avoid the computational properties of nonlinear fitting in the calculation on tau without an asymptote, the relation is linearized using a natural

Figure 15-19 Left ventricular (LV) pressure measured at 2-millisecond intervals using a micromanometer. The LV pressure from the time of minimum dP/dt (dP/dt_{min}) to mitral valve opening is described by an exponential relation (solid line). After mitral valve opening, LV pressure deviates from the exponential line. $P_o + P_b$ =pressure (P) at dP/dt_{max} ; t=time; T=time constant of relaxation; P_B =baseline pressure. (From Little WC, Downes TR: Clinical evaluation of left ventricular diastolic performance. Prog Cardiovasc Dis 32[4]:273, 1990.)

logarithm transformation to result in:

The data are then fit to this equation using the linear least squares technique to determine tau. When calculated using this method the normal range of values for tau is 28 to 45 milliseconds.[92]

The time course of LV pressure during isovolumetric relaxation can also be characterized using noninvasive Doppler measurement of the velocity of a regurgitant jet across the mitral valve.[10] [11] In this method, the modified Bernoulli equation is used to approximate LV pressure during isovolumetric relaxation allowing calculation of the maximum rate of left ventricular pressure decline and the exponential time constant.

PASSIVE DIASTOLIC CHARACTERISTICS OF THE LEFT VENTRICLE.

The passive characteristics of the left ventricle can be described as the passive diastolic pressure-volume relation.[83] [90] Optimally, the passive left ventricular diastolic pressure-volume relation should be constructed from points that are obtained after relaxation is complete and at slow filling rates so that viscous effects are not present.[90] [95] Practically, this can be approximated using points obtained late in diastole, when relaxation is assumed to be complete, or from variously loaded beats at end diastole. However, it is important to correct for the effect of respiratory changes in intrathoracic pressure. The effective chamber stiffness can be calculated from the noninvasively measured time for early filling deceleration (see later).[96]

The slope of the EDPVR is the *chamber stiffness.* Because the pressure-volume relation is nonlinear, the chamber stiffness depends on the point on the curve in which it is measured; thus, stiffness increases with increasing volume (see Fig. 15-19) . Several techniques have been proposed to correct for this effect by normalizing chamber stiffness. One approach is to approximate the pressurevolume relation by an exponential function. Another technique is to compare the chamber stiffness at a common pressure or volume. However, the analysis of chamber stiffness does not account for shifts in the pressure-volume relation that can occur from the alteration of load, diseases, or pharmacological agents.[90] The position of the diastolic pressure-volume relation indicates the distensibility of the left ventricle. For example, an upward shift indicates a less distensible ventricle.[97]

The *diastolic pressure-volume* relation represents the net passive characteristics of the left ventricular chamber. To derive information concerning the properties of the myocardium alone, the effects of wall thickness, ventricular configuration, size, and external pressure must be removed.[98] This can be accomplished by calculating the myocardial stress-strain relation from the chamber pressure-volume relation. In contrast to the slope of the pressure-volume relation, which assesses the amount of ventricular chamber distention under pressure, the stress-strain relation represents the resistance of the myocardium to stretch when subjected to stress. Thus, it should not be influenced by the configuration of the left ventricle. However, the calculation of stress requires the use of a geometric model of the left ventricle and the calculation of strain requires assumption of the unstressed left ventricular volume, which cannot be directly measured in the intact circulation. In addition to these potential theoretical limitations, these calculations require accurate measurements over a wide range of left ventricular pressures and volumes. Measurements made during rapid filling may be inappropriately influenced by active myocardial relaxation and viscoelastic effects. Observations during diastasis and atrial systole minimize this problem, but they may not supply a wide enough range of data points. The theoretical problems and the technical difficulties in determining myocardial stress-strain relations have limited their clinical application.

PATTERNS OF LEFT VENTRICULAR DIASTOLIC FILLING.

Analysis of the pattern of left ventricular filling can provide useful information about diastolic left ventricular performance. Such information can be obtained by determining the left ventricular volume or dimension throughout the cardiac cycle, using contrast or radionuclide angiography[87] or M-mode or two-dimensional echocardiography, or by measuring the left ventricular inflow velocity using a Doppler determination of mitral valve flow velocities. The most widely used method is Doppler measurement of mitral valve flow velocity.[99] [100] [101] [102] [103] The pattern of left ventricular filling can also be assessed using tissue Doppler measurements and color M-mode imaging.[100]

Mechanisms of Diastolic Filling.

To understand the significance of the patterns of left ventricular filling, it is important to consider the mechanisms of normal left ventricular filling.[99] [104] The events surrounding normal left ventricular filling are shown in Figure 15-20 (Figure Not Available) . From the time of aortic valve closure until mitral valve opening, the left ventricle is normally a closed chamber with a constant volume. Myocardial relaxation begins in the latter part of systole and causes a steep, exponential fall in intraventricular pressure as elastic elements of the left ventricle that were compressed and twisted during ejection are allowed to recoil. Although no filling occurs during isovolumetric

Figure 15-20 (Figure Not Available) Recording of left ventricular (LV) pressure (P_{LV}), left atrial pressure (P_{LA}), left ventricular volume (LVV), and the rate of change of LV volume (dV/dt), which indicates the rate of LV filling. LV filling occurs early in diastole and during atrial systole in response to pressure gradient from the left atrium to the left ventricle. The early diastolic pressure gradient is generated as LV pressure falls below left atrial pressure and the late diastolic gradient is generated as atrial contraction increases left atrial pressure above LV pressure. (Data recorded in a conscious animal from Cheng CP, Freeman GL, Santamore WP, et al: Effect of loading conditions, contractile state and heart rate on early diastolic left ventricular filling in conscious dogs. Circ Res 66:814, 1990. Copyright 1990, American Heart Association.)

relaxation, the processes that determine the rate of decline of the isovolumetric pressure influence ventricular filling after opening of the mitral valve.[94] [105] For the first 30 to 40 milliseconds after mitral valve opening, relaxation of left ventricular wall tension is normally rapid enough to cause left ventricular pressure to fall, despite a substantial increase in left ventricular volume.[104] This fall in left ventricular pressure produces a pressure gradient that accelerates blood from the left atrium into the left ventricle, resulting in rapid early diastolic filling. The rate of early left ventricular filling is determined by the mitral valve pressure gradient (left atrial pressure-left ventricle pressure).[104] [106] Although peak filling occurs after the peak pressure gradient, the two are closely related. Two major factors (myocardial relaxation and left atrial pressure) determine the early diastolic mitral valve pressure gradient and the rate of left ventricular filling. Under normal circumstances more than two thirds of the stroke volume enters the left ventricle during early diastole.

After filling of the left ventricle begins, the mitral valve pressure gradient decreases and then transiently reverses. This occurs because left ventricular relaxation is nearing completion and the flow of blood from the left atrium fills the left ventricle, raising the left ventricular pressure while lowering the left atrial pressure. This reversed mitral valve pressure gradient decelerates and then stops the rapid flow of blood into the left ventricle early in diastole.[96] The pressures in the left atrial and left ventricle equilibrate as mitral flow nearly ceases; thus, little left ventricular filling occurs during the midportion of diastole, termed *diastasis.*

Atrial contraction increases atrial pressure late in diastole producing a left atrial-to-left ventricular pressure gradient that again propels blood into the left ventricle. After atrial systole, as the left atrium relaxes, its pressure decreases below left ventricular pressure, causing the mitral valve to begin closing.[107] The onset of ventricular systole produces a rapid increase in left ventricular pressure that seals the mitral valve and ends diastole.

Normal Pattern of Left Ventricular Filling.

The normal pattern of left ventricular filling is characterized by rapid filling early in diastole with some additional filling during atrial contraction (see Figs. 7-34, p. 175, and

Figure 15-21 (Figure Not Available) Patterns of left ventricular (LV) filling as recorded by diastolic Doppler mitral flow velocities. In the normal pattern there is a large E wave and a small A wave. There are three abnormal patterns of mitral filling representing progressively worsening LV diastolic performance. With "impaired relaxation" the E wave is less than the A wave. The LV deceleration time (t_{dec}

) is prolonged. In the "pseudonormalized" pattern the E wave is larger than A wave, however, t_{dec} is shortened. In the restricted filling pattern, E is much larger than A with a very short t_{dec} . (See also Table 15-4.) (Modified from Little WC, Warner JG Jr, Rankin KM, et al: Evaluation of left ventricular diastolic function from the pattern of left ventricular filling. Clin Cardiol 21:5, 1998.)

TABLE 15-3 -- NORMAL VALUES OF PARAMETERS OF LEFT VENTRICULAR DIASTOLIC FILLING MEASURED BY DOPPLER ECHOCARDIOGRAPHY

	ADULTS <41 YR	**ADULTS <55 YR**
Peak mitral flow velocity (E) (cm/sec)	76±13	63±11
Peak mitral filling rate (A) (cm/sec)	38±8	52±9
Mitral E/A	2.1±0.6	1.3±0.3
Mitral E deceleration time	184±24	
Mitral E deceleration rate (m/sec^2)	5.6±2.7	
Isovolumetric relaxation time (msec)	74±26	
Peak pulmonary venous AR wave (cm/sec)	18±3	25±5
Peak pulmonary venous S wave (cm/sec)	41±10	60±10
Peak pulmonary venous D wave (cm/sec)	53±10	38±10

Data from Little WC, Downes TR: Clinical evaluation of left ventricular diastolic performance. Prog Cardiovasc Dis 32:273, 1990; and Rakowski H., et al: Canadian consensus recommendations for the measurements and reporting of diastolic dysfunction by echocardiography. J Am Soc Echocardiogr 9:745 and 754, 1996.

15-21). This normal filling pattern can be quantified by measuring the peak early diastolic filling rate or mitral flow velocity (E), the integral of the early diastole filling or flow velocity, and the peak filling rate (A) or mitral flow velocity during atrial contraction.[99] [100] [101] [102] [103] The relative contribution of early and late (atrial) filling is commonly expressed as the E/A ratio. Normally, the E/A ratio is greater than 1.0. The time required for deceleration of the early diastolic flow (t_{dec}) and the rate of this deceleration (E/t_{dec}) are two other important parameters of the filling pattern. A variety of other measures have also been proposed. Table 15-3 lists the ranges of normal values for these measures. The wide range of normal values is caused by variations in the technique of performing the observations, which are both operator and equipment sensitive. Furthermore, the measures can be altered by many physiological factors.

Abnormal Patterns of Left Ventricular Filling.

The normal pattern of left ventricular filling is altered in many patients with cardiac disease.[99] [100] [101] [102] [103] [108] [109] Three abnormal patterns (in patients in sinus rhythm without mitral stenosis) have been identified indicating progressively greater impairment of diastolic function (see Figs. 7-34, p. 175, and15-21) (Figure Not Available) .

The first abnormal pattern of filling has been termed *delayed relaxation.* In this pattern there is reduced peak rate and amount of early left ventricular filling and the relative importance of atrial filling is enhanced. This results in a reversed E/A ratio of less than 1.0 (i.e., E<A). The decreased peak rate of early filling is due to a decreased early diastolic left atrial to left ventricle pressure gradient, resulting from a slowed rate of left ventricular relaxation[110] (Fig. 15-22) . The E deceleration time may be prolonged, owing to relative underfilling of the ventricle early in diastole. A "delayed relaxation" pattern can be seen in patients with left ventricular hypertrophy, arterial hypertension, and coronary artery disease and in normal elderly subjects. In many of these patients, mean left atrial pressure is within the normal range at rest and the patients are asymptomatic. In this situation, the vigorous atrial contraction compensates for the reduced early filling due to impaired left ventricular relaxation while maintaining a normal mean left atrial pressure.

Figure 15-22 Recordings of left ventricular (LVP) and left atrial pressures (LAP) and the rate of change of left ventricular volume (dV/dt) during control and serially during the development of pacing-induced heart failure in an experimental animal. During control there is a normal filling pattern with E larger than A. At 4 days a pattern of "impaired relaxation" has developed with a small E and large A. This occurs in response to a slowing of the rate of left ventricular relaxation and a smaller pressure gradient from the left atrium to the left ventricle early in diastole. As heart failure subsequently worsened, left atrial pressure increased. This ultimately resulted in a pattern of "pseudonormalization" at 2 to 3 weeks and a pattern of "restricted filling" at 4 weeks. The increased early filling (E) occurring during these patterns was associated with increases in the early diastolic left atrial to left ventricular pressure gradient produced by the marked increase in left atrial pressure. (From Ohno M, Cheng CP, Little WC: Mechanism of altered patterns of left ventricular filling during the development of congestive heart failure. Circulation 89:2241, 1994. Copyright 1994, American Heart Association.)

A second pattern of abnormal filling has been termed *pseudonormalized.* This pattern, in which the E/A ratio is greater than 1.0 (as occurs in normal persons) is seen in patients with a more severe impairment of diastolic performance than the pattern of delayed relaxation. The pseudonormalized pattern is due to a restoration of the normal early diastolic left ventricular pressure gradient due to an increase in left atrial pressure that compensates for the slowed rate of left ventricular relaxation[110] (see Fig. 15-22). The pseudonormalized pattern of filling is distinguished from normal by a more rapid rate of early diastolic flow deceleration, a faster deceleration time (typically<190 msec), and alterations in pulmonary venous flow velocity, mitral annular velocity, and flow propagation (Table 15-4) . The deceleration time is proportional to the inverse of the square root of the left ventricular chamber stiffness.[96] [110] Thus, the faster deceleration time indicates an elevated left ventricular early diastolic chamber stiffness.[96]

A third abnormal pattern of left ventricular filling indicating a severe diastolic abnormality has been termed the *restrictive pattern.* In this pattern, the early filling is increased above the control level and greatly exceeds the filling that occurs during atrial contraction; thus, the E/A ratio is usually greater than 2.0. In fact, there may be little or no filling during atrial contraction. The deceleration time is less than 150 milliseconds, and the deceleration rate of early flow is rapid. This pattern is seen in patients with severe diastolic dysfunction and pulmonary congestion. The enhanced early filling in the "restrictive pattern" results from a markedly elevated left atrial pressure that more than offsets the slowing of left ventricular relaxation.[110] The "restrictive filling" pattern is seen in patients with severe pulmonary congestion,[111] constrictive pericarditis,[112] and restrictive cardiomyopathies such as cardiac amyloidosis[113] and is associated with a poor prognosis. This is particularly true if the restrictive pattern does not improve with therapy.[114]

The three abnormal patterns of left ventricular filling represent a continuum of increasing severity of diastolic abnormalities. The pattern of delayed relaxation may be observed in asymptomatic patients with only impaired diastolic reserve, whereas the pseudonormalized and restricted patterns occur in patients with progressively more severe diastolic dysfunction who almost always have pulmonary congestion.

Calculation of Early Diastolic Chamber Stiffness.

In the absence of mitral stenosis, the E deceleration time is determined by the net stiffness of the left ventricle and left atrium.[110] However, during the time of E deceleration, left atrial pressure is kept relatively constant by pulmonary venous inflow; thus, E deceleration time is predominantly influenced by left ventricular stiffness.[96] Accordingly, effective early diastolic left ventricular chamber stiffness (K_{LV}) can be estimated from the E deceleration time (t_{dec}) as:

TABLE 15-4 -- STAGES OF DIASTOLIC DYSFUNCTION

PARAMETER	**NORMAL (YOUNG)**	**NORMAL (ADULT)**	**DELAYED RELAXATION**	**PSEUDO-NORMAL FILLING**	**RESTRICTIVE FILLING**
E/A (cm/sec)	>1	>1	<1	1-2	>2
DT (msec)	<220	<220	>220	150-200	<150
IVRT (msec)	<100	<100	>100	60-100	<60

S/D	<1	1	1	<1	<1
AR (cm/sec)	<35	<35	<35	35*	25*
V_p (cm/sec)	>55	>45	<45	<45	<45
E_a (cm/sec)	>10	>8	<8	<8	<8

AR=pulmonary venous peak atrial contraction reversed velocity; DT=early left ventricular filling deceleration time; E/A=early-to-atrial left ventricular filling ratio; E_a =peak early diastolic annular myocardial velocity; IVRT=isovolumic relaxation time; S/D=systolic-to-diastolic pulmonary venous flow ratio; V_p =color M-mode flow propagation velocity.

*Unless atrial mechanical failure is present.

Pulmonary Venous Flow Patterns.

The pattern of blood flow in the pulmonary veins provides additional information on diastolic filling.[86] [100] [115] The velocity of pulmonary venous flow can be measured by transthoracic Doppler evaluation in most patients.[116] The pulmonary venous flow velocity has three waves (see Figs. 7-34, p. 175, and 15-23) : (1) the S wave, indicating antegrade flow into the left atrium during ventricular systole; (2) the D wave, indicating antegrade flow early in diastole just following the peak of the E wave mitral valve flow; and (3) the AR wave of retrograde flow out of the left atrium during atrial systole. The S and D waves correspond to the x and y descents in the left atrial pressure, whereas the pulmonary venous AR wave corresponds to the left atrial a wave. When left ventricular end-diastolic stiffness is increased, the AR wave is augmented unless atrial systolic failure or atrial fibrillation is present. Thus, pseudonormalized and restricted mitral flow patterns are associated with large, prolonged AR waves that have a peak flow velocity greater than 35 cm/sec and are prolonged beyond the termination of the "a" wave of the mitral inflow velocity.[99] [100] [115] [117] However, some patients with restricted filling may have atrial systolic failure producing small or absent AR waves.[100]

Tissue Doppler and Color M-Mode Imaging.

Tissue Doppler can measure the velocity of mitral annular motion as the left ventricle fills (Fig. 15-24) . The motion occurs early in diastole (E_m) and during late diastole (A_m) reflecting the LV filling pattern.[100] [118] Thus, the E_m /A_m ratio is similar to the mitral E/A but may be less load dependent. Color M-mode imaging (see Fig. 15-24) measures the rate of flow propagation into the left ventricle in early diastole.[100] [119] This is reduced in conditions associated with impaired relaxation.

Figure 15-23 Pulmonary venous flow velocity recording obtained with pulsed wave Doppler demonstrating normal forward flow in systole (S) and diastole (D) and regurgitant flow during atrial contraction (AR). (Modified from Jensen JL, Williams FE, Beilby BJ, et al: Feasibility of obtaining pulmonary venous flow velocity in cardiac patients using transthoracic pulsed wave Doppler technique. J Am Soc Echocardiogr 10:64, 1997. Reproduced by permission of the American Society of Echocardiography.)

Figure 15-24 Noninvasive evaluation of left ventricular filling in a patient with diastolic dysfunction due to hypertrophic cardiomyopathy. The mitral inflow velocity shows an "impaired relaxation" pattern with E/A less than 1.0. The pulmonary venous flow pattern shows a large, prolonged atrial regurgitant (Ar) flow; the tissue Doppler measurement of mitral annular motion shows an early diastolic motion (E_a) less than the atrial expansion (A_a), corresponding to the mitral inflow pattern. The early diastolic flow propaga tion velocity measured by color M-mode imaging is reduced. (Reproduced from Nagueh SF, Lakkis NM, Middleton KJ, et al: Doppler estimation of left ventricular filling pressures in patients with hypertrophic cardiomyopathy. Circulation 99:258, 1999. Copyright 1999, American Heart Association.)

The mitral annular velocity profile and flow propagation velocity can be integrated with mitral inflow and pulmonary venous velocity to help distinguish pseudonormal and restricted filling (see Table 15-4).

Clinical Evaluation of Left Ventricular Systolic and Diastolic Performance

Left ventricular systolic performance is most simply evaluated by the ejection fraction. Unless afterload is abnormally reduced, or there is valvular regurgitation or a left-to-right shunt, an ejection fraction (greater than 0.50) indicates normal systolic left ventricular performance. A reduced ejection fraction can be due to depressed myocardial contractility or elevated afterload. The ejection fraction is not importantly influenced by most physiological changes in preload.

Left ventricular diastolic performance is more difficult to simply evaluate. A patient can be suspected of having diastolic dysfunction if there is clinical evidence of elevated left-sided filling pressures (i.e., pulmonary congestion). Left ventricular diastolic dysfunction can be associated with systolic dysfunction or may be a primary abnormality if the ejection fraction is preserved. In the presence of sinus rhythm, further clinical assessment of diastolic function can be performed by Doppler echocardiographic measurement of the pattern of mitral inflow velocity. In the absence of mitral stenosis, if the E/A is greater than 1.0 and the E deceleration time is greater than 190 milliseconds, diastolic function is probably normal. This can be confirmed by an isovolumic relaxation time of less than 100 milliseconds and a pulmonary venous AR wave less than 35 cm/sec that ends before the mitral A wave. An E/A less than 1.0 (impaired relaxation pattern) associated with a pulmonary venous AR wave that is elevated (> 35 cm/sec) and prolonged beyond the mitral A wave indicates mild-to-moderate diastolic dysfunction. An E/A greater than 1.0 associated with an E deceleration time less than 190 milliseconds and/or an enlarged delayed AR wave (pseudonormalized or restricted patterns) indicates more severe diastolic dysfunction. An E deceleration time less than 150 milliseconds indicates a stiff left ventricle and a poor prognosis, especially if it does not lengthen after diuresis.

Assessment of Right Ventricular Performance

Although most attention in adult cardiology is appropriately focused on the performance of the left ventricle, the right ventricle may be an important contributor to cardiac dysfunction.[120] The concepts of preload, afterload, and contractility and most of the methods of evaluating left ventricular performance are also applicable to the right ventricle. The ejection of the thin-walled right ventricle is more sensitive to increases in afterload than the left ventricle. Right ventricular dilatation in response to increased afterload is limited by the tethering of the right ventricle to the much thicker left ventricle and the limitations imposed by the pericardium. With increased afterload, the thin-walled right ventricle dilates, causing functional tricuspid regurgitation. Right ventricular performance can be importantly influenced by the presence and severity of such regurgitation.

Right ventricular volume and ejection fraction can be measured using echocardiography, radionuclear techniques, and angiography. In addition, right ventricular stroke volume

and ejection fraction can be monitored on-line using the thermodilution technique.[121] This is performed by injecting a bolus of cold dextran solution into the right atrium while the temperature in the pulmonary artery is recorded using a rapidly responding thermistor mounted on a catheter. This technique, which allows serial measurements, is convenient, reproducible, and reasonably accurate.

The right ventricular ESPVR can be determined with a manometer-tipped catheter in the right ventricle and either an impedance catheter or a radionuclide ventriculogram to provide simultaneous measurements of right ventricular volume while varying right ventricular load.[122] [123] The right ventricular ESPVR behaves in a similar manner as the left ventricular ESPVR discussed earlier. The right ventricular ESPVR is linear in the physiological range and is shifted upward and leftward by

the positive inotropic agent dobutamine.

INTEGRATED CARDIOVASCULAR PERFORMANCE

Cardiac Output (See Chap. 11)

The integrated pumping function of the cardiovascular system results in the cardiac output. The cardiac output can be measured using indicator dilution techniques discussed in Chapter 11 or by the Fick principle (see below).[124]

The cardiac output is usually corrected for body size and expressed as the cardiac index. The normal range for the cardiac index at a basal (resting) state in the supine position is wide, between 2.5 and 4.2 liters/min/m^2 . The wide normal range makes it possible for cardiac output to decline by almost 40 percent and still remain within the normal limits. Thus, a low cardiac index of less than 2.5 liters/min/m^2 usually represents a marked disturbance of cardiovascular performance and is almost always clinically apparent. Although the resting cardiac output (or index) is insensitive in detecting mild to moderate cardiac impairment, it provides a valuable measure of the integrated function

Figure 15-25 Relation between arteriovenous oxygen (AV_{O_2}) difference (broken line) and cardiac index (solid curve) in normal subjects at rest *(center)* and during exercise *(right)*, and in the patient with progressively worsening myocardial failure *(left)*. Integrated cardiopulmonary function
Mixed venous oxygen saturation
Exercise performance

of the cardiovascular system, especially in critically ill patients.

Arterial-Venous Oxygen Difference

The most critical function of the cardiovascular system is to supply the tissues with oxygen. This requires the integrated action of the heart, circulation, lungs, and the peripheral metabolism.[125] As defined by the Fick principle, the oxygen delivered to the body is the product of the cardiac output and the difference in oxygen content of the arterial blood and the mixed venous blood (A-V_{O_2} difference).[124] Under normal circumstances at rest, adequate oxygen supply to the tissues is produced with an A-V_{O_2} difference of 40 ± 10 ml O_2 /liter. With nearly fully oxygenated arterial blood (> 98 percent saturation) and normal hemoglobin concentration and oxygen-carrying capacity, the normal A-V_{O_2} difference is achieved with a mixed venous oxygen saturation of more than 70 percent. If the cardiac output is inadequate, the tissues extract more oxygen and the A-V_{O_2} difference increases. In this situation mixed venous oxygen saturation falls (Fig. 15-25). Thus, a normal mixed venous oxygen saturation (> 70 percent) indicates that the cardiac output (and other components of the circulation) are adequate to meet the body's demands.[126] [127]

A wide A-V_{O_2} difference and reduced mixed venous oxygen saturation may result from an abnormality of cardiovascular function that is limiting the cardiac output, a defect in the oxygen-carrying capacity of the blood, or pulmonary disease. When the ability to increase oxygen extraction is exhausted, anaerobic metabolism produces lactate and venous lactate levels rise precipitously.[128]

The myocardium extracts oxygen nearly maximally from blood at rest. Thus, the coronary sinus oxygen saturation is low (<40 percent) and the myocardium cannot use an increase in oxygen extraction as a compensatory mechanism for inadequate coronary flow.

During exercise the body's oxygen consumption increases.[123A] [123B] This increased need is met by a combination of an increase in cardiac output and a widening of the A-V_{O_2} difference. [124] For example, during very strenuous exercise, the oxygen consumption increases up to 18-fold. This is accomplished by a 6-fold increase in cardiac output (from 3 to 18 liters/min/m^2) and a 3-fold increase in the A-V_{O_2} difference (from 40 to 120 ml/liter), with the mixed venous oxygen saturation decreasing from 75 to 25 percent.

Cardiopulmonary Exercise Testing

The integrated performance of the cardiovascular and pulmonary systems can be evaluated by cardiopulmonary exercise testing, which is discussed on pp. 129-131.

CLINICAL EVALUATION OF CARDIAC PERFORMANCE

Many of the measures of cardiac performance just described are important for their conceptual value and role in special situations and clinical investigations. The measures of various aspects of cardiac performance most commonly used in clinical practice are summarized in Table 15-5 .

Chapter 16 - Pathophysiology of Heart Failure

WILSON S. COLUCCI
EUGENE BRAUNWALD

Heart (or cardiac) failure is the pathophysiological state in which the heart is unable to pump blood at a rate commensurate with the requirements of the metabolizing tissues or can do so only from an elevated filling pressure. It is usually, but not always, caused by a defect in myocardial contraction, that is, by *myocardial failure.* However, in some patients with heart failure a similar clinical syndrome is present but there is no detectable abnormality of *myocardial* function. In many such cases, heart failure is caused by conditions in which the normal heart is suddenly presented with a load that exceeds its capacity or in which ventricular filling is impaired.[1] *Heart failure* should be distinguished from *circulatory failure,* in which an abnormality of some component of the circulation--the heart, the blood volume, the concentration of oxygenated hemoglobin in the arterial blood, or the vascular bed--is responsible for the inadequate cardiac output.

Thus, the terms myocardial failure, heart failure, and circulatory failure are not synonymous but refer to progressively more inclusive entities. Myocardial failure, when sufficiently severe, always causes heart failure, but the converse is not necessarily the case, because a number of conditions in which the heart is suddenly overloaded (e.g., acute aortic regurgitation secondary to acute infective endocarditis) can cause heart failure in the presence of normal myocardial function, at least early in the course of the illness. Myocardial failure may be associated with systolic dysfunction, diastolic dysfunction, or both. Also, conditions such as tricuspid or mitral stenosis and constrictive pericarditis, which interfere with cardiac filling, can cause heart failure without myocardial failure. Heart failure, in turn, always causes circulatory failure, but again the converse is not necessarily the case, because a variety of noncardiac conditions (e.g., hypovolemic shock) can produce circulatory failure at a time when cardiac function is normal or only modestly impaired.

The hemodynamic, contractile, and wall motion disorders in heart failure are discussed in the chapters on echocardiography (see Chap. 7) , cardiac catheterization (see Chap. 11) , radionuclide imaging (see Chap. 9) , and assessment of cardiac function (see Chap. 15) . In this chapter, the focus is on the physiological, neurohumoral, biochemical, molecular, and cellular changes characteristic of heart failure.

SHORT-TERM ADAPTIVE MECHANISMS

In the presence of a primary disturbance in myocardial contractility or an excessive hemodynamic burden placed on the ventricle, or both, the heart depends on a number of adaptive mechanisms for maintenance of its pumping function[2] (Table 16-1) . Most important among these are (1) the Frank-Starling mechanism, in which an increased preload helps to sustain cardiac performance; (2) activation of neurohumoral systems, especially the release of the neurotransmitter norepinephrine (NE) by adrenergic cardiac nerves (see p. 520), which augments myocardial contractility, and the activation of the renin-angiotensin-aldosterone system (see p. 524) and other neurohumoral adjustments that act to maintain arterial pressure and perfusion of vital organs; and (3) myocardial remodeling with or without cardiac chamber dilatation, in which the mass of contractile tissue is augmented (see p. 507). The first two of these adaptations occur rapidly, over minutes to hours of the onset of severe myocardial dysfunction, and may be adequate to maintain the overall pumping performance of the heart at relatively normal levels. Myocardial hypertrophy and remodeling develop more slowly, over weeks to months, and play an important role in long-term adaptation to hemodynamic overload. However, the capacity of each of these mechanisms to sustain cardiac performance in the face of hemodynamic overload is finite and, when chronically maintained, becomes maladaptive.

HEMODYNAMIC AND CIRCULATORY CONSEQUENCES OF HEART FAILURE (SeeChap. 15) .

Cardiac output is often depressed, and the arterial/mixed venous oxygen difference is widened in the basal state in patients with the common forms of heart failure secondary to ischemic heart disease, hypertension, primary myocardial disease, valvular disease, and pericardial disease (so-called low-output, systolic heart failure). In cases of mild heart failure, the cardiac output may be normal at rest but fails to rise normally during exercise. When the volume of blood delivered into the systemic arterial bed is chronically reduced, and/or when one or both ventricles has an elevated filling pressure, a complex sequence of adjustments occurs that ultimately results in the *retention of sodium and water* in the intravascular and interstitial compartments. Many of the clinical manifestations of heart failure such as dyspnea and edema

TABLE 16-1 -- SHORT-TERM AND LONG-TERM RESPONSES TO IMPAIRED CARDIAC PERFORMANCE

RESPONSE	SHORT-TERM EFFECTS*	LONG-TERM EFFECTS
Salt and water retention	Augments preload	Causes pulmonary congestion, anasarca
Vasoconstriction	Maintains blood pressure for perfusion of vital organs (brain, heart)	Exacerbates pump dysfunction (afterload mismatch); increases cardiac energy expenditure
Sympathetic stimulation	Increases heart rate and ejection	Increases energy expenditure
Sympathetic desensitization		Spares energy
Hypertrophy	Unloads individual muscle fibers	Leads to deterioration and death of cardiac cells; cardiomyopathy of overload
Capillary deficit		Leads to energy starvation
Mitochondrial density	Increase in density helps meet energy demands	Decrease in density leads to energy starvation
Appearance of slow myosin		Increases force, decreases shortening velocity and contractility; is energy sparing
Prolonged action potential		Increases contractility and energy expenditure
Decreased density of sarcoplasmic reticulum calcium-pump sites		Slows relaxation; may be energy sparing
Increased collagen	May reduce dilatation	Impairs relaxation

From Katz AM: Cardiomyopathy of overload: A major determinant of prognosis in congestive heart failure. N Engl J Med 322:100, 1990. Copyright 1990, Massachusetts Medical Society.

*Short-term effects are mainly adaptive and occur after hemorrhage and in acute heart failure.

Long-term effects are mainly deleterious and occur in chronic heart failure.

are secondary to this excessive retention of fluid (see Chap. 17).

Interaction Between the Frank-Starling Mechanism and the Adrenergic Nervous System

It is useful to consider the function of the normal and failing heart within the framework of the Frank-Starling mechanism, in which an increase in preload, reflected in an elevation of end-diastolic volume, augments ventricular performance. The normal relationship between ventricular end-diastolic volume and performance is shown in Figure 16-1 , curve 1. During exercise and other stresses, the increases in adrenergic nerve impulses to the myocardium, the concentration of circulating catecholamines (see p. 520), and tachycardia all augment myocardial contractility with a shift from curve 1 to curve 2. Ventricular performance, as reflected in stroke work or cardiac output, increases with little change in end-diastolic pressure and volume. This is represented by a shift from point A to point B in Figure 16-1. Vasodilation occurs in the exercising muscles, reducing peripheral vascular resistance and aortic impedance. This ultimately allows achievement of a greatly elevated cardiac output during exercise, at an arterial pressure only slightly greater than in the resting state. During intense exercise, cardiac output can rise to a maximal level if use is made of the Frank-Starling mechanism, as reflected in modest increases in the left ventricular end-diastolic volume and pressure (point B to point C).

In moderately severe systolic heart failure, as represented by curve 3, cardiac output and external ventricular performance at rest are within normal limits but are maintained at these levels only because the end-diastolic fiber length and the ventricular end-diastolic volume (ventricular preload) are elevated (i.e., through the operation of the Frank-Starling mechanism). The elevations of left ventricular diastolic pressure are associated with abnormally high levels of pulmonary capillary pressure, contributing to the dyspnea experienced by patients with heart failure, sometimes even at rest (point D).

Heart failure is characterized by generalized adrenergic activation and parasympathetic withdrawal[3] (Fig. 16-2) . This leads to stimulation of myocardial contractility, tachycardia, sodium retention, renin release, and generalized systemic vasoconstriction. Heart failure is frequently accompanied by reductions in NE stores and myocardial beta-adrenoceptor density (see p. 523) and therefore in the inotropic response to impulses in the cardiac adrenergic nerves. As a consequence, ventricular function (performance) curves cannot be elevated to normal levels by the adrenergic nervous system and the normal improvement of contractility that takes place during exercise is attenuated (Fig. 16-1 , curves 3 to 3
). The factors that tend to augment

Figure 16-1 Diagram showing the interrelationship of influences on ventricular end-diastolic volume (EDV) through stretching of the myocardium and the contractile state of the myocardium. Levels of ventricular EDV associated with filling pressures that result in dyspnea and pulmonary edema are shown on the abscissa. Levels of ventricular performance required during rest, walking, and maximal activity are designated on the ordinate. The dotted lines are the descending limbs of the ventricular performance curves, which are rarely seen during life but that show what the level of ventricular performance would be if end-diastolic volume could be elevated to very high levels. (Modified from Braunwald E, Ross J Jr, Sonnenblick EH: Mechanisms of Contraction of the Normal and Failing Heart. Boston, Little, Brown, 1979.)

Figure 16-2 Mechanisms for generalized sympathetic activation and parasympathetic withdrawal in heart failure. *A,* Under normal conditions, inhibitory (-) inputs from arterial and cardiopulmonary baroreceptor afferent nerves are the principal influence on sympathetic outflow. Parasympathetic control of heart rate is also under potent arterial baroreflex control. Efferent sympathetic traffic and arterial catecholamines are low, and heart rate variability is high. *B,* As heart failure progresses, inhibitory input from arterial and cardiopulmonary receptors decreases and excitatory (+) input increases. The net response to this altered balance includes a generalized increase in sympathetic nerve traffic, blunted parasympathetic and sympathetic control of heart rate, and impairment of the reflex sympathetic regulation of vascular resistance. Anterior wall ischemia has additional excitatory effects on efferent sympathetic nerve traffic. See text for details. Ach=acetylcholine; CNS=central nervous system; E=epinephrine; Na^+ =sodium; NE=norepinephrine. (From Floras JS: Clinical aspects of sympathetic activation and parasympathetic withdrawal in heart failure. J Am Coll Cardiol 22:72A, 1993.)

ventricular filling during exercise push the failing ventricle even farther along its flattened, depressed function curve. There is an inordinate elevation of ventricular end-diastolic volume and pressure and therefore of pulmonary capillary pressure.[4] The elevation of the latter intensifies dyspnea and plays an important role in limiting the intensity of exercise that the patient can perform. According to this formulation, left ventricular failure becomes fatal when the left ventricular function curve becomes depressed (curve 4) to the point at which either cardiac output is insufficient to satisfy the requirements of the peripheral tissue at rest or the left ventricular end-diastolic and pulmonary capillary pressures are elevated to levels that result in pulmonary edema or both (point E).

Vascular Redistribution of Left Ventricular Output

Maintenance of arterial pressure in the presence of a reduced cardiac output is a primitive but effective compensatory mechanism. In hypovolemia and heart failure, this important mechanism is brought into play to allow the limited cardiac output to be most useful for survival. Thus, vasoconstriction occurs earliest and is most intense in areas that are not vital for immediate survival.

INCREASED VASOCONSTRICTOR ACTIVITY.

The major mechanism of increased vascular tone is an increase in the activity of vasoconstrictor systems, in particular, the sympathetic nervous system, the renin-angiotensin system, and the endothelin system. In patients with moderately severe heart failure, in whom the cardiac output at rest is normal, abnormal vasoconstriction occurs when an additional burden (e.g., exercise, fever, or anemia) is imposed on the circulation and the cardiac output does not rise normally to meet the peripheral demands. As cardiac performance declines, left ventricular output is ultimately redistributed, even at rest. This redistribution maintains the delivery of oxygen to vital organs such as the brain and heart, whereas blood flow to less critical areas, such as the skin, skeletal muscle, gut, and kidney, is reduced.[5] [6] [7]

This underperfusion of skeletal muscle leads to anaerobic metabolism,[8] lactic acidosis, an excess oxygen debt, weakness, and fatigue. Occasionally, serious complications can result from the redistribution

of cardiac output and the resulting regional reductions of blood flow. These include marked sodium and nitrogen retention as a consequence of diminished renal perfusion, hepatic dysfunction, and, very rarely, gangrene of the tips of the phalanges and mesenteric infarction.

With heart failure there is a generalized increase in sympathetic activity. Neurograms obtained from adrenergic nerves to the limbs display an increased traffic in patients with heart failure.[9] Substantial changes also occur in the function of the adrenergic nerves that innervate splanchnic and renal vessels.[10] Although direct neurograms of these beds are not feasible in patients, it has been shown that exercise induces a much more marked reduction in mesenteric blood flow and elevation of mesenteric vascular resistance in dogs with experimental heart failure than in normal dogs.[11] Similar changes during exercise were observed in other major visceral vascular beds, such as the renal bed. Evidence that this intense vasoconstriction during exercise is mediated by the adrenergic nervous system is provided by observations on dogs with experimentally produced heart failure in which one kidney was denervated. Blood flow through the normal kidney declined precipitously during exercise, and calculated renal vascular resistance increased markedly. In contrast, little change in renal blood flow and calculated renal vascular resistance occurred in the denervated kidney.[11] This intensive visceral vasoconstriction during exercise helps to divert the limited cardiac output to exercising muscle but, conversely, may contribute to hypoperfusion of the gut and kidneys.

The renin-angiotensin and endothelin systems also contribute to the increased systemic vascular tone in heart failure. These potent vasoconstrictor systems are activated in patients with heart failure (see p. 526), where their contribution to systemic vasoconstriction has been demonstrated by the ability of specific inhibitors for

angiotensin[12] and endothelin[13] receptors to cause vasodilation in patients with heart failure.

ENDOTHELIAL DYSFUNCTION.

Both ischemia-induced and exercise-induced vasodilation in the extremities are attenuated in patients with heart failure.[14] This attenuation is related in part to endothelial dysfunction (see Chap. 34) . The response of blood flow to infused acetylcholine and methacholine, which are endothelium-dependent vasodilators, is reduced in heart failure (Fig. 16-3) . The vasodilator response can be restored by the administration of L-arginine,

Figure 16-3 Responses of forearm blood flow (FBF) to acetylcholine in patients with heart failure (HF) (
) and in control subjects (
). The FBF at rest and during infusion of acetylcholine (Ach) was less in patients with heart failure than in control subjects. The magnitudes of the increases in FBF in response to ACh were less in patients with heart failure than in control subjects. In contrast, the responses to sodium nitroprusside were comparable. (From Hirooka Y, Imaizumi T, Tagawa T, et al: Effects of L-arginine on impaired acetylcholine-induced and ischemic vasodilation of the forearm in patients with heart failure. Circulation 90:658, 1994. Copyright, 1994 American Heart Association.)

a precursor of endothelium-derived nitric oxide (NO). These findings suggest that defective endothelial function contributes to the impaired vasodilator capacity in heart failure. The mechanisms potentially responsible include impaired endothelial cell receptor function, deficiency of L-arginine substrate, abnormal expression of nitric oxide synthase (NOS), and the impaired release or rapid degradation of the endothelium-derived relaxing factor NO.[15] Impaired endothelial function is improved in patients by regular exercise.[16]

CHANGES IN THE VASCULAR WALL.

The sodium content of the vascular wall is increased in heart failure, and this contributes to the stiffening, thickening, and compression of blood vessel walls, which raises vascular resistance and also prevents normal vasodilation during exercise.[5] The veins in the extremities of patients with heart failure are also constricted by the activity of the adrenergic nervous system as well as by circulating venoconstrictors (NE, angiotensin, and endothelin). This venoconstriction results in displacement of blood to the heart and lungs.

2,3-DIPHOSPHOGLYCERATE.

A progressive decline in the affinity of hemoglobin for oxygen due to an increase in 2,3-diphosphoglycerate (DPG) also occurs in heart failure.[17] The rightward shift in the oxygen-hemoglobin dissociation curve represents a compensatory mechanism that facilitates oxygen transport; the increased DPG, tissue acidosis, and the slowed circulation characteristic of heart failure act synergistically to maintain the delivery of oxygen to the metabolizing tissues in the face of a reduced cardiac output.

CHRONIC MYOCARDIAL REMODELING

PATTERNS OF VENTRICULAR REMODELING.

The development of ventricular hypertrophy constitutes one of the principal mechanisms by which the heart compensates for an increased load.[18] Grossman and associates examined systolic and diastolic wall stresses in normal subjects and in patients with chronic pressure- and volume-overloaded left ventricles who were compensated and not in heart failure.[19] Left ventricular mass was increased approximately equally in both the pressure- and volume-overloaded groups. There was a substantial increase in wall thickness in the pressure-overloaded ventricles but only a mild increase in wall thickness in the volume-overloaded ventricles (Fig. 16-4) . The latter was just sufficient to counterbalance the increased radius, so that the ratio of wall thickness to radius remained normal for the patients with volume-overload hypertrophy. This ratio was substantially increased in patients with pressure-overload hypertrophy, in whom there was disproportionate thickening of the ventricular wall. These observations are consistent with those of other investigators, who have indicated that myocardial hypertrophy develops in a manner that maintains systolic stress within normal limits.[20] [21] Thus, when the primary stimulus to hypertrophy is pressure overload, the resultant acute increase in systolic wall stress leads to parallel replication of myofibrils, thickening of individual myocytes,[22] and concentric hypertrophy. The wall thickening is usually sufficient to maintain a normal level of systolic stress (Fig. 16-5) .

When the primary stimulus is ventricular volume overload, increased diastolic wall stress leads to replication of sarcomeres in series, elongation of myocytes, and ventricular dilatation. This, in turn, results in a modest increase in systolic stress[23] (by the Laplace relationship), which causes proportional wall thickening that returns systolic stress toward normal.[23A] Thus, in compensated subjects, both volume and pressure overload alter ventricular geometry and wall thickness, so that systolic stress does not change greatly. Pressure and volume overload also result in distinct cellular phenotypes at the molecular level with different patterns of activation of genes for several peptide growth factors.[6] This heterogeneity at the molecular level presumably reflects differences in the way the two types of hemodynamic overload activate signaling pathways and, in turn, the resultant cellular changes that manifest at the tissue and organ levels.

Figure 16-4 The morphologic response to a hemodynamic overload depends on the nature of the stimulus. When the overload is predominately due to an increase in pressure (e.g., with systemic hypertension or aortic stenosis) the increase in systolic wall stress leads to the parallel addition of sarcomeres and widening of the cardiac myocytes, resulting in concentric hypertrophy of the ventricle. When the overload is predominately due to an increase in ventricular volume, the increase in diastolic wall stress leads to the series addition of sarcomeres, lengthening of cardiac myocytes, and eccentric chamber hypertrophy. (From Sawyer DB, Colucci WS: Molecular and cellular events in myocardial hypertrophy and failure. *In* Colucci WS [ed]: Heart Failure: Cardiac Function and Dysfunction, Atlas of Heart Diseases. Vol 4. Philadelphia, Current Medicine, 1999, p 4.2.)

Left ventricular wall thickness is a critical determinant of ventricular performance in patients with pressure-overload hypertrophy due to aortic stenosis or hypertension. Impaired performance in such patients may be secondary to inadequate hypertrophy, leading to increased wall stress (afterload), which in turn may be responsible for inadequate muscle shortening.[23A] This condition has been termed "afterload-mismatch" by Ross.[24] His group found that when the aorta in conscious dogs was suddenly constricted, left ventricular systolic pressure rose, the left ventricle dilated, and the left ventricular wall thinned; this was associated with a large increase in wall stress and a reciprocal reduction in the extent and velocity of shortening.[25] During the next few weeks, the left ventricle became hypertrophied and left ventricular wall stress and shortening both returned toward normal. When the constriction was suddenly released, wall stress declined and shortening became supernormal.

Prolonged athletic training causes a moderate increase in myocardial mass (see also Chap. 59) . Isotonic exercise, such as long-distance running or swimming, resembles volume overload and causes an increase in left ventricular diastolic volume, with only mild thickening of the wall. Isometric exercise, such as weightlifting or wrestling, resembles pressure overload and causes an increase in wall thickness. Neither form of hypertrophy appears to be deleterious in the absence of heart disease and rapidly disappears when training is discontinued.

CELLULAR CHANGES IN MYOCARDIAL REMODELING.

One of the early cellular changes that occurs after a stimulus for hypertrophy is applied is the synthesis of mitochondria; presumably, the expanded mitochondrial mass provides the high-energy phosphates required to meet the increased energy demands of the hypertrophied cell. This is accompanied by an expansion of the myofibrillar mass. After the neonatal period, the increase in myocardial mass is associated with a proportional increase in the size of individual cells (i.e., hypertrophy), without any increase (or a minimal increase) in the number of cells (i.e., without hyperplasia).[2] Myocytes isolated from animals with pressure overload hypertrophy due to aortic constriction are thickened,[26] whereas myocytes from animals with volume overload due to an aortocaval fistula are elongated.[27] Myocytes from patients with heart failure due to chronic ischemic cardiomyopathy are longer and, to a lesser extent, wider[28] than normal cells (Fig. 16-6) .

These changes within the myocyte are accompanied by changes in both the quantity and quality of collagen within the extracellular matrix.[29] Taken together, these changes in myocyte geometry and the extracellular matrix result in remodeling of the myocardium. Hemodynamic overload reactivates growth factors present in the embryonic heart but dormant in the normal adult heart. These reactivated growth factors stimulate the hypertrophy of cardiac myocytes and regulate the synthesis and degradation of the extracellular matrix. Current understanding of the fundamental mechanisms responsible for myocardial remodeling is described on p. 510 .

Figure 16-5 The normal (N) relationship between left ventricular wall thickness (h) and chamber radius (r) is shown *(first panel)*. An acute increase in systolic pressure (acute load) causes an increase

in systolic wall stress, which can be approximated by the equation P×r/h, where P is left ventricular systolic pressure. Diastolic wall stress is also increased when there is chamber dilatation or when diastolic pressure is elevated *(second panel)*. If sufficient compensatory hypertrophy occurs, the increase in ventricular wall thickness may normalize the systolic and diastolic wall stresses *(third panel)*. However, if additional chamber dilatation occurs or the increase in wall thickness is insufficient, systolic and diastolic wall stresses remain abnormally elevated. In this situation, further chamber dilatation may occur in association with hemodynamic failure *(fourth panel)*. (From Sawyer DB, Colucci WS: Molecular and cellular events in myocardial hypertrophy and failure. *In* Colucci WS [ed]: Heart Failure: Cardiac Function and Dysfunction. Atlas of Heart Diseases. Vol 4. Philadelphia, Current Medicine, 1999, p 4.2.)

Figure 16-6 Isolated cardiac myocytes obtained from human left ventricular myocardium. *A,* Myocyte from a normal heart (bar=100 m). *B,* A hypertrophied myocyte from the left ventricle of a patient with ischemic cardiomyopathy, viewed at the same magnification as in *A.* This myocyte is longer than the normal myocyte. The myocytes have been stained with rhodamine-phalloidin for visualization of the sarcomere structure. In the myocyte from the failing heart there has been addition of sarcomeres. These are otherwise organized in a normal pattern. (Modified from Gerdes AM, et al: Structural remodeling of cardiac myocytes in patients with ischemic cardiomyopathy. Circulation 86:426, 1992. Copyright 1992, American Heart Association.)

ULTRASTRUCTURAL CHANGES.

There are a number of structural features of hypertrophied human myocytes (Fig. 16-7 (Figure Not Available)). These include abnormal Z-band patterns, multiple intercalated discs, and prominent collagen fibrils connecting adjacent myocardial cells. Nuclei are enlarged and lobulated and contain well-developed nucleoli; there is an abundance of ribosomes, presumably reflecting enhanced protein synthesis. However, electron microscopic studies of myocardium removed from overloaded, dilated hearts fixed at the elevated filling pressures that existed during life have revealed sarcomere lengths averaging 2.2 mum--no longer than those at the apex of the length/active tension curve of normal cardiac muscle.[30] This finding indicates that the depressed contractility of failing heart muscle is *not* due to the disengagement of actin and myosin filaments.

Mechanical Performance of Remodeled Myocardium

When an excessive pressure or volume load is imposed on the ventricle, myocardial remodeling occurs, providing one of the aforementioned key compensatory mechanisms that permits the ventricle to sustain an increased load.[18] However, as described later, a ventricle subjected to an abnormally elevated load for a prolonged period may fail to maintain compensation despite the presence of ventricular hypertrophy and pump failure may ultimately occur.[31]

ISOLATED MUSCLE.

Cardiac muscle isolated from animals in which the heart had been subjected to a controlled stress has been studied by many investigators. One convenient experimental model of ventricular pressure overload is the cat (or ferret) with pulmonary artery constriction. Papillary muscles are then removed from the right ventricles in which either hypertrophy or overt failure has developed, and the excised muscles are studied in vitro.[32] [33] Both right ventricular hypertrophy and failure reduce the maximum velocity of (unloaded) shortening (Vmax) of excised muscle below the values observed in muscles obtained from normal cats. These changes are more marked in animals in which heart failure has been present than in those with hypertrophy alone (Fig. 16-8) . Because the depression of myocardial contractility is evident in vitro, when the muscle's physical and chemical milieu is controlled, it is considered to be *intrinsic* and not the result of

Figure 16-7 (Figure Not Available) The early stage of cardiac hypertrophy *(A)* is characterized morphologically by increases in the number of myofibrils and mitochondria as well as enlargement of mitochondria and nuclei. Muscle cells are larger than normal, but cellular organization is largely preserved. At a more advanced stage of hypertrophy *(B),* preferential increases in the size or number of specific organelles, such as mitochondria, as well as irregular addition of new contractile elements in localized areas of the cell, result in subtle abnormalities of cellular organization and contour. Adjacent cells may vary in their degree of enlargement. Cells subjected to long-standing hypertrophy *(C)* show more obvious disruptions in cellular organization, such as markedly enlarged nuclei with highly lobulated membranes, which displace adjacent myofibrils and cause breakdown of normal Z-band registration. The early preferential increase in mitochondria is supplanted by a predominance by volume of myofibrils. The late stage of hypertrophy *(D)* is characterized by loss of contractile elements with marked disruption of Z bands, severe disruption of the normal parallel arrangement of the sarcomeres, deposition of fibrous tissue, and dilation and increased tortuosity of T tubules. (From Ferrans VJ: Morphology of the heart in hypertrophy. Hosp Pract 18:69, 1983. Copyright 1983, McGraw-Hill Companies, Inc.)

Figure 16-8 *A,* Relation between muscle length and tension of papillary muscles from normal (circles), hypertrophied (RVH, squares), and failing (CHF, triangles) right ventricles. Open symbols=resting tension; filled symbols=actively developed tension. Tension is corrected for cross-sectional area (g/mm^2). Numbers in parentheses=number of animals. *B,* Force-velocity relations of the three groups of cat papillary muscles. Average values ± SEM are given for each point. Velocity has been corrected to muscle lengths per second (L_0 /sec). (From Spann JF Jr, Buccino RA, Sonnenblick EH, Braunwald E: Contractile state of cardiac muscle obtained from cats with experimentally produced ventricular hypertrophy and heart failure. Circ Res 21:341, 1967. Copyright 1967, American Heart Association.)

any humoral or neural stimuli or abnormal loading conditions that are present in vivo. The depression of contractility in hypertrophied myocardium is less marked or even absent when the stress is imposed slowly and when the measurements are made during a stable phase of the ventricular response to overload.

The findings just summarized are, in general, consonant with those of a number of other investigations on cardiac muscle isolated from animals with experimentally produced pressure overload. For example, the trabeculae carnae or papillary muscles removed from the left ventricles of rats with left ventricular hypertrophy secondary to aortic constriction or renovascular hypertension also exhibit depression of the velocity of isotonic shortening and prolongation of duration of the action potential, of isometric contraction, and of the time-to-peak tension, even when the development of isometric tension is normal.[34] The force and rate of force development are also depressed in isometrically contracting myocardium obtained from hearts with totally different forms of heart failure (e.g., Syrian hamsters with hereditary cardiomyopathy), as well as papillary muscles removed from the left ventricles of patients with heart failure due to chronic valvular disease.[35] In nonfailing myocardium, the force of contraction and rate of tension development rise with increased stimulation frequency, the so-called *positive force-frequency relationship* (see Chap. 14) . However, there is evidence of an abnormal (negative) force-frequency relationship in failing human myocardium.[36] The mechanism responsible for the negative force-frequency response appears to be impaired reuptake of calcium into the sarcoplasmic reticulum (SR) due to a decrease in Ca^{2+} adenosine triphosphatase (ATPase) (SERCA2) activity in failing myocardium [37] , [38] (see p. 512).

INTACT HEARTS.

Changes in performance of the intact heart subjected to abnormal hemodynamic loads are, in general, similar to those in isolated cardiac tissue. Thus, the right ventricles of cats with pulmonary artery constriction exhibit a marked depression paralleling that observed in the isolated papillary muscles removed from these ventricles.[39] When compared with normal values, the active tension developed by the right ventricle at equivalent end-diastolic fiber lengths is markedly reduced in cats with heart failure produced by pressure overload.

Immediately after the imposition of a volume overload (e.g., the opening of a large arteriovenous fistula), the contractility of the ventricle, as reflected in the end-systolic stress-circumference relationship, may actually increase, perhaps as a consequence of adrenergic stimulation. However, it then declines, while overall hemodynamic performance (i.e., cardiac work) is sustained.[40] Later in the course of a large volume overload, overt clinical heart failure develops, accompanied by increases in left ventricular end-diastolic volume and in the ratio of left ventricular weight to body weight and by depressed indices of left ventricular contractility [41] (see Chap. 15) . As the ventricle fails, it moves to the right along a depressed performance (function) curve, so that it requires an abnormally elevated end-diastolic volume (and often an elevation of end-diastolic pressure as well) to generate a level of tension equal to that achieved by the normal heart at a normal end-diastolic volume.

Transition to Heart Failure

When the ventricle is stressed, by either a pressure or a volume overload, the initial response is an increase in sarcomere length, so that the overlap between myofilaments becomes optimal (i.e., approximately 2.2 mum). This is followed by an increase in the total muscle mass, although, as already noted (see p. 507), the pattern and extent of remodeling differ depending on whether the stress is a pressure load or a volume load.

When the hemodynamic overload is severe, myocardial contractility becomes depressed. In an animal model of pressure overload hypertrophy produced by gradually tightening a hydraulic constrictor around the ascending aorta, there was depression of myocardial contractility, as assessed by *load-independent* contractility indices, suggesting that the cardiac dysfunction in this model was not due to insufficient hypertrophy causing afterload mismatch but to a depression of the myocardium's *intrinsic* contractility.[42] Impaired myocardial contractility has also been observed in patients with hypertension and fully compensatory ventricular hypertrophy, normal

myocardial stress, and apparently normal pump function. Such patients have displayed reduction of intramural myocardial shortening, as determined by spatial modulation of magnetization, using magnetic resonance imaging techniques[43] ; this reduction indicates a depression of myocardial contractility in the presence of apparently normal loading conditions.

In its mildest form, this depression is manifested by a reduction in the velocity of shortening of unloaded myocardium (Vmax) (see Fig. 16-8) or by a reduction in the rate of force development during isometric contraction[32] but by little if any reduction in the development of maximal isometric force or in the extent of shortening of afterloaded isotonic contractions. As myocardial contractility becomes further depressed, a more extensive reduction in Vmax occurs, now accompanied by a decline in isometric force development and shortening. At this point, circulatory compensation may still be provided by cardiac dilation and an increase in muscle mass, which tend to maintain wall stress at normal levels. Although cardiac output and stroke volume remain normal in the resting state, the ejection fraction at rest as well as the maximal cardiac output that can be attained during stress decline.[43A] As contractility falls farther, overt congestive heart failure, reflected in a depression of cardiac output and work and/or an elevation of ventricular end-diastolic volume and pressure at rest, supervenes.

MOLECULAR MECHANISMS OF MYOCARDIAL REMODELING AND FAILURE

As described by Meerson[44] (Table 16-2) , immediately on imposition of a large pressure load the increase in work performed by the ventricle exceeds the augmentation of cardiac mass and the heart dilates. As discussed earlier, a compensatory phase sets in as the ventricle remodels and the contractile function returns to approximately normal levels. If the compensatory response is adequate to "match" the work demands, a period of relative stability ensues. However, if the extent or form of myocardial remodeling is insufficient or if the magnitude of the overload increases further, regardless of the initial cause, there is further deterioration in myocardial function as a consequence of "afterload mismatch," that is, inadequate hypertrophy to normalize mechanical stress on the myocyte; and a vicious circle is created. Later, in what Meerson has termed the "exhaustion" phase, several macroscopic events take place: there may be myofibrillar lysis, an increase in the number of lysosomes (presumably to digest worn-out cell constituents), distortion of the SR,[45] a reduction in the surface density of the key tubular system, and fibrous replacement of cardiac cells.[46]

It is now recognized that myocardial remodeling and the transition from compensated hypertrophy to failure of the myocardium involves a complex of events at the molecular and cellular level.[31] [47] These events include (1) myocyte growth or hypertrophy, (2) changes in myocyte phenotype with reexpression of fetal gene programs and decreased expression of adult gene programs, (3) alterations in the expression and/or function of proteins involved in excitation-contraction coupling and contraction, (3) myocyte death due to necrosis and apoptosis, (4) changes in the extracellular matrix, and (5) abnormalities in energetics (Fig. 16-9) .

TABLE 16-2 -- THREE STAGES IN THE RESPONSE TO A SUDDEN HEMODYNAMIC OVERLOAD

Stage 1: (Days) Transient Breakdown
Circulatory: Acute heart failure; pulmonary congestion, low output
Cardiac: Acute left ventricular dilatation; early hypertrophy
Myocardial: Increased content of mitochondria relative to myofibrils
Stage 2: (Weeks) Stable Hyperfunction
Circulatory: Improved pulmonary congestion and cardiac output
Cardiac: Established hypertrophy
Myocardial: Increased content of myofibrils relative to mitochondria
Stage 3: (Months) Exhaustion and Progressive Cardiosclerosis
Circulatory: Progressive left ventricular failure
Cardiac: Further hypertrophy with progressive fibrosis
Myocardial: Cell death

From Katz AM: Energy requirements of contraction and relaxation: Implications of inotropic stimulation of the failing heart. In Just H, Holubarsch C, Scholz H (eds): Inotropic Stimulation and Myocardial Energetics. New York, Springer-Verlag, 1989, p 49.

Together, these events result in changes in myocardial structure (e.g., increase in myocardial mass, chamber dilation) and function (e.g., impaired systolic and/or diastolic function) that often lead to further pump dysfunction and hemodynamic overload. Several stimuli for these changes include mechanical strain on the myocyte, neurohormones (e.g., NE, angiotensin), inflammatory cytokines (e.g., tumor necrosis factor-alpha [TNF-alpha]), other peptides and growth factors (e.g., endothelin) and reactive oxygen species (e.g., superoxide, NO).[31] [47] [48] [49] These stimuli are increased both systemically and in the myocardium in response to circulatory failure and hemodynamic overload and, therefore, are an important link in the pathogenesis of progressive myocardial failure.[23A]

Myocyte Loss

Impaired myocardial contractile function may reflect a decrease in the number of viable, fully functional myocytes, a decrement in the function of viable myocytes, or a combination of these mechanisms. Myocyte loss may occur by one of two major mechanisms--necrosis or apoptosis.

NECROSIS.

Necrosis occurs when the myocyte is deprived of oxygen or energy, leading to the loss of cellular membrane integrity, the influx of extracellular fluid, cellular swelling, and the release of proteolytic enzymes that

Figure 16-9 Overview of the pathophysiology of myocardial remodeling. Remodeling stimuli such as increased mechanical wall stress and neuroendocrine activation lead to a complex of molecular and cellular events, including hypertrophy of cardiac myocytes, changes in gene expression with a reexpression of fetal programs and decreased expression of adult programs, changes in the quantity and nature of the interstitial matrix, and cell death. These events lead to changes in the structure and function of the ventricle, which may result in further pump dysfunction and increased wall stresses, thereby promoting further pathological remodeling. (From Sawyer DB, Colucci WS: Molecular and cellular events in myocardial hypertrophy and failure. *In* Colucci WS [ed]: Heart Failure: Cardiac Function and Dysfunction, Atlas of Heart Diseases. Vol 4. Philadelphia, Current Medicine, 1999, p 4.2.)

cause cellular disruption. Myocyte necrosis may be localized, as in myocardial infarction, or diffuse, as from idiopathic dilated cardiomyopathy, myocardial damage by toxic agents such as daunorubicin (see Chap. 69) , or myocarditis. In addition, capillary density and coronary reserve are reduced in remodeled myocardium[50] and may result in diffuse ischemia, which is most severe in the subendocardium. Thus, Vatner and associates have demonstrated a diminished response of endocardial blood flow to adenosine and exercise-induced vasodilation in dogs with pressure overload hypertrophy.[51] This is caused in part by hypertrophy and in part by an exercise-induced increase in left ventricular subendocardial wall stress. The reduced subendocardial perfusion in turn may cause subendocardial ischemic cell necrosis and replacement fibrosis, which impair both systolic and diastolic function, accelerating the development of heart failure (see Chap. 34)

APOPTOSIS.

In contrast to necrosis, apoptosis (programmed cell death) is an energy-dependent process by which a specific genetic program leads to the activation of a molecular cascade that causes the degradation of nuclear DNA. Also in contrast to necrosis, apoptosis is marked by the involution of the myocyte, eventuating in phagocytosis by neighboring cells[52] [53] (Fig. 16-10) . Apoptosis is a common cellular mechanism during organogenesis and in adult cells that have a rapid turnover rate, such as blood cells and gut epithelium. Because cardiac myocytes are terminally differentiated, it was not generally believed that they would undergo apoptosis. However, there have now been several reports demonstrating the presence of apoptotic myocytes in failing human myocardium[54] (Fig. 16-11) , as well as in models of myocardial failure[55] and hemodynamic overload.[56] [57] Several factors known to be present or increased in the failing myocardium have been shown to cause apoptosis of cardiac myocytes in vitro, including catecholamines acting through beta-adrenergic receptors,[58] [59] angiotensin II, reactive oxygen species, [60] NO,[61] inflammatory cytokines,[61] and mechanical strain. [62] [63] Although the role of apoptosis in the transition to failure is not known, it appears likely that it represents an important cause of cell death in the

failing heart.[2] The therapeutic success of drugs that antagonize angiotensin II (i.e., angiotensin-converting enzyme [ACE] inhibitors) and catecholamines (i.e., beta-adrenergic

Figure 16-10 Comparison of apoptotic and necrotic cell death. Apoptosis is an energy-dependent process triggered by specific cell signals (e.g., the binding of Fas to its receptor [the FAS receptor] on the cell membrane), which leads to the activation of a biochemical cascade (caspases) that causes the fragmentation of nuclear DNA. In contrast, necrosis may result from ischemia, leading to a depletion of adenosine triphosphate that results in the loss of normal cellular membrane function, disruption of transmembrane ionic gradients, and membrane rupture. (From Haunstetter A, Izumo S: Apoptosis: Basic mechanisms and implications for cardiovascular disease. Circulation 82:1111, 1998. Copyright 1998, American Heart Association.)

Figure 16-11 Evidence of increased apoptotic death of cardiac myocytes in failing human myocardium. *A,* Two myocyte nuclei stained with propidium iodide (arrows). *B,* The same field stained with deoxyuridine triphosphate by the so-called TUNEL reaction to label fragmented DNA, a hallmark of apoptosis (arrow). Normal nucleus (arrowhead) is not stained. *C,* The frequency of apoptotic myocytes observed in myocardium obtained from patients undergoing cardiac transplantation as compared with a nonfailing heart. The frequency of apoptotic myocytes increased from about 10 per million in nonfailing hearts to about 2300 per million in failing hearts. (From Olivetti G, Abbi R, Quaini F, et al: Apoptosis in the failing human heart. N Engl J Med 336:1131-1141, 1997.)

antagonists), both of which promote apoptosis, suggests that this may be an important mechanism for myocardial failure.

Dropout of individual myocytes has also been observed in the senescent rat[64] and human heart (see Chap. 57) . Olivetti and colleagues reported a loss of an average of 38 million nuclei per year in aging persons without cardiovascular disease.[54] This loss in myocyte number was accompanied by a reciprocal increase in myocyte cell volume per nucleus, thereby preserving ventricular wall thickness.[65]

This process, which appears to reflect myocyte death by both necrosis and apoptosis,[50] may contribute to cardiac dysfunction and, when there is an additional stress such as hypertension, to the development of heart failure in the elderly (see Chap. 57) .

Alterations in Excitation-Contraction Coupling (See p. 451)

In addition to reducing the absolute number of myocytes, as described earlier, hemodynamic overload may cause a decrease in the *intrinsic* contractility of individual myocytes. Several functional abnormalities involving excitation-contraction coupling, contractile proteins, and energetics have been identified in hypertrophied and failing myocardium. At the molecular level, alterations have been observed in the expression of numerous proteins that are central to normal myocardial structure and function. There is strong evidence from both in vitro and animal studies to suggest that these molecular events are secondary to both mechanical forces and a variety of neuronal, endocrine, and autocrine/paracrine mediators that act on the myocardium. It is not clear whether these alterations are responsible for the impaired myocardial function of heart failure, are in some way adaptive, or simply accompany the heart failure state as "epiphenomena."

ROLE OF CALCIUM IN EXCITATION-CONTRACTION COUPLING.

Ca^{2+} plays a central role in the regulation of myocardial contraction and relaxation.[66] Hypocalcemia, secondary to hypoparathyroidism and a variety of other conditions, can cause heart failure that is responsive to the infusion of calcium.[67] Elevation of serum ionized Ca^{2+} has been shown to augment contractility in patients with renal failure undergoing dialysis[68] and in patients with severe heart failure secondary to cardiomyopathy who have downregulation of beta-adrenergic receptors.[69]

Myocardium obtained at the time of cardiac transplantation from patients with end-stage heart failure exhibits abnormal prolongation of the action potential and developed force and impaired relaxation.[70] Observations using the Ca^{2+} indicator aequorin in whole myocardium have shown that these alterations in electrical and contractile properties are associated with a prolonged elevation of the intracellular Ca^{2+} transient during relaxation. [70] Likewise, in myocytes obtained from patients with end-stage heart failure, the action potential is prolonged. The intracellular Ca^{2+} transient, as assessed by the fluorescent indicator fura-2, demonstrates a blunted rise with depolarization reflecting a slower delivery of Ca^{2+} to the contractile apparatus (causing slower activation) and a slowed rate of fall during repolarization (causing slowed relaxation) (Fig. 16-12) .[71] These two abnormalities could, in theory, explain both systolic and diastolic dysfunction.

Additional evidence of abnormal myocardial Ca^{2+} handling is provided by the observation that there is a reduction in the amount of tension-independent heat produced in myocardium from patients with heart failure.[72] Tension-independent heat, which is believed to reflect the energy expended for Ca^{2+} transport, can be used to estimate the amount of Ca^{2+} cycled per heartbeat. With this approach, it was shown that Ca^{2+} cycling is reduced by approximately 50 percent in failing human myocardium.[72]

FORCE-FREQUENCY RELATIONSHIP.

Excitation-contraction coupling can also be assessed by examination of the force-frequency response. As pointed out on page 466 , in normal myocardium, contractile force increases with increasing rates of stimulation, whereas in myocardium obtained from patients with end-stage heart failure the force-frequency response is markedly attenuated.[73] A similar phenomenon is observed in patients with heart failure studied at the time of catheterization.[74] In patients with normal ventricular function, left ventricular contractility (as measured by +dP/dt or the end-systolic pressure-volume ratio)

Figure 16-12 Abnormal action potential and intracellular calcium transient in failing cardiac myocytes. *Top,* The action potential recorded in a myocyte isolated from the heart of a patient with dilated cardiomyopathy is markedly prolonged, as compared with that in a myocyte from a normal heart (control). Such abnormalities could contribute to both the generation of arrhythmias and the abnormal diastolic relaxation. *Bottom,* The intracellular calcium transient measured with the fluorescent calcium indicator fura-2 is also markedly abnormal in myocytes isolated from the myocardium of patients with dilated cardiomyopathy. As compared with a normal myocyte (control), the myocyte from a patient with dilated cardiomyopathy shows an attenuated rise with depolarization (arrow) and a markedly delayed return to baseline. These abnormalities reflect the altered expression or function of key calcium handling proteins (e.g., Ca^{2+} -ATPase) and likely contribute to the abnormal action potential in the top illustration. (Modified from Beuckelmann DJ, Nabauer M, Erdmann E: Intracellular calcium handling in isolated ventricular myocytes from patients with terminal heart failure. Circulation 85:1046, 1992. Copyright 1992, American Heart Association.)

increases progressively as heart rate is increased by atrial pacing. By comparison, in patients with severe heart failure there is little or no increase in either contractile index. The normal force-frequency relationship depends on the cycling of Ca^{2+} between the SR and cytoplasm with each beat, an event that is accomplished by several enzymes and channels located in the sarcolemma, SR, and mitochondria[66] (see Chap. 14) . The expression and/or function of a number of these proteins may be altered in hypertrophied and failing myocardium[75] (Table 16-3) , thereby leading to intrinsic dysfunction of otherwise viable myocytes.

SARCOPLASMIC RETICULUM Ca^{2+} -ATPase AND PHOSPHOLAMBAN (see also p. 452).

A number of alterations in the SR in the failing heart have been described (Table 16-4) . Ca^{2+} reuptake by the SR is mediated primarily by the ATP-dependent enzyme Ca^{2+} -ATPase (SERCA2).[75] The activity of SERCA2 is inhibited by the associated protein phospholamban,[75] [76] [77] and this inhibition is relieved by cyclic adenosine monophosphate (AMP)-mediated (e.g., by beta-adrenergic receptor stimulation) phosphorylation of phospholamban, thereby resulting in increased Ca^{2+} reuptake into the SR and the acceleration of diastolic relaxation. The reuptake of Ca^{2+} by the SR is also important for normal

systolic function, which requires that ample SR Ca^{2+} be available for release during systole to mediate contraction.[75]

Several reports indicate that the levels of SERCA2 messenger RNA (mRNA) and protein are reduced in myocardium obtained from patients with end-stage heart failure[78] [79] and animal models of heart failure.[80] The decrease in SERCA2, which is part of an "adult" gene program in cardiac muscle, correlates inversely with the reexpression of fetal genes such as atrial natriuretic peptide (Fig. 16-13) . Similarly, there is a shift from the gene encoding the adult isoform of myosin heavy chain (alpha-myosin heavy chain) to that encoding the fetal isoform (beta-myosin heavy chain) (see p. 514). This shift in SERCA2 expression is associated with a corresponding reduction in SR Ca^{2+} reuptake or in Ca^{2+} -ATPase activity in some[81] [82] but not all[83] studies in explanted human myocardium from patients with severe failure. Furthermore, the decrease in SERCA protein and Ca^{2+} -ATPase activity has been shown to correlate inversely with the force-frequency relationship,[20] [82] suggesting that reduced expression of SERCA2 contributes to intrinsic myocyte dysfunction. In vitro, mechanical strain[5] and several agonists such as NE and angiotensin downregulate the expression of SERCA2 in cardiac myocytes.

Because phospholamban activity inhibits SERCA2, the net activity of SERCA2 depends on the ratio of SERCA2 to phospholamban.[84] [85] The expression of phospholamban is also decreased in failing human myocardium[37] [81] and may thereby provide a partial compensation for the downregulation of SERCA2. Viral expression vectors have been used to express SERCA2 and phospholamban in cultured cardiac myocytes.[85] [86] [87] SERCA2 has also been expressed in transgenic mice[88] and in rat heart after direct injection of an

adenovirus carrying the gene.[52] These or similar approaches might allow the use of SERCA2 or inhibitors of phospholamban to augment myocyte function in patients.

Na^{+} /Ca^{2+} EXCHANGER (see also p. 454).

The Na^{+} /Ca^{2+} exchanger is the major route by which Ca^{2+} is removed from the cardiac myocyte and can account for approximately 20 percent of the removal of Ca^{2+} from the cytoplasm during diastole. [89] The mRNA and protein levels of the Na^{+} /Ca^{2+} exchanger were found to be increased in myocardium obtained from patients with heart failure due to both ischemic and idiopathic dilated cardiomyopathy and correlated inversely with the decrease in SERCA2 mRNA levels.[89] This augmentation in Na^{+} /Ca^{2+} exchange activity might be a compensatory response to the reduction in Ca^{2+} reuptake caused by a decrease in SERCA2. In animals with experimental heart failure, impaired cytosolic Ca^{2+} removal due to reduced SERCA2 was partially compensated for by an increase in the Na^{+} /Ca^{2+} exchanger.[80] Although this would facilitate diastolic Ca^{2+} removal, it might do so at the expense of increased arrhythmogenicity, because this Ca^{2+} efflux is associated with an influx of Na^{+} that can prolong depolarization and cause afterdepolarizations.

THE Ca^{2+} RELEASE CHANNEL.

The Ca^{2+} release channel (CRC), located on the SR, mediates the release of Ca^{2+} from the SR into the myoplasm during systole.[66] Some,[78] [90] but not all,[91] studies in failing human myocardium have shown decreases in the mRNA level for the CRC.

VOLTAGE-DEPENDENT Ca^{2+} CHANNEL.

The mRNA and protein levels of the voltage-dependent Ca^{2+} channel also have been shown to be decreased in failing human myocardium obtained from patients with both ischemic heart disease and dilated cardiomyopathy.[92]

CALSEQUESTRIN.

This is the major protein in the SR that binds Ca^{2+} and thereby serves a storage function. Several studies have found calsequestrin mRNA levels to be unchanged in failing human myocardium.[93]

Alterations in the Contractile Apparatus

The fraction of cell volume composed of myofibrils is initially increased in animal models of pressure-induced hypertrophy.[94] Patients with aortic stenosis without heart failure exhibit a normal fraction of myofibrils per cell, whereas those with left ventricular failure show a significant reduction in cell volume occupied by myofibrils, suggesting that this reduction in the quantity of the contractile machinery

Figure 16-13 Inverse relationship between the mRNA levels for the fetal gene atrial natriuretic factor (ANF) and the adult muscle-specific gene encoding Ca^{2+} -ATPase in ventricular myocardium obtained from patients with various degrees of myocardial failure. The reexpression of a fetal gene program is typical of hypertrophied and failing myocardium. (Modified from Arai M, Matsui H,

may play a role in the development of cardiac decompensation.[95] In end-stage heart failure in the human, electron microscopic observations likewise show a reduction of ventricular myofibrillar protein (Table 16-5) . [96]

REDUCTION OF MYOSIN ATPASE ACTIVITY.

Considerable data suggest that qualitative, as well as quantitative, alterations of contractile proteins occur in heart failure. First, the finding that the reduced velocity of contraction of failing myocardium occurs in chemically skinned ventricular fibers suggests that this change reflects intrinsic alterations in the contractile apparatus. Early studies showed that the activity of myofibrillar ATPase is reduced in the hearts of patients who died of heart failure.[97] Furthermore, reductions in the activities of myofibrillar ATPase, actomyosin ATPase, or myosin ATPase have been demonstrated in heart failure induced in cats by pulmonary artery constriction,[98] in guinea pigs with constriction of the ascending aorta,[99] in dogs with constriction of the pulmonary artery or aorta,[100] and in rats with renovascular hypertension.[101] These depressions of enzymatic activity could occur if an altered subunit of the myosin molecule (i.e., the portion of the molecule responsible for the ATPase activity) were produced in the overloaded heart and reduced contractility by lowering the rate of interaction between actin and myosin filaments. A reduction in the Mg^{2+} -ATPase activity (which expresses the response of myofibrils to Ca^{2+}) has been demonstrated in myofibrils obtained from patients with end-stage heart failure at the time of transplantation and in less sick patients undergoing valve replacement.[102]

MYOSIN ISOFORM CHANGES.

Animal studies have indicated that when the adult heart hypertrophies, fetal and neonatal forms of contractile proteins (termed isoforms) and other proteins (such as atrial natriuretic peptide) reappear, signifying reexpression of the genes for these fetal and neonatal isoforms. Thus, hemodynamic overload leads to enhanced overall protein synthesis[2] and alters the proteins qualitatively as well (i.e., it leads to the synthesis of protein isoforms that were present during fetal and neonatal life when protein synthesis in the heart was also rapid).

Altered isoforms of cardiac proteins may arise from the expression of different members of a multigene family or from the assembly of the same gene in a different pattern.[103] In rodents the predominant myosin heavy chain (MHC) is the "fast" V_1 isoform (high ATPase activity, encoded by the alpha-MHC gene). With pressure-induced hypertrophy or myocardial failure after myocardial infarction in the rat, there is the reexpression of the "slow" V_3 isoform (low ATPase activity, encoded by the beta-MHC gene), and deinduction of the V_1 isoform.[103] Although a shift in MHC isoforms would provide an attractive explanation for the reduction in myofibrillar ATPase activity observed in failing human myocardium, the predominant MHC isoform in humans is the slower V_3 isoform (encoded by the beta-MHC gene) and alpha-MHC mRNA has been difficult to detect, thus making it appear unlikely that a shift in myosin isoforms is responsible for the observed decrease in myosin ATPase activity in failing human myocardium. However, the use of more refined methodology has demonstrated that alpha-MHC accounts for about 33 percent of MHC mRNA in normal human myocardium and is markedly reduced to about 2 percent in failing myocardium[104] [105] (Fig. 16-14) . It remains to be determined whether the decrease in alpha-MHC mRNA translates into a comparable decrease in the ratio of the beta- to alpha-MC protein isoforms, and, thus, a decrease in ATPase activity.

ALTERED REGULATORY PROTEINS.

Another possible cause of a decrease in contractile protein function is an

Figure 16-14 Change in the expression of myosin heavy chain (MHC) mRNAs in failing myocardium. The alpha- and beta-MHC mRNAs encode for "fast" and "slow" isoforms with high and low ATPase activity, respectively. The ratio of alpha-MHC to beta-MHC is low in fetal myocardium and increases during normal development to adulthood. Shown is a Northern blot of mRNA obtained from the myocardium of patients with left ventricular failure (F-LV) or with normal ventricular function (Control). The ratio of alpha-MHC to beta-MHC is markedly reduced in the failing myocardium. Theoretically, such a shift in MHC isoforms could result in a decrease in the intrinsic contractile function of the myocyte. (From Sawyer DB, Colucci WS: Molecular and cellular events in myocardial hypertrophy and failure. *In* Colucci WS [ed]: Heart Failure: Cardiac Function and Dysfunction, Atlas of Heart Diseases. Vol 4. Philadelphia, Current Medicine, 1999, p 4.9.)

Figure 16-15 The regulation of extracellular matrix degradation is determined by the balance between the activity of matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs). Both an increase in MMP activity and a decrease in TIMP activity have been observed in failing myocardium from patients. Theoretically, such an increase in the MMP/TIMP ratio could contribute to depletion of the fibrillar collagen struts that tether myocytes together and might thus contribute to chamber dilation. Conversely, an increase in extracellular matrix accumulation, which might occur as the result of a decrease in the MMP/TIMP ratio or an increase in matrix synthesis, could contribute to chamber stiffness and abnormal relaxation. (From Sawyer DB, Colucci WS: Molecular and cellular events in myocardial hypertrophy and failure. *In* Colucci WS [ed]: Heart Failure: Cardiac Function and Dysfunction, Atlas of Heart Diseases. Vol 4. Philadelphia, Current Medicine, 1999, p 4.13.)

alteration in the expression and/or activity of regulatory proteins. In animals with experimental heart failure, there are changes in the myosin light chain and the troponin-tropomyosin complex.[106] Changes in myosin light-chain isoforms have been observed in the atria and ventricles of patients subjected to increased mechanical stress[107] ; and the expression of troponin-T, a component of the troponin complex that regulates the interaction of myosin and actin, was found to be altered in failing human myocardium.[108] In normal myocardium, troponin-T is expressed as a single isoform (T_1), which accounts for approximately 98 percent of the troponin-T. In myocardium from patients with end-stage heart failure, a second isoform (T_2) was expressed at increased levels, and its level of expression was related to the severity of heart failure.[108]

Mice with deletion of the troponin-I gene are born normally but express a fetal isoform of troponin that takes the place of the absent adult isoform. Over time the expression of the fetal isoform decreases, and the mice develop lethal heart failure.[109] The functional significance of changes in the expression of troponin and other regulatory proteins is not known. However, these observations suggest that changes in myosin activity could be due to changes in regulatory proteins and need not reflect alterations in the contractile proteins themselves.

Alterations in the Matrix

The structural properties of the ventricle are determined not only by its myocytes but also by the interstitial connective tissue, which is rich in types I and III fibrillar collagen.[110] [111] The latter provide struts along which the myocytes are aligned. Branches of collagen fibers course at right angles to connect and align muscle bundles. Thus, a depletion of these struts may lead to chamber dilation. As Weber has pointed out, the amount and type of extracellular matrix can also have profound effects

on the diastolic properties of the myocardium by affecting its elasticity and physical disposition.[110]

REGULATION OF INTERSTITIAL COLLAGEN.

The quantity and nature of the collagen in the extracellular matrix is determined by the balance between synthesis and degradation. The latter is regulated by the opposing actions of matrix metalloproteinases (MMPs), a family of enzymes that degrade matrix proteins, and tissue inhibitors of metalloproteinases (TIMPs), a family of enzymes that inhibit the activity of MMPs[112] (Fig. 16-15) .

COLLAGEN STRUT DEPLETION.

In myocardium from humans

Figure 16-16 Representative photomicrographs of left ventricular myocardium from pigs with rapid pacing-induced myocardial failure showing the effects of pacing and inhibitor of matrix metalloproteinase (MMP) activity on the fibrillar collagen weave surrounding cardiac myocytes. With rapid pacing there is a disruption and depletion of fibrillar collagen. Treatment with an inhibitor of MMP activity attenuated these effects on fibrillar collagen and reduced the extent of left ventricular dilation. (Modified from Spinale FG, Coker ML, Krombach SR, et al: Matrix metalloproteinase inhibition during the development of congestive heart failure: Effects on left ventricular dimensions and function. Circ Res 85:364, 1999. Copyright 1994, American Heart Association.)

and animal models of systolic failure, ultrastructural observations have shown a depletion of the fibrillar collagen struts that help to maintain the alignment of myocytes[113] (Fig. 16-16) . It has been proposed that *depletion* of the collagen struts may contribute to chamber dilation by allowing "slippage" of myocytes.[114] [115] This observation is consistent with the observation that the activity of MMPs is increased in myocardium obtained from patients with end-stage heart failure[116] and in animal models of heart failure. [117] Likewise, the activity of TIMPs is decreased in myocardium from patients with end-stage heart failure.[118] A role for MMPs is supported by the demonstration that an MMP inhibitor partially protected against the loss of collagen struts in an animal model of heart failure.[119]

INTERSTITIAL MATRIX ACCUMULATION.

On the other hand, in experimentally induced chronic pressure overload hypertrophy,[120] as well as in patients with hypertension, there is an *increase* in the quantity of interstitial collagen, which may contribute to the characteristic abnormalities of diastolic function. The spontaneously hypertensive rat develops progressive myocardial hypertrophy and failure with age.[121] Papillary muscles from these animals have increased passive stiffness that is associated with increased left ventricular collagen concentration, interstitial fibrosis,[122] and expression of mRNAs for collagen and transforming growth factor-alpha (TGF-alpha).[123] Treatment with the ACE inhibitor captopril prevented the increases in muscle stiffness, interstitial fibrosis, and the induction of collagen and TGF-alpha mRNAs.[124] [125] Thus, it seems likely that pathways leading to increased collagen accumulation are involved in the pathogenesis of diastolic dysfunction.

Myocardial Energetics in Heart Failure (See also p. 467)

Heart failure frequently occurs in the presence of adequate myocardial perfusion, oxygen, and substrate. When contractility is acutely depressed, myocardial oxygen consumption of the intact ventricle also declines.[126] Similarly, patients with chronic impairment of left ventricular performance and reduction of the velocity of myocardial fiber shortening exhibit reduction of coronary blood flow and myocardial oxygen consumption per gram of muscle.[127] Marked reductions in myocardial oxygen consumption have been described in the Syrian hamster with hereditary cardiomyopathy.[128] Papillary muscles removed from cats with pressure overload-induced right ventricular hypertrophy exhibit a depression of both contractility and oxygen consumption per unit of tension development.[33] The pathophysiological importance of these observations is not known. Potentially, the lowered energy needs of the failing heart may reflect an appropriate matching of energy demands, a disproportionate decrease beyond the needs of the tissue, or a protective mechanism.

MYOCARDIAL ENERGY PRODUCTION.

Considerable dispute has centered on the question of whether mitochondrial oxidative phosphorylation (i.e., energy production) is abnormal in heart failure. Early studies indicated that electron transport and the tightness of respiratory control are normal in mitochondria obtained from failing human hearts[129] and cat hearts with experimental heart failure produced by pressure overload.[130] On the other hand, in one study in which mitochondria from the hearts of patients with end-stage dilated cardiomyopathy were studied, a reduction in cytochrome-a content and in cytochrome-dependent enzyme activity was reported.[131] The cytochromes are located in the inner mitochondrial membrane and are constituents of the respiratory chain that couples oxidation to the synthesis of chemical energy. Mitochondria obtained from failing human cardiac muscle have also shown reduced oxygen consumption during active phosphorylation and reduced rates of NADH-linked respiratory activity.[131] These and other observations have led to the thesis that myocardial failure in the setting of hemodynamic overload may be related to an inability of the energy-producing system, (i.e., the mitochondria) to keep pace with the needs of the contractile apparatus. Katz has proposed that the mitochondrial abnormalities in the failing heart may be the result of damage to these structures and that this damage reduces the high-energy phosphates available for the contraction of the failing heart.[2]

The nucleotide-transporting protein located on the inner mitochondrial membrane, the so-called ADP-ATP carrier, has been identified as an autoantigen in viral myocarditis and dilated cardiomyopathy. In guinea pigs immunized to this carrier protein, both myocardial oxygen consumption and cardiac work fell.[132] These findings are compatible with the hypothesis that the impaired cardiac performance in some cases of myocarditis (and dilated cardiomyopathy) may be secondary to an imbalance between energy delivery and demand.

MYOCARDIAL ENERGY RESERVES.

In compensated hypertrophy, observations on myocardial ATP concentration have shown no consistent change.[133] However, in myocardium from dogs with myocardial failure due to rapid pacing or chronic ischemia, and from humans with end-stage cardiomyopathy, total creatine kinase activity and the concentrations of phosphocreatine and creatine are decreased.[133] [134] [135] These observations have led to the hypothesis that myocardial failure may be the consequence of a decreased energy reserve[133] or at least that such decreased reserve contributes to the development of heart failure (Fig. 16-17) . The measurement of creatine kinase flux provides a sensitive measure of myocardial energy reserves and may detect abnormalities in the absence of changes in ATP and phosphocreatine concentrations. By studying high-energy flux in vivo using nuclear magnetic resonance technology, it was demonstrated that creatine kinase activity is markedly reduced in the myopathic Syrian hamster.[136] This abnormality was almost completely corrected by treatment with the converting enzyme inhibitor enalapril. Likewise, in turkeys with furazolidone-induced heart failure, contractile failure was associated with a decrease in ATP, phosphocreatine activity, and creatine kinase activity.[137] The mechanism responsible for a decrease in creatine kinase activity

Figure 16-17 Some of the vicious cycles that operate in the overloaded heart. Overload both increases energy utilization and stimulates growth. The former contributes directly to a state of energy starvation, which is made worse by several consequences of maladaptive hypertrophy that decrease energy supply. The latter include myocyte elongation, which causes remodeling, a progressive dilatation that increases wall tension so as to increase the overload. Growth stimuli also promote apoptosis, which by decreasing the number of viable cardiac myocytes increases the load on those that survive. Hypertrophy also causes architectural changes that reduce the energy supply to working cardiac myocytes. (From Katz AM: Heart Failure. Philadelphia, Lippincott Williams & Wilkins, 2000.)

is not understood but is associated with alterations in the isoforms of creatine kinase. In failing myocardium, there is a decrease in the adult (MM) isoform and an increase or no change in the fetal isoform (MB).[133] The effect of decreased creatine kinase activity on myocardial function and energetics was tested in mice with genetic deficiencies of the creatine kinase M-isoform, mitochondrial-isoform, or both.[138] Surprisingly, mice with these deficiencies had normal baseline function and responses to calcium. However, the mice lacking both isoforms had a greater increase in adenosine diphosphate (ADP) and a more pronounced decrease in the free energy released from ATP, suggesting that work was more energetically costly.

Nuclear magnetic resonance (NMR) spectroscopy with phosphorus-31, a noninvasive technique (see Chap. 9) has been employed to study the phosphocreatine to ATP ratio (PCr/ATP) in normal subjects and in patients. Reductions have been described in patients with severe aortic valve disease, cardiomyopathy, and myocardial

ischemia.[139] [140] [141] In patients with chronic mitral regurgitation the reductions in PCr/ATP have been found to be related to the severity of the hemodynamic impairment as reflected in the left ventricular end-systolic diameter (Fig. 16-18) . The extent of reduction of the ratio has been shown to correlate with the clinical severity of the heart failure and with the prognosis (Fig. 16-19). [142] These changes in the PCr/ATP may be caused by the previously mentioned reduction of creatine phosphorylation and of creatine kinase activity.[133] [134] [135] [137]

One unusual form of heart failure that is primarily related to a reduction of myocardial energy stores is that due to phosphate deficiency. Chronic hypophosphatemia induced by dietary means is associated with reversible depression of myocardial performance in isolated muscle as well as in the intact heart of animals and humans, presumably as a consequence of reduced ATP stores.[143] [144]

In the final analysis the reductions of high-energy phosphates in the failing heart results in a decrease in the quantity of energy made available by the hydrolysis of ATP. The reduction of the ATP/ADP ratio reduces the energy available to the SR for calcium uptake, thereby impairing relaxation (diastolic failure) and to the contractile apparatus, impairing cross-bridge cycling (systolic failure).[2]

Figure 16-18 Echocardiographic parameters versus PCr/ATP (LVM/BSA) is given in g/cm^2 . ESD=left ventricular end-systolic diameter. (From Conway MA, et al: Mitral regurgitation: Impaired systolic function, eccentric hypertrophy, and increased severity are linked to lower phosphocreatine/ATP ratios in humans. EFFECTS OF NITRIC OXIDE ON MYOCARDIAL ENERGETICS.

There is evidence that NO may be an important regulator of myocardial energetics. NO has been shown to inhibit myocardial oxygen consumption by means of an effect on mitochondrial respiration.[145] [146] This action of NO was demonstrated in human myocardium and found to be preserved in myocardium from patients with heart failure.[147] It has been proposed that a bradykinin-mediated increase in NO by the vascular endothelium may contribute to the beneficial effects of ACE inhibitors by inhibiting myocardial oxygen demands.[148] NO has also been shown to inhibit creatine kinase and reduce the availability of ATP. In isolated rat hearts, perfusion with the NO donor S-nitroacetylcysteine (SNAC) inhibited the ability of calcium to increase the rate-pressure product. This effect was associated with inhibition of creatine kinase activity and a decrease in ATP.[38] The level of NO in the failing heart is controversial. On the one hand, increased expression of inducible NO synthase has been observed in failing myocardium.[149] On the other hand, direct measurement of NO in dogs with pacing-induced heart failure demonstrated a decrease in tissue NO associated with an increase in respiratory quotient and a shift in substrate utilization from free fatty acids to glucose.[150]

PATHOPHYSIOLOGY OF DIASTOLIC HEART FAILURE (See also Chaps. 14 and 15)

Alterations in Diastolic Properties

Approximately one third of patients with congestive heart failure have predominantly diastolic heart failure (see Chap. 17) , which may be defined as pulmonary (or systemic)

venous congestion, and the symptoms consequent thereto, in the presence of normal or almost normal systolic function.[151] [151A] [151B] Another third have impairment of both systolic and diastolic function, and the remainder primarily have disordered systolic function. Among subjects with the clinical diagnosis of congestive heart failure in the Framingham Heart Study population, 51 percent had a left ventricular ejection fraction (LVEF) greater than or equal to 0.50.[152] Sixty-five percent of the subjects with an LVEF greater than or equal to 0.50 were women, whereas men constituted 75 percent of the subjects with an LVEF less than 0.50. The annual mortality rate in patients with an LVEF greater than or equal to 0.50 (8.7 percent) was lower than in patients with an LVEF less than 0.50 (18.9 percent) but still approximately fourfold greater than in age-matched control subjects.

ALTERED VENTRICULAR RELAXATION (See also p. 470).

Although two aspects of the heart's diastolic characteristics (i.e., relaxation and wall stiffness) are often considered together, they actually describe two different properties.[151C] Relaxation (inactivation of contraction) is a dynamic process that begins at the termination of contraction and occurs during isovolumetric relaxation and early ventricular filling (Fig. 16-20 ; see also Fig. 14-32) . The rate of ventricular relaxation is controlled primarily by the uptake of Ca^{2+} by the SR but also by the efflux of Ca^{2+} from the myocyte. These processes are regulated by SERCA2, as well as by sarcolemmal calcium pumps (see p. 513, Table 16-3) . Because these Ca^{2+} movements are against concentration gradients, they are energy consuming. Therefore, ischemia-induced ATP depletion interferes with these processes and slows myocardial relaxation (see Fig. 16-20 *A*). On the other hand, beta-adrenergic receptor stimulation, by increasing cyclic AMP and cyclic AMP-dependent protein kinase activity, causes the phosphorylation of phospholamban (see Chap. 14) , which accelerates Ca^{2+} uptake by the SR and thereby enhances relaxation.

An acute increase in ventricular afterload has also been shown to slow myocardial relaxation.[153] Thus, when pressure overload is applied (before compensatory hypertrophy has normalized afterload), ventricular relaxation is slowed. Myocardium isolated from patients with hypertrophic cardiomyopathy[154] and from ferrets with pressure-overload hypertrophy[155]

Figure 16-20 Mechanisms that cause diastolic dysfunction. Only the bottom half of the pressure-volume loop is depicted. Solid lines represent normal subjects; dashed lines represent patients with diastolic dysfunction. (From Zile MR: Diastolic dysfunction: Detection, consequences, and treatment: II. Diagnosis and treatment of diastolic function. Mod Concepts Cardiovasc Dis 59:1, 1990. Copyright 1990, American Heart Association.)

exhibits a prolonged calcium transient (i.e., a prolonged elevation of myoplasmic Ca^{2+}) associated with a prolonged tension decay, findings consistent with delayed uptake of Ca^{2+} by the SR.

ALTERED VENTRICULAR FILLING.

During early ventricular filling the myocardium normally lengthens rapidly and homogeneously. Regional variation in the onset, rate, and extent of myocardial lengthening is referred to as *ventricular heterogeneity,* or *diastolic asynergy;* temporal dispersion of relaxation, with some fibers commencing to lengthen later than others, is referred to as *diastolic asynchrony.* [156] Both diastolic asynergy and asynchrony interfere with early diastolic filling. In contrast to these early diastolic events, myocardial *elasticity* (i.e., the change in muscle length for a change in force), ventricular *compliance* (i.e., the change in ventricular volume for a given change in pressure), and ventricular *stiffness* (i.e., the inverse of compliance) are generally measured in the relaxed ventricle at end-diastole.

These diastolic properties of the ventricle are described by its curvilinear pressure-volume relation (see Fig. 16-20 *B-D*). The slope of a tangent to this curvilinear relation (dP/dv) defines the chamber compliance at any level of filling pressure. An increase in chamber stiffness may occur secondary to any one or a combination of these three mechanisms:

1. *A rise in filling pressure* (i.e., movement of the ventricle up along its pressure-volume [stress-strain] curve to a steeper portion) (see Fig. 16-20 *D*).[157] This may occur in conditions such as volume overload secondary to acute valvular regurgitation and in acute left ventricular failure due to myocarditis.
2. *A shift to a steeper ventricular pressure-volume* (see Fig. 16-20 *C*) *or stress-strain curve.* This results most commonly from an increase in ventricular mass and wall thickness. Thus, although hypertrophy constitutes a principal compensatory mechanism to sustain systolic emptying of the overloaded ventricle, it may simultaneously interfere with the ventricle's diastolic properties and impair ventricular filling. This shift to a steeper pressure-volume curve can also be caused by an increase in *intrinsic* myocardial stiffness (the stiffness of a unit of the cardiac wall regardless of the total mass or thickness of the myocardium), as occurs with disorders in which there is myocardial infiltration (e.g., amyloidosis), endomyocardial fibrosis, or myocardial ischemia.
3. *A parallel upward displacement of the diastolic pressure-volume curve.* This is generally referred to as a *decrease in ventricular distensibility* and is usually

caused by extrinsic compression of the ventricles, as occurs in cardiac tamponade or constrictive pericarditis (see Chap. 50) (see Fig. 16-20*B*).

Chronic Changes in Ventricular Diastolic Pressure-Volume Relationships

The compliance of the left ventricle, reflected in the end-diastolic pressure-volume relationship, is altered in a variety of cardiac disorders, reflecting one or more basic mechanisms (Fig. 16-20) (see Chap. 17). Substantial shifts in the diastolic pressure-volume curve of the left ventricle can be demonstrated during sustained volume overload.[158] For example, dogs with large chronic arteriovenous fistulas exhibit a rightward displacement of the entire diastolic pressure-volume curve, whereby ventricular volume is greater at any end-diastolic pressure but the slope of this curve is steeper, indicating increased chamber stiffness.[159] Patients with severe volume overloading due to chronic aortic and/or mitral regurgitation demonstrate similar shifts of the diastolic left ventricular pressure-volume relationship. Similar changes frequently occur in patients with dilated or ischemic cardiomyopathy or after large transmural myocardial infarction (see later).

In contrast, concentric left ventricular hypertrophy, as occurs in aortic stenosis, hypertension, and hypertrophic cardiomyopathy, shifts the pressure-volume relation of the ventricle to the left along its volume axis so that at any diastolic volume ventricular diastolic pressure is abnormally elevated[160] [161] [162] [162A] (see Fig. 16-20 *C*). In contrast to the changes in the diastolic properties of the ventricular *chamber,* the stiffness of *each unit of myocardium* may or may not be altered in the presence of myocardial hypertrophy secondary to pressure overload.[4] In the presence of concentric left ventricular hypertrophy, there is an inverse relationship between the thickness of the posterior wall of the ventricle and its peak thinning rate during early diastole[163] ; a higher-than-normal diastolic ventricular pressure is required to fill the hypertrophied ventricle. Patients with hypertension have demonstrated slowing of ventricular filling, even when systolic function is normal.[164]

ISCHEMIC HEART DISEASE.

Marked changes in the diastolic properties of the left ventricle can occur in the presence of ischemic heart disease. First, as already pointed out, acute myocardial ischemia slows ventricular relaxation (see Fig. 16-20 *A*) and increases myocardial wall stiffness.[165] Myocardial infarction causes more complex changes in ventricular pressure-volume relationships, depending on the size of the infarct and the time after infarction at which the measurements are made. Infarcted muscle tested very early exhibits reduced stiffness.[166] Subsequently, the development of myocardial contracture, interstitial edema, fibrocellular infiltration, and scar contribute to stiffening of the necrotic tissue and thereby to increased chamber stiffness, with a steeper ventricular pressure-volume curve (a greater increase in pressure for any increase in volume).[167] Later still, in the case of large infarcts, left ventricular remodeling and dilatation cause a rightward displacement of the pressure-volume curve,[168] resembling that observed in volume overload. The subendocardial ischemia that is characteristic of severe concentric hypertrophy (even in the presence of a normal coronary circulation) intensifies the failure of relaxation[51] ; and when coronary artery obstruction accompanies severe hypertrophy, this abnormality may be particularly severe. Tachycardia, by reducing the duration of diastole and thereby intensifying ischemia, exaggerates this diastolic abnormality and may raise ventricular diastolic pressure even while reducing diastolic ventricular volume, whereas bradycardia has the opposite effect. Successful treatment of ischemia improves diastolic relaxation and lowers ventricular diastolic and pulmonary venous pressures, thereby reducing dyspnea.

CARDIOMYOPATHY AND PERICARDIAL DISEASE.

The restrictive cardiomyopathies, especially those such as amyloid heart disease with intracardiac infiltration, the transplanted heart during rejection, and endomyocardial fibrosis (see Chap. 48), all are characterized by upward and leftward displacement of the diastolic pressure-volume relation, with a higher pressure at any volume and a greater increase in diastolic pressure for any increase in volume. Pericardial tamponade and constrictive pericarditis also change the apparent diastolic properties of the heart (see Chap. 50). Early filling is unimpaired because the myocardium is normal. However, filling is abruptly halted in mid diastole by the constricted or tamponading pericardium, which imposes its mechanical properties on those of the ventricle in the latter half of diastole (see Fig. 16-20*B*).

NEUROHORMONAL, AUTOCRINE, AND PARACRINE ADJUSTMENTS (See also Chap. 21)

A complex series of neurohormonal changes takes place consequent to the two principal hemodynamic alterations in heart failure: reduction of cardiac output and atrial hypertension.

Figure 16-21 Factors responsible for diastolic dysfunction and increased left ventricular diastolic pressure. (From Gaasch WH, Izzi G: Clinical diagnosis and management of left ventricular diastolic dysfunction. *In* Hori M, Suga H, Baan J, Yellin EL [eds]: Cardiac Mechanics and Function in the Normal and Diseased Heart. New York, Springer-Verlag, 1989, p 296.)

Many of these neurohormonal changes occur in response to the inadequate arterial volume characteristic of systolic heart failure.[169] In the early stages of severe, acute systolic failure, these changes--heightened adrenergic drive, activation of the renin-angiotensin-aldosterone axis, and the augmented release of vasopressin and endothelin--are truly compensatory and act to maintain perfusion to vital organs and to expand the inadequate arterial blood volume and renal retention of sodium and water (Figs. 16-21 and 16-22) . However, each of these mechanisms may be thought of as a "double-edged sword." As heart failure becomes chronic, several of these compensatory mechanisms can cause undesirable effects, such as excessive vasoconstriction, increased afterload, excessive retention of salt and

Figure 16-22 Mechanisms by which high-output or low-output heart failure leads to the activation of neurohumoral vasoconstrictor systems and renal sodium and water retention. (From Schrier RW, Abraham WT: Hormones and hemodynamics in heart failure. N Engl J Med 341:577, 1999; adapted from Schrier RW: Pathogenesis of sodium and water retention in high-output and low output cardiac failure, nephrotic syndrome, cirrhosis, and pregnancy. N Engl J Med 319:1065, 1988.)

Figure 16-23 Unloading of high-pressure baroceptors (circles) in the left ventricle, carotid sinus, and aortic arch generates afferent signals that stimulate cardioregulatory centers in the brain, resulting in the activation of efferent pathways in the sympathetic nervous system. The sympathetic nervous system appears to be the primary integrator of the neurohumoral vasoconstrictor response to arterial underfulling. Activation of renal sympathetic nerves stimulates the release of arginine vasopressin (AVP). Sympathetic activation also causes peripheral and renal vasoconstriction, as does angiotensin II. Angiotensin II constricts blood vessels and stimulates the release of aldosterone from the adrenal gland, and it also increases tubular sodium reabsorption and causes remodeling of cardiac myocytes. Aldosterone may also have direct cardiac effects, in addition to increasing the reabsorption of sodium and the secretion of potassium and hydrogen ions in the collecting duct. The lines designate circulating hormones. (*Modified from Schrier RW, Abraham WT: Hormones and hemodynamics in heart failure. N Engl J Med 341:577, 1999.*)

water, electrolyte abnormalities, and arrhythmias (see Table 16-1) . In contrast, other responses, such as the release of atrial natriuretic peptide (ANP) in response to atrial distention, may oppose these adverse effects by causing vasodilation, increased excretion of salt and water, and inhibition of sympathetic activity.[170]

A variety of mediators are involved in control of the cardiovascular system in heart failure. Some are circulating hormones (endocrine effect). Some act on neighboring cells of another type (paracrine effect) or on the cell of origin (autocrine effect).[171] These include peptides that act primarily locally in the vicinity of their production, such as endothelin, peptide growth factors (e.g., TGF-alpha), and inflammatory cytokines (e.g., interleukin-1-beta [IL-1beta] and TNF-alpha). These and other local mediators act in concert with the autonomic nervous system and circulating hormones to modulate cardiovascular organ function. In addition, as discussed on p. 527 , many if not all of these mediators have effects on the growth, death, and phenotype of cardiovascular tissues and may thereby play an important role in the "remodeling" of myocardium and its progression to failure (see Fig. 16-8) . [31]

Autonomic Nervous System

INCREASED SYMPATHETIC ACTIVITY (see Figs. 16-22 and 16-23).

Measurements of the concentration of the adrenergic NE in arterial blood provide an index of the activity of this system, which is crucial to the normal regulation of cardiac performance. At rest, in patients with advanced heart failure, the circulating NE concentration is much higher, generally two to three times the level found in normal subjects,[172] and is accompanied by elevation of circulating dopamine and sometimes by epinephrine as well; the latter reflects increased adrenomedullary activity. Measurement of 24-hour urinary NE excretion also reveals marked elevations in patients with heart failure.[173] In the prevention arm of the Studies of Left Ventricular Dysfunction (SOLVD) trial (see Chap. 18), plasma NE was significantly elevated, even in asymptomatic patients, and was further elevated in patients with

symptomatic heart failure (Fig. 16-24) .[174] During comparable levels of exercise, much greater elevations in circulating NE occur in patients with heart failure than in normal subjects, presumably reflecting greater activation of the adrenergic nervous system during exercise in these patients.[175]

The elevation of circulating NE may result from a combination of increased release of NE from adrenergic nerve endings and its consequent "spillover" into plasma, as well as reduced uptake of NE by adrenergic nerve endings.[176] Patients with heart failure demonstrate increased adrenergic nerve outflow, as measured by microneurography of the peroneal nerve; and the level of nerve activity correlates with the concentration of plasma NE (Fig. 16-25) . [177] The level of adrenergic nerve activity also correlates directly with the levels of left and right ventricular filling pressures.[177] Whereas the normal heart usually extracts NE, in patients with heart failure the coronary sinus NE level exceeds the arterial level, indicating increased adrenergic activation of the heart.[178] Drugs such as the $alpha_2$ -agonist guanabenz (which reduces adrenergic nerve impulse traffic) and bromocriptine[179] (a presynaptic dopamine-2 agonist) reduce plasma NE, indicating that presynaptic control of adrenergic nervous activity is intact in patients with heart failure. It has been suggested that treatment with such agents might be useful in the treatment of heart failure.[179]

The extent of elevation of plasma NE concentration that occurs in patients with heart failure correlates directly with the severity of the left ventricular dysfunction, as reflected in the height of the pulmonary capillary wedge pressure and depression of the cardiac index,[172] [180] and with cardiac mortality.[181] The augmented adrenergic outflow from the central nervous system in patients with heart failure may trigger ventricular tachycardia or even sudden cardiac death, particularly in the presence of myocardial ischemia. However, it is

Figure 16-24 Activation of neurohormonal systems in patients with heart failure. In patients studied in the SOLVD trials, plasma norepinephrine, renin activity, atrial natriuretic factor (ANF), and arginine vasopressin (AVP) were elevated in patients with symptomatic heart failure enrolled in the treatment trial, and also, albeit to a lesser degree, in asymptomatic patients enrolled in the prevention trial. (Modified from Francis GS, Benedict C, Johnstone DE, et al: Comparison of neuroendocrine activation in patients with left ventricular dysfunction with and without congestive heart failure: A substudy of the studies of left ventricular dysfunction (SOLVD). Circulation 82:1724, 1990. Copyright 1990, American Heart Association.)

not clear whether the elevated levels of circulating NE in patients who subsequently die of heart failure are causally related to death as a consequence of their vasoconstrictor, arrhythmogenic, or other actions or whether they merely reflect the severity of the underlying heart failure.

In addition to activation of beta-adrenergic receptors in the heart, the heightened activity of the adrenergic nervous system leads to stimulation of myocardial $alpha_1$ -adrenergic receptors, which elicits a modest positive inotropic effect.[182] Stimulation of myocardial $alpha_1$ -adrenergic receptors may also cause myocyte hypertrophy, changes in phenotype characterized by the reexpression of a fetal gene program,[183] and the induction of peptide growth factors.[184] $Alpha_1$ -adrenergic receptors are of low density in the human heart; however, in contrast to $beta_1$ -adrenergic receptors, which are downregulated, $alpha_1$ -adrenergic receptors appear to be unchanged in number in failing human myocardium.[185]

CARDIAC NOREPINEPHRINE DEPLETION.

The concentration of NE in atrial[173] and ventricular tissue[35] removed at operation from patients with heart failure is extremely low. In patients, it has been reported that cardiac NE content determined from endomyocardial biopsies correlates directly with the ejection fraction and inversely with plasma epinephrine concentration.[186] NE concentrations are also markedly depressed in the ventricles of dogs with right ventricular failure produced by the creation of pulmonary stenosis and tricuspid regurgitation.[187] Local cardiac NE stores do not appear to play any role in the *intrinsic* contractile state of cardiac muscle. Thus, no differences were found in the length-tension or force-velocity relationships displayed by papillary muscles removed from normal cats and from cats with NE depletion produced by chronic cardiac denervation or reserpine pretreatment.[187] However, the reduction in cardiac NE stores represents a depletion of the adrenergic neurotransmitter in adrenergic nerve endings, and, as a consequence, the response to activation of the sympathetic nervous system is blunted[188] (see Fig. 16-1) .

The mechanism responsible for cardiac NE depletion in severe heart failure is not clear; it may be an "exhaustion" phenomenon from the prolonged adrenergic activation of the cardiac adrenergic nerves in heart failure. Reductions in the activity of tyrosine hydroxylase,[189] which catalyzes the rate-limiting step in the biosynthesis of NE, and in the rate at which noradrenergic vesicles can take up dopamine have also been incriminated. In patients with cardiomyopathy, iodine-131-labeled metaiodobenzylguanidine (MIBG), a radiopharmaceutical that is taken up by adrenergic nerve endings, is not taken up normally, [190] , [191] suggesting that NE reuptake is impaired in heart failure. Treatment with the beta-adrenergic antagonist metoprolol was associated with correction of MIBG uptake.[192]

ABNORMAL BAROREFLEX CONTROL IN HEART FAILURE

Increased adrenergic activity in heart failure is due, in part, to abnormal baroreflex control of adrenergic outflow from the central nervous system (see Figs. 16-22 and 16-23) . In dogs with experimental heart failure, carotid occlusion elicits a blunted reflex response of heart rate, arterial pressure, and vascular resistance.[193] The possibility of defective adrenergic control of heart rate in patients with heart failure has been studied by observing the reflex hemodynamic responses to stimuli such as upright tilt and vasodilator-induced hypotension.[194]

An inappropriately depressed increase in heart rate in humans with heart failure was observed when arterial pressure was reduced through administration of vasodilators.[195] Whereas the changes in

Figure 16-25 Activation of the sympathetic nervous system in heart failure. There is an increased rate of sympathetic nerve activity (SNA), as measured by the rate of nerve firing in the peroneal nerve, in patients with heart failure *(A).* Studies of the clearance of plasma norepinephrine in normal (NL) subjects and patients with heart failure (CHF) indicate that both increased spillover *(B)* and decreased clearance *(C)* contribute to the higher norepinephrine levels observed in patients with heart failure. (*A,* modified from Leimbach WN Jr, Wallin G, Victor RG, et al: Direct evidence from intrarenal recordings for increased central sympathetic outflow in patients with heart failure. Circulation 73:913, 1986. Copyright 1986, American Heart Association. *B* and *C,* modified from Davis D, et al: Abnormalities in systemic norepinephrine kinetics in human congestive heart failure. Am J Physiol 254:E760, 1988.)

mean arterial pressure observed in response to the vasodilators were similar in patients with heart failure and in control subjects, the changes in heart rate after vasodilators correlated significantly with the changes in concentration of circulating NE and with the sum of circulating NE and epinephrine. In normal individuals, both heart rate and catecholamine concentrations rose, whereas in patients with heart failure, in whom resting catecholamine levels were already increased, cardiac acceleration was blunted and catecholamine concentration failed to rise normally. Similarly, during upright tilt there is a blunting of the normal increases in plasma NE, forearm vascular resistance, and hepatic vascular resistance in patients with heart failure.[196] Some patients with heart failure exhibit a major reduction in arterial pressure during tilting, analogous to what is observed in idiopathic orthostatic hypotension.[197] Further evidence for impairment of baroreflex control of the systemic circulation comes from investigations in which lower body negative pressure fails to cause normal reflex augmentation of forearm vascular resistance.[198]

ATRIAL STRETCH RECEPTORS.

Abnormal baroreflex control also contributes to the reduced ability of patients with heart failure to excrete salt and water. Under normal circumstances, elevated left atrial pressure stimulates atrial stretch receptors. The increased activity of both myelinated and nonmyelinated (C-fiber) afferents[199] inhibits the release of antidiuretic hormone, thereby increasing water excretion, which in turn reduces plasma volume and would act to restore left atrial pressure to normal. In addition, enhanced left atrial stretch receptor activation depresses renal efferent sympathetic nerve activity and increases renal blood flow and glomerular filtration rate, thereby enhancing the ability of the kidney to reduce plasma volume.

With continued stimulation as occurs in heart failure, there is desensitization of atrial (and arterial) baroreceptors. Zucker and coworkers observed that the decreased sensitivity of left atrial stretch receptors in dogs with heart failure is the result of cardiac dilatation and alterations in atrial compliance and is reversible after reversal of heart failure.[200] This resetting of atrial receptors may be responsible for the inappropriately high plasma antidiuretic hormone levels in heart failure and may contribute to the renal vasoconstriction, peripheral edema, ascites, and hyponatremia characteristic of chronic severe heart failure. With chronic heart failure and its attendant cardiac distention and decreased sensitivity of cardiac receptors, the reflex inhibition of adrenergic activity disappears. The adrenergic drive to the peripheral vascular bed and the adrenal medulla is enhanced, contributing to the sodium retention, the tachycardia, and the vasoconstricted state characteristic of heart failure.

There is evidence that abnormal baroreflex control is associated with increased activity of Na^+ ,K^+ -ATPase in the baroreceptors.[201] Digitalis glycosides can partially correct the blunted baroreceptor responsiveness in patients with heart failure.[198] This ability of digitalis to correct baroreflex function and thereby suppress adrenergic nerve activity may play a significant role in its clinical efficacy (see Chap. 18) . It has been shown that NO increases baroreflex sensitivity, whereas angiotensin II decreases it and that exogenous NO and blockade of angiotensin receptors can correct the reduced baroreceptor sensitivity in experimental heart failure.[53] [202] [203] The abnormal baroreflex response in patients with heart failure is usually corrected by cardiac transplantation[204] and is not associated with structural changes in the carotid sinus nerve fiber,[205] indicating that it is a secondary manifestation (not a cause) of heart failure.

Beta-Adrenergic Receptor-G Protein-Adenylyl Cyclase Pathway

BETA-ADRENERGIC RECEPTORS (See also p. 461).

Ventricles obtained from patients with heart failure demonstrate a marked reduction in beta-adrenergic receptor density, isoproterenol-mediated adenylyl cyclase stimulation, and the contractile response to beta-adrenergic agonists.[206] [206A] It is generally believed that the downregulation of beta-adrenergic receptors is mediated by increased levels of NE in the vicinity of the receptor. In patients with right ventricular failure secondary to primary pulmonary hypertension, $beta_1$ -adrenergic receptors are downregulated in the right ventricle but not in the normally functioning left ventricle,[207] suggesting that beta-adrenergic receptor downregulation is due to a local chamber-specific mechanism, presumably an increase in local NE concentrations. In patients with dilated cardiomyopathy, this reduction in receptor

Figure 16-26 Downregulation of beta-adrenergic receptors in myocardium from patients with heart failure. Although human ventricular myocardium expresses both $beta_1$ - and $beta_2$ -adrenergic receptor subtypes, only the $beta_1$ subtype is significantly downregulated in failing myocardium *(A).* Downregulation of $beta_1$ receptors is associated with upregulation of beta-adrenergic receptor kinase (betaARK), an enzyme that phosphorylates beta-adrenergic receptors and thereby contributes to their uncoupling from second messenger pathways *(B).* In addition, the mRNA level for $beta_1$ -, but not $beta_2$ -, adrenergic receptors is decreased in failing human myocardium *(C* and *D).* NF=nonfailure; F=congestive heart failure; DCM=dilated cardiomyopathy; ICM=ischemic cardiomyopathy. (Data from Bristow MR: Changes in myocardial and vascular receptors in heart failure. J Am Coll Cardiol 22:61A, 1993; and Ungerer M, Bohm M, Elce JS, et al: Altered expression of beta-adrenergic receptor kinase and $beta_1$ -adrenergic receptors in the failing human heart. Circulation 87:454, 1993. Copyright 1993, American Heart Association.)

density is proportional to the severity of heart failure and involves primarily $beta_1$, but not $beta_2$, receptors, thus reducing the ratio of $beta_1$ to $beta_2$ receptors (Fig. 16-26 *A*). [208] The $beta_2$ receptor, although not downregulated, becomes partially "uncoupled" from its effector enzyme (adenylyl cyclase),[209] producing a similar effect.

The relative roles of beta-adrenergic receptor downregulation versus receptor uncoupling may depend on the cause of heart failure.[209A] In myocardium obtained from patients with heart failure secondary to ischemic heart disease, there is a relatively greater degree of receptor desensitization than in myocardium from patients with ischemic cardiomyopathy.[210] This observation, together with apparent differences in the regulation of G-protein function (discussed later), has led to the suggestion that there are differences in the behavior of the beta-adrenergic receptor-G-protein complex in these forms of heart failure. In myocardium from patients with heart failure the level of $beta_1$ -adrenergic receptor mRNA is decreased, indicating that downregulation of $beta_1$ -adrenergic receptors is mediated, at least in part, by a decrease in receptor synthesis, whereas the level of $beta_2$ -adrenergic receptor mRNA is unchanged (see Fig. 16-26 *C* and *D*). In addition, there are increases in the expression of beta-adrenergic receptor kinase (betaARK) and its mRNA level in failing human myocardium (see Fig. 16-26 *B*). [211] betaARK is an enzyme that phosphorylates both $beta_1$ - and $beta_2$ -adrenergic receptors and thereby plays a central role in uncoupling of the receptor from its G protein.[211] Increased betaARK activity may therefore contribute to the uncoupling of both $beta_1$ - and $beta_2$ -adrenergic receptors in patients with heart failure.

Downregulation of $beta_1$ receptors in patients with heart failure may be reversed by the administration of metoprolol, a relatively specific $beta_1$ antagonist. The long-term clinical benefit of beta blockade in heart failure (see Chap. 18) has been reported to be associated with both a restoration of myocardial beta receptor density and the contractile response to administered catecholamines.[212] Although these effects may contribute to improved adrenergic responsiveness, they are not seen with all beta blockers[213] and therefore do not appear to be critical to the beneficial effects of these drugs on ventricular remodeling or clinical outcomes.

G PROTEINS AND ADENYLYL CYCLASE (See also p. 455).

G proteins play a crucial role in coupling receptors, including beta-adrenergic receptors, to effector enzymes such as adenylyl cyclase (see Chap. 14) . Cardiac cells contain at least two types of G proteins: (1) G_s , which mediates the stimulation of adenylyl cyclase (and thereby causes a rise in intracellular cyclic AMP, which in turn stimulates Ca^{2+} influx into the myocyte through Ca^{2+} channels in the sarcolemmal membrane and accelerates the uptake of Ca^{2+} by the SR); and (2) G_i , which mediates the inhibition of adenylyl cyclase and has the opposite effect on the movements of Ca^{2+} .

Heart failure caused by dilated cardiomyopathy is associated with an increase in G_i activity and protein level in heart muscle,[214] which may be accompanied by a reduction

in the activity of adenylyl cyclase.[215] The mechanism responsible for the increase in G_i activity is not known. The mRNA levels of G_i are not increased in the myocardium of patients with heart failure,[216] suggesting that the increase in G_i activity reflects events at the posttranscriptional level. G_s appears normal in failing human myocardium.[216] Overall, heart failure is characterized by an increase in the ratio of G_i to G_s .[216] The functional consequences of an increase in G_i activity remain to be established.

REDUCED ADRENERGIC SUPPORT OF THE FAILING HEART.

The importance of the adrenergic nervous system in maintaining ventricular contractility when myocardial function is depressed in heart failure is demonstrated by the effects of adrenergic blockade. *Acute* pharmacological blockade of the adrenergic nervous system may cause intensification of heart failure as well as sodium and water retention.[217] [218] [219] The *acute* administration of beta blockers to patients with heart failure results in reductions in both systolic and diastolic myocardial function.[220] Despite the long-term salutary effects of beta-blocker therapy in patients with heart failure[220A] (see Chaps. 18 and 21) , caution should be exercised in using these agents, particularly at the initiation of therapy and in patients in whom heart failure is severe or of recent onset.

Because of the depletion of cardiac NE stores and desensitization of the postsynaptic beta-adrenoceptor pathway, the capacity of the myocardium to produce cyclic AMP is diminished, sometimes profoundly, in patients with heart failure.[221] As a consequence, the failing heart loses an important compensatory mechanism. In patients with heart failure, downregulation of postsynaptic beta-adrenoceptors in the sinoatrial node contributes to the attenuated chronotropic response to exercise.[175] Likewise, the positive inotropic response to an intracoronary infusion of the beta-adrenergic agonist dobutamine is markedly reduced in patients with heart failure.[222] The degree of attenuation of both the chronotropic and positive inotropic responses to adrenergic stimulation are correlated with the level of baseline adrenergic activation as reflected by the concentration of plasma NE.[175] [222] An important therapeutic consequence of the alterations of the beta-adrenergic pathway described earlier is that the positive inotropic response to beta-adrenoceptor agonists, and to a lesser extent to phosphodiesterase inhibitors, is markedly reduced in myocardium obtained from patients with end-stage heart failure.

ADVERSE EFFECTS OF ADRENERGIC STIMULATION

Although increased adrenergic activity may play a compensatory role over the short term, *chronic* adrenergic activation may be deleterious by increasing afterload and precipitating cardiac arrhythmias. Thus, it has been postulated that in heart failure there may be a positive feedback loop causing a vicious circle. According to this concept, heart failure activates the adrenergic nervous system (as well as activating the renin-angiotensin system and stimulating the release of vasopressin and endothelin); this causes increases in preload and afterload that further depress ventricular function and increase the heart's demands for energy.

Increased adrenergic nerve activity may also influence the chronic remodeling of the myocardium by affecting the progression of myocardial failure through direct

harmful effects of NE on adrenergic receptors located on several cell types in the myocardium, including cardiac myocytes and fibroblasts. The tonic stimulation of beta-adrenergic receptors, or the downstream cyclic AMP pathway to which they are coupled, results in death of cardiac myocytes by apoptosis. In vitro, tonic exposure to NE causes apoptosis of adult rat cardiac myocytes that is mediated through the beta-adrenergic receptor adenylyl cyclase and cyclic AMP[58] (Fig. 16-27) . A similar effect is seen in neonatal rat cardiomyocytes.[59] Likewise, the chronic infusion of isoproterenol to rats causes myocardial failure associated with apoptosis,[223] and transgenic mice that overexpress either the beta$_1$ -adrenergic receptor or G_s [224] [225] [225A] develop myocardial failure associated with myocyte apoptosis. When viewed from this perspective, the desensitization of the beta-adrenergic pathway, although impairing short-term myocardial function, may protect the myocardium from increased adrenergic activation.

Stimulation of alpha$_1$ -adrenergic receptors can induce hypertrophy in cardiac myocytes associated with the reappearance of fetal genes and fetal isoforms of proteins involved in the development of

Figure 16-27 Effect of norepinephrine (NE) on myocyte apoptosis. Adult rat cardiac myocytes in tissue culture were exposed to control media *(A)* or NE *(B)* for 24 hours and apoptosis was measured by the TUNEL staining for fragmented DNA shown in two nuclei in this panel. NE caused an approximately fourfold increase in TUNEL-positive myocytes *(C).* This effect of NE was abolished by a beta-adrenergic antagonist and mimicked by beta-adrenergic agonists but not affected by an alpha-adrenergic antagonist. (From Sawyer DB, Colucci WS: Molecular and cellular events in myocardial hypertrophy and failure. *In* Colucci WS [ed]: Heart Failure: Cardiac Function and Dysfunction, Atlas of Heart Diseases. Vol 4. Philadelphia, Current Medicine, 1999, p 4.12.)

contractile force, the regulation of myocardial energetics, and excitation-contraction coupling.[183] [226] In addition, NE, acting on both alpha$_1$ -adrenergic and beta-adrenergic receptors located on cardiac myocytes and fibroblasts,[184] [227] can induce the expression of a variety of peptide growth factors that have been shown to have important effects on the growth and phenotype of myocytes and fibroblasts.[228]

PARASYMPATHETIC FUNCTION IN HEART FAILURE

Cardiac enlargement, with or without heart failure, is associated with marked disturbances of parasympathetic as well as sympathetic function.[229] The parasympathetic restraint on sinoatrial node automaticity is markedly reduced in patients with heart failure (see Fig. 16-2) , who exhibit less heart rate slowing for any given elevation of systemic arterial pressure than do normal subjects. The sensitivity of the baroreceptor reflex to an increase in pressure has also been shown to be significantly reduced in dogs with heart failure.[193] Measurements of heart rate variability, which indirectly reflect autonomic nervous system function, indicate that parasympathetic activity in patients with heart failure is abnormal both at rest and in response to exercise.[230]

Abnormal parasympathetic function may also be altered at the level of the peripheral nerve and the postsynaptic receptor. Cardiomyopathic hamster hearts display a reduction in the activity of choline acetyltransferase, an enzyme that provides an estimate of the density of parasympathetic innervation,[231] and there is evidence that the density of high-affinity muscarinic receptors is reduced in the hearts of dogs with experimental heart failure.[232]

Renin-Angiotensin System

In low cardiac output states, there is activation of the renin-angiotensin system (RAS), which operates in concert with the activated adrenergic nervous-adrenal medullary system to maintain arterial pressure and to retain sodium and water

Figure 16-28 The systemic and tissue components of the renin-angiotensin system. Several tissues, including myocardium, vasculature, kidney, and brain, have the capacity to generate angiotensin II independent of the circulating renin-angiotensin system. Angiotensin II produced at the tissue level may play an important role in the pathophysiology of heart failure. (Modified from Timmermans PB, Wong PC, Chiu AT, et al: Angiotensin II receptors and angiotensin II receptor antagonists. Pharmacol Rev 45:205, 1993.)

(see Figs. 16-22 and 16-24 *B*). These two compensatory systems are clearly coupled; stimulation of beta$_1$ -adrenoceptors in the juxtaglomerular apparatus of the kidneys as a consequence of heightened adrenergic drive is a principal mechanism responsible for the release of renin in acute heart failure. Activation of the baroreceptors in the renal vascular bed by a reduction of renal blood flow is also responsible for the release of renin; and, in patients with severe chronic heart failure after salt restriction and diuretic treatment, reduction of the sodium presented to the macula densa contributes to the release of renin. Elevated plasma renin activity is a common, although not universal, finding in heart failure.[172] [174] [233] In the SOLVD study, plasma angiotensin II was significantly elevated even in asymptomatic patients and was further elevated in patients with symptomatic heart failure (see Fig. 16-24) .[174]

ADVERSE EFFECTS OF RAS ACTIVATION.

Angiotensin II is a potent peripheral vasoconstrictor and contributes, along with increased adrenergic activity, to the excessive elevation of systemic vascular resistance and the vicious circle already referred to (see p. 520) in patients with heart failure. Angiotensin II also enhances the adrenergic nervous system's release of NE. Aldosterone has potent sodium-retaining properties and contributes to the development of edema (see Fig. 16-22) . Therefore, it is not surprising that interruption of the renin-angiotensin-aldosterone axis by means of an ACE inhibitor reduces system vascular resistance, diminishes afterload, and thereby elevates cardiac output in heart failure. In some patients these compounds also exert a mild diuretic action, presumably by lowering the angiotensin II-stimulated production of aldosterone.[233A] [233B] [233C]

Angiotensin II may also play a direct role in modifying the structure and function of the myocardium.[233D] In cardiac myocytes in culture, angiotensin caused cellular hypertrophy, the induction of fetal gene programs,[234] and apoptosis.[235] Angiotensin also appears to play a role in mediating the apoptotic effect of mechanical strain and is a potent stimulator of several signaling pathways,[236] including those involved in the regulation of the extracellular matrix.[124] [236A]

TISSUE RENIN-ANGIOTENSIN SYSTEM (RAS).

The major portion (90 to 99 percent) of ACE in the body is found in tissues, and only 1 to 10 percent is found in the circulation.[237] All of the necessary components of the RAS (Fig. 16-28) are likewise present in several organs and tissues, including the vasculature, heart, and kidneys. In myocardium from animals with experimental myocardial hypertrophy or failure, there is increased expression of ACE[238] and angiotensinogen,[239] the substrate for angiotensin I production by renin. It has been suggested that the tissue RAS may be activated during compensated heart failure at a time when activity of the circulating system can be relatively normal (Fig. 16-29) . The tissue production of angiotensin II may also occur by a pathway not dependent on ACE (the chymase pathway). This pathway may be of major importance in the myocardium,[240] particularly when the levels of renin and angiotensin I are increased by the use of ACE inhibitors. The density of ACE binding sites is increased in myocardium from patients with end-stage heart failure due to idiopathic cardiomyopathy.[241]

ANGIOTENSIN RECEPTORS.

The predominant angiotensin receptor in the vasculature is the angiotensin$_1$ subtype. In human myocardium it appears that both angiotensin$_1$ (AT_1) and angiotensin$_2$ (AT_2) receptor subtypes are present, and the AT_2 receptor predominates in a ratio of 2:1.[242] The number of AT_1 and AT_2 receptors is normal in patients with moderate heart failure but downregulated in patients with end-stage heart failure.[243] [243A] Downregulation of the AT_1 subtype has been observed in myocardium from patients

Figure 16-29 Relative roles of the circulating and tissue renin-angiotensin systems postulated in patients with heart failure. The tissue system may have alternative pathways for the production of angiotensin II that do not depend on converting enzyme (e.g., chymase) and that therefore are not suppressed by converting enzyme inhibitors. It has been proposed that activation of the tissue renin-angiotensin system may follow a different time course than that of the circulating system, particularly during the compensated phase of heart failure when the circulating renin-angiotensin system may be relatively quiescent and during treatment with converting enzyme inhibitors that may increase the activity of the tissue system by elevating circulating renin levels. (Modified from Dzau VJ: Tissue renin-angiotensin system in myocardial hypertrophy and failure. Arch Intern Med 153:937, 1993. Copyright 1993, American Medical Association.)

with both ischemic and idiopathic dilated cardiomyopathy and associated with a decrease in the mRNA level for the receptor.[2]

ARGININE VASOPRESSIN

Arginine vasopressin (AVP) is a pituitary hormone that plays a central role in the regulation of free water clearance and plasma osmolality (see Fig. 16-23) . Circulating AVP is elevated in many patients with heart failure,[244] even after correction for plasma osmolality. Patients with acute heart failure secondary to massive myocardial infarction may have particularly elevated levels,[245] which are usually associated with elevated concentrations of catecholamines and renin. The plasma AVP concentration was significantly elevated in asymptomatic patients in the prevention arm of the SOLVD study and was elevated further in patients with symptomatic heart failure (see Fig. 16-24) . [174] Control of circulating AVP concentration is abnormal in patients with heart failure who fail to show the normal reduction of AVP with a reduction of osmolality. This may contribute to their inadequate ability to excrete free water and hence to the plasma hypoosmolarity in some patients with heart failure. Decreased sensitivity of atrial stretch receptors, which normally inhibit AVP release with atrial distention, may contribute to the elevation of circulating AVP. In addition, patients with heart failure exhibit failure of the normal suppression of AVP after administration of ethanol.[246]

Two types of AVP receptors (V_1 and V_2) have been identified in a variety of tissues. In dogs with pacing-induced heart failure, the selective inhibition of V_1 receptors increased cardiac output without affecting electrolytes or hormone levels.[247] In contrast, inhibition of V_2 receptors increased serum sodium concentration, plasma renin activity, and plasma AVP levels but did not affect hemodynamics. When the two inhibitors were combined, the hemodynamic effects were potentiated. These results suggest that, in addition to regulating free water clearance through the V_2 receptor, in heart failure AVP may contribute to systemic vasoconstriction through the V_1 receptor.

Natriuretic Peptides

Three natriuretic peptides--atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-natriuretic peptide (CNP)--have been identified in humans.[248] ANP is stored mainly in the right atrium and released in response to an increase in atrial distending pressure. This peptide causes vasodilation and natriuresis and counteracts the water-retaining effects of the adrenergic, renin-angiotensin, and AVP systems. BNP is stored mainly in cardiac ventricular myocardium and may be responsive--albeit less so than ANP--to changes in ventricular filling pressures.[249] BNP has a high level of homology with ANP at the structural level and, like ANP, causes natriuresis and vasodilation. CNP is located primarily in the vasculature. Although the physiological role of CNP is not yet clarified, it appears that it may play an important regulatory role in juxtaposition to the RAS system. At least three receptors for natriuretic peptides (A, B, and C) have been identified.[248] The A and B receptors mediate the vasodilatory and natriuretic effects of the peptides. The C type receptor appears to act primarily as a clearance receptor, which, along with neutral endopeptidase, regulates available levels of the peptides.

Circulating levels of both ANP and BNP are elevated in the plasma of patients with heart failure.[250] In normal human hearts, ANP predominates in the atria, where there is also a low level of expression of BNP and CNP. In patients with heart failure, the atrial content of ANP is unchanged and the contents of BNP and CNP increase 10-fold and 2- to 3-fold, respectively. [250] [250A] In the SOLVD study, the level of plasma ANP was elevated even in asymptomatic patients and was further elevated in patients with symptoms (see Fig. 16-24) .[174] Although the atrial peptides are present only in very low levels in normal ventricular myocardium, in patients with heart failure all three peptides are markedly elevated,[250] and ventricular production contributes significantly to the circulating levels.[251] The secretion of ANP and BNP appears to be regulated mainly by wall tension. The N-terminal of the ANP free-hormone (N-terminal pro-ANP) has a longer half-life and greater stability than ANP and has been shown to be a powerful and independent predictor of cardiovascular mortality and the development of heart failure.[252] ANP levels normalize after cardiac transplantation.[253]

The hemodynamic and natriuretic responses to an infusion of ANP are attenuated in patients and experimental animals with heart failure.[254] However, studies using an ANP receptor antagonist in dogs with pacing-induced heart failure showed that, despite attenuated hemodynamic and renal effects, the peptide continues to exert an important suppressive effect on the activity of the RAS and NE levels.[255] One approach that attempts to capitalize on the beneficial effects of the natriuretic peptides is to inhibit their degradation through the use of neutral endopeptidase inhibitors. The infusion of the endopeptidase inhibitor candoxatrilat into patients with heart failure mimics the action of infused ANP; it causes a reduction in left- and right-sided heart filling pressures associated with suppression of plasma NE levels and a transient reduction in plasma vasopressin, aldosterone, and renin activity.[256] In addition to the beneficial effect of natriuretic peptides on neurohormones, renal function, and hemodynamics, there is evidence that the natriuretic peptides may directly inhibit myocyte and vascular smooth muscle hypertrophy and interstitial fibrosis.[257] [258]

Endothelin and Other Peptides

Endothelin is a potent peptide vasoconstrictor released by endothelial cells throughout the circulation. [259] , [260] Three endothelin peptides (endothelin-1, endothelin-2, and endothelin-3) have been identified, all of which are potent constrictors. At least two subtypes of endothelin receptors (types A and B) have been recognized. The release of endothelin from endothelial cells in vitro can be enhanced by several vasoactive agents (e.g., NE, angiotensin II, thrombin) and cytokines (e.g., TGF-beta and IL-1beta). Several reports have documented an increase in circulating levels of endothelin-1 in patients with heart failure.[261] [262] [262A] Plasma endothelin correlates directly with pulmonary artery pressures and, in particular, the pulmonary vascular resistance and the resistance ratio of pulmonary vascular resistance to systemic resistance. This has led to the suggestion that endothelin plays a pathophysiological role in mediating pulmonary hypertension in patients with heart failure. In normal subjects, plasma endothelin levels increase with orthostatic stress. However, in heart failure patients, endothelin levels are already elevated and show no further increase with orthostatic stress, similar to the pattern of response seen with a variety of other vasoconstrictor substances, including angiotensin and NE.[262] Plasma endothelin levels have been shown to be increased in patients with acute myocardial infarction and to correlate with the Killip class in these patients.[263]

Antagonists of endothelin receptors are available and have been used to demonstrate the physiological effects of endothelin. When administered to rats with heart failure after myocardial infarction, the endothelin antagonist bosentan, which blocks both $endothelin_A$ and $endothelin_B$ receptors, decreased arterial pressure and had an additive effect to that of an ACE inhibitor.[264] In cultured cardiac myocytes, endothelin induces cellular hypertrophy associated with the induction of fetal genes.[265] In rats with pressure overload-induced hypertrophy caused by aortic banding, administration of the $endothelin_A$ receptor antagonist BQ123 transiently inhibited myocyte hypertrophy and prevented fetal gene induction.[266] In rats with myocardial infarction, chronic administration of endothelin antagonists resulted in a reduction in left ventricular chamber remodeling enlargement, improved hemodynamic function, and improved survival (Fig. 16-30) . [267] [268] [269] These observations suggest that endothelin receptor antagonists may be of value in both the acute and chronic treatment of patients with heart failure.[270] Administration of endothelin antagonists to patients has been shown to improve hemodynamic function,[271] [272] [273] but the long-term effects on disease progression and survival are not known.

Figure 16-30 Effect of the endothelin receptor antagonist bosentan on left ventricular remodeling 8 weeks after a myocardial infarction in the rat. The left ventricular diastolic pressure-volume relationship was shifted rightward after infarction indicative of chamber dilation. In rats with a large infarction, bosentan reduced the extent of rightward shift. (Modified from Fraccarollo D, Hu K, Galuppo P, et al: Chronic endothelin receptor blockade attenuates progressive ventricular dilation and improves cardiac function in rats with myocardial infarction: Possible involvement of myocardial endothelin system in ventricular remodeling. Circulation 96:3963-3973, 1998. Copyright 1998, American Heart Association.)

Several other peptides, including acidic fibroblast growth factor, basic fibroblast growth factor, TGF-beta1, and platelet-derived growth factor have been shown to affect the growth and phenotype of cardiac myocytes or fibroblasts in vitro.[274] The expression of these and other peptides is increased in myocardium after myocardial infarction[275] [276] [277] or with hemodynamic overload,[278] suggesting that they may play a role in the orchestration of myocardial remodeling.

Inflammatory Cytokines, Including TNF-alpha (See also p. 461)

Inflammatory cytokines, including TNF-alpha and IL-1beta, may play an important role in the pathogenesis of myocardial failure.[278A] In vitro, these and other inflammatory cytokines can regulate growth and gene expression in cardiac myocytes and other cells present in the myocardium. The circulating levels of TNF-alpha and interleukin-6 (IL-6) are increased in patients with heart failure.[279] [280] The failing myocardium, itself, may be a source of inflammatory cytokines, which might thus be present in high local concentrations.[281]

Inflammatory cytokines have protean effects on the myocardium. TNF-alpha can induce immediate myocardial dysfunction and has been shown to attenuate intracellular calcium transients in vitro.[282] [283] [284] [284A] In cultured cardiac myocytes, TNF-alpha and IL-1beta can stimulate hypertrophy and re-expression of a fetal gene program,[285] [286] [287] and both can cause apoptosis,[61] [288] which may be mediated, in part, by NO.[61] [289] The chronic systemic infusion of TNF-alpha in rats

resulted in left ventricular failure[290] (Fig. 16-31) , and mice that overexpress TNF-alpha in the myocardium developed a dilated cardiomyopathy that was associated with increased myocyte apoptosis.[291] [292] Pilot clinical trials with soluble TNF-alpha receptors that reduce the level of TNF-alpha available to the tissues have suggested that this may a feasible form of therapy for patients.[293]

Nitric Oxide

Two isoforms of nitric oxide synthase (NOS), termed NOS2 and NOS3, are expressed in human myocardium. NOS2 is an inducible isoform that is not normally expressed in the myocardium but is synthesized de novo in response to inflammatory cytokines, thereby causing high levels of NO production. The expression and activity of NOS2 are increased in myocardium obtained from patients with severe heart failure,[149] [294] possibly as a result of stimulation by inflammatory cytokines.

There are several ways that NO might affect the myocardium.[295] It has been shown that NO mediates the inhibitory effect of inflammatory cytokines on the contractile response to beta-adrenergic stimulation in cardiac myocytes and myocardium by the induction of NOS2.[296] [297] In normal subjects, the intracoronary infusion of nitroprusside, an NO donor, improved left ventricular distensibility,[298] whereas inhibition of NO synthesis by the intracoronary infusion of an NOS inhibitor potentiated the positive inotropic response to dobutamine in patients with left ventricular dysfunction.[299] As discussed earlier, NO may also act directly on myocytes to cause apoptosis[61] [289] or regulate phenotype.[300]

Oxidative Stress

There is evidence that oxidative stress is increased both systemically and in the myocardium of patients with heart failure.[23] [48] [301] [302] Increased oxidative stress may be due to reduced antioxidant capacity[23] or the increased production of reactive oxygen species, which may be a consequence of mechanical strain on the myocardium[62] or stimulation by inflammatory cytokines. Reactive oxygen species can stimulate myocyte hypertrophy, reexpression of fetal gene programs, and apoptosis in cardiac myocytes in culture.[60] Mice with knockout of the antioxidant enzyme manganese superoxide dismutase (MnSOD) develop dilated cardiomyopathy and die at a young age.[303] Conversely, in animal models of hemodynamic overload-induced remodeling and failure, treatment with antioxidants prevented the progression to myocardial failure,[304] leading to the suggestion that antioxidants might be of therapeutic value in patients.

Figure 16-31 Transgenic mice that overexpress tumor necrosis factor-alpha in the heart developed a dilated cardiomyopathy that was associated with reduced survival. Survival was worst in a line of mice with the highest level of TNF-alpha expression, intermediate in mice with a lower level of TNF-alpha expression, and best in nontransgenic controls. Chapter 17 - Clinical Aspects of Heart Failure: High-Output Failure; Pulmonary Edema

MICHAEL M. GIVERTZ
WILSON S. COLUCCI EUGENE BRAUNWALD

Definition

Heart failure is a principal complication of virtually all forms of heart disease. A panel of the National Heart, Lung and Blood Institute described this condition as follows: Heart failure occurs when an abnormality of cardiac function causes the heart to fail to pump blood at a rate required by the metabolizing tissues or when the heart can do so only with an elevated filling pressure. The heart's inability to pump a sufficient amount of blood to meet the needs of the body tissues may be due to insufficient or defective cardiac filling and/or impaired contraction and emptying. Compensatory mechanisms increase blood volume and raise cardiac filling pressures, heart rate, and cardiac muscle mass to maintain the heart's pumping function and cause redistribution of blood flow. Eventually, however, despite these compensatory mechanisms, the ability of the heart to contract and relax declines progressively, and the heart failure worsens.[1]

An alternative definition, which focuses more on the clinical consequences of heart failure, has been offered by Packer: "Congestive heart failure (CHF) represents a complex clinical syndrome characterized by abnormalities of left ventricular function and neurohormonal regulation, which are accompanied by effort intolerance, fluid retention, and reduced longevity."[2] Included in these two definitions is a wide spectrum of clinical and pathophysiological states, ranging from the rapid impairment of pumping function (occurring when, for example, a massive myocardial infarction suddenly develops) to the gradual but progressive impairment of myocardial function, observed at first only during stress in a patient whose heart sustains a pressure or volume overload for a prolonged period. *Myocardial failure,* a term used to denote abnormal systolic or diastolic function, may be asymptomatic or progress to heart failure. Circulatory failure is not synonymous with heart failure, because a variety of noncardiac conditions (e.g., hemorrhagic shock) can lead to circulatory collapse while cardiac function is preserved.

The clinical manifestations of heart failure vary enormously and depend on a variety of factors, including the age of the patient, the extent and rate at which cardiac performance becomes impaired, and the ventricle initially involved in the disease process. A broad spectrum of severity of impairment of cardiac function is ordinarily included within the definition of heart failure, ranging from the mildest, which is manifest clinically only during stress, to the most advanced form, in which cardiac pump function is unable to sustain life without external support.

Useful criteria for the diagnosis of heart failure emerged from the Framingham Study[3] (Table 17-1) .

TABLE 17-1 -- FRAMINGHAM CRITERIA FOR CONGESTIVE HEART FAILURE

Major Criteria
Paroxysmal nocturnal dyspnea
Neck vein distention
Rales
Radiographic cardiomegaly
Acute pulmonary edema
S_3 gallop
Central venous pressure>16 cm H_2 O
Circulation time 25 sec
Hepatojugular reflux
Pulmonary edema, visceral congestion, or cardiomegaly at autopsy
Weight loss 4.5 kg in 5 days in response to treatment of congestive heart failure
Minor Criteria
Bilateral ankle edema
Nocturnal cough
Dyspnea on ordinary exertion
Hepatomegaly
Pleural effusion
Decrease in vital capacity by one third from maximal value recorded
Tachycardia (rate 120 beats/min)

The diagnosis of congestive heart failure in this study required that two major or one major and two minor criteria be present concurrently. Minor criteria were acceptable only if they could not be attributed to another medical condition.

From Ho KL, Pinsky JL, Kannel WB, Levy D. The epidemiology of heart failure: The Framingham Study. J Am Coll Cardiol 22(Suppl A):6A, 1993.

Incidence and Prevalence

Heart failure is a relatively common disorder. It is estimated that 4.6 million persons in the United States are being treated for heart failure, with 550,000 new cases diagnosed each year.[4] [5] The prevalence of heart failure increases dramatically with age, occurring in 1 to 2 percent of persons aged 50 to 59 and up to 10 percent of individuals older than the age of 75 (Fig. 17-1) .[3] [5] Approximately 80 percent of all heart failure admissions occur in patients older than 65; as a result, heart failure is the leading discharge diagnosis in persons aged 65 years or older in the United States.[6] Despite a steady decline in the incidence of coronary artery disease and stroke, both the incidence and prevalence of heart failure continue to rise. Between 1985 and 1995 the number of heart failure hospitalizations increased by 51

percent,[7] and 870,000 hospital discharges for heart failure occurred in 1996.[4] In the United States, approximately 45,000 deaths each year are primarily caused by heart failure and heart failure is listed as a contributing cause in 260,000 deaths.[8] [9] This trend may be due in part to the aging of the population and in part to the improved survival of patients with cardiovascular disease. Heart failure has an enormous economic impact on the U.S. health care system, owing to direct medical costs, disability, and loss of employment. Estimated treatment costs in 1994 were $38 billion, of which $23 billion were spent on hospitalizations.[10] The cost of hospitalizations for heart failure is twice that for all forms of cancer and myocardial infarctions combined.[10]

Forms and Causes of Heart Failure

Forward Versus Backward Heart Failure

The clinical manifestations of heart failure arise as a consequence of inadequate cardiac output and/or damming up of blood behind one or both ventricles. These two principal mechanisms are the basis of the so-called forward and backward pressure theories of heart failure. The *backward failure hypothesis,* first proposed in 1832 by James Hope, contends that when the ventricle fails to discharge its contents, blood accumulates and pressure rises in the atrium and the venous system emptying into it.[11] There is substantial physiological evidence in favor of this theory. As discussed in Chapters 14 and 15 , the inability of cardiac muscle to shorten against a load alters the relationship between ventricular end-systolic pressure and volume so that end-systolic volume rises. The following sequence then occurs, which at first maintains cardiac output at a normal level: (1) ventricular end-diastolic volume and pressure increase; (2) the volume and pressure rise in the atrium behind the failing ventricle; (3) the atrium contracts more vigorously (a manifestation of Starling's law, operating on the atrium)[12] ; (4) the pressure in the venous and capillary beds behind (upstream to) the failing ventricle rises; and (5) transudation of fluid from the capillary bed into the interstitial space (pulmonary or systemic) increases. Many of the symptoms characteristic of heart failure can be traced to this sequence of events and the resultant increase in fluid in the interstitial spaces of the lungs, liver, subcutaneous tissues, and serous cavities.

In many patients, the entire sequence of events just outlined may transpire while cardiac output *at rest* is still within normal limits. Indeed, the backward failure hypothesis invokes one of the principal compensatory mechanisms in heart failure, that is, Starling's law of the heart, in which distention of the ventricle helps to maintain cardiac output. The failing ventricle operates on an ascending, albeit depressed and flattened, function curve,[13] and the augmented ventricular

Figure 17-1 Prevalence rates of congestive heart failure (CHF) among Framingham Heart Study subjects, by gender and age. Among men (open bars), the prevalence increased from 8 cases/1000 in those aged 50-59 years to 66 cases/1000 in those aged 80-89 years. Among women (solid bars), the prevalence increased from 8 cases/1000 in those aged 50-59 years to 79 cases/1000 in those aged 80-89 years. (From Ho KK, et al: The epidemiology of heart failure: The Framingham Study. J Am Coll Cardiol 22:6A, 1993.)

end-diastolic volume and pressure characteristic of heart failure may aid in the maintenance of cardiac output.

An important extension of the backward failure theory is the development of right ventricular failure as a consequence of left ventricular failure. According to this concept, the elevation of left ventricular diastolic, left atrial, and pulmonary venous pressures results in backward transmission of pressure into the pulmonary arterial circulation and leads to pulmonary hypertension, which ultimately causes right ventricular failure. Often, pulmonary vasoconstriction plays a part in this form of pulmonary hypertension as well.

Eighty years after publication of Hope's work, Mackenzie proposed the *forward failure hypothesis,* which relates clinical manifestations of heart failure to inadequate delivery of blood into the arterial system.[14] According to this hypothesis, the principal clinical manifestations of heart failure are due to reduced cardiac output, which results in diminished perfusion of vital organs, including the brain, leading to mental confusion; skeletal muscles, leading to weakness; and kidneys, leading to sodium and water retention through a series of complex neurohormonal mechanisms.[15] This retention of sodium and water, in turn, augments extracellular fluid volume and ultimately leads to symptoms of heart failure due to congestion of organs and tissues.

Although these two seemingly opposing views concerning the pathogenesis of heart failure led to lively controversy during the first half of the 20th century, it no longer seems fruitful to make a rigid distinction between backward and forward heart failure, because *both* mechanisms appear to operate in the majority of patients with chronic heart failure. Exceptions may occur, however, and some patients, particularly those with *acute* decompensation, develop relatively pure forms of forward or backward failure. For instance, a massive myocardial infarction may result in either (1) forward failure with a marked reduction of left ventricular output and cardiogenic shock and clinical manifestations secondary to impaired perfusion (e.g., hypotension,

mental confusion, oliguria) or (2) backward failure with a small transient inequality of output between the two ventricles, resulting in acute pulmonary edema. More commonly, patients with large myocardial infarctions develop a combination of forward and backward failure, with symptoms resulting from both inadequate cardiac output and pulmonary congestion.

RIGHT-SIDED VERSUS LEFT-SIDED HEART FAILURE

Implicit in the backward failure theory is the idea that fluid localizes behind the specific cardiac chamber that is *initially* affected. Thus, symptoms secondary to pulmonary congestion initially predominate in patients with left ventricular infarction, hypertension, or aortic or mitral valve disease; that is, they manifest *left-sided heart failure.* With time, however, fluid accumulation becomes generalized, and ankle edema, congestive hepatomegaly, ascites, and pleural effusion occur; thus, the patients subsequently exhibit *right-sided heart failure* as well.

FLUID RETENTION IN HEART FAILURE.

Fluid retention in heart failure is caused in part by reduction in glomerular filtration rate and in part by activation of the renin-angiotensin-aldosterone system. Reduced cardiac output is associated with a lowered glomerular filtration rate and an increased elaboration of renin, which, through the activation of angiotensin, results in the release of aldosterone (see Chap. 16). The combination of impaired hepatic function, owing to hepatic venous congestion, and reduced hepatic blood flow, interferes with the metabolism of aldosterone, further raising its plasma concentration and augmenting the retention of sodium and water.

Cardiac output (and glomerular filtration rate) may be normal in many patients with heart failure, particularly when they are at rest. However, during stress, such as physical exercise or fever, the cardiac output fails to rise normally, the glomerular filtration rate declines, and the renal mechanisms for salt and water retention described earlier come into play. In addition, ventricular filling pressure and therefore pressures in the atrium and systemic veins behind (upstream to) the ventricle may be normal at rest, only to rise abnormally during stress. This, in turn, may cause transudation and symptoms of tissue congestion (pulmonary in the case of the left ventricle and systemic in the case of the right) during exercise. For this reason, simple rest may induce diuresis and relieve symptoms in many patients with mild-to-moderate heart failure.

ACUTE VERSUS CHRONIC HEART FAILURE

The clinical manifestations of heart failure depend importantly on the *rate* at which the syndrome develops and specifically on whether sufficient time has elapsed for compensatory mechanisms to become operative and for fluid to accumulate in the interstitial space (Table 17-2) . For example, when a previously normal individual suddenly develops a serious anatomical or functional abnormality of the heart, such as massive myocardial infarction, tachyarrhythmia with a very rapid rate, or rupture of a valve secondary to infective endocarditis, a marked reduction in cardiac output will occur, associated with symptoms due to inadequate organ perfusion and/or acute congestion of the venous bed behind the affected ventricle. If the same anatomical abnormality develops gradually, or if the patient survives the acute insult, a number of adaptive mechanisms become operational, especially cardiac remodeling and neurohormonal activation, and these allow the patient to adjust to and tolerate not only the anatomical abnormality but also a reduction in cardiac output with less difficulty.

LOW-OUTPUT VERSUS HIGH-OUTPUT HEART FAILURE

Low cardiac output at rest, or in milder cases during exertion and other stresses, characterizes heart failure occurring in most forms of cardiovascular disease (i.e., congenital, valvular, rheumatic, hypertensive, coronary, and cardiomyopathic). A variety of high cardiac output states, including thyrotoxicosis, arteriovenous fistulas, beriberi, Paget's disease of bone, and anemia (discussed later in this chapter), may lead to heart failure as well. Low-output heart failure is characterized by clinical evidence of systemic vasoconstriction with cold, pale, and sometimes cyanotic extremities. In advanced forms of low-output failure, marked reduction in the stroke volume is reflected by a narrowing of the pulse pressure.[16] In contrast, in high-output heart failure, the extremities are usually warm and flushed and the pulse pressure

is widened or at least normal.

The ability of the heart to deliver the oxygen required by the metabolizing tissues is reflected in the arterial-mixed venous oxygen difference, which is abnormally widened (i.e., >50 ml/liter in the resting state) in patients with low-output heart failure. This difference may be normal or even reduced in high-output states, owing to elevation of the mixed venous oxygen saturation by the admixture of blood that has been shunted away from metabolizing tissues.

Systolic Versus Diastolic Heart Failure

Implicit in the physiological definition of heart failure (inability to pump an adequate volume of blood and/or to do so only from an abnormally elevated filling pressure) is that heart failure can be caused by an abnormality in systolic function leading to a defect in the expulsion of blood (i.e., *systolic heart failure*) or by an abnormality in diastolic function leading to a defect in ventricular filling (i.e., *diastolic heart failure*) (Fig. 17-2) . The former is the more familiar, classic heart failure associated with an impaired inotropic state. Less familiar, but perhaps just as important, is diastolic heart failure, in which the ability of the ventricle(s) to accept blood is impaired.[17] [18] [18A] (See also pp. 456, 493, and 517.) This may be due to slowed or incomplete ventricular relaxation, which may be transient, as occurs in acute ischemia, or sustained, as in concentric myocardial hypertrophy or restrictive cardiomyopathy secondary to infiltrative conditions such as amyloidosis. The principal clinical manifestations of systolic failure result from an inadequate cardiac output and secondary salt and water retention (forward heart failure), whereas the major consequences of diastolic failure relate to elevation of the ventricular filling pressure, and the high venous pressure upstream to the ventricle, causing pulmonary and/or systemic congestion (backward heart failure).

TABLE 17-2 -- ACUTE VS. CHRONIC HEART FAILURE

FEATURE	ACUTE HEART FAILURE	DECOMPENSATED CHRONIC HEART FAILURE	CHRONIC HEART FAILURE
Symptom severity	Marked	Marked	Mild to moderate
Pulmonary edema	Frequent	Frequent	Rare
Peripheral edema	Rare	Frequent	Frequent
Weight gain	None to mild	Frequent	Frequent
Whole-body fluid volume load	No change or mild increase	Moderate to marked increase	Mild to marked increase
Cardiomegaly	Uncommon	Usual*	Common*
Ventricular systolic function	Reduced, normal, or hypercontractile	Reduced*	Reduced*
Wall stress	Elevated	Markedly elevated	Elevated
Activation of sympathetic nervous system	Marked	Marked	Mild to marked
Activation of renin-angiotensin-aldosterone system	Often increased	Marked	Mild to marked
Reparable, reversible causative lesion(s)	Common	Occasional	Occasional

Clinical and pathophysiological characteristics of the two major categories of unstable heart failure (acute heart failure and decompensated chronic heart failure) are compared with those of chronic heart failure.

Adapted from Leier CV: Unstable heart failure. In Colucci WS (ed): Heart Failure: Cardiac Function and Dysfunction. 2nd ed. In Braunwald E (series ed): Atlas of Heart Diseases, vol 4. Philadelphia, Current Medicine, 1999, pp 9.1-9.17.

*Patients with diastolic heart failure may have little to no cardiomegaly and normal systolic function.

Figure 17-2 *A,* Schematic of a pressure-volume loop from a normal subject (dotted line) and a patient with diastolic dysfunction (solid line). Dashed lines represent the diastolic pressure-volume relation. Isolated diastolic dysfunction is characterized by a shift in the pressure-volume loop to the left. Contractile performance is normal (normal or increased ejection fraction, normal or slightly decreased stroke volume). However, left ventricular (LV) pressures throughout diastole are increased: at a common diastolic volume=70 ml/m[2] , LV diastolic pressure is 25 mm Hg in the patient with diastolic failure compared with a diastolic pressure of 5 mm Hg in the normal subject. *B,* Schematic of pressure-volume loop from a normal subject (dotted line) and a patient with systolic dysfunction (solid line). Dashed line represents the diastolic pressure-volume relation. Systolic dysfunction is characterized by displacement of the pressure-volume loop to the right. Despite compensatory dilation, stroke volume or ejection fraction remains low. LV diastolic pressures are increased as a result of large LV volume. (From Zile MR: Diastolic dysfunction: Detection, consequences, and treatment: II. Diagnosis and treatment of diastolic dysfunction. Mod Concepts Cardiovasc Dis 59:1, 1990.)

There are many examples of pure systolic or diastolic heart failure. Examples of the former are patients with acute massive myocardial infarction or pulmonary embolism, whereas examples of the latter are patients with hypertrophic or restrictive cardiomyopathy. Community-based, epidemiological studies have demonstrated that diastolic heart failure is more common than was previously thought and is particularly prevalent in elderly women with hypertension.[19] [20] However, in many patients, systolic and diastolic heart failure coexist. The most common form of heart failure, that caused by chronic coronary artery disease, is an example of combined systolic and diastolic failure. In this condition, systolic failure is caused by both the chronic loss of contracting myocardium secondary to prior myocardial infarction and the acute loss of myocardial contractility induced by transient ischemia. Diastolic failure is due to the ventricle's reduced compliance caused by replacement of normal, distensible myocardium with nondistensible fibrous scar tissue and by the acute reduction of diastolic distensibility during ischemia. A number of clinical features and laboratory findings characterize these two forms of heart failure (Table 17-3) . However, it is important to recognize that the clinical features of heart failure may be similar whether left ventricular systolic function is normal or depressed,[20] [21] underscoring the need for evaluation of ventricular function in all patients with heart failure.

CAUSES OF HEART FAILURE

From a clinical viewpoint, it is useful to classify the causes of heart failure into three broad categories: (1) *underlying causes,* comprising the structural abnormalities--congenital or acquired--that affect the peripheral and coronary vessels, pericardium, myocardium, or cardiac valves and lead to the increased hemodynamic burden or myocardial or coronary insufficiency responsible for heart failure; (2) *fundamental causes,* comprising the biochemical and physiological mechanisms through which either an increased hemodynamic burden or a reduction in oxygen delivery to the myocardium results in impairment of myocardial contraction (see Chap. 16 ;) and (3) *precipitating causes,* including the specific causes or incidents that precipitate heart failure in 50 to 90 percent of episodes of clinical heart failure.[22]

It is helpful for the clinician to identify both the underlying and the precipitating causes of heart failure. Appropriate management of the underlying heart disease (e.g., surgical correction of a congenital defect or an acquired valvular abnormality or pharmacological management of hypertension) may prevent the development or recurrence of heart failure. Similarly, treatment of a precipitating cause such as an infection will often terminate an episode of heart failure and may be lifesaving. More important, *avoidance* of a precipitating cause can *prevent* heart failure.

Reduced ejection fraction	++++	-

Certain aspects of the history and physical examination, along with clinical measurements, may help to distinguish diastolic dysfunction from systolic heart failure. For example, patients with hypertensive heart disease, and particularly severe left ventricular hypertrophy, often experience heart failure because of diastolic dysfunction.

Plus signs indicate "suggestive" (the number reflects relative weight). *Minus signs* indicate "not very suggestive."*Adapted from Young JB: Assessment of heart failure. In Colucci WS (ed): Heart Failure: Cardiac Function and Dysfunction. 2nd ed. In Braunwald E (series ed): Atlas of Heart Diseases, vol 4. Philadelphia, Current Medicine, 1999, pp 7.1-7.19.*

Overt heart failure may also be precipitated by the progression of the underlying heart disease. A previously stable, compensated patient may develop heart failure that is apparent clinically for the first time when the intrinsic process has advanced to a critical point, such as with further narrowing of a stenotic aortic valve or progressive obliteration of the pulmonary vascular bed in a patient with cor pulmonale. Alternatively, decompensation may occur as a result of failure or exhaustion of the compensatory mechanisms, but without any change in the load on the heart, in patients with chronic severe pressure or volume overload.

Precipitating Causes of Heart Failure

In one study of 101 patients admitted to an inner city municipal hospital with the diagnosis of heart failure, precipitating factors could be identified in 93 percent.[23]

INAPPROPRIATE REDUCTION OF THERAPY.

Perhaps the most common cause of decompensation in a previously compensated patient with heart failure is inappropriate reduction in the intensity of treatment, be it dietary sodium and fluid restriction, pharmacological therapy, or both. Many patients with serious underlying heart disease, regardless of whether they have previously experienced heart failure, may be relatively asymptomatic for as long as they carefully adhere to their treatment regimen. Dietary excesses of sodium, incurred frequently on vacations or holidays or during an illness of the spouse responsible for preparing the patient's meals, are frequent causes of rapid cardiac decompensation. Education of the patient and family is a simple and effective measure to prevent this common clinical problem. Self-discontinuation or physician withdrawal of effective pharmacotherapy such as angiotensin-converting enzyme (ACE) inhibitors or digoxin can precipitate heart failure.[24]

ARRHYTHMIAS.

Cardiac arrhythmias are common in patients with underlying structural heart disease and commonly precipitate or intensify heart failure. The development of arrhythmias may precipitate heart failure through several mechanisms:

1. *Tachyarrhythmias,* most commonly atrial fibrillation, reduce the time available for ventricular filling. When there is already an impairment of ventricular filling, as in mitral stenosis, or reduced ventricular compliance, as in left ventricular hypertrophy, tachycardia will raise atrial pressure and reduce cardiac output further. In addition, tachyarrhythmias increase myocardial oxygen demands and, in a patient with obstructive coronary artery disease, may induce or intensify myocardial ischemia. This, in turn, impairs both diastolic and systolic function, thereby raising left atrial and pulmonary capillary pressure further and causing pulmonary congestion. Tachycardia may also directly impair contractility in failing human myocardium, owing in part to a negative force-frequency relationship[25] (see Chap. 14), and, if persistent, may cause a reversible dilated cardiomyopathy.[26]
2. *Marked bradycardia* in a patient with underlying heart disease usually depresses cardiac output, because stroke volume may already be maximal and cannot rise farther to maintain cardiac output.
3. *Dissociation between atrial and ventricular contraction,* which occurs in many arrhythmias, results in loss of the atrial booster pump mechanism, which impairs ventricular filling, lowers cardiac output, and raises atrial pressure.[12] This loss is particularly deleterious in patients with impaired ventricular filling due to concentric cardiac hypertrophy (e.g., in systemic hypertension, aortic stenosis, and hypertrophic cardiomyopathy).
4. *Abnormal intraventricular conduction,* which occurs in many arrhythmias such as ventricular tachycardia, impairs myocardial performance because of loss of the normal synchronicity of ventricular contraction. In addition to precipitating heart failure, arrhythmias (sometimes fatal) may be *caused* by heart failure.[27]

MYOCARDIAL ISCHEMIA OR INFARCTION.

In patients with obstructive coronary artery disease, acute myocardial infarction (see Chap. 35), unstable angina (see Chap. 36), or silent ischemia (see Chap. 37) can precipitate heart failure. Reduced myocardial oxygen delivery may be exacerbated by the increase in myocardial oxygen demand resulting from tachycardia and hypertension. Mitral regurgitation due to ischemic papillary muscle dysfunction may contribute to heart failure and lead to acute pulmonary edema.

SYSTEMIC INFECTION.

Any serious infection may precipitate cardiac failure. The mechanisms include increased total body metabolism as a consequence of fever, discomfort, and cough, which increase the hemodynamic burden on the heart; the accompanying sinus tachycardia plays an additional adverse role. Patients with congestive heart failure are particularly susceptible to pulmonary infections, presumably because of the diminished ability of congested lungs to expel respiratory secretions. Furthermore, it is postulated that increased circulating levels of proinflammatory cytokines, such as tumor necrosis factor-alpha and interleukin-1beta, which impair myocardial function in

sepsis,[28] may precipitate heart failure in the setting of non-life-threatening bacterial or viral infections.[29] [29A]

PULMONARY EMBOLISM (see also Chap. 52).

Patients with heart failure, particularly when obese or confined to bed, are at high risk of developing pulmonary emboli. Such emboli may increase the hemodynamic burden on the right ventricle by elevating pulmonary artery pressure and pulmonary vascular resistance further and may cause fever, tachypnea, hypoxemia, and tachycardia, the deleterious effects of which have already been discussed. Congestive heart failure, when present in patients with acute pulmonary embolism, is a strong independent predictor of both short-term[30] and long-term[31] mortality.

PHYSICAL, EMOTIONAL, AND ENVIRONMENTAL STRESS.

Intense, prolonged exertion or severe fatigue, such as may result from prolonged travel or emotional crises, and a severe climatic change (e.g., to a hot, humid environment) are relatively common precipitants of cardiac decompensation.

CARDIAC INFECTION AND INFLAMMATION.

Myocarditis as a consequence of a variety of inflammatory, allergic, or infectious processes, including viral myocarditis (see Chap. 48), or of infective endocarditis (see Chap. 47) may impair myocardial function directly and exacerbate existing heart disease. The anemia, fever, and tachycardia that frequently accompany these processes are also deleterious. In patients with infective endocarditis, additional valvular damage resulting, for example, in marked aortic or mitral regurgitation may also precipitate cardiac decompensation.

DEVELOPMENT OF AN UNRELATED ILLNESS.

Heart failure may be precipitated in patients with compensated cardiovascular disease when an unrelated illness develops. For example, the development of acute or acute-on-chronic renal failure[31A] may further impair the ability of patients with heart failure to excrete sodium and thus may exacerbate fluid retention (see Chap. 72). Similarly, blood transfusion or the administration of sodium-containing fluid during and after a noncardiac operation may result in sudden heart failure in patients with underlying heart disease.

ADMINISTRATION OF CARDIAC DEPRESSANTS OR SALT-RETAINING DRUGS.

A number of drugs depress myocardial function; among these are beta-adrenergic antagonists, nondihydropyridine calcium antagonists (verapamil and diltiazem), many antiarrhythmic agents, inhalation and intravenous anesthetics (see Chap. 61), and antineoplastic drugs such as doxorubicin and cyclophosphamide (see Chap. 69). Others, such as estrogens, corticosteroids, and nonsteroidal antiinflammatory agents,[31B] may cause salt and water retention. Any of these drugs, when administered to a patient with already impaired cardiac function, can precipitate or aggravate heart failure.

CARDIAC TOXINS.

Alcohol is a potent myocardial depressant and may be responsible for the development of cardiomyopathy (see Chap. 48), arrhythmias, and sudden death.[32] In patients with asymptomatic or mildly symptomatic left ventricular dysfunction, excessive alcohol consumption may precipitate heart failure, either directly by an acute depression of myocardial contractility[33] or indirectly through the development of tachyarrhythmias, most commonly atrial fibrillation,[34] or thiamine deficiency. Illicit use of cocaine may precipitate acute heart failure by a number of mechanisms, including myocardial ischemia or infarction,[35] severe hypertension, arrhythmias, myocarditis, or, in the case of injection drug users, acute infective endocarditis (see Chap. 47).

HIGH-OUTPUT STATES.

Acute heart failure may be precipitated in patients with underlying heart disease, such as valvular heart disease, by the development of one of the hyperkinetic circulatory states, such as pregnancy or anemia (see later in this chapter).

DEVELOPMENT OF A SECOND FORM OF HEART DISEASE.

Patients with one form of heart disease often remain compensated until they develop a second form. For example, a patient with chronic hypertension and left ventricular hypertrophy but without left ventricular failure may be asymptomatic until a myocardial infarction (which may be silent) develops and precipitates heart failure. Alternatively, a patient with chronic, well-compensated mitral regurgitation may develop heart failure secondary to uncontrolled hypertension or superimposed infective endocarditis.

It is essential to search for these precipitating causes systematically in all patients with congestive heart failure, because lack of recognition or treatment or both may be responsible for refractory or recurrent heart failure. In most instances, the precipitant can be treated effectively, after which appropriate measures should be instituted to avoid recurrence. When a precipitating cause of heart failure can be identified, it generally signifies a better prognosis than when a similar degree of heart failure is due simply to progression of the underlying cardiac disease.

SYMPTOMS OF HEART FAILURE

Respiratory Distress

Breathlessness, a cardinal manifestation of left ventricular failure, may present with progressively increasing severity as (1) exertional dyspnea, (2) orthopnea, (3) paroxysmal nocturnal dyspnea, (4) dyspnea at rest, and (5) acute pulmonary edema.

EXERTIONAL DYSPNEA (see Chap. 3).

The principal difference between exertional dyspnea in normal subjects and in patients with heart failure is the degree of activity necessary to induce the symptom.[36] Indeed, as heart failure first develops, exertional dyspnea may simply appear to be an aggravation of the breathlessness that occurs in normal subjects during activity. An effort should be made to ascertain whether a *change* in the extent of exertion that causes dyspnea has actually occurred. As left ventricular failure advances, the intensity of exercise resulting in breathlessness declines progressively. However, there is no close correlation between subjective exercise capacity and objective measures of left ventricular performance at rest in patients with heart failure.[37] [38] Also, exertional dyspnea may be absent in patients with heart failure who are sedentary for a variety of reasons, such as habit, severe angina, intermittent claudication, or a noncardiovascular condition (e.g., osteoarthritis).

ORTHOPNEA.

This symptom may be defined as dyspnea that develops in the recumbent position and is relieved by elevation of the head with pillows. As in the case of exertional dyspnea, it is a *change* in the number of pillows required that is important. In the recumbent position there is reduced pooling of fluid in the lower extremities and abdomen; blood is displaced from the extrathoracic to the thoracic compartment. The failing left ventricle cannot accept and pump out the extra blood volume delivered to it by the competent right ventricle without dilating. Pulmonary venous and capillary pressures rise further, causing interstitial pulmonary edema, reduced pulmonary compliance, increased airway resistance, and dyspnea. In contrast to paroxysmal nocturnal dyspnea (see later), orthopnea occurs rapidly, often within a minute or two of assuming recumbency and develops when the patient is awake. It is a nonspecific symptom and may occur in *any* condition in which vital capacity is low. Marked ascites, for example, whatever its cause, may cause orthopnea. Likewise, a large pleural effusion of any etiology may cause a sensation of breathlessness on lying down. Patients with severe chronic obstructive lung disease sometimes complain of orthopnea. *Trepopnea* is a rare form of orthopnea limited to one lateral decubitus position. It has been attributed to distortions of the great vessels in one position but not in the other.

The patient with orthopnea generally elevates his or her head and chest on several pillows to prevent nocturnal breathlessness and subsequently the development of paroxysmal nocturnal dyspnea. In advanced left ventricular failure, orthopnea may be so severe that the patient cannot lie down and must spend the night in the sitting

position. Often such patients are observed sitting at the side of the bed, slumped over a bedside table, or sleeping upright in a chair.

COUGH.

This may be caused by pulmonary congestion, occurs under the same circumstances as dyspnea (i.e., during exertion or recumbency), and is relieved by treatment of heart failure. Thus a nonproductive cough in patients with heart failure is often a "dyspnea equivalent," whereas a cough on recumbency may be considered an "orthopnea equivalent." If cough does not improve with diuresis, other common causes to consider in patients with heart failure include cough due to concomitant pulmonary disease (see later) and cough related to angiotensin-converting enzyme inhibitors.[39]

PAROXYSMAL NOCTURNAL DYSPNEA.

Attacks of paroxysmal dyspnea usually occur at night. The patient awakens, often quite suddenly, and with a feeling of severe anxiety and suffocation, sits bolt upright and gasps for breath. Bronchospasm, which may be caused by congestion of the bronchial mucosa and by interstitial pulmonary edema compressing the small airways, increases ventilatory difficulty and the work of breathing and is a common complicating factor. The associated wheezing is responsible for the alternate name of this condition, *cardiac asthma.* In contrast to orthopnea, which may be relieved immediately by sitting upright at the side of the bed with the legs dependent, attacks of paroxysmal nocturnal dyspnea may require 30 minutes or longer in this position for relief. Episodes of paroxysmal nocturnal dyspnea may be so frightening that the patient may be afraid to go back to sleep, even after the symptoms have abated.

The reason for the common occurrence of these episodes at night is not clear, but it seems likely that the combination of (1) the slow resorption of interstitial fluid from the dependent portion of the body and the resultant expansion of thoracic blood volume, (2) elevation of thoracic blood volume and of the diaphragm that occurs immediately on assuming recumbency (as described earlier for orthopnea), (3) reduced adrenergic support of left ventricular function during sleep, and (4) normal nocturnal depression of the respiratory center all play major roles. Paroxysmal nocturnal dyspnea is a common clinical feature associated with Cheyne-Stokes respiration in patients with heart failure (see later).[40]

TABLE 17-4 -- MECHANISMS OF DYSPNEA IN HEART FAILURE

Decreased Pulmonary Function
Decreased compliance Increased airway resistance
Increased Ventilatory Drive
Hypoxemia: PCW
dot(V)/dot(Q) mismatch: PCW, CO Increased CO_2 production: CO, lactic acidosis
Respiratory Muscle Dysfunction
Decreased strength Decreased endurance Ischemia

Adapted from Mancini DM: Pulmonary factors limiting exercise capacity in patients with heart failure. Prog Cardiovasc Dis 37:347, 1995.

MECHANISMS OF DYSPNEA (Table 17-4)

Increased awareness of respiration or difficulty in breathing is commonly associated with pulmonary capillary hypertension caused by an elevation of left atrial or left ventricular filling pressure.[36] Patients with left ventricular failure typically exhibit a restrictive ventilatory defect, characterized by a reduction of vital capacity as a consequence of the replacement of the air in the lungs with blood or interstitial fluid or both. Consequently, the lungs become stiffer, air trapping occurs because of earlier than normal closure of dependent airways, and the work of breathing is increased because higher intrapleural pressures are needed to distend the stiff lungs.[41] Tidal volume is reduced, and respiratory frequency rises in a compensatory fashion. Engorgement of blood vessels may reduce the caliber of the peripheral airways, increasing airway resistance. In addition, there are alterations in the distribution of ventilation and perfusion, resulting in widened alveolar-arterial differences for oxygen, hypoxemia, and an increased ratio of dead space to tidal volume. Thus, dyspnea and orthopnea in heart failure are clinical expressions of pulmonary venous and capillary congestion. Paroxysmal nocturnal dyspnea reflects the presence primarily of *interstitial* edema, whereas pulmonary edema, in which there is transudation and expectoration of blood-tinged fluid (see p. 553), is often a manifestation of *alveolar* edema.

Whatever abnormalities in mechanics and gas exchange function of the lung exist at rest, they are aggravated during exercise (and sometimes during recumbency) when pulmonary venous and capillary pressures rise further. Transudation of fluid from the intravascular to the extravascular space results in greater stiffening of the lungs, an augmentation in the work of breathing, and increased resistance to air flow.[41] There is an increased ventilatory drive, as a consequence of the stimulation of stretch receptors in the pulmonary vessels and interstitium, as well as of hypoxemia and metabolic acidosis. The increased work of breathing, combined with a low cardiac output and resulting impaired perfusion of the respiratory muscles, causes fatigue and ultimately the sensation of dyspnea.[42] [43]

Dyspnea occurs whenever the work of respiration is excessive. Increased force generation is required for the respiratory muscles to move a given volume of air if the compliance of the lungs is reduced or the resistance to air flow is increased[44] [45] ; both of these changes occur in left-sided heart failure. Dyspnea at rest also may occur in the late stages of heart failure when very low cardiac output, hypoxemia, and acidosis combine to reduce the delivery of oxygen to the respiratory muscle.[42] [45] Dyspnea may occur *without* pulmonary congestion in patients with right ventricular failure, a fixed low cardiac output, and/or a right-to-left shunt.

Differentiation Between Cardiac and Pulmonary Dyspnea

In most patients with dyspnea there is obvious clinical evidence of disease of either the heart *or* the lungs, but in some the differentiation between cardiac and pulmonary dyspnea may be difficult.[36] Like patients with heart failure, those with chronic obstructive pulmonary disease also may awaken at night with dyspnea, but this is usually associated with sputum production; the dyspnea is relieved after patients rid themselves of secretions by coughing rather than specifically by sitting up. When the dyspnea arises after a history of intensified cough and expectoration, it is usually primarily pulmonary in origin. *Acute cardiac asthma* (paroxysmal nocturnal dyspnea with prominent wheezing) usually occurs in patients who have obvious clinical evidence of heart disease and may be further differentiated from acute bronchial asthma by diaphoresis and bubblier airway sounds and the more common occurrence of cyanosis.

The difficulty in distinguishing between cardiac and pulmonary dyspnea may be compounded by the coexistence of diseases involving both organ systems. Thus, patients with a history of chronic bronchitis or asthma who develop left ventricular failure tend to develop particularly severe bronchoconstriction and wheezing in association with bouts of paroxysmal nocturnal dyspnea and pulmonary edema. Airway obstruction and dyspnea that respond to bronchodilators or smoking cessation favor a pulmonary origin of the dyspnea, whereas symptomatic improvement with diuretics and/or nitrates supports heart failure as the cause of dyspnea. Dyspnea that persists despite appropriate cardiovascular or respiratory pharmacotherapy may be related to psychosocial factors (e.g., anxiety, emotional stress).[46]

PULMONARY FUNCTION TESTING.

This should be carried out in patients in whom the etiology of dyspnea is unclear despite detailed clinical evaluation. The major alterations in pulmonary function tests in heart failure are reductions of vital capacity, total lung capacity, pulmonary diffusion capacity, and pulmonary compliance; resistance to air flow is moderately increased; residual volume and functional residual volume are normal. Often there is hyperventilation at rest and during exercise, an increase in dead space, and some

abnormalities of ventilation-perfusion relations with slight reductions in arterial Pco_2 and Po_2 . With pulmonary capillary hypertension, pulmonary compliance decreases and there is air trapping because of earlier than normal closure of dependent airways. The airway resistance rises,[47] as does the work of breathing.

Rarely, it may be difficult, on clinical examination, to differentiate among cardiac dyspnea, dyspnea based on *malingering,* and dyspnea caused by *anxiety*.[46] Careful observation for the appearance of effortless or irregular respiration during exercise testing often helps to identify the patient in whom dyspnea is related to the latter two noncardiac causes. Patients whose anxiety focuses on the heart may exhibit sighing respiration and difficulty in taking a deep breath as well as dyspnea at rest. Their breathing patterns are not rapid and shallow, as in cardiac dyspnea. Rarely a "therapeutic test" is helpful, and amelioration of dyspnea, accompanied by a weight loss exceeding 2 kg induced by administration of a diuretic, supports a cardiac origin for the dyspnea. Conversely, failure of these measures to achieve such weight reduction and to diminish dyspnea weighs heavily against a cardiac origin.

Reduced Exercise Capacity

MECHANISMS OF EXERCISE INTOLERANCE.

A nearly universal manifestation of heart failure is a reduction in exercise capacity.[48] Although exercise capacity may be limited for a variety of reasons in patients with heart failure, the most common causes are the development of dyspnea due to pulmonary vascular congestion and the failure of the cardiovascular system to provide sufficient blood flow to exercising muscles. The latter reflects primarily an inadequate cardiac output response to exercise due to reductions in stroke volume and heart rate.[49] [50] [51] In addition to the impaired central hemodynamic response to exercise, a number of other factors may contribute to reduced exercise capacity in patients with heart failure, including an attenuated peripheral vascular response,[52] [53] [54] abnormal skeletal muscle metabolism,[55] deconditioning of skeletal and respiratory muscles,[41] [55] [56] and patient anxiety related to the development of exertional symptoms. A recent study demonstrated a rapid improvement in the peripheral vascular response to exercise after intensive, hemodynamically guided therapy.[54] There is evidence that the judicious use

of cardiac rehabilitation can improve functional capacity, quality of life, and outcomes in patients with heart failure,[57] [58] possibly by improving autonomic control of the circulation and peripheral muscle blood flow,[58A] reversing abnormalities of skeletal muscle metabolism, and improving patients' perceptions of their quality of life and symptom severity[59] (see also Chap. 39).

Exercise Testing (See also Chap. 6.)

MAXIMAL EXERCISE CAPACITY.

Exercise stress testing may be an exceedingly useful adjunct in the *clinical assessment* of patients with suspected or known heart failure.[48] [60] With use of a bicycle ergometer or treadmill and a progressively increasing load, the maximum level of exercise that can be achieved can be determined; the latter correlates closely with the total oxygen uptake ($dot(V)o_2$). Close observation of the patient during an exercise test may disclose obvious difficulty in breathing at a low level of exercise (or the opposite). Thus, this simple test may be considered to be an extension of the clinical examination.

A more formal assessment, in which $dot(V)o_2$ is measured at each stage of exercise, or preferably in which $dot(V)o_2$ and $dot(V)co_2$ are measured continuously, allows determination of maximum $dot(V)o_2$. It also permits measurement of the anaerobic threshold (i.e., the point during the exercise test at which the respiratory quotient rises as a consequence of the production of excess lactate). A progressive exercise test is carried out until (1) $dot(V)o_2$ fails to rise with further increases in activity or (2) the patient is limited by severe dyspnea and/or fatigue. When the $dot(V)o_2$ is less than 25 ml/kg/min and the reduction is caused by a cardiac abnormality (rather than by pulmonary disease, anemia, peripheral vascular disease, an orthopedic disability, marked obesity, severe deconditioning, or malingering), it may be used to classify the severity of heart failure. It may also be used to follow the progress of the patient, assess the efficacy of therapeutic maneuvers, and assess prognosis.[60] [61] [62]

SUBMAXIMAL EXERCISE CAPACITY.

Because usual daily activities generally require much less than maximal exercise capacity, the measurement of submaximal exercise capacity may provide information that is complementary to that provided by maximal exercise testing.[63] [64] In contrast to maximal exercise capacity, which reflects the adequacy of the central hemodynamic response, the ability to sustain a submaximal exercise effort may reflect regulation of blood flow to the skeletal musculature. Submaximal exercise capacity can be assessed by measuring the duration of exercise at a constant workload that is generally chosen to be at or below the patient's anaerobic threshold.[65] A rough approximation of the submaximal exercise capacity can be obtained by measuring the distance walked in a fixed period of time.[66] The "6-minute walk test," most common of the fixed-time tests, measures the distance walked on level ground in 6 minutes.[67] [68] In this test, the patient is asked to walk along a level corridor as far as he or she can in 6 minutes. The patient can slow down or even stop, may be given a carefully controlled level of encouragement, and is told when 3 and 5 minutes have elapsed. The 6-minute walk test and other similar submaximal tests[69] are being evaluated in clinical trials to determine if they are capable of detecting a therapeutic response. They are moderately predictive of maximal oxygen consumption (Fig. 17-3) , and as noted later, the 6-minute walk test independently predicts morbidity and mortality.[68] [70] Another form of submaximal exercise test measures the distance walked on a self-powered treadmill.[71]

Figure 17-3 Relationship between the distance walked in 6 minutes and the peak oxygen consumption in 45 patients with advanced heart failure (age 49 ± 8 years; New York Heart Association Class 3.3 ± 0.6; left ventricular ejection fraction 0.20 ± 0.06) (r=0.64, p=0.0001). In this study, distance walked less than 300 meters predicted an increased likelihood of death or hospital admission for inotropic or mechanical support. Because the 6-minute walk test involves only a submaximal exercise effort, it may be sensitive to changes in exercise function in the work range that is relevant to normal daily activities. (From Cahalin LP, et al: The six-minute walk test predicts peak oxygen uptake and survival in patients with advanced heart failure. Chest 110:325, 1996.)

OTHER SYMPTOMS

FATIGUE AND WEAKNESS.

These symptoms, often accompanied by a feeling of heaviness in the limbs, are generally related to poor perfusion of the skeletal muscles in patients with a lowered cardiac output. They may be associated with impaired vasodilation and altered metabolism in skeletal muscle.[52] [55] However, fatigue and weakness are nonspecific symptoms and may be caused by a variety of noncardiopulmonary diseases, as well as by neurasthenia and depression. In heart failure, fatigue and weakness may also be caused by sodium depletion, hypovolemia, or both, usually resulting from excessive treatment with diuretics and restriction of dietary sodium and oral fluid intake. Beta-adrenergic antagonists also may cause fatigue.

URINARY SYMPTOMS.

Nocturia may occur relatively early in the course of heart failure. Urine formation is suppressed during the day when the patient is upright and active; this is due, at least in part, to a redistribution of blood flow away from the kidneys during activity. When the patient rests in the recumbent position at night, the deficit in cardiac output in relation to oxygen demand is reduced, renal vasoconstriction diminishes, and urine formation increases. Nocturia may be troublesome in that it prevents the patient with heart failure from obtaining much-needed rest. The diurnal pattern of urine flow characteristic of heart failure contrasts sharply to that existing in renal failure, in which urine formation occurs at a reasonably constant rate, both day and night. *Oliguria* is a sign of late cardiac failure and is related to the suppression of urine formation as a consequence of severely reduced cardiac output.

CEREBRAL SYMPTOMS.

Confusion, impairment of memory, anxiety, headache, insomnia, bad dreams or nightmares, and, rarely, psychosis with disorientation, delirium, and even hallucinations may occur in elderly patients with advanced heart failure,[72] particularly in those with accompanying cerebral arteriosclerosis.

SYMPTOMS OF PREDOMINANT RIGHT-SIDED HEART FAILURE.

Breathlessness is not as prominent in isolated right ventricular failure as it is in left-sided heart failure because pulmonary congestion is usually absent. Indeed, when a patient with mitral stenosis or left ventricular failure develops right ventricular failure, the more severe forms of dyspnea (i.e., paroxysmal nocturnal dyspnea and episodic pulmonary edema) tend to diminish in frequency and intensity.

Congestive hepatomegaly may produce discomfort, generally described as a dull ache or heaviness, in the right upper quadrant or epigastrium. This discomfort, which is caused by stretching of the hepatic capsule, may be severe when the liver enlarges rapidly, as in acute right-sided heart failure. In contrast, chronic, slowly developing hepatic enlargement is generally painless. Other gastrointestinal symptoms, including anorexia, nausea, bloating, a sense of fullness after meals, and constipation, are due to congestion of the liver and gastrointestinal tract. In severe, preterminal heart failure, inadequate bowel perfusion can cause abdominal pain, distention, and bloody stools.

Functional Classification

A classification of patients with heart disease based on the relation between symptoms and the amount of effort required

to provoke them was developed by the New York Heart Association (NYHA).[73] Although there are obvious limitations to assigning numerical values to subjective findings, this classification is nonetheless useful in comparing groups of patients as well as the same patient at different times. In addition, NYHA Class has proven to be a strong, independent predictor of survival in patients with chronic heart failure.[74]

Class I--*No limitation:* Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.

Class II--*Slight limitation of physical activity:* Such patients are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina.

Class III--*Marked limitation of physical activity:* Although patients are comfortable at rest, less than ordinary activity will lead to symptoms.

Class IV--*Inability to carry on any physical activity without discomfort:* Symptoms of congestive failure are present even at rest. With any physical activity, increased discomfort is experienced.
As discussed in Chapter 3 , the accuracy and reproducibility of this classification are limited. To overcome these limitations, Goldman and associates[75] have developed a useful classification based on the estimated metabolic cost of various activities (see Table 3-11).

QUALITY OF LIFE.

The three main goals of treatment for heart failure are to reduce symptoms, prolong survival, and improve quality of life. A good "quality of life" implies the ability to live as one wants, free of physical, social, emotional, and economic limitations. Heart failure can have an enormous deleterious impact on the quality of life. Although a number of generic instruments are available to assess health-related quality of life,[76] the Minnesota Living with Heart Failure (MLHF) questionnaire was designed specifically for use in these patients.[77] It consists of 21 brief questions, each of which is answered on a scale of 0 to 5. Eight questions have a strong relationship to the symptoms of dyspnea and fatigue and are referred to as *physical dimension measures.* Five other questions that are strongly related to emotional issues are referred to as *emotional dimension measures.* The test is self-administered and takes only 5 to 10 minutes to complete. For each question, the patient selects a number from 0 to 5. Zero indicates that heart failure had no effect, and 5 indicates a very large effect. Although such questionnaires have little role in routine clinical management of patients, they have provided valuable information in clinical research settings by allowing the response to various pharmacological therapies to be quantified.[77] [78] [78A] Quality of life instruments have also been used to assess response to cardiac rehabilitation (Fig. 17-4) [58] and multidisciplinary, disease management programs.[79]

Physical Findings (See also Chap. 4)

GENERAL APPEARANCE.

Patients with mild or moderate heart failure appear to be in no distress after a few minutes of rest. However, they may be obviously dyspneic during and immediately after moderate activity. Patients with left ventricular failure may become uncomfortable if they lie flat without elevation of the head for more than a few minutes. Those with severe heart failure appear anxious and may exhibit signs of air hunger in this position. Patients with heart failure of recent onset appear acutely ill but are usually well nourished, whereas those with chronic heart failure often appear malnourished and sometimes even cachectic. Chronic, marked elevation of systemic venous pressure may produce exophthalmos and severe tricuspid regurgitation and may lead to visible systolic pulsation of the eyes[80] and of the neck veins. Cyanosis, icterus,

Figure 17-4 Changes in the Minnesota Living with Heart Failure (MHL) questionnaire scores for stable heart failure patients enrolled in a 12-month exercise training program (open circles) compared with untrained controls (closed circles) at baseline (test 1) and after 2, 14, and 24 months (tests 2, 3, and 4). MHL scores improved significantly in trained patients after 2 months and remained stable after the subsequent 12-month exercise training program and during follow-up (*$p<0.001$ for all comparisons). Exercise training was associated with an increase in peak dot(V)$_{O_2}$ and reductions in both mortality and hospital readmission for heart failure. (From Belardinelli R, et al: Randomized, controlled trial of long-term moderate exercise training in chronic heart failure: Effects on functional capacity, quality of life, and clinical outcome. Circulation 99:1173, 1999. Copyright 1999, American Heart Association.)

and a malar flush may be evident in patients with severe heart failure.

In mild or moderate heart failure, stroke volume is normal at rest; in severe heart failure, it is reduced, and this is reflected in a diminished pulse pressure and dusky discoloration of the skin. With very severe heart failure, particularly if the cardiac output has declined acutely, systolic arterial pressure may be reduced. The pulse may be rapid, weak, and thready. The proportional pulse pressure (pulse pressure/systolic pressure) shows some correlation with the cardiac output. In one study,[16] when it was less than 25 percent, it usually reflected a cardiac index of less than 2.2 liters/min/m^2 .

INCREASED ADRENERGIC ACTIVITY.

This is responsible for a number of physical signs, including peripheral vasoconstriction, manifested as pallor and coldness of the extremities and cyanosis of the digits. There may be diaphoresis with sinus tachycardia, loss of normal sinus rhythm, and obvious distention of the peripheral veins secondary to venoconstriction. Diastolic arterial pressure may be slightly elevated.

PULMONARY RALES.

Moist rales result from the transudation of fluid into the alveoli and then into the airways. Rales heard over the lung bases are characteristic of congestive heart failure of at least moderate severity. In acute pulmonary edema, coarse, bubbling rales and wheezes are heard over both lung fields and are accompanied by the expectoration of frothy, blood-tinged sputum (see p. 555). However, the absence of rales does not exclude considerable elevation of pulmonary capillary pressure.[16] With congestion of the bronchial mucosa, excessive bronchial secretions or bronchospasm or both may give rise to rhonchi and wheezes. Rales are usually heard at both lung bases, but if unilateral they occur more commonly on the right side.

SYSTEMIC VENOUS HYPERTENSION.

This can be detected more readily by inspection of the jugular veins, which provides a useful index of right atrial pressure.[81] The upper limit of normal of the jugular venous pressure is approximately 4 cm above the sternal angle when the patient

is examined at a 45-degree angle, corresponding to a right atrial pressure of less than 10 cm of water. When tricuspid regurgitation is present, the *v* wave and *y* descent are most prominent. The jugular venous pressure normally declines on inspiration, but in patients with heart failure (and in those with constrictive pericarditis; see Chap. 50) it rises, a finding known as *Kussmaul's sign.*[81] Rarely, venous pressure may be so high that the peripheral veins on the dorsum of the hands or in the temporal region are dilated.

HEPATOJUGULAR REFLUX.

In patients with mild right-sided heart failure, the jugular venous pressure may be normal at rest but rises to abnormal levels with compression of the right upper quadrant, a sign known as the *hepatojugular reflux.* To elicit this sign, the right upper quadrant should be compressed firmly, gradually, and continuously for up to 1 minute while the veins of the neck are observed. The patient should be advised to avoid straining, holding the breath, or carrying out a Valsalva maneuver. A positive test (i.e., expansion of the jugular veins during and immediately after compression) usually reflects the combination of a congested abdomen and inability of the right side of the heart to accept or eject the transiently increased venous return.

CONGESTIVE HEPATOMEGALY.

The liver often enlarges *before* overt edema develops, and it may remain so even after other symptoms of right-sided heart failure have disappeared. If hepatomegaly has occurred rapidly and relatively recently, the liver is usually tender, owing to rapid stretching of its capsule. In long-standing heart failure this tenderness disappears, even though the liver remains enlarged. *Splenomegaly* may also occur in the presence of severe congestive hepatomegaly in patients with tricuspid valve disease or constrictive pericarditis.

EDEMA.

Although a cardinal manifestation of heart failure, edema does not correlate well with the level of systemic venous pressure. In patients with chronic left ventricular failure and a low cardiac output, extracellular fluid volume may be sufficiently expanded to cause edema in the presence of only slight elevations of systemic venous pressure. A substantial gain of extracellular fluid volume, a minimum of 4 liters in adults, must usually take place before peripheral edema is manifested.

Edema in heart failure is usually symmetrical, is pitting, and generally occurs first in the dependent portions of the body, where the systemic venous pressure rises to its highest levels. Accordingly, cardiac edema in ambulatory patients is usually first noted in the feet or ankles at the end of the day and generally resolves overnight. In bedridden patients it is most commonly found over the sacrum. Late in the course of heart failure, edema may become massive and generalized (anasarca).
Long-standing edema results in pigmentation, reddening, and induration of the skin of the lower extremities, usually the dorsum of the feet and the pretibial areas. In patients with advanced heart failure and cachexia, associated hypoalbuminemia may exacerbate the accumulation of extravascular fluid.

HYDROTHORAX (PLEURAL EFFUSION).

Because the pleural veins drain into both the systemic and the pulmonary venous beds, hydrothorax is observed most commonly in patients with hypertension involving both venous systems; it also may occur when there is marked elevation of pressure in either venous bed. An increase in capillary permeability probably also plays a role in the pathogenesis of cardiac hydrothorax, since the protein content of the pleural fluid may be significantly greater (2 to 3 gm/dl) than that found in edema fluid (0.5 gm/dl). Hydrothorax is usually bilateral, but when unilateral it is usually confined to the right side of the chest. When hydrothorax develops, dyspnea usually intensifies, owing to a further reduction in vital capacity. Although the excess fluid in hydrothorax usually resorbs as heart failure improves, loculated, interlobar effusions may persist.

ASCITES.

This finding occurs in patients with increased pressure in the hepatic veins and in the veins draining the peritoneum. Ascites usually reflects long-standing systemic venous hypertension. In patients with organic tricuspid valve disease and chronic constrictive pericarditis, ascites may be more prominent than subcutaneous edema. As in the case of hydrothorax, there is increased capillary permeability because the protein content is similar to that of hepatic lymph (i.e., four to six times that of edema fluid). Protein-losing enteropathy may rarely occur in patients with visceral congestion,[82] [83] and the resultant reduced plasma oncotic pressure may lower the threshold for the development of ascites.

Cardiac Findings

The presence of cardiac disease is usually readily evident on clinical examination of patients with congestive heart failure.

CARDIOMEGALY.

This finding is nonspecific and occurs in the majority of patients with chronic systolic heart failure. Notable exceptions include diastolic heart failure due to chronic hypertension, heart failure associated with chronic constrictive pericarditis or restrictive cardiomyopathy, and acute forms of heart failure.

GALLOP SOUNDS.

Protodiastolic sounds, generally emanating from the left ventricle (but occasionally from the right) and occurring 0.13 to 0.16 second after the second heart sound, are common findings in healthy children and young adults. Such physiological sounds are seldom audible in healthy persons after age 40 but occur in patients of all ages with heart failure and are referred to as *protodiastolic,* or S_3 *, gallops.*[84] In older adults they generally signify the presence of heart failure.

PULSUS ALTERNANS.

This sign is characterized by a regular rhythm with alternating strong and weak ventricular contractions (Fig. 17-5) .

Figure 17-5 Pulsus alternans in a 51-year-old woman with long-standing hypertension and severe biventricular heart failure. The aortic pressure tracing reveals prominent alternations in the systolic blood pressure. The regularity of the pulsus alternans is interrupted by a ventricular premature beat (arrow). (From McLaughlin DP: Pulsus alternans. N Engl J Med 341:955, 1999.)

It should be distinguished from the alternation of strong and weak beats that occurs in pulsus bigeminus, in which the weak beat follows the strong beat by a shorter time interval than the strong beat follows the weak. In pulsus alternans, the beats are equally spaced or the weak beat is slightly closer to the succeeding than to the preceding beat. Severe pulsus alternans may be detected either by palpation of the peripheral pulses (the femoral more readily than the brachial, radial, or carotid) or by sphygmomanometry. As the cuff is slowly deflated, only alternate beats are audible for a variable number of millimeters of mercury below the systolic level, depending on the severity of the alternans, and then all beats are heard. Rarely, the weak beat is so small that the aortic valve is not opened, and this results in an apparent halving of the pulse rate, a condition referred to as *total alternans.* Pulsus alternans may be accompanied by alternation in the intensity of the heart sounds and of existing heart murmurs.

Pulsus alternans occurs most commonly in systolic heart failure. It is usually associated with a ventricular protodiastolic gallop sound (S_3). It signifies advanced myocardial disease and often disappears with treatment of heart failure. Pulsus alternans often can be elicited by assumption of the erect posture and tends to be present during tachycardia. It is often initiated by a premature beat.

Pulsus alternans is attributed to an alternation in the stroke volume ejected by the left ventricle[85] and, ultimately, to a deletion in the number of contracting cells in every other cycle, presumably owing to incomplete myocardial recovery.[86] Rarely, pulsus alternans is accompanied by *electrical alternans;* however, the latter condition is usually not due to mechanical alternans but to alternating positions of the heart within the fluid-filled pericardial sac. Demonstration of *sympathetic alternans* (i.e., alternation in the amplitude of muscle sympathetic nerve activity) in association with pulsus alternans has provided direct evidence for arterial baroreflex

control of muscle sympathetic nerve activity in congestive heart failure.[87]

ACCENTUATION OF P_2 AND SYSTOLIC MURMURS.

With the development of left ventricular failure, pulmonary artery pressure rises and P_2 becomes accentuated--often louder than A_2 -- and more widely transmitted. *Systolic murmurs* are common in heart failure, owing to the functional mitral or tricuspid regurgitation that may occur secondary to ventricular dilatation. Often these murmurs diminish or disappear when compensation is restored.[88]

ABNORMAL RESPONSE TO THE VALSALVA MANEUVER (Fig. 17-6) .

Performance of this maneuver--forced expiration against a closed glottis--is helpful in the diagnosis of heart failure. The test has been standardized as follows: The patient is asked to blow against an aneroid manometer and to maintain a pressure of 40 mm Hg for 30 seconds. Intrathoracic pressure rises, venous return to the heart diminishes, stroke volume falls, and venous pressure rises. Arterial pressure tracings normally show four distinct phases (Fig. 17-6 *A*): (1) an initial rise in arterial pressure, which represents transmission to the periphery of the increased intrathoracic pressure; (2) with continuation of the strain and the accompanying reduction of venous return, reductions in systolic, diastolic, and pulse pressures accompanied by a reflex increase in heart rate; (3) on release of the strain, a sudden drop of arterial pressure equivalent to the fall in intrathoracic pressure; and (4) an overshoot of arterial pressure to above control levels, with a wide pulse pressure and bradycardia, due to a transient rise in cardiac output as blood pooled in the venous system returns to the heart with the release of the strain.

In heart failure (see Fig. 17-6 *C*), phases 1 and 3 are normal; that is, there is normal transmission of the elevated intrathoracic pressure into the arterial tree during phase 1 and sudden loss of this with the release of the strain during phase 3. However, because the heart operates on the flat portion of its Starling curve, the impedance of venous return during phase 2 does not affect stroke volume. Therefore, the baroreceptor reflex is not activated, and there is no overshoot on release of the strain. This results in a "square-wave" appearance of the tracing. The abnormal blood pressure response is associated with "pseudonormalization" of the transmitral filling velocity pattern observed by Doppler echocardiography. An intermediate response (the so-called absent-overshoot response) to the Valsalva maneuver has been demonstrated in patients with moderate depression of left ventricular systolic function (see Fig. 17-6 *B*).

Although the Valsalva maneuver can be recorded most accurately through an indwelling needle, careful palpation of the pulse in normal individuals allows detection of phases 2 and 4 and their absence and slowing of the pulse in phase 4.[89] Alternatively, bedside sphygmomanometric determination of arterial blood pressure may be used with the Valsalva maneuver.[90] [90A]

FEVER.

A low-grade fever (38°C), which results from cutaneous vasoconstriction and therefore impairment of heat loss, may occur in severe heart failure. Fever usually subsides when compensation is restored. Greater elevations of temperature usually signify the presence of infection, pulmonary infarction, or infective endocarditis.

CARDIAC CACHEXIA.

Long-standing, severe congestive heart failure, particularly right ventricular failure, may lead to anorexia as a consequence of hepatic and intestinal congestion, and mesenteric hypoperfusion. Occasionally, there is impaired intestinal absorption of fat[91] and, rarely, protein-losing enteropathy.[82] [83] Patients with heart failure also may exhibit increased total metabolism secondary to (1) an augmentation of myocardial oxygen consumption, as occurs in patients

Figure 17-6 Arterial pressure responses during the bedside Valsalva maneuver. *A,* "Sinusoidal" arterial pressure response in a patient with normal left ventricular function. (The four distinct phases are discussed in detail in the text.) *B,* "Absent overshoot" arterial pressure response in a patient with moderate depression of left ventricular systolic function. *C,* "Square-wave" arterial pressure response in a patient with chronic heart failure due to severe depression of left ventricular systolic function. Because the heart operates on the flat portion of the ventricular function curve, the impedance of venous return during phase 2 does not affect stroke volume. Therefore, the baroreceptor reflex is not activated, and there is no overshoot on release of the strain (see text). (From Zema MJ, et al: Left ventricular dysfunction: Bedside Valsalva manoeuvre. Br Heart J 44:560, 1980.)

with aortic stenosis and hypertension, (2) excessive work of breathing, (3) low-grade fever, (4) increased activity of the sympathetic nervous system, and (5) elevated levels of circulating tumor necrosis factor-alpha.[92] This proinflammatory cytokine is produced by monocytes and contributes to cachexia and anorexia. There is also evidence that inflammatory cytokines, including tumor necrosis factor-alpha, may depress myocardial contractility,[93] [94] and contribute to ventricular remodeling by stimulating myocyte apoptosis[95] and turnover of the extracellular matrix.[29A] [96]

Other metabolic pathways that cause catabolic/anabolic imbalance and that have been implicated in wasting associated with heart failure include the growth hormone-insulin-like growth factor-1 system and the pituitary-thyroid hormone axis.[97] [98] The combination of reduced caloric intake and increased caloric expenditure may lead to a reduction of tissue mass and, in severe cases, to cardiac cachexia. In some patients the cachexia may be severe enough to suggest the presence of disseminated malignant disease. In others, the loss of lean body mass may be masked by the accumulation of edema. Cardiac cachexia is a marker of increased mortality in heart failure.[98]

CHEYNE-STOKES RESPIRATION.

Also known as *periodic* or *cyclic respiration,* Cheyne-Stokes respiration is characterized by the combination of depression in the sensitivity of the respiratory center to carbon dioxide and left ventricular failure.[40] [99] During the apneic phase, arterial P_{O_2} falls and P_{CO_2} rises; this combination excites the depressed respiratory center, resulting in hyperventilation and, subsequently, hypocapnia, followed by another period of apnea. The principal causes of depression of the respiratory center in patients with Cheyne-Stokes respiration are cerebral lesions such as cerebral arteriosclerosis, stroke, or head injury. These causes are often exaggerated by sleep, barbiturates, and narcotics, all of which further depress the sensitivity of the respiratory center. Left ventricular failure, which prolongs the circulation time from the lung to the brain, results in a sluggish response of the system and is responsible for the oscillations

between apnea and hyperpnea that prevent return to a steady state of ventilation and blood gases.

Cheyne-Stokes respiration is seen in up to 40 percent of heart failure patients. Usually patients are not aware of Cheyne-Stokes respiration. However, it can be readily observed in a sleeping patient or a history can be elicited from the patient's bed partner. Cheyne-Stokes respiration may contribute to daytime sleepiness,[100] insomnia, and snoring.

PATHOLOGICAL FINDINGS

LUNGS.

In patients who have died of left ventricular failure, the lungs are enlarged, firm, and dark and may be filled with bloody fluid. With long-standing pulmonary congestion, they are brown with deposition of hemosiderin and usually do not seep edema fluid. On microscopic examination, the capillaries are engorged, and there is thickening of the alveolar septa as well as extravasation of large mononuclear cells containing red blood cells or hemosiderin granules or both.[101] Often the pulmonary vessels show medial hypertrophy and intimal hyperplasia.

LIVER.

In acute right-sided heart failure, the liver is enlarged, firm, and filled with fluid. On microscopic examination, the central hepatic veins and sinusoids are dilated. With chronic right-sided heart failure, the liver returns to normal size, subsequently atrophies, and becomes "nutmeg" in appearance as a consequence of the dark red areas of central venous congestion and the lighter, fatty area in the periphery of the lobule. Cardiac cirrhosis is characterized by central lobular necrosis and atrophy, as well as extensive or patchy fibrous retraction. In addition, there may be fibrosis and thrombosis of the hepatic veins.[102] Because cardiac cirrhosis is a function of the level of hepatic venous pressure and the duration of its elevation, it is not surprising that it occurs most commonly in patients with chronic constrictive pericarditis and organic

tricuspid valve disease. In patients with left ventricular failure, central hepatic necrosis without evidence of passive congestion may be present.[103]

Liver biopsy specimens in patients with acute heart failure exhibiting fulminant hepatic failure show bridging centrolobular necrosis. Presumably, the hypoxia caused by hypoperfusion produces hepatocyte necrosis[104] ; erythrocytes may then enter the space of Disse between damaged endothelial cells. The changes resulting from acute heart failure may be transient if there is hemodynamic recovery.[105]

OTHER VISCERA.

Patients with chronic hepatic venous hypertension develop portal hypertension that results in congestive splenomegaly. On microscopic examination, the spleen shows dilatation of the sinusoids and fibrosis with thickening of the splenic capsule; and there is chronic passive congestion of the pancreas and of the veins and capillaries of the gastrointestinal tract. Rarely, intense mesenteric vasoconstriction without thrombotic or embolic occlusion of a mesenteric artery may lead to a hemorrhagic, nonbacterial enterocolitis, with hemorrhagic necrosis.

Laboratory Findings

Proteinuria and a high urine specific gravity are common findings in heart failure. Blood urea nitrogen and creatinine levels are often moderately elevated secondary to reductions in renal blood flow and glomerular filtration rate[15] (prerenal azotemia).

SERUM ELECTROLYTES.

Serum electrolyte values are generally normal in patients with mild or moderate heart failure before treatment. However, in severe heart failure, prolonged sodium restriction, coupled with intensive diuretic therapy and the inability to excrete free water, may lead to dilutional hyponatremia. Hypervolemic hyponatremia occurs because of substantial expansion of extracellular fluid volume and a normal or only slightly increased level of total body sodium. It may be accompanied by, and presumably is caused in part by, elevated circulating levels of arginine vasopressin.[106] Serum potassium levels are usually normal, although the prolonged administration of kaliuretic diuretics, such as the thiazides or loop diuretics, may result in hypokalemia. Secondary hyperaldosteronism may also contribute to hypokalemia. Hyperkalemia may occur in patients with severe heart failure[107] who show marked reductions in glomerular filtration rate and inadequate delivery of sodium to the distal tubular sodium-potassium exchange sites, particularly if such patients are also receiving potassium-retaining diuretics and/or angiotensin-converting enzyme inhibitors. Other common electrolyte abnormalities observed in heart failure include hypophosphatemia and hypomagnesemia[108] (commonly associated with alcohol use) and hyperuricemia, which may precipitate gout.

LIVER FUNCTION TESTS.

Congestive hepatomegaly and cardiac cirrhosis are often associated with impaired hepatic function, characterized by abnormal values of aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactic dehydrogenase (LDH), and other liver enzymes.[109] Hyperbilirubinemia, both direct and indirect, is common; and in severe cases of acute (right or left) ventricular failure, frank jaundice may occur. *Acute* hepatic venous congestion can result in severe jaundice with a bilirubin level as high as 15 to 20 mg/dl, elevation of AST to more than 10 times the upper limit of normal, and elevation of the serum alkaline phosphatase level, as well as prolongation of the prothrombin time. Both the clinical and the laboratory pictures may resemble viral hepatitis, but the impairment of hepatic function is rapidly ameliorated by successful treatment of heart failure.[105] In patients with long-standing cardiac cirrhosis, albumin synthesis may be impaired, with resultant hypoalbuminemia, intensifying the accumulation of fluid. Fulminant hepatic failure and coma are uncommon, late, and sometimes terminal complications of cardiac cirrhosis. In general, disturbances of hepatic function are frequent when right atrial pressure rises above 10 mm Hg and cardiac index declines below 1.5 l/min/m^2 .

The Chest Roentgenogram (See also Chap. 8)

Two principal features of the chest roentgenogram are useful in the evaluation of patients with heart failure.

The *size and shape of the cardiac silhouette* provide important information concerning the precise nature of the underlying heart disease. Both the cardiothoracic ratio and the heart volume determined on the plain film are relatively specific but insensitive indicators of increased left ventricular end-diastolic volume. Although there is a weak, inverse correlation between the cardiothoracic ratio and left ventricular ejection fraction in patients with heart failure, the relationship is not clinically useful in the individual patient.[110]

In the presence of normal pulmonary capillary and venous pressure, the lung bases are better perfused than the apices in the erect position, and the vessels supplying the lower lobes are significantly larger than are those supplying the upper lobes. With elevation of left atrial and pulmonary capillary pressures, interstitial and perivascular edema develops and is most prominent at the lung bases because hydrostatic pressure is greater there. When pulmonary capillary pressure is slightly elevated (i.e., 13 to 17 mm Hg), the resultant compression of pulmonary vessels in the lower lobes causes equalization in size of the vessels at the apices and bases. With greater pressure elevation (18 to 23 mm Hg), actual pulmonary vascular redistribution occurs[111] (i.e., further constriction of vessels leading to the lower lobes and dilatation of vessels leading to the upper lobes) (see Fig. 8-18*A* (p. 255). When pulmonary capillary pressures exceed 20 to 25 mm Hg, interstitial pulmonary edema occurs (see Fig. 8-18*B*). This may be of several varieties: (1) *septal,* producing Kerley's lines (i.e., sharp, linear densities of interlobular interstitial edema); (2) *perivascular,* producing loss of sharpness of the central and peripheral vessels; and (3) *subpleural,* producing spindle-shaped accumulations of fluid between the lung and adjacent pleural surface. When pulmonary capillary pressure exceeds 25 mm Hg, alveolar edema, with a cloudlike appearance and concentration of the fluid around the hili in a "butterfly" pattern, and large pleural effusions may occur (see Fig. 8-18*C*). With elevation of systemic venous pressure, the azygos vein and superior vena cava may enlarge.

In patients with chronic left ventricular failure, higher pulmonary capillary pressures can be accommodated with

fewer clinical and radiological signs,[16] , [81a] , [112] presumably due to enhanced lymphatic drainage. In one study of 22 patients with advanced heart failure referred for cardiac transplant evaluation, all of whom had pulmonary capillary wedge pressures greater than or equal to 25 mm Hg, 68 percent had "no" or "minimal" pulmonary congestion on chest roentgenogram.[112]

PROGNOSIS

Survival is reduced in patients with heart failure, which accounts for a substantial portion of all deaths from cardiovascular diseases. The overall 5-year mortality for all patients with heart failure is approximately 50 percent, and the 1-year mortality in patients with severe heart failure may be as high as 35 to 40 percent. In the United States alone, approximately 250,000 patients die of heart failure each year.[8] The Framingham Heart Study found that between the years 1948 and 1988, patients with a diagnosis of heart failure had a median survival of 1.7 years for men and 3.2 years for women, despite the fact that the patients with the poorest prognosis, that is, those dying within 90 days of the diagnosis, were excluded from the analysis.[113] More recent data from the Framingham Study demonstrates improved survival in patients with heart failure and preserved systolic function,[19] although data from Olmstead County, Minnesota, suggests equally poor survival in patients with systolic or diastolic heart failure.[20] Over 90 percent of deaths in patients with congestive heart failure are due to cardiovascular causes, most commonly progressive heart failure and sudden cardiac death.

A large number of factors have been found to correlate with mortality in patients with heart failure (Table 17-5) .[74] These fall into four major categories:

CLINICAL.

In general, male gender,[113] [114] the presence of coronary artery disease as the etiology of heart failure,[115] the presence of an audible S_3 , low pulse and systolic arterial pressures, a high NYHA Class (Fig. 17-7) , and reduced exercise capacity (Fig. 17-8) [51] , [62] ,[62a] have each been shown to be associated with increased mortality. When the NYHA Class is integrated with the maximal O_2 consumption (dot(V)O_2 max) determined during exercise, the mortality is 20 percent per year in patients in Class III with a dot(V)O_2 max of

TABLE 17-5 -- FACTORS AFFECTING SURVIVAL IN PATIENTS WITH HEART FAILURE

Clinical

Male gender
Coronary artery disese etiology
New York Heart Association class
Exercise capacity
Heart rate at rest
Systolic arterial pressure
Pulse pressure

10 to 15 ml/kg/min and rises to 60 percent in patients in Class IV with a dot$(V)_{O_2}$ max of less than 10 ml/kg/min.[116] The distance walked in 6 minutes predicted both morbidity and mortality in the Studies of Left Ventricular Dysfunction

Figure 17-7 Clinical correlates of survival in heart failure. Based on data from several contemporary, placebo-controlled clinical trials, it can be estimated that the 1-year mortality is on the order of 50 to 60 percent in patients with New York Heart Association (NYHA) functional Class IV symptoms, 15 to 30 percent in patients with Class II-III symptoms, and 5 to 10 percent in asymptomatic patients with left ventricular dysfunction. Patients in CONSENSUS I were in NYHA Class IV and were treated with digitalis and diuretics; patients in SOLVD (prevention) and SAVE had reduced LV ejection fractions (35 and 40 percent, respectively) but no or mild limitation (NYHA Classes I or II). Patients in PROMISE, SOLVD (treatment) and VHeFT-I were in moderate failure (NYHA Classes II or III). (From Young JB: Assessment of heart failure. *In* Colucci WS [ed]: Heart Failure: Cardiac Function and Dysfunction. 2nd ed. *In* Braunwald E [series ed]: Atlas of Heart Diseases. Vol 4. Philadelphia, Current Medicine, 1999, pp 7.1-7.19.)

Figure 17-8 Kaplan-Meier survival analysis in patients with severe left ventricular dysfunction stratified by peak oxygen consumption (dot$(V)_{O_2}$) as measured by cardiopulmonary exercise testing during evaluation for cardiac transplantation. Patients with a peak dot$(V)O_2$ of 10 ml/kg/min or less had significantly reduced survival rates compared with patients with peak dot$(V)_{O_2}$ > 14 ml/kg/min. Copyright 1991, American Heart Association.)

(SOLVD) trial [70] (Fig. 17-9) . Other clinical predictors of mortality in chronic heart failure include Cheyne-Stokes respiration,[117] cardiac cachexia,[98] and exercise capacity (see Fig. 17-12 *B*).

HEMODYNAMIC.

Variables such as cardiac index, stroke work index, left ventricular cavity size, and both left and right ventricular ejection fraction[118] [119] (Fig. 17-10) have been shown to correlate directly with survival in patients with heart failure, whereas systemic vascular resistance and heart rate correlate inversely. Combinations of hemodynamic abnormalities, such as depression of stroke work associated with elevation of filling pressure and systemic vascular resistance, are associated with a poor prognosis. More recent studies have examined the impact of exercise hemodynamics on survival and found that the stroke work index[120] and cardiac output[51] responses to exercise provide valuable independent prognostic information (Fig. 17-11) . In one study, patients with reduced cardiac output response to exercise and dot$(V)_{O_2}$ max less than or equal to 10 ml/

Figure 17-9 Mortality (%) as a function of performance level (based on distance walked). Mortality decreased as performance on the 6-minute walk test improved. (From Bittner V, et al: Prediction of mortality and morbidity with a 6-minute walk test in patients with left ventricular dysfunction. JAMA 270:1702, 1993. Copyright 1993, American Medical Association.)

Figure 17-10 In a multivariate analysis of survival in the VHeFT studies, the left ventricular ejection fraction (LVEF) and the peak oxygen consumption (peak dot$(V)_{O_2}$) were found to have independent prognostic value. An LVEF
0.28 and a peak dot$(V)_{O_2}$
14.5 ml/kg/min each predicted a poor survival, and the finding of both predicted a worse survival than if only one or the other were present. (From Cohn JN, et al: Ejection fraction, peak exercise oxygen consumption, cardiothoracic ratio, ventricular arrhythmias, and plasma norepinephrine as determinants of prognosis in heart failure. Circulation 87:VI-5, 1993. Copyright 1993, American Heart Association.)

kg/min had an extremely poor prognosis (i.e., 1-year survival rate of 38 percent).[51] Others have shown that dot$(V)_{O_2}$ max is superior to hemodynamic measurements in predicting outcome in severe heart failure.[121]

BIOCHEMICAL.

The observation that there is activation of the neurohormonal axis in heart failure has prompted examination of the relations between a variety of biochemical measurements and clinical outcome (Figs. 17-12 , Fig. 17-13, , Fig. 17-14). Strong inverse correlations have been reported between survival and plasma levels of norepinephrine (see Fig. 17-12 *A*), [74] [122] [123] [124] renin,[74] [124] [125] arginine vasopressin,[125]

Figure 17-11 Hemodynamic responses to exercise were measured in ambulatory patients with chronic heart failure referred for cardiac transplant evaluation. Patients with normal cardiac output (CO) response to exercise (83 patients) had a better 1-year survival rate (95%) than did those with reduced CO responses (102 patients; 1-year survival, 72%). (From Chomsky DB, et al: Hemodynamic exercise testing: A valuable tool in the selection of cardiac transplantation candidates. Circulation 94:3176, 1996. Copyright 1996, American Heart Association.)

Figure 17-12 Markers of survival in heart failure. *A,* Life-table analysis of survival, according to tercile, based on level of plasma norepinephrine (PNE). Group 1 (<400 pg/ml) contained 27 patients, group 2 (400 to 800 pg/ml) had 49 patients, and group 3 (> 800 pg/ml) had 30 patients. The probability of survival in each group was significantly different from the probabilities in the other two groups. (From Cohn JN, et al: Plasma norepinephrine as a guide to prognosis in patients with chronic congestive heart failure. N Engl J Med 311:822, 1984.) *B,* Kaplan-Meier survival curve for patients with coronary artery disease with a short (3-min) or long (12-min) exercise time in the modified Bruce protocol. atrial and brain natriuretic peptide (see Figs. 17-13 *A* and Figs. 17-13*B*), [126] [127] endothelin-1 (see Fig. 17-14*A*) [128] and interleukin-6 (see Fig. 17-14*B*).[129] The concentrations of these substances reflect the severity of the underlying impairment of circulatory function. In addition, some may exert adverse hemodynamic effects; norepinephrine, angiotensin II, and arginine vasopressin are potent vasoconstrictors, augmenting ventricular afterload and thereby reducing the shortening of myocardial fibers. Furthermore, they may be directly responsible for adverse biochemical effects on the myocardium. For example, the elevated norepinephrine concentration may be responsible for ventricular tachyarrhythmias, as may hypokalemia and reduction of total-body potassium stores resulting from the activation of the renin-angiotensin-aldosterone system (and the administration of potassium-losing diuretics).[130] Norepinephrine also exerts direct toxic effects on the myocardium, including stimulation of cellular hypertrophy, apoptosis, and changes in extracellular matrix regulation, and thus contributes directly to ventricular remodeling and disease progression[131] (see Chap. 16). Like norepinephrine, endothelin-1 is a potent vasoconstrictor peptide that exerts growth-promoting effects on the myocardium.[29] Hyponatremia also correlates well with increased mortality,[125] but it is likely that this variable reflects activation of the renin-angiotensin-aldosterone axis.

In many studies, the aforementioned variables have been assessed in a univariate manner (i.e., independently of one another) and there is disagreement regarding which provides *independent* prognostic information. However, Cohn and Rector have shown that while ventricular function, as expressed in ejection fraction, appears to have the most profound effect on survival in patients with advanced heart failure, exercise tolerance (as reflected in peak O_2 consumption during a progressive exercise test) and activation of the sympathetic nervous system (as reflected in the plasma norepinephrine concentration) *each* provide important independent information.[74]

Figure 17-13 *A,* Kaplan-Meier analysis of cumulative rates of survival in patients with heart failure stratified into two groups on the basis of median plasma concentration of atrial natriuretic peptide (ANP) (125 pg/ml). (From Tsutamoto T, et al: Interleukin-6 spillover in the peripheral circulation increases with the severity of heart failure, and the high plasma level of interleukin-6 is an important prognostic predictor in patients with congestive heart failure. J Am Coll Cardiol 31:391, 1998.)

ELECTROPHYSIOLOGICAL.

Death in patients with severe congestive heart failure occurs either by progressive pump failure or, in as many as one half of all patients, suddenly and unexpectedly, presumably from an arrhythmia. When present, a variety of arrhythmias, especially frequent ventricular extrasystoles,[132] ventricular tachycardia, [133] left bundle branch block, and atrial fibrillation,[134] [135] have been shown to be predictors of mortality. What is not yet clear is whether these arrhythmias are simply indicators of the severity of left ventricular dysfunction or whether they are responsible for and trigger fatal arrhythmias. Although there is some evidence that ventricular arrhythmias confer independent adverse prognostic effects,[133] this may not hold true after adjusting for other variables, especially ejection fraction.[136] ,[136a] Furthermore, the routine treatment of patients with heart failure-associated arrhythmias with antiarrhythmic drugs has not been shown to exert a protective effect and reduce mortality. The role of amiodarone and the implantable cardioverter-defibrillator in the primary prevention of sudden cardiac death in patients with left ventricular dysfunction is currently being tested in two large, randomized controlled trials.[137]

High-Output Heart Failure (Table 17-6)

High-cardiac output states by themselves are seldom responsible for heart failure, but their development in the presence of underlying heart disease often precipitates heart failure.[138] In these conditions, which are often characterized by arteriovenous shunting, the requirements of the peripheral tissues for oxygen can be satisfied only by an increase in cardiac output. Although the normal heart is capable of augmenting its output on a long-term basis, this may not be true of the diseased heart.

Anemia (See also Chap. 69)

Chronic anemia is associated with high cardiac output when hemoglobin is less than or approximately 8 gm/dl. Reduced systemic vascular resistance, which results from decreased arteriolar tone and decreased blood viscosity, plays an important role in the pathophysiology of this high-output state (Fig. 17-15) (Figure Not Available) . Enhanced basal production of endothelium-derived nitric oxide may be responsible, in part, for the low systemic vascular resistance in anemia patients.[139]

HISTORY.

Chronic anemia in the absence of underlying heart disease produces surprisingly few symptoms, which may consist of easy fatigability, mild exertional dyspnea, and occasionally palpitations and cardiac awareness. Anemia, even when severe, rarely causes heart failure or angina pectoris in patients with normal hearts; when these problems occur, it is likely that the high cardiac output is superimposed on some specific cardiac abnormality, such as valvular or ischemic heart disease.

PHYSICAL EXAMINATION.

The anemic patient often has a pale, "pasty" appearance; in African Americans, the finding of paleness of the conjunctivae, mucous membranes, and palmar creases is helpful. Arterial pulses are bounding; "pistol shot" sounds can be heard over the femoral arteries (Traube's sign), and subungual capillary pulsations (Quincke's pulse) are present, as in patients with aortic regurgitation. A medium-pitched, midsystolic murmur along the left sternal border, generally grade 1/6 to 3/6 in intensity (seldom accompanied by a thrill), is common. Heart sounds are accentuated, and the pulmonic component of the second heart sound may be particularly prominent in patients with sickle cell anemia and pulmonary hypertension; in such patients, a right ventricular lift can usually be palpated. A mid-diastolic flow murmur secondary to augmented blood flow across the mitral orifice, holosystolic murmurs resulting from tricuspid and mitral regurgitation

secondary to ventricular dilatation, and, rarely, diastolic murmurs resulting from aortic and pulmonic valve incompetence secondary to dilatation of these vessels may be heard. A protodiastolic gallop sound (S_3) frequently is audible at the cardiac apex. Jugular venous distention is uncommon; and although peripheral edema and hepatomegaly are occasionally present, they may be due not only to heart failure but also to accompanying abnormalities such as hypoalbuminemia and nutritional deficiency.

DIAGNOSTIC TESTING.

In patients with severe chronic anemia without underlying heart disease, the chest roentgenogram usually demonstrates mild to moderate cardiomegaly. The electrocardiogram often does not show any specific changes but may reveal tachycardia and T wave inversions in the lateral precordial leads. The echocardiogram generally shows a modest and symmetrical increase in the size of all chambers, with large systolic excursions of the septal and posterior left ventricular walls. In addition, an attenuated increase in the fractional shortening in response to exercise and abnormal ventricular filling may be seen.[140] These findings are superimposed on those resulting from the underlying heart disease. Hematological and blood chemistry findings reflect the specific type of anemia present.

MANAGEMENT.

Treatment of heart failure associated with severe anemia should be specific for the anemia (e.g., iron, folate, vitamin B_{12}). When heart failure is present, diuretics and cardiac glycosides are advisable, although some believe that the latter drugs are not helpful in this condition.

When both heart failure and anemia are severe, treatment must be carried out on an urgent basis and presents a difficult challenge. On the one hand, correction of the anemia is desirable to increase oxygen delivery to metabolizing tissues and thereby decrease the need for a sustained high cardiac output. On the other hand, rapid expansion of the blood volume may intensify the manifestations of heart failure.

The diagnostic steps for determining the etiology of the anemia should be taken immediately (e.g., blood drawn for serum iron, folate, and vitamin B_{12} and reticulocyte count, review of peripheral smear, and stool guaiac). The patient should be placed at bed rest and given supplementary oxygen. *Packed red blood cells* should then be transfused slowly (250 to 500 ml/24 hr), preceded and/or accompanied by vigorous diuretic therapy (e.g., furosemide, 40 mg intravenously every 8 to 12 hours), and the patient should be observed closely for the development or exacerbation of dyspnea and pulmonary rales. If worsening heart failure occurs, the transfusion should

be discontinued or slowed to avoid precipitating pulmonary edema. Vasodilator therapy is seldom helpful, because impedance to left ventricular emptying is already markedly reduced in most cases.

Systemic Arteriovenous Fistulas

Systemic arteriovenous fistulas may be congenital or acquired; the latter are usually posttraumatic or iatrogenic. Increased cardiac output associated with such fistulas depends on the size of the communication and the magnitude of the resultant reduction in systemic vascular resistance.

The *physical findings* depend on the underlying disease and the location and size of the shunt. In general, a widened pulse pressure, brisk carotid and peripheral arterial pulsations, and mild tachycardia are present. The extremities are often warm and flushed. *Branham's sign* (also called *Nicaladoni-Branham's sign*), which consists of slowing of the heart after manual compression of the fistula,[141] is present in the majority of cases; this maneuver also raises arterial and lowers venous pressure. It appears to result from the operation of a cardioaccelerator reflex with both afferent and efferent pathways in the vagus nerves.[142] The decrease in heart rate after fistula occlusion correlates with the flow in the fistula.[141]

The skin overlying the fistula is warmer than normal, and a continuous "machinery" murmur and thrill are usually present over the lesion. Third and fourth heart sounds are commonly heard, as well as a precordial midsystolic murmur secondary to increased cardiac output. The electrocardiographic changes of left ventricular hypertrophy are often seen. Rarely, the fistula may become infected, leading to bacterial endarteritis.

ACQUIRED ARTERIOVENOUS FISTULAS.

These occur most frequently after such injuries as gunshot wounds and stab wounds and may involve any part of the body, most frequently the thigh. Blood flow in the affected limb distal to the fistula diminishes after the creation of the fistula but then returns to normal and often increases with the passage of time. As a consequence, the affected limb is usually larger than its opposite member and the overlying skin is warmer; cellulitis, venostasis, edema, and dermatitis with pigmentation frequently occur, in part as a consequence of chronically elevated venous pressure. Surgical repair or excision is generally advisable in fistulas that develop after gunshot wounds or trauma.

Femoral arteriovenous fistulas following diagnostic or interventional cardiac catheterization are uncommon but may result in high-output cardiac failure.[143] When a continuous bruit is heard over the femoral artery site, a duplex vascular

Figure 17-15 (Figure Not Available) Diagram showing the pathophysiological mechanisms underlying the high cardiac output state associated with anemia. Decreased blood viscosity and a reduction in arteriolar tone resulting from tissue hypoxia and lactic acidosis contribute to reduced systemic vascular resistance, which in turn increases cardiac output. (From Hassapoyannes CA, et al: Other causes and contributing factors to congestive heart failure. *In* Hosenpud JD, Greenberg BH [eds]: Congestive Heart Failure, New York, Springer-Verlag, 1994, pp 281-300.)

ultrasound should be obtained to rule out an arteriovenous fistula; rarely, angiography is required to make the diagnosis. Although the traditional approach to management of catheterization-related femoral artery injuries has been surgical repair, newer techniques include ultrasound-guided compression and percutaneous stent placement.[143]

A rare form of acquired arteriovenous fistula results from spontaneous rupture of an aortic aneurysm into the inferior vena cava.[144] This usually produces an enormous arteriovenous shunt and rapidly progressive left ventricular failure. On physical examination, a pulsating mass can be readily palpated superficially in the abdomen and a continuous bruit is audible. Survival depends on prompt diagnosis and surgical closure. Massive fistulas may also be associated with Wilms' tumors of the kidney, and these have been reported to cause high-output cardiac failure in children.[145]

High-output heart failure resulting from the arteriovenous shunts surgically constructed for vascular access in patients undergoing long-term hemodialysis is common.[146] Cardiac outputs as high as 10 liters/min, which decrease substantially during temporary occlusion of the shunt, have been found in such patients. These values also reflect the chronic anemia present in many of these patients, but it is clear that it is the added hemodynamic burden imposed by the shunt that precipitates heart failure in patients who had previously tolerated chronic anemia without apparent impairment of cardiac function. It is usually possible to revise or band the fistula to reduce it to the appropriate size for dialysis without compromising cardiac function. If this is ineffective, the shunt should be surgically closed and a new arteriovenous fistula created.

CONGENITAL ARTERIOVENOUS FISTULAS

Congenital arteriovenous fistulas result from arrest of the normal embryonic development of the vascular system and are structurally similar to embryonic capillary networks. They range from barely noticeable strawberry birthmarks to enormous clusters of engorged vascular channels that may deform an entire extremity.[147] Most frequently, the vessels of the lower extremities are involved. When fistulas are large, patients generally complain of disfigurement as well as swelling and pain in the limb. On physical examination, erythema and cyanosis are often present, as are venous varices, a continuous murmur, and thrill. Examination also shows hemangiomatous changes associated with venous distention, deformity, and increased limb length. The fistulous connection may involve any vascular bed, including an internal mammary artery-pulmonary artery connection. *Left-sided heart failure* occurs, particularly in patients with larger lesions that involve the pelvis as well as the extremities.[148] Angiography is useful in confirming the diagnosis and in determining the physical extent of the anomaly.

Surgical excision is the ideal treatment,[149] but in many instances the lesions are not sufficiently localized to permit this. The results of ligation and excision have been unsatisfactory in the majority of cases, because the congenital arteriovenous communications are usually not confined to a single anatomical segment or to a circumscribed anatomical region. Complete cure of these lesions is possible in only a few instances. Embolization of Gelfoam pellets delivered through a catheter has been reported to obliterate multiple systemic arteriovenous fistulas and thereby diminish high-output heart failure.

HEREDITARY HEMORRHAGIC TELANGIECTASIA.

Also known as *Osler-Weber-Rendu disease,* this condition may be associated with arteriovenous fistulas, particularly in the lungs[150] and liver. Involvement of the liver, in particular, can produce a hyperkinetic circulation,[151] with heart failure as well as hepatomegaly, abdominal bruits, abdominal angina, or severe portal hypertension. Because of the presence of oxygenated blood in the inferior vena cava and right atrium, this condition may be misdiagnosed as atrial septal defect. Staged embolization of hepatic arteries may result in clinical improvement.[151] [152]

The congenital arteriovenous communications resulting from *infantile hemangioendothelioma of the liver* are commonly associated with marked increases in cardiac output, sometimes as high as 10 liters/min, and congestive heart failure.[153] These lesions may be quite large, increase in size with time, and lead to heart failure, even in infancy. They are often associated with sizable cutaneous hemangiomas, which should alert the clinician to the possibility of their presence. Ultrasonography and computed tomography are the most useful noninvasive diagnostic tools. Treatment strategies include medical management with corticosteroids or interferon alfa or, in cases of failed medical therapy, use of percutaneous or surgical intervention, including hepatic artery ligation or embolization, resectional surgery, or orthotopic liver transplant.

Hyperthyroidism (See also Chap. 64.)

The principal findings on the physical examination of the cardiovascular system are tachycardia, a widened pulse pressure, brisk carotid and peripheral arterial pulsations, a hyperkinetic cardiac apex, and loud first heart sound. A midsystolic murmur along the left sternal border, secondary to increased flow, is common; occasionally, this murmur has an unusual scratchy component (the so-called Means-Lerman scratch), thought to be due to the rubbing together of normal pleural and pericardial surfaces by the hyperdynamic heart. Rarely, systolic murmurs of mitral and tricuspid regurgitation, presumably secondary to papillary muscle dysfunction, may occur.

THYROTOXIC HEART DISEASE

As in many other high-output states, the hyperkinetic state of hyperthyroidism does not usually lead to heart failure in the absence of underlying cardiovascular disease. The normal heart appears capable of tolerating the burden imposed by hyperthyroidism simply by means of dilatation and hypertrophy.[154] , [155] ,[155a] However, heart failure may be precipitated when the elevated flow load of hyperthyroidism is superimposed on a reduced cardiovascular reserve (i.e., a patient with heart disease who is compensated). Similarly, in patients with obstructive coronary artery disease who are asymptomatic or who have only mild evidence of ischemia in the euthyroid

state, the demand for increased coronary blood flow with hyperthyroidism frequently leads to an exacerbation of angina. Rarely, hyperthyroidism may cause a reversible dilated cardiomyopathy with low cardiac output heart failure. The high output cardiac failure of hyperthyroidism is frequently accompanied by and exacerbated by atrial fibrillation and a rapid ventricular rate.

MANAGEMENT.

Beta-adrenergic antagonists may be both helpful and harmful in patients with thyrotoxic heart disease and heart failure. Although they may be beneficial by lowering the ventricular rate, particularly by prolonging the refractory period of the atrioventricular conduction system in patients with atrial fibrillation, these agents also may diminish myocardial contractility by blocking the adrenergic support of the heart. Therefore, beta-adrenergic blockade must be administered cautiously to the patient with thyrotoxic heart disease and heart failure and only after treatment with a digitalis glycoside, with the patient at rest and under careful observation. The initial dose should be small (e.g., propranolol, 0.5 mg intravenously or 10 mg orally two to three times daily), and the patient should be observed after the administration to be sure that heart failure is not intensified. In addition to beta-adrenergic blockade, appropriate antithyroid medication (e.g., methimazole, propylthiouracil) should be prescribed.

It is particularly important to recognize *apathetic hyperthyroidism,* [156] a condition in the elderly in which the usual clinical manifestations of thyrotoxicosis, such as palpitations, tachycardia, and moist skin, are not present. In such patients, the first clinical signs of hyperthyroidism may be unexplained heart failure, an exacerbation of angina pectoris, or unexplained atrial fibrillation,[157] usually but not always with a rapid ventricular rate.

Beriberi Heart Disease (Table 17-7)

PATHOGENESIS AND CLINICAL CONSIDERATIONS.

Thiamine pyrophosphate (TPP), the most abundant thiamine ester found in tissues, is essential for carbohydrate metabolism. Beriberi heart disease is due to severe thiamine deficiency persisting for at least 3 months. Clinical beriberi is found most frequently in the Far East,[158] although even in that part of the world it is far less prevalent now than in the past. It occurs predominantly in those individuals whose staple diet consists of polished rice, which is deficient in thiamine but high in carbohydrates, or foods containing thiaminases. The presence of thiamine in the enriched flour used in white bread has virtually eradicated this disease in the United States and western Europe, where beriberi is found most commonly in diet faddists[159] and alcoholics. Like polished rice, alcohol is low in vitamin B_1 but has a high carbohydrate content. In the West, alcoholics become thiamine deficient not only because of a low intake and impaired absorption and storage of the vitamin but also because they eat "junk" foods[159] or drink large quantities of beer. The high carbohydrate content of these foods leads to a greater requirement for thiamine.

Patients in Asia present with edema, ranging from peripheral edema to anasarca, as well as general malaise, and fatigue. The elevation of cardiac output[160] is presumably secondary to the reduced systemic vascular resistance and augmented venous return (Fig. 17-16) .

PHYSICAL FINDINGS.

In most cases in Western countries, physical findings of the high-output state and usually of severe generalized malnutrition and vitamin deficiency are present. Evidence of peripheral polyneuropathy with sensory and motor deficits is common ("dry beriberi"), as is the presence of nutritional "cirrhosis" characterized by paresthesias of the extremities, absent or decreased knee and

TABLE 17-7 -- DIAGNOSTIC CRITERIA FOR BERIBERI HEART

Clinical Features
Dependent edema
Low peripheral vascular resistance: decreased minimum blood pressure and increased pulse pressure
Hyperkinetic circulatory state: midsystolic murmur and third heart sound
Cardiomegaly
T-wave changes (inverted, diphasic, depressed) on electrocardiogram
Peripheral neuritis
Dietary deficiency for at least 3 months or chronic alcoholism
Presence of Thiamine Deficiency
Decrease in blood thiamine concentration
Decrease in erythrocyte transketolase activity
Increase in TTP effect
Improvement After Adequate Thiamine Replacement

From Kawai C, Nakamura Y: The heart in nutritional deficiencies. In Abelmann WH (ed): Cardiomyopathies, Myocarditis, and Pericardial Disease. In Braunwald E (series ed): Atlas of Heart Diseases, vol 2. Philadelphia, Current Medicine, 1995, pp 7.1-7.18.

ankle jerks, painful glossitis, the anemia of combined iron and folate deficiency, and hyperkeratinized skin lesions.

Beriberi heart disease[158] [160] [161] is characterized by biventricular failure, sinus rhythm, and marked edema ("wet beriberi"). There is arteriolar vasodilatation; and the cutaneous vessels may be dilated, or in later cases with heart failure they may be constricted. Therefore, the absence of warm hands does not exclude the diagnosis of beriberi. A third heart sound and an apical systolic murmur are heard almost invariably, and there is a wide pulse pressure characteristic of the hyperkinetic state.

Heart failure may develop explosively in beriberi, and some patients succumb to the illness within 48 hours of the onset of symptoms. *Shoshin* (Japanese for "acute damage to the heart") *beriberi,* found most frequently in Asia and Africa, is a fulminant form of thiamine deficiency[162] [163] characterized by hypotension, tachycardia, and lactic acidosis. If left untreated, patients with this disorder die within hours of cardiogenic shock and pulmonary edema. Thus, because the course of the disease may advance rapidly, treatment must be begun immediately once the diagnosis has been established. In the Western world, this fulminant form of the disease is uncommon.

LABORATORY FINDINGS.

The electrocardiogram characteristically exhibits low voltage of the QRS complex, prolongation of the QT interval, and low voltage or inversion of T waves, most commonly in the right precordial leads. The chest roentgenogram usually shows biventricular enlargement, pulmonary congestion, and pleural effusions. In alcoholics with beriberi heart disease, the left ventricular ejection fraction and peak rate of rise of left ventricular pressure are usually reduced.[161] The role played by alcoholic cardiomyopathy (see Chap. 48) in this hemodynamic picture is not clear. The cardiac output falls, and the peripheral resistance rises acutely when thiamine is administered in the catheterization laboratory (see Fig. 17-16). [160] [161]

Laboratory diagnosis of thiamine deficiency can be made by demonstration of increased serum pyruvate and lactate levels in the presence of a low red blood cell transketolase level.[160] [164] Enhancement in transketolase activity resulting from added thiamine pyrophosphate (TPP) is referred to as the TPP effect. A TPP effect greater than 15 percent suggests thiamine deficiency. The thiamine concentration may be determined in biological fluids to confirm the diagnosis. Finally, an objective clinical and hemodynamic response to thiamine administration (see later) is considered diagnostic.

At *postmortem examination,* the heart usually shows simple dilation without other changes. On microscopic examination, there is sometimes edema and hydropic degeneration of the muscle fibers. Nonspecific but abnormal histological and electron microscopic changes have been found in cardiac biopsy specimens.

TREATMENT.

Akbarian and coworkers have reported careful hemodynamic studies that suggest that vasomotor depression or paralysis may be responsible for the depressed vascular resistance.[165] They studied four patients in whom ethanol excess was responsible for the thiamine deficiency. All had increased heart rate and cardiac index

(averaging 6 liters/min/m^2) and reduced arterial-mixed venous oxygen difference and systemic vascular resistance. Right and left ventricular filling pressures and blood volume were also elevated.

Patients with beriberi heart disease fail to respond adequately to digitalis and diuretics alone. However, improvement after the administration of thiamine (up to 100 mg intravenously followed by 25 mg/day orally for 1 to 2 weeks) may be dramatic. Marked diuresis, decrease in heart rate and size, and clearing of pulmonary congestion may occur within 12 to 48 hours.[158] [165] However, the acute reversal of the vasodilation induced by correction of the deficiency may cause

Figure 17-16 Hemodynamic changes in beriberi heart disease before and after treatment with intravenous thiamine in patients younger than or older than or equal to 20 years of age. Wet beriberi is characterized by increases in cardiac index *(A),* stroke index *(B),* heart rate *(C),* blood turnover rate *(D)* and circulating blood volume *(E),* and a decrease in peripheral vascular resistance *(F),* particularly in younger patients. Thiamine replacement results in a rapid reversal of the high output state. (From Kawai C, Nakamura Y: The heart in nutritional deficiencies. *In* Abelmann WH [ed]: Cardiomyopathies, Myocarditis, and Pericardial Disease. *In* Braunwald E [series ed]: Atlas of Heart Diseases. Vol 2. Philadelphia, Current Medicine, 1995, pp 7.1-7.18.)

the unprepared left ventricle to go into low-output failure. Therefore, patients should receive a glycoside and diuretic therapy along with thiamine. Thiamine replacement also results in improvement in the polyneuropathy caused by thiamine deficiency.[166]

In endemic areas, effective management of beriberi heart disease also involves disease prevention. Recommendations include (1) ingestion of germ-retaining polished rice, undermilled rice, or rice enriched with thiamine, (2) avoidance of excessive intake of carbonated beverages and strenuous exercise during hot summer months, (3) avoidance of chronic diuretic therapy, and (4) baking or boiling foods that contain thiaminase, such as clams or raw fish.

Latent thiamine deficiency may occur in conditions such as alcoholic cardiomyopathy and in other forms of refractory heart failure, possibly related to chronic furosemide therapy.[167] Postulated mechanisms for the thiamine-wasting effects of furosemide include increased urinary excretion[168] and decreased myocardial uptake.[169] Other clinical situations in which latent thiamine deficiency may develop include chronic ambulatory peritoneal dialysis or hemodialysis and refeeding after starvation. The possibility of thiamine deficiency should be considered in patients with heart failure of obscure origin.

Paget's Disease

PATHOGENESIS.

Paget's disease of bone (osteitis deformans) is an asymmetrical process characterized by excessive resorption of bone followed by replacement of normal marrow with vascular, fibrous connective tissue and of resorbed bone with coarse, trabecular bone. Paget's disease is most commonly asymptomatic and is diagnosed on a plain film or because of a high serum alkaline phosphatase level obtained for other reasons. Because of the increased vascularity of bone affected by Paget's disease, it has been assumed that this high flow occurred through the involved bone. However, it appears that the additional blood flow through an affected, resting limb passes through the *cutaneous tissue* overlying the involved bone, possibly secondary to local heat production resulting from the increased metabolic activity of affected bone.[170] Increased production of interleukin-6 by pagetic bone and marrow cells of Paget's disease,[171] and secondary hyperparathyroidism contribute to the progression of disease.

CLINICAL FINDINGS.

These are a function of the extent of the disease and the specific bones involved. Involvement of at least 15 percent of the skeleton by Paget's disease in an active stage, accompanied by a high alkaline phosphatase level, is necessary before a clinically significant augmentation of cardiac output is observed. Such a high-output state may be well tolerated for years with the patient remaining asymptomatic.[171] However, if a specific cardiac disorder (e.g., valvular disease, coronary stenosis) is present, the combination may cause rapid clinical deterioration.

The cardiovascular findings are not distinguishable from those in other conditions with high-output states. However, metastatic calcifications are characteristic, and, if they involve the heart, may lead to sclerosis and calcification of the valve rings, with extension into the interventricular septum. The electrocardiogram may show atrioventricular conduction disturbance or bundle branch block. Echocardiograms often demonstrate aortic sclerosis or stenosis, as well as left ventricular dilation, hypertrophy, and mild systolic dysfunction.[172]

Other Causes of High-Output Cardiac Failure

FIBROUS DYSPLASIA.

This condition, in which there is proliferation of fibrous tissue in bone, also may be associated with an elevated cardiac output, especially when multiple bones are involved.[173] *McCune-Albright syndrome*, a congenital disorder characterized by polyostotic fibrous dysplasia, cafe au lait spots, and sexual precocity, is more common in females (10:1) and has been linked to post-zygotic mutations in genes encoding G_{alphas} proteins.[174] Calcitonin may be an effective treatment in widespread disease.

MULTIPLE MYELOMA.

Increased cardiac output and less commonly high-output heart failure have been described in this condition.[175] The mechanism is not clear; it may be due to the associated anemia and/or hyperperfusion of the neoplastic tissue, especially in patients with extensive bone disease.[176] Arteriovenous shunting has been demonstrated in involved bones using intraarterial injection of radiolabeled albumin and correlates with cardiac index.[177]

OTHER CONDITIONS.

High-output heart failure also occurs in pregnancy (see Chap. 65), renal disease, especially glomerulonephritis (see Chap. 72), cor pulmonale (see Chap. 54), polycythemia vera (see Chap. 69), the carcinoid syndrome (see Chap. 48), and marked obesity.[177A]

Pulmonary Edema

MECHANISM OF PULMONARY EDEMA

ALVEOLAR-CAPILLARY MEMBRANE.

Pulmonary edema develops when the movement of liquid from the blood to the interstitial space, and in some instances to the alveoli, exceeds the return of liquid to the blood and its drainage through the lymphatics.[178] The barrier between pulmonary capillaries and alveolar gas, the alveolar-capillary membrane, consists of three anatomical layers with distinct structural characteristics: (1) cytoplasmic projections of the capillary endothelial cells that join to form a continuous cytoplasmic tube; (2) the interstitial space, which varies in thickness and may contain connective tissue fibrils, fibroblasts, and macrophages between the capillary endothelium and the alveolar epithelium, terminal bronchioles, small arteries and veins, and lymphatic channels; and (3) the lining of the alveolar wall, which is continuous with the bronchial epithelium and is composed predominantly of large squamous cells (type I) with thin cytoplasmic projections.

There is normally a continuous exchange of liquid, colloid, and solutes between the vascular bed and interstitium.[179] A pathological state exists only when there is an increase in the net flux of liquid, colloid, and solutes from the vasculature into the interstitial space. Experimental studies have confirmed that the basic principles outlined in the classic Starling equation apply to the lung as well as to the systemic circulation.$Q_{(iv\text{-}int)} = K_f [(P_{iv} - P_{int}) - sigma_f (II_{iv} - II_{int})]$where Q=net rate of transudation (flow of liquid from blood vessels to interstitial space), P_{int} =interstitial hydrostatic pressures, P_{iv} =intravascular hydrostatic pressures, II_{int} =interstitial colloid osmotic pressure, II_{iv} =intravascular colloid osmotic pressure, $sigma_f$ =reflection coefficient for proteins, and K_f =hydraulic conductance.

LYMPHATICS.

These vessels serve to remove solutes, colloid, and liquid derived from the blood vessels. Because of a more negative pressure in the peribronchial and perivascular interstitial space and the increased compliance of this nonalveolar interstitium, liquid is more likely to increase here once the pumping capacity of the lymphatic channels is exceeded. As a consequence of the development of interstitial edema, small airways and blood vessels may become compressed.

The lymphatics play a key role in removing liquid from the interstitial space, and if the pumping capacity of the lymphatic channels is exceeded, pulmonary edema will occur. It has been estimated that an average 70-kg person at rest has a Q_{lymph} of approximately 20 ml/hr,[180] and experimentally, lymph flow rates of up to 10 times control values have been reported. Thus it is possible that lymphatic pumping capacity can be as great as 200 ml/hr in an average-sized adult. With chronic elevations of left atrial pressure, the pulmonary lymphatic system hypertrophies and is able to transport greater quantities of capillary filtrate, thereby protecting the lungs from edema. By contrast, a sudden marked increase in pulmonary capillary pressure can be rapidly fatal in a patient not preconditioned by growth of the lymphatic drainage system.

SEQUENCE OF FLUID ACCUMULATION DURING PULMONARY EDEMA.

Whether initiated by an imbalance of Starling forces or by primary damage to the various components of the alveolar-capillary membranes, the sequence of liquid exchange and accumulation in the lungs is the same and can be represented in three stages. In *stage 1,* there is an increase in mass transfer of liquid and colloid from blood capillaries through the interstitium. Despite the increased filtration, there is no measurable increase in interstitial volume because there is an equal increase in lymphatic outflow. *Stage 2* occurs when the filtered load from the pulmonary capillaries is sufficiently large that the pumping capacity of the lymphatics is approached or exceeded, and liquid and colloid begin to accumulate in the more compliant interstitial compartment surrounding bronchioles, arterioles, and venules. In *stage 3,* further increments in filtered load exceed the volume limits of the loose interstitial spaces, causing distention of the less compliant interstitial space of the alveolar-capillary septum and resulting in alveolar flooding.

GRAVITY DEPENDENCE OF PULMONARY EDEMA.

Because blood is more dense than gas-containing lung, the effects of gravity are much greater on the distribution of blood flow than on the distribution of tissue forces in the lung. From apex to base, the effective perfusion pressure of the pulmonary circulation (P_{pa}) increases by approximately

Figure 17-17 Schematic representation of the gravity-dependent, apex-to-base distribution of pulmonary blood flow in an upright lung. Pulmonary artery pressure (P_a) and pulmonary venous pressure (P_v) increase on a hydrostatic basis as the base is approached. Alveolar pressure (P_A) is constant with vertical distance. (The three zones are described in detail in the text.)

1 cm H_2O/cm vertical distance, whereas pleural pressures (P_{p1}) increase by only 0.25 cm H_2O/cm vertical distance.[181] Pulmonary capillaries (or alveolar vessels) are exposed to alveolar pressure (P_{alv}), which does not vary from apex to base. In contrast, pulmonary arteries, arterioles, veins, and venules (extraalveolar vessels) are exposed to pleural pressure, which does vary from apex to base. The consequences of these differences in forces on ventilation-perfusion relationships are described in three zones (Fig. 17-17) . In *zone 1* (apex), pulmonary arterial pressure is less than alveolar pressure, and thus blood flow is strikingly diminished. In *zone 2* (midlung), arterial pressure exceeds alveolar pressure, which in turn exceeds venous pressure. In *zone 3* (base), venous pressure exceeds alveolar pressure, resulting in distention of collapsible capillaries. Mean intravascular pressures are greatest in this zone; hence, with elevations of venous pressure or with disruption of alveolar-capillary membranes, edema formation is both more rapid and greatest at the lung bases.

In normal, erect humans, perfusion is greater in the basilar lung regions than in the apical ones. Deviation from this gravity-dependent pattern has been called *vascular redistribution,* a relative reduction in perfusion of the bases with a relative increase in apical perfusion. This phenomenon is most likely due to compression of the lumina of basilar vessels secondary to the greater and more rapid formation of edema at the lung bases and the tendency for extravascular liquid formed elsewhere to gravitate toward the bases. The situation that occurs with chronic elevations of left atrial pressure, as in mitral stenosis or chronic heart failure, should be contrasted to that of acute pulmonary edema. Clinical experience with such chronic conditions suggests that redistribution of blood flow does occur, but with minimal or no evidence of interstitial edema and often in the absence of alveolar edema.

Classification of Pulmonary Edema

The two most common forms of pulmonary edema are that initiated by an imbalance of Starling forces and that initiated by disruption of one or more components of the alveolar-capillary membrane (Table 17-8) .[182] [183] Less often, lymphatic insufficiency can be involved as a predisposing, if not initiating, factor in the genesis of edema. Although the initiating or primary mechanism may be clearly identifiable, multiple factors come into play during the development of edema; and irrespective of the

initiating event, the stage of alveolar flooding is characterized to some degree by disruption of the alveolar-capillary membrane.[184]

Imbalance of Starling Forces

INCREASED PULMONARY CAPILLARY PRESSURE.

Pulmonary edema will occur only when the pulmonary capillary pressure rises to values exceeding the plasma colloid osmotic pressure, which is approximately 28 mm Hg in the human. Because the normal pulmonary capillary pressure is 8 to 12 mm Hg, there is a substantial margin of safety in the development of pulmonary edema. Although pulmonary capillary pressures must be abnormally high to increase the flow of interstitial fluid, at a time when edema is clearly present these pressures may not correlate with the severity of pulmonary edema.[185] In fact, pulmonary capillary wedge pressures may have returned to normal at a time when there is still considerable pulmonary edema, because time is required for removal of both interstitial and alveolar edema. Other factors obscure the relationship between the severity of edema and measured pulmonary capillary pressures in addition to slower rates of removal after edema has collected. The rate of increase in lung liquid at any given elevation of capillary pressure is

TABLE 17-8 -- CLASSIFICATION OF PULMONARY EDEMA BASED ON INITIATING MECHANISM

I. Imbalance of Starling forces
A. Increased pulmonary capillary pressure
1. Increased pulmonary venous pressure without left ventricular failure (e.g., mitral stenosis)
2. Increased pulmonary venous pressure secondary to left ventricular failure
3. Increased pulmonary capillary pressure secondary to increased pulmonary arterial pressure (so-called overperfusion pulmonary edema)*
B. Decreased plasma oncotic pressure: hypoalbuminemia secondary to renal, hepatic, protein-losing enteropathic, or dermatological disease or nutritional causes
C. Increased negativity of interstitial pressure
1. Rapid removal of pneumothorax with large applied negative pressures (unilateral)
2. Large negative pressures due to acute airway obstruction along with increased end-expiratory volumes (asthma)*
D. Increased interstitial oncotic pressure: no known clinical or experimental example
II. Altered alveolar-capillary membrane permeability (acute respiratory distress syndrome)
A. Infectious pneumonia--bacterial, viral, parasitic
B. Inhaled toxins (e.g., phosgene, ozone, chlorine, Teflon fumes, nitrogen dioxide, smoke)
C. Circulating foreign substances (e.g., snake venom, bacterial endotoxins, alloxan , alpha-naphthyl thiourea)
D. Aspiration of acidic gastric contents
E. Acute radiation pneumonitis
F. Endogenous vasoactive substances (e.g., histamine, kinins*)
G. Disseminated intravascular coagulation
H. Immunological--hypersensitivity pneumonitis, drugs (nitrofurantoin), leukoagglutinins
I. Shock lung in association with nonthoracic trauma
J. Acute hemorrhagic pancreatitis
III. Lymphatic insufficiency
A. Post lung transplant
B. Lymphangitic carcinomatosis
C. Fibrosing lymphangitis (e.g., silicosis)
IV. Unknown or incompletely understood
A. High-altitude pulmonary edema
B. Neurogenic pulmonary edema
C. Heroin overdose
D. Pulmonary embolism
E. Preeclampsia-eclampsia
F. Post cardioversion
G. Post anesthesia
H. Post cardiopulmonary bypass

*Not certain to exist as a clinical entity.

Not certain that this, as a single factor, leads to clinical pulmonary edema.

Predominantly an experimental technique.

related to the functional capacity of lymphatics, which may vary from patient to patient, and to variations in interstitial oncotic and hydrostatic pressures.

HYPOALBUMINEMIA.

Pulmonary edema does not develop with hypoalbuminemia alone. However, hypoalbuminemia may alter the fluid conductivity of the interstitial space so that liquid moves more easily between capillaries and lymphatics.[186] Therefore, in addition to hypoalbuminemia, there must be some elevations of pulmonary capillary pressure, but only small increases are necessary before pulmonary edema ensues in the presence of hypoalbuminemia. Indeed, in such patients, only moderate fluid overload can precipitate overt pulmonary edema in the absence of left ventricular failure.

INCREASED NEGATIVE INTERSTITIAL PRESSURE.

Pulmonary edema may be associated with rapid removal of pleural air to relieve a pneumothorax--so-called reexpansion pulmonary edema.[187] Usually, the pneumothorax has been present for several hours to days, allowing time for alterations in surfactant so that large negative pressures are necessary to open collapsed alveoli. In these instances, the edema is unilateral and is most often only a radiographic finding with few clinical findings. In rare cases, reexpansion pulmonary edema may be severe and require rapid and extensive clinical treatment.[187] Studies using radiolabeled transferrin suggest that an abnormality in microvascular permeability contributes to the development of localized pulmonary edema.[188]

PRIMARY ALVEOLAR-CAPILLARY MEMBRANE DAMAGE

Many diverse medical and surgical conditions are associated with pulmonary edema that is due to damage of the alveolar-capillary membrane, rather than to a primary alteration in Starling forces. These conditions include acute pulmonary infections and pulmonary effects of gram-negative sepsis and nonthoracic trauma, as well as any condition associated with disseminated intravascular coagulation.[182] [189] Despite the diversity of underlying causes, once diffuse alveolar-capillary injury has occurred, the pathophysiological and clinical sequence of events is quite similar in most patients. Because of the resemblance of the clinical picture to that seen with respiratory distress of the neonate, these conditions have been referred to as the *acute respiratory distress syndrome* (ARDS).[190] [191]

Direct evidence for increased capillary permeability has come mainly from experimental studies in which pulmonary edema has been produced by endotoxin infusion; hemorrhagic shock[192] ; infusion of oleic acid,[193] alloxan, thiourea,[194] phorbol myristate acetate, or complement fragments[195] ; freebase cocaine smoking [196] ; and inhalation of high concentrations of oxygen[197] or toxic gases, such as phosgene, ozone,[198] and nitrogen dioxide.[199] It is probable, though not yet proved, that increased permeability of the alveolar-capillary membrane is an initiating event in most of the cases designated as ARDS.

Cardiogenic Pulmonary Edema

CLINICAL MANIFESTATIONS.

During *stage 1*, the distention and recruitment of small pulmonary vessels secondary to elevation of left atrial pressure may actually improve gas exchange in the lung and augment slightly the diffusing capacity for carbon monoxide. It is doubtful that any symptoms, except for exertional dyspnea, accompany these abnormalities, and physical findings in the lungs would be scarce except for mild inspiratory rales due to opening of closed airways. With progression to *stage 2*, *interstitial edema* attributable to increased liquid in the loose interstitial space contiguous with the perivascular tissue of larger vessels may cause a loss of the normally sharp radiographic definition of pulmonary vascular markings, haziness and loss of demarcation of hilar shadows, and thickening of interlobular septa (Kerley B lines)[200] (see Fig. 8-18*B*). Competition for space between vessels, airways, and increased liquid within the loose interstitial space may compromise small airway lumina, particularly in the dependent portions of the lungs, and there may be reflex bronchoconstriction. A mismatch exists between ventilation and perfusion that results in hypoxemia and more wasted ventilation. Indeed, in the setting of acute myocardial infarction, the degree of hypoxemia correlates with the degree of elevation of the pulmonary capillary wedge pressure. Tachypnea is a frequent finding with interstitial edema and has been attributed to stimulation by the edema of interstitial J-type receptors or to stretch receptors in the interstitium rather than to hypoxemia, which is rarely of sufficient magnitude to stimulate breathing. There are few changes in the standard spirometric indices.

With the development of alveolar flooding, or *stage 3* edema, gas exchange is quite abnormal, with severe hypoxemia and often hypocapnia. Alveolar flooding can proceed to such a degree that many large airways are filled with blood-tinged foam that can be expectorated. Vital capacity and other lung volumes are markedly reduced. A right-to-left intrapulmonary shunt develops as a consequence of perfusion of the flooded alveoli. Although hypocapnia is the rule, hypercapnia with acute respiratory acidemia can occur in more severe cases or in patients with concomitant chronic obstructive pulmonary disease. It is in such instances that morphine, with its well-known respiratory depressant effects, should be used with caution.

DIAGNOSIS.

Acute cardiogenic pulmonary edema is the most dramatic symptom of left-sided heart failure.[201] Impaired left ventricular systolic and/or diastolic function, mitral stenosis, or whatever causes elevated left atrial and pulmonary capillary pressures leads to cardiogenic pulmonary edema, which, in turn, interferes with oxygen transfer in the lungs and depresses arterial oxygen tension. Simultaneously, the sensation of suffocation and oppression in the chest intensifies the patient's fright, elevates heart rate and blood pressure, and further restricts ventricular filling. The increased discomfort and work of breathing place an additional load on the heart, and cardiac function becomes depressed further by the hypoxia. If this vicious circle is not interrupted, it may lead rapidly to death.

Acute cardiogenic pulmonary edema differs from orthopnea and paroxysmal nocturnal dyspnea in the more rapid and extreme development of pulmonary capillary hypertension. Acute pulmonary edema is a terrifying experience for the patient and often the bystander as well. Usually extreme breathlessness develops suddenly, and the patient becomes extremely anxious, coughs, and expectorates pink, frothy liquid, causing him or her to feel as if he or she is literally drowning. The patient sits bolt upright, or may stand, exhibits air hunger, and may thrash about. The respiratory rate is elevated, the alae nasi are dilated, and there is inspiratory retraction of the intercostal spaces and supraclavicular fossae that reflects the large negative intrapleural pressures required for inspiration. The patient often grasps the sides of the bed to allow use of the accessory muscles of respiration. Respiration is noisy, with loud inspiratory and expiratory gurgling sounds that are often easily audible across the room. Sweating is profuse, and the skin is usually cold, ashen, and cyanotic, reflecting low cardiac output and increased sympathetic drive.

On auscultation, there are many adventitious lung sounds, with rhonchi, wheezes, and moist and fine crepitant rales that appear at first over the lung bases but then extend upward to the apices as the condition worsens. Cardiac auscultation may be difficult because of the respiratory sounds, but a third heart sound and an accentuated pulmonic component of the second heart sound are frequently present.

The patient may suffer from intense precordial pain if the pulmonary edema is secondary to acute myocardial infarction (see Chap. 35). Unless cardiogenic shock is present, arterial pressure is usually elevated above the patient's normal level as a result of excitement and discomfort, which cause adrenergically mediated vasoconstriction. Because of the presence of systemic hypertension, it may be suspected (inappropriately) that the pulmonary edema is due to hypertensive heart disease. However, it should be noted that the latter condition is now quite uncommon, and if arterial pressure is elevated, examination of the fundi will usually indicate whether or not hypertensive heart disease is actually present.

DIFFERENTIATION FROM BRONCHIAL ASTHMA.

It may be difficult to differentiate severe bronchial asthma from acute pulmonary edema, since both conditions may be associated with extreme dyspnea, pulsus paradoxus, demands

for an upright posture, and diffuse wheezes that interfere with cardiac auscultation. In bronchial asthma, there is usually a history of previous similar episodes and the patient is frequently aware of the diagnosis. During the acute attack, the asthmatic patient does not usually sweat profusely, and arterial hypoxemia, although present, is not usually of sufficient magnitude to cause cyanosis. In addition, the chest is hyperexpanded and hyperresonant and use of accessory muscles is most prominent during respiration. The wheezes are more high pitched and musical than in pulmonary edema, and other adventitious sounds such as rhonchi and rales are less prominent.

The patient with acute cardiogenic pulmonary edema usually perspires profusely and is frequently cyanotic, owing to desaturation of arterial blood and decreased cutaneous blood flow. The chest is often dull to percussion, there is no hyperexpansion, accessory muscle use is less prominent than in asthma, and moist, bubbly rales and rhonchi are heard in addition to wheezes. As the patient recovers, the radiological appearance of pulmonary edema usually resolves more slowly than the elevated pulmonary capillary wedge pressure.

PULMONARY CAPILLARY WEDGE PRESSURE MEASUREMENTS.

Measurement of pulmonary capillary wedge pressure by means of a flow-directed catheter (see Chap. 11) may be critical in the differentiation between pulmonary edema secondary to an imbalance of Starling forces (i.e., cardiogenic pulmonary edema) and that secondary to alterations of the alveolar-capillary membrane. Specifically, a pulmonary capillary wedge or pulmonary artery diastolic pressure exceeding 25 mm Hg in a patient without previous pulmonary capillary pressure elevation (or exceeding 30 mm Hg in a patient with chronic pulmonary capillary hypertension) and with the clinical features of pulmonary edema strongly suggests that the edema is cardiogenic.

After effective treatment of the pulmonary edema, patients are often restored rapidly to the condition that existed before the attack, although they usually feel exhausted. Between attacks of pulmonary edema, there may be few symptoms or signs of heart failure.

Pulmonary Edema of Unknown Pathogenesis

HIGH-ALTITUDE PULMONARY EDEMA (HAPE).

HAPE is a noncardiogenic pulmonary edema that occurs most commonly in healthy young adults who ascend rapidly to altitudes in excess of 2500 m and who then engage in strenuous exercise at that altitude before they have become acclimated.[202] [203] [204] [205] [206] Estimates place the incidence at 6.4 clinically apparent cases per 100 exposures to high altitude in persons younger than 21 years of age and 0.4 cases per 100 exposures in those older than 21 years. In addition to age, the major factors that determine the occurrence of HAPE are the altitude, the speed of ascent, and individual susceptibility. Usually within 1 day of ascent, affected individuals complain of cough, dyspnea, and reduced exertional tolerance. These symptoms may progress rapidly as pulmonary edema worsens and may be associated with chest pain, orthopnea, and pink frothy sputum. Clinical evaluation reveals tachycardia, bilateral rales, and cyanosis, accompanied by marked arterial hypoxemia and radiographic evidence of discrete, patchy pulmonary infiltrates. As HAPE progresses and then resolves, pulmonary infiltrates often become diffuse and homogeneous.

A central abnormality in the pathophysiology of HAPE is an abnormal rise in pulmonary artery pressures and pulmonary vascular resistance in response to hypoxia (Fig. 17-18) . [202] [204] Possible mechanisms underlying the exaggerated hypoxic pulmonary vascular response in susceptible individuals include a decreased hypoxic ventilatory response, increased sympathetic activity, and augmented release and/or decreased clearance of endothelin-1.[205] The association of HAPE with the major histocompatibility antigens HLA-DR6 and HLA-DQ4 also suggests an immunogenetic susceptibility.[206] [206A] Inhomogeneous vasoconstriction during exercise resulting in overperfused areas and "stress failure" of the pulmonary capillaries[203] is believed to contribute to the development of pulmonary edema.

Reversal of this syndrome is both rapid (less than 48 hours) and certain, either by returning the patient to a lower altitude and/or by administering a high inspiratory concentration of oxygen. Sleeping below 2500 m, slow ascent with gradual acclimatization, and avoidance of heavy exertion for the first 2 or 3 days at high altitude are thought to be preventive. Nifedipine has been used successively both in the treatment of clinical HAPE and as prophylaxis.[207] Inhaled nitric oxide, either alone or in combination with supplemental oxygen, may also be effective in lowering pulmonary vascular resistance and improving gas exchange.[208]

NEUROGENIC PULMONARY EDEMA.

A variety of central nervous system disorders including head trauma, seizures, and subarachnoid hemorrhage can be associated with acute pulmonary edema (without detectable left ventricular dysfunction).[209] [210] It is believed that sympathetic overactivity shifts blood from the systemic to the pulmonary circulation, with secondary elevations of left atrial and pulmonary capillary pressures. Thus, an imbalance of Starling forces (i.e., a hydrostatic

Figure 17-18 Diagram to show the sequence of events in the pathogenesis of high altitude pulmonary edema (HAPE). (From West JB, Mathieu-Costello O: High-altitude pulmonary edema is caused by stress failure of pulmonary capillaries. Int J Sports Med 13:S54, 1992.)

mechanism[211]) may be the basis for this form of pulmonary edema. Pulmonary capillary leak due to pressure-induced mechanical injury and/or direct nervous system control over capillary permeability may also play a contributory role.[212] [213] Treatment consists of ventilatory support and maneuvers to reduce intracranial pressure. A reversible impairment in left ventricular systolic function resulting in hypotension may accompany noncardiogenic pulmonary edema.[214]

NARCOTIC OVERDOSE PULMONARY EDEMA.

First described by Osler in 1880, acute pulmonary edema is a well-recognized sequela of heroin overdose.[215] [216] [217] Because of the illicit traffic in this drug, which is given by the intravenous route, the syndrome was initially thought to be due to injected impurities rather than to the heroin itself. However, because oral methadone and dextropropoxyphene also can be associated with pulmonary edema,[218] [219] the syndrome cannot be attributed entirely to injected impurities. The fact that edema fluid contains protein concentrations nearly identical to those found in plasma[220] and that pulmonary capillary wedge pressures, when measured, are normal[221] argues for an alveolar-capillary membrane leak as the initiating cause.

PULMONARY EMBOLISM (see Chap. 52).

Acute pulmonary edema in association with either a massive embolus or multiple smaller emboli has been well described and most often attributed to concomitant left ventricular dysfunction due to a combination of hypoxemia and encroachment of the interventricular septum on the left ventricular cavity.[222] It has been suggested that in the pulmonary edema due to pulmonary microthrombi an increase in permeability of the alveolar-capillary membrane occurs.[189] [223]

ECLAMPSIA (see Chap. 65).

Acute pulmonary edema is a well-recognized complication of preeclampsia-eclampsia, occurring with an overall frequency of 3 percent.[224] [225] The incidence is higher in women who are older, who are multiparous, and who have preexisting chronic hypertension. The majority of cases, approximately 70 percent, occur post partum. Multiple factors including cerebral dysfunction with massive sympathetic discharge, left ventricular dysfunction secondary to acute systemic hypertension, hypervolemia due to excessive colloid and crystalloid infusions, hypoalbuminemia secondary to renal losses, and disseminated intravascular coagulation may play a role in the pathogenesis. Invasive studies commonly reveal increased pulmonary capillary pressures, elevated cardiac index, and normal systemic vascular resistance, although hemodynamics consistent with pulmonary capillary leak have also been reported.[226] [227] Echocardiography may show normal, hyperdynamic, or depressed left ventricular systolic function with or without diastolic dysfunction.[228] The occurrence of pulmonary edema in obstetrical patients is associated with high maternal and perinatal morbidity and mortality.[225]

POST CARDIOVERSION.

Although pulmonary edema has been documented to occur after cardioversion,[229] the mechanism is poorly understood. Ineffective left atrial function immediately after cardioversion has been suggested as a contributing factor, yet left ventricular dysfunction[229A] and neurogenic mechanisms are also possible. Additional contributory factors may include underlying cardiac disease, cardiodepressant anesthetic agents, and pulmonary and/or cardiac emboli. One half of cases occur within 3 hours after cardioversion, and mortality has been reported to be as high as 18 percent.[229]

POST ANESTHESIA.

In previously healthy subjects, pulmonary edema has been found in the early postanesthesia period without a clear relationship to fluid overload or any subsequent evidence of left ventricular dysfunction.[230] The basis for this disorder is unknown, but proposed mechanisms include postanesthesia laryngospasm with marked negative intrathoracic pressure,[230A] hypoxia, and/or a hyperadrenergic state.

POST CARDIOPULMONARY BYPASS.

Although all patients who undergo cardiopulmonary bypass obviously have significant heart disease, the development of edema has been associated with normal left atrial pressures.[231] Alterations of surfactant due to prolonged collapse of the lung during the procedure, with subsequent need to apply high negative intrapleural pressures for reexpansion, and release of toxic substances including thromboxane have been suggested as mechanisms. Some data suggest that allergic reactions to fresh frozen plasma or protamine may account for some episodes.[231] The matter is far from settled, but the syndrome is fortunately rare.

HANTAVIRUS PULMONARY SYNDROME.

In Asia, hantaviruses are associated with hemorrhagic fever and renal disease. In 1993, an outbreak of severe respiratory illness occurred in the southwestern United States and was attributed to a newly described hantavirus.[232] The majority of patients affected were Native American. Prodromal symptoms included fever, myalgia, cough, dyspnea, and gastrointestinal symptoms. Most infected patients developed rapidly progressive noncardiogenic pulmonary edema associated with profound hypotension, with a case-fatality rate of 76 percent. Local T cells acting on the infected pulmonary vascular endothelium result in the production of cytokines, including interferon gamma and tumor necrosis factor-alpha, which may play an important role in the reversible increase in vascular permeability.[233]

Differential Diagnosis of Pulmonary Edema

The differentiation between the two principal forms of pulmonary edema, that is, cardiogenic (hemodynamic) and noncardiogenic (caused by alterations in the alveolar-capillary membrane), usually can be made through assessment of the clinical context in which it occurs and through examination and consideration of the clinical data as shown in Table 17-9 . Although this approach suggests an either/or situation, this may not be the case in reality. For example, sudden and large increases in intravascular pressure may disrupt the capillary and alveolar membranes leading to interstitial edema and alveolar loading with macromolecules that produce an edema liquid more compatible with noncardiogenic causes.[234] Thus, a primary hemodynamic event can cause an alveolar-capillary membrane leak. Furthermore, only mild elevations in capillary hydrostatic pressures in the presence of alveolar capillary damage can cause an increase in the rate and extent of edema formation. Therefore, hemodynamic factors can and do play a role in increasing and perpetuating increased permeability.

TABLE 17-9 -- INITIAL DIFFERENTIATION OF CARDIOGENIC FROM NONCARDIOGENIC PULMONARY EDEMA

	CARDIOGENIC PULMONARY EDEMA	NONCARDIOGENIC PULMONARY EDEMA
History		
Acute cardiac event	Usually	Uncommon (but possible)
Physical Examination		
Cardiac output state	Low-flow state (cool periphery)	High-flow state (warm periphery, bounding pulses)
S_3 gallop	Present	Absent
Jugular venous distention	Present	Absent
Crackles	Wet	Dry
Underlying noncardiac disease (e.g., peritonitis)	Usually absent	Present
Laboratory Tests		
Electrocardiogram	Ischemia/infarction	Usually normal
Chest x-ray	Perihilar distribution	Peripheral distribution
Cardiac enzymes	May be elevated	Usually normal
Pulmonary capillary pressure	>18 mm Hg	<18 mm Hg
Intrapulmonary shunting	Small	Large
Edema fluid/serum protein	<0.5	>0.7

Chapter 18 - Treatment of Heart Failure: Pharmacological Methods

MICHAEL R. BRISTOW
J. DAVID PORT RALPH A. KELLY

Pharmacological therapy for heart failure (HF) is divided into two distinct settings and approaches: treatment of *decompensated HF* and treatment of *chronic stable HF* (Table 18-1) . The goals of these two types of treatment are different, and part of the challenge of treating individual HF patients is the art of converting patients in the former category to the latter. In the treatment of patients with decompensated HF, the goals are to stabilize the patient clinically, restore organ perfusion, return filling pressure to optimal levels, and begin the conversion to chronic therapy. In contrast, the goals of treatment of patients with chronic stable HF are to enhance survival and minimize symptoms. As discussed below, diuretics, vasodilators, and positive inotropic agents are used for both purposes, while neurohormonal/cytokine inhibitors are primarily used to enhance survival.

TABLE 18-1 -- CLASSES OF DRUGS USED TO TREAT HEART FAILURE

DRUG CLASS	USE
Diuretics	
Carbonic anhydrase inhibitors (acetazolamide) Na+, K+, 2Cl-- cotransporter inhibitors ("loop" diuretics) Na+/Cl-- cotransporter inhibitors (thiazides) Epithelial Na+ channel inhibitors (triamterene, amiloride) Type I (mineralocorticoid/glucocorticoid) receptor antagonists (spironolactone) Vasopressin V_2 receptor antagonists Natriuretic peptides	DHF (IV), CSHF (p.o.) stage B-D (NYHA Class II-IV)
Vasodilators	
Nitrovasodilators "Directly acting" or unknown mechanism vasodilators Calcium channel blockers ATP-regulated K+ channel activators Vasodilator prostaglandins Natriuretic peptides Neurohormonal inhibitors	DHF (IV), CSHF (p.o.) stage B-D (NYHA Class II-IV)
Positive Inotropic Agents	
Digitalis derivatives Beta-adrenergic receptor agonists Phosphodiesterase inhibitors Phosphodiesterase inhibitors with calcium sensitizer action Pure calcium sensitizers	DHF (IV), CSHF (p.o.) stage B-D (NYHA Class II-IV)
Neurohormonal or Cytokine Inhibitors	
Renin-angiotensin-aldosterone inhibitors Antiadrenergic compounds Endothelin antagonists Neutral endopeptidase inhibitors Tumor necrosis factor-alpha inhibitors	CSHF (p.o. or other) stage A-D (NYHA Class I-IV)
Future/Novel Directions	
Gene therapy Pharmacogenomic-based therapy Novel molecular targets	No current indications

ATP=adenosine triphosphate; CSHF=chronic stable heart failure; DHF=decompensated heart failure; NYHA=New York Heart Association.

Diuretics

The importance of diuretics in the treatment of HF relates to the central role of the kidney as the target organ of many of the neurohumoral and hemodynamic changes that occur in response to a failing heart.[1] [2] [3] [4] The net effect of these physiological responses is an increase in salt and water retention, which results in expansion of the extracellular fluid volume. This effect is highlighted in Figure 18-1 , where the adrenergic and the renin-angiotensin (RAS) systems, two very important compensatory neurohormonal mechanisms that are activated in concert early in the course of HF, produce volume expansion. In the case of adrenergic mechanisms, volume expansion occurs via beta-adrenergic receptor-mediated nonosmotic release of vasopressin from the pituitary gland, and in the case of RAS mechanisms, volume expansion occurs through angiotensin II-mediated increases in aldosterone and vasopressin secretion and stimulation of thirst.[2] , [4] In the short-term, volume expansion serves to sustain cardiac output and tissue perfusion by allowing the heart to operate higher on the ventricular function (Frank-Starling) curve. However, these physiological adaptations also result in higher end-diastolic filling pressure and increased wall stress in diastole and systole, which contributes to hypertrophy and remodeling (see Chap. 16) and may cause dyspnea or even pulmonary edema.

With the exception of the aldosterone antagonist spironolactone (see p. 566), diuretics do not influence the natural history of chronic HF. However, diuretics improve congestive symptoms and may also slow the progression of ventricular remodeling by reducing ventricular filling pressure and wall stress. The acute effect of diuretics in patients with HF-related volume overload is to decrease left ventricular filling pressure without much change in cardiac output, because of the depressed and flat

Frank-Starling curve in these subjects as depicted in Figure 18-2 .

Figure 18-1 Hemodynamic and biological consequences of coordinated activation of the adrenergic and renin-angiotensin systems in heart failure.

Figure 18-2 Frank-Starling relationship for ventricular function in heart failure. In patients with heart failure, the normal relationship between cardiac output (y-axis) and filling pressure (x-axis) is shifted lower and to the right such that a low-output state and congestive symptoms may be coincident. At one extreme, the addition of a pure inotropic agent, such as digoxin, primarily increases stroke volume with minimal impact on filling pressure. Conversely, the addition of a diuretic primarily decreases filling pressure without having an impact on cardiac output. Clinically, it is common to use multiple classes of agents, or agents with combined effects, to produce both increased cardiac output and decreased filling pressure. (Adapted from Cohn JN, Franciosa JA: Vasodilator therapy of cardiac failure [first of two parts]. N Engl J Med 297:27-31, 1977.)

RENAL ADAPTATION TO HEART FAILURE (see also Chap. 72)

Increased salt and water retention by the kidney is due primarily to characteristic alterations in intrarenal hemodynamics that occur in response to decreased cardiac output. In addition, salt and water retention activates the adrenergic nervous system and several hormonal and cytokine systems (see Chap. 16) . A decrease in cardiac output results in increased peripheral and intrarenal vascular resistance, activation of intrarenal and other tissue vasoconstrictor systems such as endothelin, and release of arginine vasopressin (AVP, antidiuretic hormone) from the posterior pituitary gland. Increased adrenal cortical activity promotes aldosterone synthesis and release, while increased intraatrial and intraventricular pressure promotes the production and secretion of atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) in cardiac muscle.

INTRARENAL HEMODYNAMICS IN HEART FAILURE.

The changes in intrarenal hemodynamics that occur early in the course of HF result in preservation of the glomerular filtration rate (GFR) despite a decline in cardiac output and renal blood flow.[1] [2] [3] [4] Although increases in adrenergic activity and local release of angiotensin II act to increase resistance in both the afferent and efferent glomerular arterioles, preservation of the GFR is due in large part to a greater increase in efferent than in afferent arteriolar tone. Pressure differences across the glomerulus (P_{Gc}), and across the glomerular capillary membrane and Bowman's space (P_t) are two major determinants of single-nephron GFR. The other main determinants of single-nephron GFR are the glomerular membrane ultrafiltration coefficient (K_f), which tends to decline in HF, and differences between glomerular capillary and proximal tubular colloid osmotic pressure, which are usually unchanged in HF.

Maintenance of single-nephron GFR, despite a fall in renal blood flow and glomerular plasma flow, results in an increase in the fraction of renal plasma flow that is filtered by the kidney (i.e., the "filtration fraction"). This increase in the fraction of glomerular plasma flow, which alters the proximal tubule, leads to an increase in protein concentration and therefore in colloid osmotic pressure in the postglomerular,

peritubular capillaries since most proteins that contribute to oncotic pressure are not filtered by normal glomerular membranes. The increased filtration fraction also leads to an increase in hydrostatic pressure in the proximal tubule relative to the peritubular capillaries, which in addition to the increase in colloid osmotic pressure in this portion of the nephron, favors the reuptake of solute and water by the proximal tubule.

Besides their importance in mediating increased renal salt and water resorption in HF, these characteristic alterations in glomerular hemodynamics are often significantly affected by several classes of drugs used in the treatment of HF. The kidney's ability to autoregulate and sustain the GFR, despite a falling cardiac output in worsening HF, will be compromised by any drug that lowers mean arterial pressure. Therefore, the GFR may fall despite an increase in cardiac output after the administration of a vasodilator. The importance of efferent arteriolar tone to maintenance of the GFR in HF also means that administration of RAS antagonists may result in a decline in GFR in some patients despite clinically significant increases in cardiac output.

NEUROHORMONAL/CYTOKINE ACTIVATION.

In addition to these hemodynamic changes in the proximal nephron, increased renal sympathetic nerve activity activates the intrarenal RAS and has direct tubular effects that result in augmented salt retention along the nephron.[2] , [5] Activation of a local endothelin-1-generating system also occurs.[6] As a result of these renal vasoconstrictor influences, renal blood flow is directed away from superficial cortical nephrons to the more efficient solute-resorbing juxtamedullary nephrons. These nephrons rely on the high capacity of the ion transport carriers in the loop of Henle and the countercurrent mechanism of the medulla to allow the formation of concentrated urine. Elevated AVP levels cause further reductions in free water clearance by the kidney. This reduced clearance of free water, coupled with the increased thirst of many patients with advanced HF (perhaps caused by higher intracerebral angiotensin II levels), often leads to a hypotonic edematous state. As with other complex biological systems, countervailing intrarenal and humoral responses also occur, including increased prostaglandin E_2 and prostacyclin levels within the kidney and the release of humoral natriuretic factors, including ANP and BNP.[1] [4] [5]

MECHANISMS OF ACTION OF DIURETICS

By definition, a diuretic is any drug that increases urine flow. However, the term "diuretic" is commonly used to refer to agents that enhance the delivery of sodium chloride, other small ions, and water into urine. In this context, agents such as cardiac glycosides and dopamine may indirectly increase urine production by enhancing renal blood flow and the GFR, which promotes a fall in the glomerular filtration fraction and thereby diminishes water and solute resorption by the proximal tubule. Furthermore, endogenous substances such as ANP or BNP, when administered as drugs, may have salutary effects on cardiovascular function, as well as on intrarenal hemodynamics and tubular sodium resorption.

Most diuretics, however, act directly on the kidney to inhibit solute and water reabsorption. A number of classification schemes for diuretics have been proposed on the basis of their mechanism of action, their anatomical locus of action in the nephron, and the form of diuresis that they elicit. Diuretics can be classified according to whether they induce a "solute" or "water" diuresis. Of the latter ("aquaretics"), only three agents are of clinical relevance: demeclocycline, lithium, and vasopressin V_2 receptor antagonists, each of which, by different mechanisms, inhibits the action of AVP on the collecting duct, thereby increasing free water clearance. Drugs that cause solute diuresis are subdivided into two types: osmotic diuretics, which are nonresorbable solutes that osmotically retain water and other solutes in the tubular lumen, and drugs that selectively inhibit ion transport pathways across tubular epithelia, which constitute the majority of potent, clinically useful diuretics.

Since many of the specific ion transport proteins that are the molecular targets for diuretics have recently been cloned and their intrarenal distribution characterized, a new classification of these drugs based on their molecular pharmacology has been advocated.[6] This classification scheme, rather than the more traditional schemes, i.e., chemical classification (e.g., "thiazide" diuretic), site of action (e.g., "loop" diuretics), or efficacy and clinical outcome (e.g., "high-ceiling" and "potassium-sparing" diuretics), will be used throughout this chapter.

Functional Regions of the Nephron

PROXIMAL TUBULE.

Fluid resorption across the proximal tubule is isosmotic and accounts for approximately two-thirds of the resorption of filtered Na^+ and H_2O. Resorption of sodium bicarbonate from the tubular lumen is facilitated by the action of luminal and cytosolic carbonic anhydrase in proximal tubular epithelial cells. This substance raises the intraluminal chloride concentration and thereby allows further isosmotic resorption of NaCl along the proximal tubule. In addition to Na^+ , Cl^{--} , and HCO_3^{--} , this segment of the nephron resorbs most of the K^+ and two-thirds of the Ca^{2+} filtered at the glomerulus, as well as most of the inorganic phosphate.

Agents that alter intrarenal regulation of the formation of glomerular filtrate, such as renin-angiotensin antagonists, may enhance the delivery of solute and water to more distal segments of the nephron that are sensitive to diuretics that inhibit ion transport. Predictably, other drugs, such as nonsteroidal antiinflammatory drugs (NSAIDs), may diminish glomerular filtrate formation, thus reducing the flow of urine to distal diuretic-sensitive portions of the nephron. Many diuretics that are not freely filtered at the glomerulus obtain access to the tubular lumen by organic ion transport proteins in the distal *pars recta* portion of the proximal tubule.

THE LOOP OF HENLE.

About one-third of the glomerular filtrate arrives at the descending limb of Henle's loop; however, no active transport of solute occurs here. The tubular epithelium in Henle's loop is highly permeable to water, which leaves the nephron and passes into the hyperosmotic medullary interstitium. Most of the solute transport responsible for maintaining the hypertonicity of the medullary interstitium occurs in the urea- and water-impermeable thick ascending limb of Henle's loop. Here, the Na^+ /K^+ /$2Cl^{--}$ cotransporter, which resides in the luminal membrane, facilitates electroneutral ionic transport. The Na^+ /K^+ /$2Cl^{--}$ cotransporter is the "receptor" for loop diuretics (e.g., furosemide, bumetanide, torsemide, and probably ethacrynic acid).

Before reaching the distal convoluted tubule, the thick ascending limb of the loop of Henle passes near the afferent arteriole of its own glomerulus in a specialized epithelium known as the macula densa. These epithelial cells release locally acting autacoids that regulate afferent arteriolar tone and therefore glomerular perfusion pressure and the filtration fraction in accordance with the volume and solute concentration of the luminal fluid reaching this portion of the glomerulus (i.e., "tubuloglomerular feedback"). Drugs that inhibit the Na^+ /K^+ /$2Cl^-$ cotransporter in the epithelial cell of the macula densa, such as furosemide, ablate this "sensing" mechanism of the macula densa, thereby preventing a rapid feedback decline in the GFR despite large increases in solute delivery out of the loop of Henle.

DISTAL CONVOLUTED TUBULE AND COLLECTING DUCT.

Like the ascending limb of the loop of Henle, the distal convoluted tubule is impervious to water; therefore, luminal fluid is hypotonic. Na^+ - and Cl^- -facilitated transport is mediated by the thiazide diuretic-sensitive Na^+ /Cl^- cotransporter in the apical membranes of epithelial cells in this segment. Increased delivery of Na^+ and luminal fluid to the distal nephron, after the administration of furosemide or a thiazide diuretic, for example, directly enhances K^+ and H^+ secretion by this portion of the nephron. Importantly, the number and activities of the apical membrane epithelial Na^+ channels and H^+ ,K^+ -ATPase, as well as basolateral membrane Na^+ /K^+ -ATPase, are increased by the mineralocorticoid aldosterone.

CLASSES OF DIURETICS

Inhibitors of the Na+/K+/2Cl- Cotransporter (Loop Diuretics)

The agents traditionally classified as loop or high-ceiling diuretics, including furosemide, bumetanide, and torasemide (torsemide), have been known for over a decade to reversibly inhibit the Na^+ /K^+ /$2Cl^-$ symporter (cotransporter) when applied to the luminal, but not the basolateral membranes of epithelial cells of the thick ascending limb of the loop of Henle. A second functional class of these drugs, typified by ethacrynic acid, are also effective only from the tubule lumen but exhibit a slower onset of action and delayed and only partial reversibility. Individual agents that act as Na^+ /K^+ /$2Cl^-$ cotransporter inhibitors are listed in Table 18-2 .

The molecular targets of these drugs have recently been cloned and sequenced and were found to encompass a family of cation chloride symporters that have now been described in a number of cell types and tissues.[7] Within the

TABLE 18-2 -- COMMON DIURETICS USED IN THE TREATMENT OF CONGESTIVE HEART FAILURE

DIURETIC	BRAND NAME	PRINCIPAL SITE AND MECHANISM OF ACTION	EFFECTS ON URINARY ELECTROLYTES	EFFECTS ON BLOOD ELECTROLYTES AND ACID-BASE BALANCE	EXTRARENAL EFFECTS	USUAL DOSAGE* (mg/d)	DRUG INTERACTIONS
Carbonic Anhydrase Inhibitors							
Acetazolamide	Diamox	Proximal tubule	Na+, K+, HCO_3 --	Metabolic acidosis	Ventilatory drive	250-1000	May be useful in alkalemia caused by other diuretics
Dichlorphenamide	Daranide	Carbonic anhydrase inhibition			Intraocular pressure	25-200	
Methazolamide	Neptazane					100-300	
Na+/K+/2Cl-- Cotransporter Inhibitors (Loop Diuretics)							
Furosemide	Lasix	Thick ascending limb of the loop of Henle: Inhibition of the Na+/K+/2Cl-- cotransporter	Na+	Hypochloremic alkalosis HCO_3 -- K+, Na+ Cl--, Mg^{2+} Uric acid	Acute: Venous capacitance, systemic vascular resistance	20-360	Tubular secretion delayed by competing organic acids (renal failure) and some drugs
Bumetanide	Bumex		Cl--			0.5-20	
Ethacrynic acid	Edecrin				Chronic: Cardiac preload, ototoxicity	50-200	Additive ototoxicity with aminoglycosides
Torsemide	Demadex					10-200	Longer duration of action than furosemide
Na+/Cl-- Cotransporter Inhibitors (Thiazide and Thiazide-like Diuretics)							
Chlorothiazide	Diuril	Distal tubule: Inhibit Na+/Cl-- cotransporter	Na+, Cl--, K+	Na+, particularly in elderly patients	Glucose	500-2000	Efficacy reduced by prostaglandin inhibitors
Hydrochlorothiazide	Hydrodiuril				LDL/triglycerides (may be dose related)	25-50	
Chlorthalidone	Hygroton		Mg^{2+} , Ca^{2+}	Cl--, HCO_3 -- (mild alkalosis)		25-100	Additive effect on NaCl and K^+ excretion with loop diurectics

Metolazone	Mykrox Zaroxolyn			Uric acid, Ca^{2+} K+, Mg^{2+}		5-10	
Indapamide	Lozol					2.5-5	
Epithelial Na+ Channel Inhibitors (K+-Sparing Diuretics)							
Triamterene	Dyrenium	Collecting duct: Inhibit apical membrane Na+ conductance	HCO_3 --	GFR; metabolic acidosis		100-300	Useful when used with K+-wasting diuretics; may induce hyperkalemia with ACE inhibitors
Amiloride	Midamor			Mg^{2+}		5-10	
Type I Mineralocorticoid Receptor Antagonists (K+-Sparing Diuretics)							
Spironolactone	Aldactone	Collecting duct: Aldosterone antagonists	K+, Na+, Cl--	K+	Gynecomastia	25-200	Useful adjunct to K+ -wasting diuretics

Not yet licensed in the United States.

ACE=angiotensin-converting enzyme; GFR=glomerular filtration rate; LDL=low-density lipoprotein.

Vasodilator prostaglandins VENODILATION ARTERIOLAR DILATION

*Dosages are approximate (p.o.).

mammalian kidney, three alternatively spliced variants with approximately 60 percent overall amino acid homology have been described that encode proteins with 12 membrane-spanning domains and large cytosolic N-terminal and C-terminal regions. These cytosolic regions contain amino acid sequences that serve as potential sites of posttranslational modification, thereby resulting in the regulation of cotransporter activity within the tubular epithelial cell.

Inhibition of this cotransporter results in a marked increase in the fractional excretion of Na^+ and Cl^- and indirectly results in the fractional excretion of Ca^{2+} and Mg^{2+} . By inhibiting the concentration of solute within the medullary interstitium, these drugs also reduce the driving force for water resorption in the collecting duct, regardless of the presence of AVP; the decreased resorption of water in turn results in the production of urine that is nearly isotonic with that of plasma at the height of the diuresis. The delivery of large amounts of Na^+ and fluid to the distal nephron increases both K^+ and H^+ secretion, a process that is accelerated by aldosterone.

Na^+ /K^+ /2Cl^- cotransporter inhibitors also exhibit several characteristic effects on intracardiac pressure and systemic hemodynamics. An increase in venous capacitance and lowering of pulmonary capillary wedge pressure within minutes of a bolus infusion of intravenous furosemide (0.5 to 1.0 mg/kg) have been well documented in patients with congestive symptoms following acute myocardial infarction or in those with valvular heart disease.[8] [9] Some increase in pulmonary venous compliance probably occurs as well. Similar data, although not as extensive, have accumulated for bumetanide and torsemide.[10] Despite the fall in left ventricular end-diastolic filling pressure, systemic vascular resistance often increases acutely in response to loop diuretics, an effect that has been attributed to transient activation of the systemic or intravascular RAS. The net effect of these actions of cardiac function may contribute to some improvement in congestive HF systems. However, the potentially deleterious rise in left ventricular afterload reinforces the importance of initiating vasodilator therapy with diuretics in patients with acute pulmonary edema and adequate blood pressure.

All the rapid hemodynamic actions of Na^+ /K^+ /2Cl^- cotransporter inhibitors are attenuated in patients with chronic congestive HF. Although most of these effects have been attributed in the past to activation of the RAS by the kidney in response to a loop diuretic, with subsequent release of renal and intravascular prostaglandins, recent evidence indicates that these drugs have direct effects on endothelial cells and vascular smooth muscle. In in vitro experiments, furosemide stimulates the release of prostacyclin and endothelium-derived relaxing factor (EDRF, now known to be nitrogen oxide and related congeners) by increasing the release of vasoactive kinins, presumably after inhibition of Na^+ /K^+ /2Cl^- cotransporter function in endothelial cells in vitro.[11] Furosemide has also been shown to relax precontracted pulmonary venous rings by a direct effect on smooth muscle that was dependent on inhibition of vascular smooth muscle Na^+ /K^+ /2Cl^- cotransporter function in these cells.[12] Interestingly, this effect was apparent only on pulmonary venous, not arterial vascular tissue and was apparent in these in vitro studies only at drug concentrations achievable transiently after bolus infusions.[12]

Inhibitors of the Na+/Cl- Cotransporter (Thiazide and Thiazide-Like Diuretics)

This class of diuretic, of which chlorothiazide is the prototype, includes the first effective orally bioavailable diuretics with acceptable safety profiles to become widely used in clinical practice, and they supplemented the much more toxic mercurial diuretics in the 1950s. A number of these agents are now available for clinical use in the United States (see Table 18-2) . Although not all are technically benzothiadiazine derivatives, they are often collectively referred to as "thiazide" diuretics. The site of action of these drugs within the distal convoluted tubule has been identified at a molecular level as being the Na^+ /Cl^- cotransporter of the distal convoluted tubule.[13] It has 12 membrane-spanning domains and shares 60 percent amino acid homology with the Na^+ /K^+ /2Cl^- cotransporter of the ascending limb of the loop of Henle; however, it is insensitive to the effects of furosemide. This cotransporter (or related isoforms) is also present on cells within the vasculature and many cell types within other organs and tissues and may contribute to some of the other actions of these agents.

By blocking solute uptake in the distal convoluted tube, Na^+ /Cl^- cotransporter inhibitors prevent maximal dilution of urine, decrease the kidney's ability to increase free water clearance, and may contribute to the development of hyponatremia. Thiazides increase Ca^{2+} resorption in the distal nephron by several mechanisms, occasionally resulting in a small increase in serum Ca^{2+} levels. In contrast, Mg^{2+} resorption is diminished and hypomagnesemia may occur with prolonged use. Increased delivery of NaCl and fluid into the collecting duct directly enhances K^+ and H^+ secretion by this segment of the nephron and may lead to clinically important hypokalemia.

Inhibitors of Epithelial Na+ Channels (Potassium-Sparing Diuretics)

The apical (luminal) membranes of the principal cells of the late distal convoluted tubule and the cortical collecting duct contain Na^+ -selective channels that permit Na^+ entry from within the tubular lumen, driven by the electrochemical gradient established by Na,K-ATPase in the basolateral membranes of these cells.[14] The number of epithelial Na^+ channels available for entry into tubular epithelial membranes is regulated in part by mineralocorticoid levels. The activity (conductance) of these Na^+ channels appears to be regulated by both protein kinase A-mediated phosphorylation and guanosine triphosphate (GTP)-binding proteins (i.e., G_{alphal}). [15] Na^+ conductance by these channels is inhibited by *amiloride* and by *triamterene*, which subsequently diminishes the electrochemical potential for K^+ secretion into the urine. Thus, these agents, along with mineralocorticoid inhibitors (see below), are commonly referred to as "potassium-sparing" diuretics.

Neither amiloride nor triamterene is effective in achieving a net negative Na^+ balance when given alone. Amiloride and its congeners also inhibit Na^+ /H^+ antiporters in renal epithelial cells and in many other cell types, but only at concentrations that are higher than those used clinically. Both amiloride and triamterene affect cardiac repolarization, possibly by inhibiting delayed rectifier K^+ currents (I_K), and may exaggerate the prolonged repolarization observed with Singh-Vaughan Williams class IA antiarrhythmics[16] [17] (e.g., quinidine).

Inhibitors of Mineralocorticoid/Glucocorticoid Receptors (Spironolactone)

Spironolactone and its active metabolites canrenone and potassium canrenoate have been known for over two decades to competitively inhibit the binding of aldosterone to mineralocorticoid or type I receptors in many tissues, including epithelial cells of the distal convoluted tubule and collecting duct.[18] These cytosolic receptors are members of a "superfamily" of cytosolic proteins that are ligand-dependent transcription factors, which upon ligand binding translocate to the cell nucleus, where they bind to specific DNA sequences and regulate the transcription and synthesis of a number of gene products, including apical membrane Na^+ channels, H^+ ,K^+ -ATPase, and Na^+ ,K^+ -ATPase, among others.[19]

The spironolactone-bound type I receptor complex is inactive and diminishes K^+ and H^+ secretion by this portion of the nephron, particularly in patients with high plasma aldosterone levels, as in HF.[20] [20A] Hyperkalemia and, unusually, a metabolic acidosis may result from the use of these drugs. In addition, gynecomastia may be observed in male patients. It is now recognized that the molecular pharmacology of steroid receptors is complex and relatively poorly understood. Endogenous glucocorticoids appear to be the principal ligand for the type I "mineralocorticoid" receptor in most cell types, for example.[21] [22] Additional information may clarify the mechanism of some of the side effects of spironolactone and its metabolites, such as gynecomastia, as well as their potential beneficial effects in nonrenal tissue.

Recently, spironolactone has been shown to markedly decrease mortality in subjects with stage C, advanced HF,[23] as further discussed in the section on neurohormonal inhibitors.

VASOPRESSIN ANTAGONISTS

Increased levels of circulating AVP (antidiuretic hormone) contribute to the increased systemic vascular resistance and positive solute and water balance in patients with advanced HF.[24] Physiologically, a primary site of action of AVP is the renal collecting duct, where it acts to increase water permeability (see below); however, it is clear that AVP has a number of nonrenal effects on the cardiovascular and central nervous system and on blood coagulation.

Vasopressin receptors have been divided into V_1 and V_2 receptor subtypes, which exhibit different ligand-binding specificities. V_{1a} (vascular/hepatic) and V_{1b} (anterior pituitary) receptors, like angiotensin II (AT_1) and $alpha_1$ -adrenergic receptors, are coupled via the G_{alpha} q subtype of G proteins to activation of phospholipase C in the plasma membranes of vascular smooth muscle cells and other tissues. Stimulation of V_1 receptors results in vasoconstriction, platelet activation, glycogenolysis, and adrenocorticotropic hormone release, as well as stimulation of the transcription factors c-fos and c-jun, which ultimately results in cell growth. In contrast, V_2 receptors, found largely in distal nephron segments within the kidney, are coupled through stimulatory G_{alpha} s proteins to the stimulation of adenylyl cyclase activity, increased production of the second messenger cyclic adenosine monophosphate (cAMP), and activation of protein kinase A. By interrupting this phosphorylation cascade, V_2 -selective receptor antagonists inhibit recruitment of aquaporin-CD water channels,[25] amiloride-sensitive Na^+ channels, and urea transporters into the apical membranes of collecting duct epithelial cells. Therefore, the ability of the collecting duct to resorb water is reduced.

The prototypical orally bioavailable nonpeptide V_2 -selective antagonist is OPC-31260.[25] In general, this agent increases free water clearance, thereby increasing plasma osmolality as well as increasing the serum Na^+ concentration. A general consensus from studies in animal models with both the V_1 -selective antagonist OPC-21268[26] and OPC-31260[27] suggests that AVP contributes to the development of HF more through the actions of V_2 receptor-mediated fluid retention and less so through alterations in systemic hemodynamics.[28] More recently, other V_2 -selective antagonists such as WAY-VPA-985[29] or nonselective antagonists such as YM087[30] have been developed. In a clinical trial of WAY-VPA-985 in HF patients with dilutional hyponatremia, a significant increase in solute-free water clearance was demonstrated.[31] Clinical trials with YM087 are currently ongoing.

While the pharmacology of these drugs will undoubtedly prove to be complex in patients with HF, most of whom will be receiving other vasodilators and natriuretic aquatic drugs and in whom AVP levels will vary as a function of plasma osmolality and cardiac output among other factors, these agents may prove to be valuable adjuncts to the treatment of HF.

NATRIURETIC PEPTIDES (ANP AND BNP)

The contribution of the natriuretic peptides ANP, BNP, and related proteins, including urodilatin and fragments of the pro-ANP protein, to the physiological adaptations that accompany HF and their potential role in pharmacotherapy for this syndrome have been the subject of intensive research efforts by cardiovascular and renal pharmacologists in academia and by the pharmaceutical industry for more than a decade.[32] [33] Apart from C-type natriuretic peptide, which is synthesized in endothelial (and other) cells in a number of organs and tissues and has limited natriuretic activity, plasma levels of these peptides are increased in most patients with HF[34] and exhibit a direct natriuretic effect on the kidney.[35]

The natriuretic peptides act at both particulate (i.e., membrane-bound) guanylyl cyclase-linked (GC-A and GC-B or NPR-A and NPR-B) receptors and so-called clearance receptors (NPR-C) that are linked through inhibitory GTP-binding proteins to adenylyl cyclase or through stimulatory GTP-binding proteins to phospholipase C. For a complete discussion of the complex pharmacology of natriuretic peptides, the reader is referred to recent comprehensive reviews.[36] [37] Aside from actions that indirectly affect renal function, such as inhibition of AVP release by the pituitary, inhibition of aldosterone synthesis by adrenal zona glomerulosa cells, sympathoinhibitory effects, and relaxant effects on systemic vascular resistance and venous capacitance, natriuretic peptides directly affect renal solute and water homeostasis. Acting predominantly through guanylyl cyclase (GC-A and GC-B)-linked receptors, natriuretic peptides alter the hemodynamic forces regulating glomerular filtration and tubular Na^+ resorption, particularly in the distal nephron.

Infusions of ANP have been shown to cause afferent arteriolar dilation and efferent arteriolar constriction, which result in an increase in the GFR.[5] Even when infused at concentrations that do not affect the GFR, ANP induces natriuresis by inhibiting the resorptive capacity of the proximal tubular epithelium largely by inhibiting the actions of locally acting antinatriuretic agents such as angiotensin II and by augmenting the activity of intrarenal dopamine. In the distal nephron, particularly in the medullary portion of the collecting duct, there is evidence that natriuretic peptides acting through GC-A receptors decrease Na^+ influx from the tubular lumen through amiloride-sensitive epithelial Na^+ channels. The result is a natriuresis with minimal effect on urinary potassium excretion. ANP, which is likewise synthesized and released by vascular endothelial cells,[38] may also be important in regulating blood pressure, particularly during physiological stress. For example, the blood pressure of mice that have had their pro-ANP gene disrupted by gene-targeting techniques--and therefore have no detectable circulating ANP--is very sensitive to dietary salt intake.[39] Very little evidence has been presented for any clinically significant direct effect of ANP[40] or BNP[41] on ventricular function.

BRAIN NATRIURETIC PEPTIDE.

While ANP would appear to have a favorable pharmacological profile in HF, therapeutic trials with ANP have been disappointing because of its short biological half-life, end-organ resistance, the development of pharmacological tolerance, and undesirable hemodynamic effects.[42] [43] [44] [424A] However, results with BNP have been more promising.[44] [45] [46] When infused continuously into patients with HF, recombinant human BNP (hBNP, nesiritide, Natrecor) produces vasodilator and cardiac output-increasing effects[45] [46] Although BNP was natriuretic and diuretic in two studies,[44] [45] in another study, approximately half the subjects were resistant to the natriuretic effects of BNP. Moreover, the diuretic and natriuretic effects of BNP were either absent or not very pronounced in the two studies conducted in moderate or advanced HF.[45] [46] In addition, episodes of bradycardia noted previously with ANP have been observed with BNP.[46] It therefore appears that hBNP will be useful primarily as a vasodilator, and it continues to be evaluated in phase III trials.

NEUTRAL ENDOPEPTIDASE.

Since receptor-mediated clearance and metabolism by the zinc metallopeptidase neutral endopeptidase (NEP) are the two predominant mechanisms for natriuretic peptide inactivation and removal, two approaches have been taken to lengthening the biological half-life of endogenous and exogenously infused natriuretic peptides.[42] Analogs of ANP have been developed that bind to ANP-R_2 receptors with high affinity but exhibit little biological activity. Several classes of NEP inhibitors have also been developed that alone or in combination with ANP-R_2 antagonists induce natriuresis and delay the clearance of exogenously infused ANP. NEP antagonists have been shown to increase plasma ANP levels and induce natriuresis with little effect on potassium excretion in patients with HF. However, in limited clinical trials in patients with HF, NEP inhibitors had relatively little efficacy.[47] [48]

NEP-ACE INHIBITION.

The combination of an NEP antagonist with an angiotensin-converting enzyme (ACE) inhibitor has been shown to result in more sustained natriuretic effects than has

an NEP antagonist alone in experimental animal models of HF, in part because of the inhibition of angiotensin II-mediated effects but also because of the fact that both NEP and ACE degrade bradykinin, a vasodilatory and natriuretic peptide.[49] [50]

Some evidence has shown that ACE inhibition in HF patients may favorably affect the release and/or clearance of endogenous ANP, but not BNP, by resetting the relationship between ANP levels and atrial pressure, although confirmation will require additional studies.[51] With these actions in mind, single agents with dual metalloproteinase inhibitor activity (i.e., NEP and ACE inhibition) have been developed that address the mechanisms contributing to both pharmacological tolerance and end-organ resistance to natriuretic peptides in HF.[52] [53] Indeed, both renal (natriuresis) and humoral (decrease in renin) responses to omapatrilat are superior to an ACE inhibitor in subjects with HF.[54] Moreover, omapatrilat was compared with the ACE inhibitor lisinopril in two recently completed phase II trials, and the results are quite promising.[55] In fact, if the two medium-sized trials with omapatrilat are combined, a statistically significant reduction in mortality (by 28 percent) in comparison to 20 mg/day of lisinopril was noted.[55] It therefore seems likely that this form of therapy will prove to be useful in the treatment of chronic HF.

Carbonic Anhydrase Inhibitors

The representative of this class of agents is acetazolamide (Diamox), whose use as a diuretic in HF patients is confined

to temporary administration to correct the metabolic alkalosis that occurs as a "contraction" phenomenon in response to the administration of other diuretics.

DIURETIC RESISTANCE AND MANAGEMENT

Inhibitors of the Na^+ /K^+ /2Cl^- cotransporter (loop diuretics) have been the only class of diuretics that are effective as single agents in moderate and advanced HF. The rationale for this assumption was the magnitude of their maximal ("ceiling") natriuretic effect and the fact that the natriuretic effect of more distally acting drugs may be limited by the increased resorption of solute and water by proximal nephron segments in individuals with HF. However, even the effectiveness of potent loop diuretics can decrease with worsening HF. Although the bioavailability of these drugs is not generally decreased in HF, the potential delay in their rate of absorption may result in peak drug levels within the tubular lumen in the ascending loop of Henle that are insufficient to induce maximal natriuresis.[56] [57] Resorting to an intravenous formulation typically obviates this problem. However, even with intravenous dosing, a rightward shift of the dose-response curve is observed between the diuretic concentration in the tubular lumen and its natriuretic effect in HF; in addition, the maximal effect or "ceiling" is lower. This rightward shift has been termed "diuretic resistance" and can be due to several contributing factors.[58] A point of distinction is that diuretic resistance should be distinguished from "diuretic adaptation" or the "breaking" phenomenon that is observed even in normal subjects given multiple doses of a short-acting loop diuretic.[59]

Diuretic-induced alterations in intrarenal hemodynamics, caused by tubuloglomerular feedback and increased sympathetic nerve activity among other possible mechanisms (see below), result in avid renal sodium retention by all nephron segments as intraluminal drug levels decline. If dietary salt intake is sufficiently high, as in many Western diets, a daily net negative sodium balance may not be achieved despite several daily intravenous doses of a loop diuretic. *These data imply that salt intake must be restricted in normal subjects and particularly in patients with HF to obtain a negative sodium balance*. The data also indicate that short-acting diuretics, particularly furosemide and bumetanide, must be administered several times per day to obtain consistent daily salt and water loss unless dietary sodium intake is severely restricted. An alternative strategy in hospitalized patients is to administer the same daily parenteral dose of a loop diuretic by continuous intravenous infusion,[60] which leads to sustained natriuresis from the continuous presence of high drug levels within the tubular lumen. This approach requires the use of a constant-infusion pump but permits more precise control over the natriuretic effect achieved over time, particularly in carefully monitored patients. It also diminishes the potential for a too rapid decline in intravascular volume and hypotension, as well as the risk of ototoxicity in patients given large bolus intravenous doses of a loop diuretic. A typical continuous furosemide infusion is initiated with a 20- to 40-mg intravenous loading dose as a bolus injection, followed by a continuous infusion of 5 to 10 mg/hr for a patient who had been receiving 200 mg of oral furosemide (or 100 mg of intravenous drug) per day in divided doses.

Even in normal subjects with an Na^+ -restricted diet, the natriuretic effect of diuretics will decline with time; that is, a rightward and downward shift will been seen in the sigmoidal concentration-effect relationship as a result of the "braking phenomenon." This effect is now known to be due in large part to compensatory hypertrophy of the tubular epithelium distal to the site of action of the Na^+ /K^+ /2Cl^- cotransporter inhibitor, which increases the solute resorptive capacity of the kidney, as well as other adaptive mechanisms.[58] [61] In this context, Morsing and colleagues demonstrated that chronic and perhaps even acute treatment with loop diuretics causes rapid (60 minutes) upregulation of the thiazide-sensitive Na^+ /Cl^- cotransporter in the distal tubule (as measured by increased ^{3} H-metolazone binding). [61] In addition, many patients with HF also manifest some degree of renal impairment, which also shifts the diuretic concentration-effect relationship downward and to the right. While the maximum effect expressed as the fractional excretion of sodium may be unchanged in patients with some degree of intrinsic renal disease, the absolute natriuretic effect will be limited by the reduced filtered load of sodium into the remaining functional nephrons.

The cause of apparent resistance to diuretics in patients who initially achieve an acceptable natriuretic and diuretic response may be multifactorial, as indicated. In the absence of an abrupt decline in cardiac or renal function or noncompliance with either the drug regimen or dietary salt restriction, *the usual reason for diuretic resistance is the concurrent administration of other drugs*. In this regard, one of the biggest offending classes of agents is NSAIDs, which reduce renal function by decreasing the renal synthesis of vasodilator prostaglandins.[62] All NSAIDs, including aspirin, can diminish diuretic efficacy. Rarely, drugs such as probenecid or high plasma concentrations of some antibiotics may compete with the organic ion transporters in the proximal tubule responsible for the transfer of most diuretics from the recirculation into the tubular lumen.

The use of increasing doses of vasodilators, with or without a marked decline in intravascular volume as a result of concomitant diuretic therapy, is a common cause of diuretic resistance. It is often difficult to clinically distinguish between intravascular volume depletion following aggressive diuretic and vasodilator therapy and a decrease in cardiac output caused by primary HF, although a more marked decline in urea clearance than in creatinine clearance suggests intravascular volume depletion. Pulmonary arterial and venous or left atrial pressure monitoring may be required to make this distinction. In addition, all vasodilators commonly used as afterload-reducing agents in HF dilate a number of central and peripheral vascular beds. Therefore, renal blood flow may be reduced despite an increase in cardiac output, and the effectiveness of the diuretic declines. Vasodilator therapy also may lower renal perfusion pressure below that necessary to maintain normal autoregulation and glomerular filtration in patients with renal artery stenosis from atherosclerotic disease.

Treatment of Diuretic Resistance

Among the vasodilators, RAS antagonists can uniquely augment the effectiveness of diuretics by mechanisms that are independent of their ability to reduce systemic vascular resistance (see below).[63] However, by reducing efferent arteriolar tone, these drugs may also diminish diuretic effectiveness by reducing the transglomerular perfusion pressure to the point that the GFR declines abruptly. This response is most commonly observed in patients with decreased renal arterial perfusion pressure caused either by renal artery stenosis or by limited cardiac output; in these patients, high efferent arteriolar tone mediated by angiotensin II is necessary to maintain glomerular filtration. This cause of diuretic resistance is usually characterized by an abrupt rise in the serum creatinine concentration and should be distinguished from the more common, limited increases in serum creatinine levels that often accompany initiation of ACE inhibitor therapy. In addition to ACE inhibitors, the $alpha_1$ -adrenergic antagonist prazosin has been shown to have direct tubular action in reducing sodium resorption at doses below those necessary to lower arterial pressure (e.g., 0.50 mg).[64]

With a cardiac output and mean arterial pressure adequate to sustain autoregulation of glomerular filtration, diuretic resistance can be managed by increasing the frequency

of loop diuretic dosing or by switching to a continuous intravenous infusion. If this treatment is ineffective, concomitant administration of a more distally acting diuretic, usually an Na/Cl symport inhibitor (e.g., a thiazide or thiazide-like diuretic such as intravenous chlorothiazide or oral metolazone), will usually result in substantial natriuresis.[58] [65] [66] While effective, this diuretic combination may cause profound intravascular volume depletion, hypotension, renal potassium wasting, hyponatremia, and eventually a fall in cardiac output and GFR. Accordingly, this combination should be used cautiously and with careful monitoring of renal function and serum potassium and sodium, especially in outpatients. A type I mineralocorticoid receptor antagonist (e.g., spironolactone) may also be capable of increasing the diuretic effectiveness of more proximally acting diuretics, although patients are at increased risk for hyperkalemia if they are concomitantly receiving another renin-angiotensin-aldosterone system (RAAS) antagonist. Despite this possibility, to reduce the oral KCl requirement and to maintain potassium serum levels well in the normal range, most subjects receiving large doses of loop diuretics or loop diuretics plus thiazides benefit from a potassium-sparing diuretic. If tolerated, spironolactone should be the potassium-sparing diuretic used because of its mortality-reducing effects.

In hospitalized patients, as discussed below, dopamine administered at doses that cause selective dopaminergic receptor stimulation may increase renal blood flow and decrease tubular solute resorption (i.e.,
2 mug/kg/min, based on estimated lean body weight). Assuming that it will ultimately be approved by the Food and Drug Administration (FDA), in some subjects a short-term infusion of hBNP may be beneficial. In addition, selective V_1 and V_2 vasopressin receptor antagonists, once approved, may individually or in combination increase the efficacy of Na^+ /K^+ /2Cl^- symporter inhibitors based on experimental animal data and preliminary evidence in humans. Finally, mechanical circulatory support may become necessary in patients with marginal cardiac output for diuretics to be effective, particularly in patients recovering from cardiac surgery or myocarditis or as a "bridge" to transplantation. Discrete renal arterial stenoses that limit renal blood flow and systemic vasodilator therapy may be amenable to percutaneous angioplasty in patients with adequate cardiac output and diuretic resistance from marginal renal perfusion.

Electrolyte and Metabolic Disorders in Heart Failure: Complications of Diuretic Therapy

POTASSIUM HOMEOSTASIS.

All the diuretics discussed in this chapter, with the possible exceptions of V_2 vasopressin receptor antagonists and hBNP, affect renal K^+ handling.[66] [67] In patients with chronic HF, both hypokalemia caused by K^+ -wasting diuretics and hyperkalemia caused by K^+ supplements administered with a K^+ -sparing diuretic or an RAS antagonist may contribute to morbidity and mortality. Renal K^+ losses from diuretic use can be exacerbated by the hyperaldosteronism characteristic of patients with untreated HF and by the persistent chloride depletion and metabolic alkalosis that follow chronic use of Na^+ /K^+ /2Cl^- cotransporter inhibitors. The level of dietary salt intake may also contribute to the extent of renal K^+ wasting with diuretics. High-salt diets increase delivery of NaCl to distal tubular K^+ secretory sites, while very low salt diets may stimulate aldosterone-induced K^+ secretion. Extrarenal regulators of the serum K^+ concentration may also produce effects additive to renal losses of K^+ , such as the shift of K^+ into cells accompanying the release of epinephrine in response to stress, myocardial ischemia, pulmonary edema, or the administration of insulin, regardless of whether glucose is given concurrently. Long-term infusion of heparin, conversely, reduces aldosterone synthesis and may cause hyperkalemia, particularly in patients with insulin-dependent diabetes and in patients receiving potassium replacement and/or potassium-sparing drugs.[67] Importantly, any beta-agonist or phosphodiesterase inhibitor (PDEI) will lower potassium levels by shifting potassium into skeletal muscle, which is a $beta_2$ -adrenergic/cAMP pathway effect.[68] [69]

Despite the absence of conclusive data to determine whether routine administration of K supplements and/or K-sparing diuretics reduces serious morbidity or mortality in the treatment of patients with either primary hypertension or chronic HF, it is recommended that serum K^+ be maintained between 3.5 and 5.0 mEq/L.[70] [71] However, for patients with HF, the recommendation is to maintain serum K^+ between 4.3 and 5.0 mEq/L. One of the reasons for the higher serum K^+ is that HF subjects are often being treated with agents in which the proarrhythmic effects are exacerbated by hypokalemia, including digoxin, type III antiarrhythmics, and beta-agonists or PDEIs. Since chronic HF patients are at much higher risk for malignant ventricular arrhythmias and sudden death than are hypertension patients, it is sound clinical practice to monitor K^+ levels frequently and maintain them well up in the normal range.

The metabolic consequences of diuretic therapy must be established from limited and potentially biased data. Despite this limitation, the majority of the data that are available, much of it obtained from retrospective or subgroup analysis of clinical trials evaluating diuretic use in hypertension, are reassuring.[70] [71] Even when thiazide diuretic use was associated with a higher risk of primary cardiac arrest in a retrospective, case-control study, concomitant administration of a potassium-sparing diuretic lowered this risk below that of control patients receiving a beta-adrenergic antagonist.[71]

If supplementation is necessary, oral K supplements in the form of KCl extended-release tablets or liquid concentrate should be used whenever possible. Intravenous K is potentially hazardous and should be avoided except in emergencies. The routine use of "sliding scales" for intravenous K administration in hospitalized patients is also potentially dangerous and should be discouraged.

OTHER METABOLIC AND ELECTROLYTE DISTURBANCES.

Diuretics may be associated with multiple other metabolic and electrolyte disturbances, including hypomagnesemia, hyponatremia, metabolic alkalosis, hyperglycemia, hyperlipidemia, and hyperuricemia.[72] None of these disturbances are limiting in the usual patient with HF. Hypomagnesemia can be caused by both loop and thiazide diuretics, but its detection (because of the poor correlation of total serum magnesium levels with either ionized levels or total-body stores) is difficult and its impact is uncertain. Magnesium replacement should be given for signs or symptoms that could be due to hypomagnesemia (arrhythmias, muscle cramps), and it can be routinely given (with uncertain benefit) to all subjects receiving large doses of diuretics or requiring large amounts of K^+ replacement. Hyponatremia is usually a manifestation of advanced HF with very high degrees of activation of the vasopressin system and/or inadequate RAS inhibition. Hyponatremia can typically be treated by more stringent water restriction and/or an increase in RAS inhibition. Once V_2 receptor antagonists are available as diuretics, this problem will probably be eliminated.

Metabolic alkalosis can generally be treated by increasing KCl supplementation, lowering diuretic doses, and/or transiently treating with acetazolamide as discussed above. The small level of glucose intolerance and/or hyperlipidemia produced by thiazide diuretics is not usually clinically important, and blood glucose and lipids should be controlled according to standard guidelines regardless of the presence of any perceived diuretic effect. Hyperuricemia from thiazide diuretics is occasionally a problem and may precipitate gout, particularly in predisposed subjects or in the presence of renal dysfunction. If a thiazide diuretic is absolutely necessary in such patients, allopurinol can be administered to reduce uric acid synthesis.

Vasodilators

The rationale for the use of vasodilators grew out of experience with parenteral sympatholytic agents and nitroprusside in patients with severe HF. Cohn and Franciosa, in an influential 1977 article, reviewed the evidence and advocated the use of these drugs in decompensated HF.[73] As originally conceived, the pharmacological rationale for the use of vasodilators in HF was purely hemodynamic and based on the application of Ohm's law to blood flow: Flow=DeltaP/R, where DeltaP is the difference between arterial and venous pressure and R is resistance across the vascular bed. Since systemic vascular resistance is usually increased in HF as a result of neurohormonal activation, vasodilation of resistance vessels will increase central cardiac output and flow to some organs. Figure 18-1 illustrates this point: Activation of the adrenergic and RAS systems results in multiple effects that are detrimental to the natural history of HF, including vasoconstriction.

Vasoconstriction serves the short-term purpose of redistributing blood flow to the brain and the heart because these organs exhibit autoregulatory control of flow. When neurohormonal-mediated vasoconstriction occurs in peripheral vascular beds, the brain and heart, the first priorities in the homeostatic hierarchy, will receive redistributed flow because their resistance vessels are maximally vasodilated as a result of local regulation. This short-term strategy is effective for dealing with trauma and blood loss, but because the function of important organs such as the kidney, skeletal muscle, liver, and splanchnic beds is ultimately compromised, this strategy is not the optimal way to deal with the blood flow compromise associated with chronic HF. Thus, the vasodilator approach to treating HF was and is well grounded in targeting the correction of a basic abnormality afflicting patients with HF.

VENTRICULAR-VASCULAR COUPLING.

As described in Chapters 14 and 15 , myocardial function is dependent on loading conditions. From the point of view of the ventricles, *afterload* is the force opposing contraction and *preload* is the amount of stretch applied to ventricular myocardium before contraction. Vasodilator-mediated arteriolar relaxation reduces vascular resistance, which is a major component of afterload.[74] From a biomechanical point of view, the circulatory system is defined by *ventricular-vascular coupling*. [75] The force ejecting blood from the ventricle is known as end-systolic elastance, a load-independent measure of contractility, and the force resisting ejection of blood is termed vascular elastance. When end-systolic elastance overcomes vascular elastance, blood is ejected as stroke volume. For a given end-diastolic volume, the major determinants of the size of the stroke volume are the velocity of shortening of ventricular contraction and the amount of vascular elastance.[76] For the left ventricle, systemic vascular resistance is a major component of vascular elastance.[77] From these relationships it is obvious that stroke volume can be increased by increasing the velocity of shortening (positive inotropic effect) or by decreasing systemic vascular resistance (vasodilator effect) to overcome the abnormal respective decreases and increases in these parameters inherent in HF resulting from systolic dysfunction.

EFFECTS ON DIFFERENT VASCULAR BEDS.

An extremely important aspect of vasodilator use in chronic HF is that the potential exists to affect different types of vascular beds. The original concept of vasodilator use was based on small arteriolar dilatation since this is the biggest contribution to systemic vascular resistance. However, perhaps even more important is the ability of certain classes of agents to effect venodilation of "capacitance" vessels, which will reduce venous return by enlarging the effective blood volume reservoir and will therefore reduce end-diastolic, pulmonary, and systemic venous pressure. The clinical consequence of this reduction in preload is to reduce pulmonary and hepatic congestion and, more importantly, diastolic wall stress. As described in Chapter 21 , increased wall stress is a major signaling pathway for hypertrophy and other changes in gene expression that are important in producing the dilated cardiomyopathy phenotype of ventricular dilatation and systolic dysfunction. Since a chronically failing heart is usually operating on a flat portion of the preload-performance relationship (see Fig. 18-2), pharmacological reduction in preload will not ordinarily reduce cardiac output in that setting, but it may do so in acute situations. The hemodynamic consequences of alterations in preload and afterload by vasodilators are described in Figure 18-2 , and the vasodilator profiles of individual agents or classes are given in Table 18-3 .

V-HEFT-I.

Studies of vasodilators in the 1980s demonstrated that they were well tolerated and effective in improving symptoms in patients with HF. These short-term trials eventually led to the first mortality-based clinical trial in chronic HF, V-HeFT-I (Vasodilator HF Trial).[77] V-HeFT-I was a comparison of the alpha$_1$ -adrenergic receptor blocking agent prazosin, the combination of isosorbide dinitrate and hydralazine, and placebo for their effects on total mortality.[78] In this trial, prazosin was not different from placebo, but isosorbide dinitrate-hydralazine reduced mortality at 2 years by 34 percent ($p < 0.03$) but did not reduce mortality over the entire period of follow-up by the log-rank test ($p=0.09$). Based on these statistically marginal results (because of a relatively underpowered sample size as opposed to an inadequate effect size), the FDA has not approved the hydralazine-isosorbide dinitrate combination for the treatment of HF.

V-HeFT-I served to introduce the idea that the natural history of HF could be favorably influenced by medical therapy, and it also provided strong support to the vasodilator approach to treating HF. However, subsequent clinical trials with "pure" (i.e., that are not also neurohumoral inhibitors) vasodilating agents have not demonstrated a reduction in mortality, and in fact, the powerful vasodilators flosequinan[79] and epoprostenol[80] markedly (by respective values of 43 and 29 percent) *increased mortality* despite salutary effects on exercise tolerance in smaller studies.[81] [82] [83] Therefore, vasodilation per se is not a particularly effective method for improving the natural history of chronic HF, but it is an important strategy for dealing with acute, decompensated HF.

NITROVASODILATORS

Despite the fact that nitrovasodilators are among the oldest vasodilators in common clinical practice, the cellular mechanisms by which these drugs lead to the relaxation of vascular smooth muscle has only become apparent since 1990. It is now understood that these drugs mimic the activity of nitric oxide and its congeners. These autocrine and paracrine signaling autacoids are formed in endothelial and smooth muscle cells throughout the vasculature, as well as in many other cell types, including cardiac muscle cells[84] [85] [86] (see also Chap. 34) . Nitrogen oxides were originally identified as the bioactive factor(s) ("EDRF") responsible for endothelium-dependent relaxation of blood vessels.[87] Their primary mechanism of action in vascular smooth muscle cells is based on their ability to bind to a heme moiety in soluble guanylyl cyclase, with a subsequent increase in intracellular cyclic guanosine monophosphate. The pharmacological activity of each of the nitrovasodilators

TABLE 18-3 -- PROFILE OF VARIOUS VASODILATOR CLASSES FOR PRODUCING VENOUS OR ARTERIOLAR DILATION

CLASS/COMPOUND	VENODILATION	ARTERIOLAR DILATION
Nitrovasodilators	+++	+
Hydralazine	+	+++
Flosequinan	++	+++
Calcium channel blockers	+	+++
K+ channel activators	++	+++

Vasodilator prostaglandins	+++	++
Natriuretic peptides	++	+
Neurohormonal inhibitors	++	+

depends on their biotransformation into nitrogen oxides within the blood and vascular tissue.[84]

Nitroprusside

Intravenous nitroprusside is an effective venous and arterial vasodilator and acts to reduce both ventricular preload and afterload. Because of the fact that it is quickly metabolized to cyanide and nitric oxide, its onset of action is rapid and upward titration can usually be achieved expeditiously to produce an optimal and predictable hemodynamic effect. For these reasons, nitroprusside is commonly used in intensive care settings for the management of acutely decompensated HF when blood pressure is adequate to maintain cerebral, coronary, and renal perfusion. Nitroprusside has balanced effects on afterload and preload, and ventricular filling pressures are rapidly reduced by an increase in venous compliance.[88]

Nitroprusside is among the most effective afterload-reducing agents because of its spectrum of vasodilating activity on different vascular beds. It reduces systemic vascular resistance, increases aortic wall compliance, and at optimal doses, improves ventricular-vascular coupling. Nitroprusside also decreases pulmonary vascular resistance, as well as improves other components of right ventricular afterload, including the amplitude and timing of reflected pressure waves during ejection.[89]

Hydrocyanic acid and cyanide are byproducts of the biotransformation of nitroprusside. However, cyanide toxicity is uncommon because cyanide is rapidly metabolized by the liver to thiocyanate, which is cleared by the kidney. Thiocyanate and/or cyanide toxicity may occur in the presence of hepatic or renal failure and after prolonged infusions of nitroprusside in patients with marginal cardiac output or passive congestion of the liver. Thiocyanate toxicity, which is more common in patients with renal insufficiency, should be suspected in any patient receiving this drug who has unexplained abdominal pain, mental status changes, or convulsions. Clinical manifestations of cyanide toxicity are more subtle in onset and are usually manifested as a decline in cardiac output accompanied by metabolic acidosis from the accumulation of lactic acid.

Nitroprusside should not be used in active ischemia because its powerful intramyocardial afterload-reducing effects may "steal" coronary blood flow from segments of myocardium supplied by epicardial vessels with high-grade lesions.[90] This phenomenon is probably the reason why nitroprusside increased mortality in an acute myocardial infarction study.[91] In the setting of ischemia, any indicated vasodilator therapy should be delivered by organic nitrates, which are less powerful intramyocardial afterload reducers than nitroprusside is and which produce greater epicardial vasodilation.

Organic Nitrates and Molsidomine*

The organic nitrates and molsidomine are powerful venodilators and mild arteriolar vasodilators and produce the most extensive epicardial coronary vasodilation of any class of vasodilator. Because of their relatively selective vasodilating effects on the epicardial coronary vasculature, organic nitrates may directly increase systolic and diastolic ventricular function by improving coronary flow in patients with ischemic cardiomyopathy, in addition to their activity in reducing ventricular filling pressure, wall stress, and oxygen consumption.[92] In acute myocardial infarction, however, the effect of the routine use of nitrovasodilators on mortality remains controversial.[93] [94]

Experience with the newer nitrovasodilators, including isosorbide mononitrates and molsidomine, in the treatment of HF is limited in comparison to their use in the treatment of angina. Molsidomine, after formation of its active metabolite linsidomine (SIN-1) in the liver, does not require the intermediate biotransformation with sulfhydryl groups needed to form nitric oxide in vascular smooth muscle that is required of organic nitrates. Molsidomine given intravenously or orally is effective in reducing systemic vascular resistance, pulmonary capillary wedge pressure, and right atrial pressure.[95] Tolerance to the arteriolar and venular vasodilating effects of molsidomine does develop, although its extent and time course may differ from that of tolerance associated with organic nitrates. The spectrum of activity of 5-isosorbide mononitrate would not be expected to differ from that of isosorbide dinitrate in HF. Although isosorbide mononitrate's greater bioavailability and longer elimination half-life may provide a convenient pharmacokinetic profile, only isosorbide dinitrate among the nitrate formulations has been shown to increase exercise tolerance[96] and, in combination with hydralazine, may have prolonged survival in patients with HF.[77]

TOLERANCE.

The main problem with longer-term (>24 hours) use of organic nitrates and molsidomine is the development of tolerance (see Chap. 37) . Rapid development of tolerance to the venous and arteriolar dilating effects of organic nitrates has been known for over a century.[97] While well documented, the mechanism(s) responsible for nitrate tolerance are not clearly understood. It is likely that several mechanisms contribute to decreased responsiveness to nitrovasodilators with time and that the importance of the relative contribution of each potential mechanism differs with the specific drug used, the underlying disease (HF vs. angina), and the specific vascular bed.[97]

Most of the data on the efficacy of intermittent versus continuous nitroglycerin dosing protocols have been obtained in patients with angina rather than chronic congestive HF symptoms.[98] Indeed, it is somewhat controversial whether HF patients should be exposed to a long nitrate-free period. Nevertheless, it seems prudent to recommend nitrate-free intervals in patients receiving chronic doses of isosorbide dinitrate, which can usually be achieved by providing the last dose of isosorbide dinitrate in the early evening.

"DIRECTLY ACTING" AND OTHER VASODILATORS (see also Chap. 29)

Hydralazine

Hydralazine, an effective afterload-reducing agent whose cellular mechanism of action remains poorly understood, is best used in chronic HF when combined with isosorbide dinitrate to provide more effective venodilation.[77] This combination produces a more balanced form of vasodilation, and in addition, some evidence indicates that hydralazine can attenuate nitrate tolerance.[99] In HF, hydralazine reduces right and left ventricular afterload by reducing systemic as well as pulmonary artery input impedance and vascular resistance.[100] Unlike the use of hydralazine to treat hypertension, this reduction in afterload is usually accompanied by only minor reflex increases in sympathetic nervous system activity unless symptomatic hypotension occurs. These hemodynamic changes result in an increase in forward stroke volume and reductions in ventricular systolic wall stress and the regurgitant fraction in mitral or aortic regurgitation. Hydralazine's effects on regional blood flow consist of an increase in renal and skeletal muscle blood flow.[101]

One of the problems with the use of hydralazine is its short half-life, which necessitates dosing four times daily. In addition, side effects that may necessitate dose adjustment or withdrawal of hydralazine therapy are common. For example, in the V-HeFT-I Trial, 20 percent of patients complained of symptoms that could have been related to hydralazine. The most common complaints--headache and dizziness--could also have been due to the concomitantly administered nitrates. However, with time, the symptoms diminish or respond to a reduction in dose.

Hydralazine metabolism is primarily via hepatic acetylation, although many additional potential metabolic pathways

have been described.[102] Therefore, patients with a "slow-acetylater" phenotype will have a prolonged elimination half-life of the drug. At the usual doses and dosing intervals of hydralazine, these patients are at greater risk of arthritis or other components of a lupus-like syndrome.

Because of the somewhat equivocal results of hydralazine-isosorbide dinitrate in V-HeFT-I[100] and the superiority of the ACE inhibitor enalapril to this combination in V-HeFT-II,[103] hydralazine-isosorbide dinitrate is reserved for subjects who cannot tolerate ACE inhibitors or who have need for additional afterload reduction (blood pressure remaining high normal or greater in the face of full-dose ACE inhibition). Another potential use for hydralazine-isosorbide dinitrate is in American blacks, who in V-HeFT-II had better clinical responses to the combination than to enalapril.[104]

Flosequinan

Flosequinan is a powerful balanced vasodilator with an unknown mechanism of action that was FDA approved briefly for the treatment of HF and then withdrawn from the market by the sponsor because of a substantial increase in mortality[79] in a study that was not completed at the time of approval. Although flosequinan has weak positive inotropic effects in isolated human heart preparations,[105] the major pharmacological property of this compound is vasodilation. The flosequinan "story" is described here because of its multiple important lessons in HF therapy and drug development.

The hemodynamic effects of flosequinan are sustained[106] and associated with a consistent and impressive increase in maximum exercise tolerance.[81] [82] Although flosequinan produced an excess of deaths when compared with placebo in medium-sized phase III trials,[81] [82] this result was initially disregarded because it was not statistically significant and the agent's vasodilator class was not thought to confer high risk for increasing mortality. However, the Prospective Randomized Flosequinan Longevity Evaluation (PROFILE) mortality trial[79] confirmed the increased mortality, with a nearly identical percent increase in death in comparison to placebo as occurred in the exercise trials.[81] [82] In retrospect, one clue to the mortality-enhancing potential of flosequinan was its positive chronotropic effects in that the drug increased the resting heart rate by an average of 7 beats/min in earlier phase II and III trials. In general, compounds that increase the heart rate increase mortality and vice versa.[107]

The clinical trial results with flosequinan demonstrated that sustained vasodilation without concomitant neurohormonal antagonism has an adverse, rather than favorable effect on the natural history of HF. This observation, coupled with the results of V-HeFT-II,[103] spelled the end of the "vasodilator era" of therapy for chronic HF. Moreover, the flosequinan results, combined with the adverse survival results seen with higher doses of inotropic agents, ended the pure hemodynamic approach to the treatment of HF or the notion that simple pharmacological correction of hemodynamic abnormalities would improve the natural history.[108]

Calcium Channel Antagonists

Although all three classes of calcium channel antagonists (i.e., phenylalkylamines such as verapamil; benzothiazepines such as diltiazem; and dihydropyridines such as nifedipine, nitrendipine, felodipine, nicardipine, isradipine, or amlodipine) are effective arteriolar vasodilators, none has been shown to produce sustained improvement in symptoms or natural history in HF patients with predominant systolic ventricular dysfunction. Indeed, some of these agents appear to worsen symptoms and may increase mortality in patients with systolic dysfunction.[109] The reason for these adverse effects or lack of efficacy of calcium channel blockers in HF is unclear. It may be related to the known negative inotropic effects of these drugs, to reflex neurohumoral activation, or a combination of these and other effects.

Second-generation calcium channel antagonists of the dihydropyridine class, such as amlodipine, nicardipine, and felodipine, have fewer negatively inotropic effects than do earlier drugs of this class as a result of their higher degrees of vasoselectivity. All three have recently been evaluated in medium or large-scale randomized trials.[110] [111] [112] In V-HeFT-III,[110] felodipine and, in the Prospective Randomized Amlodipine Survival Evaluation (PRAISE) Study,[111] amlodipine did not increase mortality, thus indicating that these agents and probably nicardipine[112] are safe for use in treating angina in subjects with HF.

K+ CHANNEL ACTIVATORS

K^+ channels are composed of diverse families of integral plasma membrane proteins, the K^+ conductance of which is specific to each family. [113] K^+ channels are regulated by a number of mechanisms, including changes in transmembrane voltage, intracellular Ca^{2+} activity, intracellular adenosine triphosphate (ATP) levels, and other mechanisms.[114] [115] The distribution of K^+ channel isoforms is tissue and cell type specific, [116] which permits the possibility of relatively selective tissue pharmacological activity of drugs acting on a specific family of K^+ channels. In vascular smooth muscle, increased outward K^+ conductance causes cellular hyperpolarization and decreased Ca^{2+} entry, thereby resulting in vasorelaxation. Diazoxide and minoxidil, classic "directly" acting vasodilators, are now known to act at ATP-regulated K^+ channels.

Nicorandil*, pinacidil,* and cromakalim* are representatives of a new class of ATP-regulated K^+ channel activators that exhibit a unique spectrum of activity among vasodilator drugs. Like minoxidil, nicorandil is primarily an arteriolar vasodilator, but it is also effective in dilating epicardial coronary arteries and in reducing preload in experimental animals and patients with HF.[117] Nicorandil, pinacidil, and cromakalim have been tested in humans, primarily for hypertension and angina, and are effective and relatively well tolerated with fewer adverse effects than seen with the older vasodilators of this class. In addition, ATP-regulated K^+ channel activators may have cardioprotective effects in terms of preventing ischemic damage.[118] More recently, the calcium-sensitizing inotrope-vasodilator levosimendan, which is in phase III HF clinical trials in both intravenous and oral form, has been shown to be an activator of ATP-regulated K^+ channels at higher doses (see below).

The experience to date with these agents in patients with HF has not been extensive. Unlike nitrovasodilators, tolerance to nicorandil has not been observed in angina studies.[119] As with any novel class of vasodilator, the utility of nicorandil and other ATP-regulated K^+ channel activators must await the design and completion of large controlled efficacy and survival trials.

Vasodilator Prostaglandins

Prostaglandins are biologically active eicosanoids that produce either vasodilation (e.g., prostaglandin E_1 , prostacyclin) or vasoconstriction (e.g., thromboxane). One of them, prostacyclin (epoprostenol), has been developed as an intravenous vasodilator and has been used in clinical trials in right ventricular failure from primary pulmonary hypertension (PPH)[120] (see Chap. 53) and in advanced chronic biventricular failure.[80] In both trials, prostacyclin was given intravenously by continuous infusion. The remarkable finding in these two clinical trials was that prostacyclin *decreased* mortality in PPH[120] but *increased* it in biventricular failure.[80] These findings initially seem paradoxical until the underlying pathophysiology of the two disorders is examined. In PPH, the pathophysiology is dominated by a marked increase in right ventricular afterload to levels that are severalfold above normal. The natural history of PPH is dependent on the ability of the right ventricle to withstand this insult, and any measure that can reduce afterload, such as prostacyclin, can improve the natural history of PPH. In contrast, in biventricular failure from a dilated cardiomyopathy phenotype, elevated left or right ventricular afterload is not usually the dominant pathophysiology. Rather, the natural history is related to the vicious cycle of contractile dysfunction and remodeling described in Chapter 16 . When a powerful vasodilator such as prostacyclin is administered, neurohormonal signaling pathways are probably progressively activated, thereby leading to an increase in mortality and generally worsening the natural history of HF. Indeed, results of the prostacyclin chronic HF ("Flolan International Randomized Survival Trial" [FIRST]) trial are part of the evidence that vasodilation per se is not a beneficial approach to the treatment of chronic HF.[108]

Natriuretic Peptides

As discussed above in the section on diuretics, the natriuretic peptides are hormones that are produced by the heart in response to increased wall stress and are secreted into the circulation as a marker of hypertrophy or failure. In fact, one of them, BNP, has promise as a blood test for HF or left ventricular dysfunction.[121] [122] Natriuretic peptides are not simply markers of myocardial hypertrophy and failure; they are also vasodilators and are natriuretic and diuretic in some patients.[45] [46] The vasodilator properties are both venous and arteriolar.[45] [46]

Because of these favorable vascular and renal effects, recombinant natriuretic peptides have been evaluated as intravenous therapy in decompensated HF, and one of them, hBNP, is in phase III clinical development. In subjects with HF, intravenous BNP increases cardiac output and lowers pulmonary wedge mean and mean pulmonary

artery pressure without increasing the heart rate.[45] [46] The latter is probably due to the sympathoinhibitory properties of BNP[123] because systemic norepinephrine levels actually decrease[46] despite the vasodilator effects of the compound. The unique combination of vasodilation and diuresis/natriuresis creates a potentially useful acute HF treatment for certain subjects.

Another approach to the use of natriuretic peptides is to deliver them subcutaneously, where they could then be used to treat chronic HF.[124] Thus far, proof of concept for the route of administration[124] has been accomplished, but no controlled trial data are available.

Neurohormonal/Cyokine Inhibitors

Although initially investigated within the vasodilator paradigm, inhibitors of vasoconstrictor neurohormones or cytokines do far more than produce vasodilation. That is,

inhibitors of the renin-angiotensin, adrenergic, and endothelin systems probably exert their primary action on the heart in that they attenuate or even reverse the dysfunction/remodeling process, as discussed in Chapter 16 . However, their vasodilator properties are also useful because they tend to improve rather than worsen hemodynamics. Inhibitors of neurohormonal or cytokine systems are discussed in detail in a later section.

Positive Inotropic Agents

CARDIAC GLYCOSIDES

Cardiac glycosides are used to treat chronic HF in patients in sinus rhythm and to control the response of the ventricular rate to supraventricular arrhythmias, including atrial fibrillation.[124A] The first drug used to treat chronic HF was digitalis, an extract of the common foxglove plant *Digitalis purpurea*. Digoxin is now the most commonly prescribed cardiac glycoside because of its convenient pharmacokinetics, alternative routes of administration, and the widespread availability of serum drug level measurements. Both deslanoside, a rapidly acting agent available only for parenteral use, and digitoxin continue to be marketed in the United States. The discussion is confined to digoxin since it is the cardiac glycoside of choice worldwide.

MOLECULAR MECHANISM OF ACTION.

Digoxin is an extremely complex agent in that its mode of action, inhibition of Na^+ ,K^+ -ATPase, affects multiple cellular processes, including several critical to cardiac myocyte function (see Chap. 14) . Digoxin is also extremely toxic, not surprising in view of its role in nature. Cardiac glycosides bind to a specific high-affinity site on the extracytoplasmic face of the alpha subunit of Na^+ ,K^+ -ATPase, the enzymatic equivalent of the cellular "sodium pump."[125] The affinity of the subunit for cardiac glycosides varies among species and among the three known mammalian subunit isoforms, each of which is encoded by a separate gene.[125]

Cardiac glycoside binding to and inhibition of the Na^+ ,K^+ -ATPase sodium pump are reversible and entropically driven. Under physiological conditions, these drugs preferentially bind to the enzyme after phosphorylation of a beta-aspartate on the cytoplasmic face of the alpha subunit, thus stabilizing this "E_2 P" conformation.[125] [126] Extracellular K^+ promotes dephosphorylation at this site, resulting in a decrease in the cardiac glycoside binding affinity for the enzyme.[126] This action presumably explains why increased extracellular K^+ tends to reverse some manifestations of digitalis toxicity.

POSITIVE INOTROPIC EFFECT.

Cardiac glycosides increase the velocity and extent of shortening of cardiac muscle, thereby resulting in an upward and left shift of the ventricular function curve (Frank-Starling) relating cardiac performance to filling volume or pressure (see Fig. 18-2) . This process occurs in normal as well as failing myocardium and in atrial as well as ventricular muscle. The effect appears to be sustained for periods of weeks or months without evidence of desensitization or tolerance.[127] The positive inotropic effect is due to an increase in the availability of cytosolic Ca^{2+} during systole, thus increasing the velocity and extent of sarcomere shortening. The increase in intracellular Ca^{2+} is a consequence of cardiac glycoside-induced inhibition of sarcolemmal Na^+ ,K^+ -ATPase.[125] [126] Inhibition of Na^+ ,K^+ -ATPase causes intracellular Na^+ to increase, which is then exchanged for extracellular Ca^{2+} via the Na^+ -Ca^{2+} exchanger.[128] The net effect of these adjustments is to increase intracellular Ca^{2+} during systole, which increases systolic function.

In part because cardiac glycosides produce an increase in contractile function without increasing the heart rate, the positive inotropic effects are more energetically efficient than are the effects of beta-adrenergic agonists and higher doses of PDEIs.[129] This difference may be one of the reasons why low-dose digoxin does not increase mortality in patients with HF.[130]

ANTIADRENERGIC PROPERTIES.

Na^+ ,K^+ -ATPase is involved in baroreflex afferent signaling and may be upregulated in the carotid sinus in HF.[131] Decreased baroreflex control[132] is one of the mechanisms responsible for an increase in generalized and cardiac[133] adrenergic activity in HF. Inhibition of Na^+ ,K^+ -ATPase by ouabain modulates baroreflex function toward normal in HF animal models,[131] which is likely to be the mechanism by which cardiac glycosides inhibit adrenergic activity in HF. Ferguson and colleagues demonstrated in patients with moderate to severe HF that infusion of the cardiac glycoside deslanoside increases forearm blood flow and the cardiac index and decreases the heart rate, concomitant with a marked decrease in skeletal muscle sympathetic nerve activity measured as an indicator of centrally mediated sympathetic nervous system activity.[134] In addition, controlled clinical trial data have indicated that digoxin reduces systemic[135] and cardiac[136] norepinephrine levels in subjects with chronic HF. This reduction in adrenergic activity may be another reason why digoxin does not increase mortality when used in low doses in patients with chronic HF.

ELECTROPHYSIOLOGICAL ACTIONS.

Cardiac glycosides have complex electrophysiological effects that are a combination of indirect, parasympathetic, and direct effects of specialized cardiac pacemaker and conduction tissue.[137] At low to moderate therapeutic serum concentrations (0.5 to 1.9 ng/ml), digoxin usually decreases automaticity and increases maximal diastolic resting membrane potential in atrial and atrioventricular (AV) nodal cells as a result of augmented vagal tone and decreased sympathetic nervous system activity. These effects are accompanied by prolongation of the effective refractory period and decreased AV nodal conduction velocity. At higher, toxic digoxin levels or in the presence of underlying disease, patients are susceptible to sinus bradycardia or arrest, prolongation of AV conduction, or heart block. At toxic levels, cardiac glycosides can also increase sympathetic nervous system activity, potentially contributing to the generation of arrhythmias. Increased intracellular Ca^{2+} loading and increased sympathetic tone both contribute to an increased rate of spontaneous (phase 4) diastolic depolarization and also to delayed afterdepolarizations that may reach threshold and generate propagated action potentials. The combination of increased automaticity and depressed conduction in the His-Purkinje network predisposes to arrhythmias, including ventricular tachycardia and fibrillation. Recent data from the Digitalis Investigation Group (DIG) Trial[138] suggest that the increase in ventricular arrhythmia manifested in chronic HF as an increase in sudden death extends down to digoxin serum levels of 1.0 ng/ml, inasmuch as higher concentrations were associated with an increase in mortality.

Clinical Trial Results

Despite its use for over 200 years in the treatment of HF, the debate over the use of cardiac glycosides in chronic HF continues. Small and medium-size trials conducted in the 1970s and 1980s yielded equivocal results, with some apparently

demonstrating efficacy[139] [140] [141] and some not.[142] [143] [144] In the early 1990s, two relatively large digoxin withdrawal studies, the Randomized Assessment of Digoxin and Inhibitors of Angiotensin-Converting Enzyme (RADIANCE)[145] [146] and the Prospective Randomized Study of Ventricular Function and Efficacy of Digoxin (PROVED),[146] [147] provided strong support for clinical benefit from digoxin in that worsening HF developed in more patients and they had to be hospitalized if digoxin therapy was withdrawn than in patients who had placebo withdrawn and were maintained on a regimen of digoxin. However, withdrawal studies are difficult to interpret, so a large placebo-controlled mortality trial, the DIG Trial, was conducted.[130]

The DIG Trial had all-cause mortality as its primary endpoint and had secondary endpoints of hospitalization and worsening HF.[130] This trial enrolled 6800 Class I to III

HF patients with an average left ventricular ejection fraction of 28 percent and monitored them for an average of 37 months. Remarkably, the DIG Trial finished with a relative risk ratio of 1.00 (confidence intervals of 0.91 and 1.07, *p*=0.80), which indicates that at the doses (0.125 to 0.375 mg/d, with 70 percent receiving 0.25 mg/d) and serum levels of digoxin studied, this positive inotrope does *not* increase mortality in chronic HF. The data indicated a strong trend (*p*=0.06) toward a decrease in deaths assigned to a progressive pump failure etiology, balanced by an increase in sudden and other non-pump failure cardiac deaths (*p*=0.04). [130] The number of patients hospitalized was statistically significantly reduced (by 4 percent) by digoxin therapy, and the total number of hospitalizations per subject was significantly reduced by 6 percent.[130] Therefore, evidence of efficacy was seen in the DIG Trial, but in view of its large size and power, this evidence is modest.

One of the most important findings to emerge from the DIG Trial was that mortality was directly related to the digoxin serum level.[138] In addition, data from other studies have demonstrated that the beneficial effects of digoxin on ventricular function[148] and neurohormonal activation[148] [149] occur at the "safe" lower serum levels of 0.5 to 1.0 ng/ml. This information means that if digoxin is used in subjects with HF, *trough levels should be kept between 0.5 and 1.0 ng/ml.*

Overall, these clinical trial results support the routine use of digoxin in patients in sinus rhythm who have mild to moderate HF, which is why most HF practice guidelines recommend the use of digoxin. Because the DIG Trial,[130] as well as RADIANCE[145] and PROVED,[147] were conducted in patients with Class II to III HF, no firm recommendation is possible for more advanced HF patients in sinus rhythm. In addition, digoxin is indicated in all HF patients with atrial fibrillation in whom ventricular response slowing is required. However, in both the sinus rhythm and atrial fibrillation settings, digoxin must be used in such a way to avoid overt toxicity or an increase in sudden death without obvious toxicity.

PHARMACOKINETICS AND DOSING

Orally administered digoxin is variably absorbed, depending on the preparation, but Lanoxin is 60 to 80 percent absorbed. Digoxin is approximately 25 percent protein bound in plasma, has a large volume of distribution (4 to 7 liter/kg), and crosses both the blood-brain barrier and the placenta. Digoxin is eliminated primarily by renal mechanisms, both glomerular filtration and tubular secretion. Tubular excretion is via the energy-dependent membrane-bound efflux pump/transport enzyme P-glycoprotein, which is modulated by many other drugs. Digoxin is largely excreted in the urine unchanged with a clearance rate proportional to the GFR, which results in the excretion of approximately one-third of body stores daily. The half-life for digoxin elimination of 36 to 48 hours in patients with normal or near-normal renal function permits once-daily or every-other-day dosing.[150]

In the presence of an elevated blood urea nitrogen-to-creatinine ratio (i.e., "prerenal azotemia"), digoxin clearance more closely parallels urea clearance, thus indicating that under these circumstances some drug filtered at the glomerulus undergoes tubular reabsorption.[150] In patients with HF, increased cardiac output and renal blood flow in response to treatment with vasodilators or sympathomimetic agents may increase renal digoxin clearance and necessitate dosage adjustment. Digoxin is not removed effectively by peritoneal dialysis or hemodialysis because of its large volume of distribution.[150] The principal body reservoir is skeletal muscle and not adipose tissue. Accordingly, dosing should be based on estimated lean body mass. Although neonates and infants tolerate and may require higher doses of digoxin (e.g., 0.01 mg/kg/d) for a therapeutic effect equivalent to that of older children or adults, once-daily dosing appears to be as effective as twice-daily dosing in this population.[151]

Digoxin can be loaded at a dose of 0.75 to 1.25 mg orally (or intravenously at doses 25 percent lower) over a 24-hour period in three to four divided doses and then given at a maintenance dose, or a daily maintenance dose of 0.0625 to 0.25 mg/d orally can be started, depending on renal function, body size, and the presence or absence of coadministered drugs causing pharmacokinetic interactions. In the absence of loading doses, nearly steady-state blood levels are achieved in four to five half-lives, or about 1 week after initiation of maintenance therapy if normal renal function is present. If given intravenously, administration should be carried out over at least 15 minutes to avoid vasoconstrictor responses to more rapid injection. Intramuscular digoxin is absorbed unpredictably, causes local pain, and is not recommended.

Patients with HF usually have a reduced volume of distribution and reduced renal function, and both may be influenced by other treatment and by the ebb and flow of the HF. Although nomograms on digoxin dosing have been published, these nomograms should not be used in patients with HF because of the narrow therapeutic index and the unpredictability of the numerous factors that can alter digoxin pharmacokinetics. Instead, patients should be started on a dose as described above and trough levels (see below) measured 1 to 2 weeks later and at frequent intervals (every 1 to 3 months) thereafter.

DRUG INTERACTIONS WITH DIGOXIN.

Multiple drugs interact with digoxin at multiple levels, including reduced renal tubular excretion by drugs inhibiting P-glycoprotein renal tubular transport,[152] induction of gut P-glycoprotein,[153] alterations in gut flora by antibiotics causing less gut metabolism of digoxin before absorption, displacement from plasma protein-binding sites, or reduction in renal function. A partial list of these interactions is given in Table 18-4 .

THERAPEUTIC DRUG MONITORING

Digoxin has an extremely low therapeutic index, and its use should be carefully monitored by serum blood levels. The various clinical conditions and drug interactions that can alter digoxin's pharmacokinetics are also reflected in the serum digoxin level. Reduced thyroid function and renal function both decrease the volume of distribution of digoxin and thus necessitate downward adjustments in loading and maintenance doses. Hypochlorhydria (i.e., gastric pH >7), which is common in elderly patients and patients receiving histamine H_2 receptor antagonists or gastric H^+ ,K^+ -ATPase inhibitors, reduces gastric metabolism of digoxin and nonrenal clearance of the drug.[154] This abnormality may lead to higher steady-state blood levels in these patients with reduced renal function, particularly in the elderly. Both hypokalemia and hypercalcemia can independently increase ventricular automaticity and lower the threshold for digoxin-induced cardiac arrhythmias. Hypomagnesemia may also contribute to arrhythmias with digoxin. Hyperkalemia may exacerbate digoxin-induced conduction disorders and cause high-grade AV nodal block.

Studies using noninvasive indices of ventricular function suggest a nonlinear relationship between the serum digoxin concentration and observed inotropic or neurohormonal antagonism, with the majority of the increase in contractility[148] or neurohormonal effects[148] [149] occurring by the time that steady-state levels around 1.4 ng/ml are reached. *This information, plus DIG Trial mortality data, indicates that the optimal trough digoxin serum level is 0.5 to 1.0 ng/ml.* This concentration range is also the one that should be used to control the ventricular rate response to atrial fibrillation in HF patients, particularly since digoxin is not a very effective agent in this regard in the setting of high amounts of adrenergic activity.[155] Blood samples for measurement of serum digoxin levels should be taken at least 6 to 8 hours following the last digoxin dose.

Digitalis Toxicity

In patients with HF, overt clinical toxicity tends to emerge at serum concentrations greater than 2.0 ng/ml, but it must always be remembered that substantial overlap in serum levels exists among patients exhibiting symptoms and signs of toxicity and those with no clinical evidence of intoxication.[156] Disturbances in cardiac impulse formation, conduction, or both are the hallmarks of digitalis toxicity.[157] Among the common electrocardiographic manifestations are ectopic beats of AV junctional or ventricular origin, first-degree AV block, an excessively slow ventricular rate response to atrial fibrillation, or an accelerated AV junctional pacemaker. These manifestations may require only dosage adjustment and monitoring as clinically appropriate. Sinus bradycardia, sinoatrial arrest or exit block, and second- or third-degree AV conduction delay often respond to atropine, but temporary ventricular pacing is sometimes necessary and should be available.

TABLE 18-4 -- PARTIAL LIST OF DRUG INTERACTIONS WITH DIGOXIN

DRUG	EFFECT ON SERUM DIGOXIN LEVEL	MECHANISM
Amiodarone	Increases	? Renal clearance
Verapamil	Increases	Renal clearance
Nifedipine	Increases	Renal clearance
Diltiazem	Increases	Renal clearance

Quinidine	Increases	Displacement of protein binding, renal clearance
Propafenone	Increases	Renal clearance
Captopril	? Increases	? Renal clearance
Carvedilol	Increases	Oral bioavailability
Spironolactone	Increases	Renal clearance
Amiloride	Increases	Renal clearance
Triamterene	Increases	Renal clearance
Salbutamol	Decreases	Unknown
Macrolide antibiotics (erythromycin, clarithromycin)	Increases	Altered gut flora, renal clearance
Tetracycline	Increases	Altered gut flora
Indomethacin	Increases	Renal clearance
Alprazolam	Increases	? Renal clearance
Itraconazole	Increases	Renal clearance
Rifampin	Decreases	Induction of gut P-glycoprotein
Sucralfate	Decreases	Decreased gut absorption
Cholestyramine	Decreases	Decreased gut absorption
Cyclosporine	Increases	Renal clearance
Saint Johns wort	Increases	Renal clearance

MANAGEMENT.

Oral potassium administration is often useful for atrial, AV junctional, or ventricular ectopic rhythms, even when the serum potassium is in the normal range, unless high-grade AV block is also present. However, [K^+] must be monitored carefully to avoid hyperkalemia, especially in patients with renal failure. Magnesium may be useful in patients with atrial fibrillation and an accessory pathway in whom digoxin administration has facilitated a rapid accessory pathway-mediated ventricular response; again, careful monitoring is required to avoid hypermagnesemia.[158] Lidocaine and phenytoin, which in conventional doses have minimal effects on AV conduction, are useful in the management of worsening ventricular arrhythmias that threaten hemodynamic compromise. Electrical cardioversion can precipitate severe rhythm disturbances in patients with overt digitalis toxicity and should be used with particular caution. Neurological or gastrointestinal complaints can also be manifestations of digitalis toxicity. Occasionally, gynecomastia results from digoxin administration, apparently because of the similarity of the glycoside structure to that of estrogens.

ANTIDIGOXIN IMMUNOTHERAPY.

Potentially life-threatening digoxin or digitoxin toxicity can be reversed by antidigoxin immunotherapy. Purified Fab fragments from digoxin-specific antisera are available at most poison control centers and larger hospitals in North America and Europe. The smaller (molecular weight 50,000) Fab fragments have a larger volume of distribution, more rapid onset of action, and more rapid clearance, as well as reduced immunogenicity in comparison to intact IgG.[159] Clinical experience in adults and children has established the effectiveness and safety of antidigoxin Fab in treating life-threatening digoxin toxicity, including cases of massive ingestion with suicidal intent.[160] Doses of Fab are calculated by using a simple formula based on either the estimated dose of drug ingested or the total-body digoxin burden (Table 18-5) and are administered intravenously in saline over a period of 30 to 60 minutes. Recrudescent digoxin toxicity is unusual but can occur 24 to 48 hours after Fab administration in patients with normal renal function or later in patients with renal impairment. Determination of the efficacy and cost-effectiveness of less than complete neutralizing doses of digoxin-specific Fab fragments for suspected or moderate cases of digoxin toxicity awaits further assessment.[159] [161]

ADRENERGIC AGONISTS

The most powerful way to increase contractility in the human heart is by a beta-adrenergic receptor agonist. Beta-agonists operate through the mechanism that regulates contractility and heart rate on a beat-to-beat basis in the intact heart, the cardiac myocyte beta receptor pathways (see

TABLE 18-5 -- DOSES OF FAB CALCULATED ON THE BASIS OF THE AMOUNT OF INGESTED DIGOXIN OR THE TOTAL-BODY DIGOXIN BURDEN

Estimation of Total-Body Digoxin Burden (mg)

Total drug ingested following acute digoxin poisoning (i.e., amount ingested×0.80 [average oral bioavailability of tablet formulations])

or

Known or suspected toxicity during chronic digoxin therapy:

Serum digoxin concentration×volume of distribution (5.6 liter/kg)×weight in kg ÷ 1000

Calculation of Fab Fragment Dose

Molecular mass of Fab fragments =50,000×64×total-body digoxin content (mg) ÷ Molecular mass of digoxin=781

=dose of Fab fragments (mg)

or

Use a standard formulation (e.g., Digibind [Burroughs Wellcome])

Estimated total-body load of digoxin (mg) ÷ 0.6 (mg/vial) =Digibind dose in numbers of vials

For reversal of digitoxin toxicity, substitute 1.0 for oral bioavailability and 0.56 liter/kg for volume of distribution in the formulas above.

protein kinase A; SR=sarcoplasmic reticulum.

Chap. 14) . As depicted in Figure 18-3 , this system is composed of two cell surface membrane receptors (beta$_1$ and beta$_2$), two G proteins (the "stimulatory G protein G$_{alpha}$ s and the inhibitory G protein G$_{alpha}$ i), the adenylyl cyclase enzyme (which converts Mg-ATP to cAMP), cAMP-activated protein kinase (protein kinase A), and target structures whose phosphorylation leads to a positive inotropic effect by changes in Ca^{2+} handling (phospholamban, the ryanodine release channel, and slow inward current calcium channels). The end result is a powerful positive inotropic as well as positive chronotropic effect.

In the failing human heart, beta-adrenergic pathways undergo *desensitization*, a pharmacological term encompassing the regulatory changes that occur in receptors, G proteins, and adenylyl cyclase.[162] [163] In advanced HF, the degree of desensitization approaches 50 to 60 percent of the maximum capacity of signal transduction,[164] [165] and in severe HF, beta-agonists may no longer be able to support myocardial function.[166] The degree of desensitization present in end-stage HF patients who underwent cardiac transplantation can be appreciated in Figure 18-4 , which gives maximum responses to the full, nonselective beta-agonist isoproterenol and other agents in isolated right ventricular trabeculae removed from nonfailing and failing human hearts. However, the vast majority of patients with advanced HF still exhibit a substantial inotropic response to beta-agonists,[165] which is the basis for their usefulness as inotropic agents in the treatment of decompensated HF.

All beta-agonists are given intravenously for short-term support in decompensated HF. They are all arrhythmogenic

Figure 18-4 Effects of various inotropic agents on the systolic tension response in nonfailing and failing human right ventricular trabeculae, mean+SEM. OPC 8212=vesnarinone; FLSQ=flosequinan; ENOX=enoximone; MIL=milrinone; ISO=isoproterenol.

to some extent via direct mechanisms, as well as through increasing the skeletal muscle deposition of potassium[68] and decreasing serum magnesium.[167] Obviously, their administration should be carefully monitored and the lowest possible effective doses used. In addition, all beta-agonists are subject to the development of desensitization phenomena when used continuously, another reason to keep the doses low and the use short term or intermittent. Beta-agonists all have short (in minutes) half-lives, which is an advantage for powerful inotropes that may have adverse effects. As shown in Table 18-6 , from a therapeutic standpoint it is important to understand how beta-agonists differ from one another with respect to intrinsic activity; affinity for binding to beta$_1$, beta$_2$, and alpha$_1$ receptors; and affinity for the cardiac adrenergic neuronal reuptake system (uptake$_1$).[168] Neuronal reuptake is an important consideration in the heart, which has the most active uptake$_1$ system of any organ and uses neuronal reuptake to terminate the majority of the action of released norepinephrine.[173] [174]

Although beta$_1$ - and beta$_2$ -adrenergic receptors are both coupled to positive inotropic and chronotropic responses via cAMP-dependent mechanisms, these two receptors have important differences. For one thing, beta$_1$ receptors are positioned inside or near the synaptic cleft area to mediate the effects of released norepinephrine,[176] which also means that catecholamines that have high affinity for uptake$_1$ will not reach myocardial beta$_1$ receptors unless neuronal reuptake is functionally decreased (as it is myocardial failure) or absent (as it is in a recently [<2 years] transplanted heart). In addition, a growing body of evidence indicates that chronic beta$_1$ receptor agonist occupancy and/or pathway activation is more deleterious than beta$_2$ receptor activation.[177] However, from an acute support standpoint, both receptors can be used in supporting cardiac function in decompensated patients.

NEURONAL AFFINITIES FOR SYMPATHOMIMETIC AMINES.

Table 18-6 lists the adrenergic receptor and neuronal uptake (uptake$_1$) affinities for catecholamines that are used therapeutically to increase cardiac performance and/or increase systemic vascular resistance or blood pressure. Although the primary action of uptake$_1$ is to terminate the action of norepinephrine, the functional status of uptake$_1$ is also an important determinant of catecholamine therapeutic action when these agents are administered exogenously. For example, epinephrine, which has an affinity for uptake$_1$ that is slightly lower than that of norepinephrine, is a much more potent therapeutic catecholamine when administered to denervated cardiac transplant hearts than to innervated hearts.[178] [179] When the heart is innervated, uptake$_1$ removes much of the systemically administered epinephrine before it can reach myocardial beta$_1$ -adrenergic receptors, which are preferentially located within the synaptic cleft area.[176] In contrast, isoproterenol, which has essentially no affinity for uptake$_1$, is equally effective in innervated and denervated hearts.[178] [179]

The failing human heart has a functional impairment in uptake$_1$ that essentially creates functional denervation, which in the case of catecholamines with higher affinity for uptake$_1$, can offset some of the postsynaptic desensitization changes. Another way in which uptake$_1$ can influence drug action is to compete with neurotransmitter norepinephrine for neuronal reuptake, which will increase the amount of norepinephrine available in the synaptic cleft area. As can be observed in Table 18-6 , the substituted synthetic catecholamine dobutamine and the endogenous catecholamine dopamine have even higher affinity for uptake$_1$ than norepinephrine does, and at least in the case of dopamine, this higher affinity contributes to its predominant inotropic action, which is to potentiate norepinephrine release.

Dobutamine

Dobutamine is an extremely useful inotropic agent for moderately decompensated HF.[179A] As available clinically, dobutamine is a racemic mixture that stimulates both beta$_1$ - and beta$_2$ -adrenergic receptor subtypes (binding at an approximately 3:1 ratio)[180] and either binds to but does not activate alpha-adrenergic receptors ([+] enantiomer) or stimulates alpha$_1$ and alpha$_2$ receptor subtypes ([-] enantiomer). As discussed above, dobutamine also has relatively high affinity for uptake$_1$. The affinity constants for racemic dobutamine binding to beta$_1$, beta$_2$, and alpha$_{1B}$ receptors are given in Table 18-6 , where it can seen that dobutamine is relatively nonselective for binding to beta$_1$ vs. beta$_2$ receptors and binds to alpha$_1$ receptors and uptake$_1$ at slightly higher affinity. When compared with isoproterenol, in human cardiac preparations dobutamine is a partial beta-agonist with an intrinsic activity of approximately 0.5.[181] The binding to alpha receptors by each isomer of dobutamine results in a mixture of antagonist and agonist action that when coupled with some peripheral vascular beta$_2$ -agonism, usually produces a net mild degree of vasodilation at lower (
5 mug/kg/min) doses. At these doses, dobutamine reduces aortic impedance and systemic vascular resistance, thus reducing afterload and improving ventricular-vascular coupling by reducing aortic impedance.[182] [183] In contrast, dopamine (see below) may have either no effect or increase ventricular afterload by increasing systemic vascular resistance and causing more rapid return of reflected aortic pressure waves, depending on the infusion rate. Therefore, dobutamine is preferable to dopamine for most patients with advanced decompensated HF who have not responded adequately to intravenous diuretics.

The neuronal uptake inhibition of dobutamine means that in subjects with preserved neuronal uptake mechanisms, dobutamine may increase synaptic cleft area norepinephrine concentrations in the heart, in addition to its intrinsic receptor-mediated actions. Dobutamine does not stimulate dopaminergic receptors and, unlike dopamine,

TABLE 18-6 -- PHARMACOLOGICAL CHARACTERISTICS OF VARIOUS ADRENERGIC AGONISTS USED TO TREAT DECOMPENSATED HEART FAILURE

AGENT	BETA$_1$ RECEPTOR AFFINITY (K_d , nM)	BETA$_2$ RECEPTOR AFFINITY (K_d , nM)	ALPHA$_1$ RECEPTOR AFFINITY (K_d , nM)	UPTAKE$_1$ AFFINITY (nM)	INTRINSIC ACTIVITY* FOR HUMAN BETA$_1$ RECEPTORS
Dobutamine	470	570	130	190,330	0.5
Dopamine	25,000	100,000	36,000	130,230	0.2
Epinephrine	30	30	160	1400	1.0

Norepinephrine	10-30	250-750	200	500,670	1.0
Phenylephrine	>10,000	>10,000	1000	>10,000	0

*Relative to isoproterenol=1.0 in nonfailing isolated human right ventricular trabeculae. Affinity data are based on radioligand-cold ligand competition curves in (1) human ventricular myocardial membrane preparations (beta$_1$, in nonfailing hearts with greater than 80 percent beta$_1$ receptors; alpha$_1$, norepinephrine, epinephrine [168]), (2) human recombinant beta$_2$ receptors in COS cell membranes (isoproterenol, norepinephrine, and epinephrine), (3) DTT$_1$ cell membranes (beta$_2$, dobutamine and dopamine), and (4) rat heart membranes (alpha$_1$, dobutamine).[169] Additional alpha$_1$ -agonist affinity data are derived from irreversible dibenamine antagonism in rabbit aorta, with relative affinities corrected for human/rabbit alpha$_1$ receptor-norepinephrine *K* values (dopamine,

phenylephrine, epinephrine).[170] Uptake$_1$ data are from the human recombinant protein cloned from SK-N-SH neuroblastoma cells (norepinephrine, dopamine),[171] rabbit brain synaptosomes (dobutamine, dopamine, isoproterenol),[172] or the original data in rat heart (epinephrine, norepinephrine, phenylephrine) from Iversen.[173] [174] Data on concentrations inhibiting 50 percent (IC_{50}) were converted to affinity constants by using the Cheng-Prusoff equation.[175]

does not selectively alter renal blood flow.[184] The importance of the vascular effects of dobutamine has been demonstrated by experiments in animals[185] [186] with artificial hearts. Even in the presence of a mechanical heart, dobutamine increased cardiac output by 10 to 15 percent and decreased systemic vascular resistance. Interestingly, dobutamine also decreased venous capacitance and increased right atrial pressure, possibly as a result of alpha$_1$ -adrenergic agonism of the (-) enantiomer.[186] These experiments also demonstrated that the (+) enantiomer is responsible for the racemic drug's effects on aortic input impedance, wave reflectance, and systemic vascular resistance.[185] These favorable actions on left ventricular afterload are also responsible for the reduction in functional mitral regurgitation often observed with dobutamine infusions in patients with large dilated ventricles and high left ventricular end-diastolic pressure.[187] Dobutamine also causes a mild decline in pulmonary vascular resistance that is present regardless of chronic background vasodilator therapy.

At higher doses, the (-) isomer of dobutamine begins to exert alpha$_1$ -adrenergic agonist action, thereby preventing progressive vasodilation and usually leading to only minimal changes in afterload and preload. The advantage of this alpha-adrenergic effect of dobutamine is that since preload and afterload do not change dramatically, dobutamine can be administered without pulmonary artery catheter monitoring of left ventricular filling pressure. Another advantage of the relative lack of vasodilation coupled to the partial agonist action is that dobutamine does not produce much increase in the heart rate at doses of 10 mug/kg/min or less. Because of its partial agonist activity, desensitization to prolonged infusions of dobutamine is not pronounced.[188] Dobutamine infusions are initiated at 2 to 3 mug/kg/min and are titrated upward according to the patient's hemodynamic response (usually not higher than 20 mug/kg/min).[183] [184]

The limitations of dobutamine are that it (1) is a relatively weak beta-agonist,[181] (2) only modestly lowers elevated pulmonary artery pressure, (3) eventually produces desensitization phenomena when used chronically,[188] [190] and (4) cannot be effectively used in the presence of high levels of beta-adrenergic receptor blockade.[190] The first three of these limitations can be overcome by combining dobutamine with a PDEI, which results in additive effects on myocardial performance,[191] [192] substantial reductions in pulmonary wedge and pulmonary artery pressure,[191] [192] and a protective effect on desensitization [190] related to being able to lower the dobutamine dose.

Dopamine

Dopamine is an endogenous catecholamine that is the precursor to norepinephrine in the catecholamine synthetic pathway. When administered therapeutically, dopamine is a complex agent. Dopamine through its direct effects is a weak partial agonist. When initially administered, it releases norepinephrine through a tyramine-like effect.[192] It is a potent (relative to its receptor affinities) neuronal uptake inhibitor and by direct action acts as an agonist at dopamine D_1 postsynaptic vasodilator receptors[193] and D_2 presynaptic receptors on blood vessels and in the kidney.[194] The affinities for beta$_1$, beta$_2$, and alpha$_{1B}$ receptors are shown in Table 18-6 , where it can be seen that dopamine has extremely low affinity for all three adrenergic receptors.

At lower doses (
2 mug/kg/min), dopamine causes relatively selective vasodilation of splanchnic and renal arterial beds. This effect may be useful in promoting renal blood flow and maintaining the GFR in selected patients who become refractory to diuretics, especially when caused by marginal renal perfusion. Dopamine also has direct renal tubular effects that promote natriuresis. At intermediate (2 to 10 mug/kg/min) infusion rates, dopamine, by virtue of its tyramine and neuronal uptake-inhibiting properties, enhances norepinephrine release from vascular and myocardial adrenergic neurons, thereby resulting in increased cardiac beta-adrenergic receptor activation and an increase in peripheral vascular resistance. In patients with advanced HF, who often have depleted intracardiac norepinephrine stores, dopamine is a less effective positive inotropic drug than other "directly" acting inotropes are.[184] [185] At higher infusion rates (5 to 20 mug/kg/min), peripheral vasoconstriction occurs as a result of direct alpha-adrenergic receptor stimulation. Increases in systemic vascular resistance are common even at intermediate infusion rates. On initial administration, tachycardia and arrhythmia tend to be more pronounced than with dobutamine[184] and are related to cardiac norepinephrine release.[192] [195]

In patients with advanced, decompensated HF, dopamine should not be used as a positive inotropic agent, but rather used in low doses for renal perfusion and in intermediate to high doses to increase peripheral resistance. The latter property is often necessary for a variety of reasons, including sepsis, iatrogenic overvasodilation, and brain injury.

Epinephrine

Epinephrine is an endogenous full beta-agonist catecholamine that like dobutamine, produces relatively balanced effects between vasodilation and vasoconstriction. This balance between vasodilation and vasoconstriction occurs because epinephrine has relatively equal high affinities for beta$_1$, beta$_2$, and alpha$_1$ receptors (see Table 18-6) . Epinephrine has moderately high affinity for neuronal reuptake, which means that the majority of administered drug may not reach beta$_1$ -adrenergic receptors in the normal heart. However, neuronal reuptake is markedly reduced in the failing heart,[196] [197] which will allow epinephrine to reach more beta$_1$ -adrenergic receptors in this setting. Epinephrine is an excellent positive inotropic agent in the denervated, transplanted heart[178] [179] because neuronal reuptake is no longer a factor. The dose of epinephrine usually ranges from 0.05 to 0.50 mug/kg/min.

When cardiogenic shock is profound, calcium is often added to an epinephrine infusion to produce synergistic increases in contractility[198] and an increase in vascular tone. This combination, made by adding 1 gm of $CaCl_2$ to 250 ml of intravenous solution containing epinephrine and called "Epi-Cal," has never been subjected to a clinical trial and should be used in resuscitative settings only.

Isoproterenol

Isoproterenol is a full, nonselective beta-agonist that produces powerful positive chronotropic, inotropic, and vasodilator responses. At therapeutic doses, isoproterenol does not bind to the neuronal uptake system (see Table 18-6) . As a therapeutic inotrope, isoproterenol has only one indication--postoperatively after heart transplantation. Isoproterenol is useful in this setting because an increase in heart rate is not a problem in the presence of normal coronary arteries, and the chronotropic stimulation is useful in the newly transplanted heart, which often has a sluggish sinus node mechanism. The pulmonary vasodilator properties of isoproterenol are also useful in this setting, where pulmonary artery pressure and pulmonary vascular resistance are usually elevated.

The dose of isoproterenol ranges from 0.005 to 0.05 mug/kg/min.

Norepinephrine

As shown in Table 18-6 , norepinephrine is a mildly (10- to 30-fold) beta$_1$ vs. beta$_2$ receptor-selective agonist with relatively high affinity for alpha$_1$ receptors and for uptake$_1$. This constellation of properties means that norepinephrine will be a powerful vasoconstrictor, but not a very powerful

inotrope in hearts with functioning neuronal uptake. Norepinephrine does not have any recommended uses in subjects with cardiac decompensation; subjects who need peripheral vascular resistance support (such as in sepsis, iatrogenic overvasodilation, or brain injury) are served better by dopamine or dopamine plus phenylephrine administration.

Phenylephrine

Phenylephrine is a pure alpha-agonist with no beta-agonist activity and low affinity for uptake$_1$. Even though alpha$_1$ receptors can mediate a small inotropic response in the human heart, phenylephrine should be used only to increase systemic vascular resistance in settings in which dopamine is not effective. The usual dose of

phenylephrine ranges from 0.3 to 3 mug/kg/min.

PHOSPHODIESTERASE INHIBITORS

MECHANISMS OF ACTION.

As shown in Figure 18-3 , the enzyme phosphodiesterase type III is associated with the sarcoplasmic reticulum (SR) in human cardiac myocytes[199] and vascular smooth muscle, where it breaks down cAMP into AMP. Type III phosphodiesterase is also found in platelets. It has an SR-anchoring moiety[200] that accounts for its compartmentation in cardiac myocytes and vascular smooth muscle. Elevations in cAMP in the vicinity of the SR can then activate locally compartmentalized[201] protein kinase A, which will phosphorylate phospholamban[197] and relieve this molecule's inhibition of SR function.[203] Thus, specific type III PDEIs, particularly at low doses, may have a relatively selective effect on phospholamban phosphorylation[202] [204] and SR function, which explains why they lower diastolic Ca^{2+} and increase systolic Ca^{2+} in cultured cardiac myocytes.[205] This SR-selective effect is probably the reason why highly type III-specific PDEIs increase contractile function without much increase in the heart rate,[206] similar to transgenic mice with phospholamban knockout, which exhibit an increase in contractility without an increase in heart rate.[207] However, PDEIs also increase the calcium channel current,[208] and higher doses increase the phosphorylation of sarcolemmal proteins, similar to beta-agonists.[209]

Type III PDEIs are also potent vasodilators, particularly on venous capacitance and pulmonary vascular beds. The vasodilator properties of PDEIs substantially exceed that of beta-agonists,[191] [210] including isoproterenol.[210] The reason for this superior vasodilation appears to be that in vascular smooth muscle, PDEI-induced elevations in cAMP activate protein kinase G,[211] [212] which leads to prominent vasodilation that is not unlike a nitrovasodilator effect in its regional distribution. PDEIs are among the best agents for lowering pulmonary artery pressure and pulmonary vascular resistance, which is why they have assumed an important role in postoperative cardiac surgical regimens, including cardiac transplantation.[213] [214] [215]

Type III PDEIs inhibit platelet aggregation[216] [217] and dilate epicardial coronary arteries and bypass grafts,[218] [219] and at least one of them has been shown to have potent antiischemic effects.[220] [221] In addition, type III PDEIs inhibit neointimal formation after vascular injury,[222] [223] and they inhibit proinflammatory cytokine formation[224] and the effects of endotoxin.[225] Thus, type III PDEIs have multiple properties that might prove valuable in the setting of advanced or severe HF.

Similar to beta-agonists, a PDEI's inotropic response is blunted in failing versus nonfailing hearts[191] [226] (see Fig. 18-5) . In a failing human heart the reason for blunting of the response to PDEIs is not an alteration in myocardial type III phosphodiesterase,[199] but rather upregulation of the inhibitory G protein $G_{alpha\ i}$[227] [228] [229] because a decrease in $G_{alpha\ i}$[230] leads to augmentation of the PDEI response.[231] However, when compared with beta-agonists, little or no subsensitivity develops to the inotrope-vasodilator effects of more potent type III PDEIs such as milrinone[232] and enoximone.[190] [233] [234]

HEMODYNAMIC EFFECTS.

As discussed above, the substantial preload- and pulmonary artery pressure-reducing properties of PDEIs are both a strength and a weakness of this class of agents, inasmuch as before their acute intravenous administration, it is necessary to be certain of an elevated left ventricular filling pressure. Therefore, in the absence of elevated right-sided venous pressure in a subject with biventricular failure, pulmonary artery catheter-determined documentation of a pulmonary wedge mean pressure greater than 15 mm Hg is desirable before administering a PDEI intravenously. Otherwise, a precipitous drop in blood pressure may accompany drug administration.

PDEIs are absorbed orally, and their attractive hemodynamic profile has led to multiple clinical trials in chronic HF. The increase in cardiac output from PDEIs is preferentially distributed to skeletal muscle,[235] [236] which should theoretically increase maximum exercise responses. Such does appear to be the case.[234] [237] In addition, in a dilated, failing heart, PDEIs have a favorable energetic effect,[238] [239] and PDEIs improve diastolic[240] [241] as well as systolic[242] [243] function. All these observations suggest that PDEIs would be useful in the long-term treatment of chronic HF.

CLINICAL EFFECTS.

However, when subjected to placebo-controlled clinical trials, selective type III PDEIs given in doses that produce large hemodynamic effects have increased mortality.[244] [245] [246] Moreover, agents with PDEI activity and K^+ channel antagonism (vesnarinone), [247] as well PDEI activity and Ca^{2+} sensitization (pimobendan),[248] are also associated with increased mortality. The basis for the increase in mortality is increased sudden death,[246] [249] presumably on an arrhythmic basis.

Despite these discouraging results, PDEIs continue in development for the treatment of chronic HF via two new approaches. One is a "low-dose" approach[250] that takes advantage of the fact that doses that are one-sixth to one-third those used in earlier clinical trials are hemodynamically active,[251] increase exercise tolerance,[234] do not increase the heart rate, [234] are not proarrhythmic,[234] and apparently do not increase mortality.[190] [234] That a positive inotropic agent can increase mortality at higher doses but be safely given at low doses has been established by the DIG Trial, but it remains to be seen whether the same will be true for PDEIs. The second approach to the safe, long-term use of PDEIs in chronic HF is to combine them with a beta-blocking agent.[252] [253] This combination is possible because the site of action of PDEIs is beyond the beta-adrenergic receptor (see Fig. 18-3) and the combination appears to produce additive efficacy and subtractive adverse effects.[252] Treatment with beta-blocking agents actually enhances the hemodynamic effects of PDEIs[231] [246] [254] because of a beta blocker-related reduction in upregulated $G_{alpha\ i}$. [230] One practical consequence of these findings and realizations is that subjects chronically receiving beta-blocking agents who decompensate to the point of needing positive inotropic support should be treated with a PDEI rather than dobutamine or some other beta-agonist. [252]

Individual PDEIs available for use or in late-stage development will now be discussed.

AMRINONE.

Originally, the mechanism of action of amrinone and its more potent analog milrinone was unkown,[255] then ascribed to a direct effect on Ca^{2+} influx,[256] [257] and ultimately attributed to type III phosphodiesterase inhibition.[258] [259] Because amrinone causes thrombocytopenia[260] and may be associated with rapid subsensitivity in subjects with advanced HF,[261] it is no longer widely used to treat decompensated heart failure.

MILRINONE.

Unlike amrinone, milrinone does not commonly cause thrombocytopenia.[262] The incidence of thrombocytopenia reported with milrinone use is 0.4 percent.[263] Although milrinone is a highly selective type III PDEI,[258] [259] other actions capable of producing an inotropic effect have been described, including stimulation of the Ca^{2+} release channel,[264] Ca^{2+} channel agonism,[257] and effects on sarcolemmal Ca^{2+} -ATPase.[265]

Milrinone produces sustained inotropic and vasodilator effects when administered intravenously.[266] [266A] The elimination half-life is 2.3 hours, and milrinone is usually administered as a 25- to 75-mug/kg bolus over a 10- to 20-minute period, followed by a 0.375- to 0.75-mug/kg/min continuous infusion.[263] Development of oral milrinone has been abandoned because of the increase in mortality in the Prospective Randomized Milrinone Survival Evaluation (PROMISE) Trial,[244] which was conducted at doses that are at least four times higher than the minimum effective hemodynamic dose.[267] Milrinone is mostly (80 percent) excreted by the kidney unchanged, and in renal failure, the continuous-infusion dose should be decreased by 50 percent.

ENOXIMONE.*

Enoximone is approved for intravenous use in Europe and is in development in the United States for oral use as both low-dose enoximone alone and in combination with $beta_1$ -selective blockade. Enoximone is a highly selective type III PDEI[268] with no other known pharmacological actions at therapeutic plasma concentrations. Enoximone rarely causes thrombocytopenia and produces sustained hemodynamic effects with intravenous[269] or oral[233] [234] administration.

Enoximone is about one-tenth as potent as milrinone for inhibiting type III phosphodiesterase, which translates to oral and intravenous doses of enoximone being approximately 10 times those of milrinone. The intravenous loading dose is 0.25 to 0.75 mg/kg, with the continuous infusion rate being 1.25 to 7.5 mug/kg/min. Enoximone is extensively metabolized by the liver to sulfoxide derivatives, including at least one active metabolite.[270] [271] Sulfoxide metabolites (about 75 percent within 24 hours in HF subjects) are eliminated by the kidney, and dose reductions in renal failure are the same as with milrinone.[272] Enoximone doses should also be reduced in patients with hepatic failure.

VESNARINONE AND OTHER QUINOLINONE INOTROPES.*

This class of compounds has recently had members in development in the United States for advanced, chronic HF in oral (vesnarinone) and intravenous (toborinone) formulations. Vesnarinone is approved for the treatment of HF in Japan. Several unique features about the pharmacology and clinical trial experience are associated with these agents. In human myocardium, therapeutic concentrations of these agents produces phosphodiesterase inhibition and K^+ channel (delayed rectifier current) antagonism.[273] This action results in a hemodynamic profile similar to that of enoximone or milrinone, but coupled with type III antiarrhythmic properties. The benefit of this combination is that the heart rate will not be increased and may even decrease slightly in response to treatment, thus providing an energetic advantage.[274] The disadvantage of this combination of properties is that the quinolinone inotropic agents have two potentially proarrhythmic properties, and in fact, *torsades de pointes* was a frequent adverse event with higher doses of these agents.[275] Evidence has also been presented that members of this class have more potent anti-proinflammatory cytokine properties than other PDEIs do,[276] but such did not prove to be the case when subjected to testing in a large multicenter trial.[277]

In the first phase III trial conducted in the United States, vesnarinone lowered the primary endpoint of mortality plus HF hospitalization requiring intravenous inotropic agents by 50 percent and also lowered mortality alone.[278] Unfortunately, this experience could not be repeated in a subsequent mortality trial (Vesnarinone Survival Trial [VEST]) that had longer follow-up.[247] VEST demonstrated that vesnarinone produced small, but dose-related increases in mortality at 30 mg (by 11 percent) and 60 mg (by 21 percent) orally daily.[247] After these results, vesnarinone's development in the United States was discontinued. The fact that two consecutive HF trials can result in diametrically opposite effects on mortality with the same drug dose (60 mg/d) highlights the vagaries of HF clinical trials, where patient selection, subtle details of ancillary treatment, length of follow-up, and other factors can greatly influence results.

PHOSPHODIESTERASE INHIBITORS WITH CALCIUM SENSITIZER ACTIVITY

These positive inotropic agents act in part by increasing the sensitivity of troponin C or some other part of the myofibrillar Ca^{2+} -binding apparatus to ionized calcium. This property alone would prolong contraction time and decrease diastolic function, which would not be desirable in an inotropic agent. However, all agents that have gone on to clinical development are also PDEIs, and this property will "cancel" the increased contraction time and provide favorable effects on diastolic function.[279] Under these circumstances, the advantage of calcium sensitization is that the pharmacological effect of the drug does not rely on increasing systolic calcium concentrations, although this action will occur if the compound also has PDEI activity. Another advantage would be in not increasing the heart rate, but again, PDEI activity would lead to a chronotropic effect at higher doses. The combination of not increasing intracellular Ca^{2+} or the heart rate would confer an energetic advantage to Ca^{2+} sensitizers.

The mixed-action Ca^{2+} sensitizers levosimendan and pimobendan have undergone the most clinical experience, and their hemodynamic profile,[280] [281] including increasing the heart rate at higher doses, does not differ from that of milrinone and enoximone. This similarity occurs because, as discussed below, the dominant pharmacological action of both compounds is type III phosphodiesterase inhibition.

PIMOBENDAN.*

Pimobendan is available in oral form for the treatment of HF only in Japan. Pimobendan has weak Ca^{2+} -sensitizing properties through facilitating the interaction of Ca^{2+} with troponin C,[282] but its major mechanism of action is phosphodiesterase inhibition.[283] In several medium-sized trials, pimobendan increased exercise performance and/or improved quality of life,[284] [285] [286] but its development in the Unites States and Europe was put on hold when a strong trend (relative risk 1.8, confidence interval 0.9 to 3.5) toward an increase in mortality was noted in the Pimobendan in Congestive Heart Failure (PICO) Trial, which was conducted in subjects with mild to moderate HF.[248]

LEVOSIMENDAN.*

Levosimendan was discovered as part of a screening strategy for identifying compounds that bind to a troponin C affinity column,[287] and levosimendan does bind to free troponin C.[288] However, recent data indicate that levosimendan does not bind to the human troponin C-troponin I complex,[289] which is the natural state of the regulatory thin filament proteins.

Pharmacological studies clearly demonstrate that levosimendan is a potent (IC_{50} of 25 nM) and specific type III PDEI.[290] In model systems, the positive inotropic effects of levosimendan have been shown to be exclusively via phosphodiesterase inhibition[289] or through a combination of phosphodiesterase inhibition and calcium sensitization.[291] [292] In human ventricular myocardium, one study has found evidence of calcium sensitization at smaller inotropic effects of levosimendan, with evidence of positive inotropy via phosphodiesterase inhibition for larger increases in inotropic response.[293] However, another study in isolated human ventricular myocardium found no evidence of calcium sensitization for an inotropic effect that was associated with phosphodiesterase inhibition.[294] Finally, very recent work in isolated human heart preparations has demonstrated that levosimendan stimulates L-type Ca^{2+} current at low concentrations (10 nM), which indicates that it is acting as a type III PDEI at concentrations that produce positive inotropic effects.[295] Thus, without question, levosimendan is a potent and selective type III PDEI, but it is not clear whether calcium sensitization is contributing to its inotropic action in the human heart.

Levosimendan is a potent vasodilator that also increases heart rate at higher doses.[296] While these effects may well be due to phosphodiesterase inhibition, levosimendan has also recently been found at somewhat higher concentrations than those that produce phosphodiesterase inhibition to activate vascular smooth muscle ATP-sensitive K^+ channels [297] in a manner similar to cromakalim, nicorandil, or diazoxide. These effects also occur in the heart,[298] which appeared to explain why levosimendan reduced infarct size in a dog model.[299] However, other studies of levosimendan's vasodilator effects have not found evidence for ATP-sensitive K^+ channel activity while demonstrating phosphodiesterase inhibition, [300] and in human cardiac cells, activation of ATP-sensitive K^+ channels by levosimendan occurs at substantially higher concentrations (10 muM) than therapeutic concentrations (20 nM).[295] In addition, other PDEIs have reduced infarct size in model systems,[301] and a direct comparison of levosimendan to milrinone and amrinone in an infarct rabbit model found no difference in the antiischemic effects of the three agents.[302] Thus, ATP-sensitive K^+ channel activation, the newest addition to the pharmacological profile of levosimendan, is an unproved candidate for the mechanism of vasodilation and for protection against ischemic damage. Since it is not operative in the human heart at therapeutic concentrations, it is unlikely that this mechanism will provide cardioprotection from ischemic injury.

Levosimendan is in clinical development in both oral and intravenous forms. In intravenous form, levosimendan has been evaluated in two clinical trials that have been presented at national meetings but not yet published. In an acute myocardial infarction study conducted in Russia, levosimendan was randomized against placebo, and not surprisingly, the positive inotropic agent produced better circulatory support.[303] In another study where approximately 40 percent of the subjects were taking beta blockers, levosimendan performed better than dobutamine in hemodynamic response.[304] This result is also expected

*Not approved by the FDA.

since by virtue of their respective sites of action, beta blockade would inhibit the response to dobutamine but not to levosimendan. These studies do not provide evidence that levosimendan is superior to other PDEI-positive inotropic agents currently available in intravenous form.

CALCIUM SENSITIZERS

Some compounds are in development whose principal or dominant action is calcium sensitization, and they may have potential as positive inotropic agents, provided that diastolic function is not adversely affected and that vasoconstriction is not part of their pharmacological profile. One such compound is CGP 48506,[294] and another is EMD 57033.[305] EMD 57033 is the (+) enantiomer of EMD 53998, a racemic thiadiazinone compound whose other, (-) isomer (EMD 57439) is a pure type III PDEI.[305] In model systems, EMD 57033 increases systolic function without affecting blood pressure or the heart rate, which are respectively decreased and increased by EMD 57439.[305] Moreover, EMD 57033 binds to the human troponin I-troponin C complex.[289] The problem is that EMD 57033 causes diastolic dysfunction in human ventricular myocardium, with failing hearts much more adversely affected than nonfailing hearts.[306] Moreover, the racemic compound EMD 53998, even though it contains the phosphodiesterase III enantiomer, causes diastolic dysfunction that becomes more pronounced in ischemia.[307] However, some evidence indicates that the calcium sensitizer CGP 48506 does not inhibit relaxation.[308] Thus, it is unclear whether pure calcium sensitizers will have a therapeutic role as positive inotropic agents.

Neurohormonal Cytokine Inhibitors

Without question, the greatest advance in the treatment of chronic HF has been the application of agents that inhibit harmful neurohormonal systems that are activated to support the failing heart (see Chaps. 16 and 21) . This generally useful paradigm had multiple origins, including work done by the Minnesota group in the late 1970s and early 1980s that documented the nature and extent of neurohormonal activation in chronic HF,[309] [310] the association of systemic neurohormonal activation with adverse outcomes,[311] [312] observations in the failing human heart that excessive adrenergic activation produces harmful biological effects,[164] [313] and astute clinical observations regarding the degree of improvement effected by inhibitors of the adrenergic[314] [315] [316] and renin-angiotensin[317] [318] [319] systems. By the mid to late 1980s, influential commentaries on the validity of the "neurohormonal hypothesis" were being articulated,[309] [320] [321] [322] and all these developments ultimately culminated in the performance of large-scale clinical trials that demonstrated that inhibition of the renin-angiotensin[323] [324] and adrenergic[325] [326] [327] [328] [329] systems improved the natural history of chronic HF caused by a dilated cardiomyopathy (primary or secondary) phenotype. The success with inhibition of the adrenergic and renin-angiotensin systems has led to extension of the general paradigm to other neurohormonal or cytokine systems that promote growth and remodeling in the failing heart, such as endothelin antagonists and inhibitors of tumor necrosis factor-alpha (TNF-alpha).

The general mechanisms by which neurohormonal activation worsens and neurohormonal inhibition improves the natural history of myocardial dysfunction and remodeling are discussed in Chapter 21 . In essence, multiple neurohormonal signaling pathways, such as beta$_1$ -, beta$_2$ -, and alpha$_1$ -adrenergic receptor,[177] angiotensin II AT$_1$ receptor,[330] endothelin-1 ET$_A$ receptor,[331] and TNF-alpha receptor pathways,[332] are activated in the failing heart and promote maladaptive growth, remodeling, and progressive myocardial dysfunction.[108] Inhibition of these systems prevents or reverses these adverse biological processes, thereby leading to improvement in the natural history of HF. Therapy targeting individual neurohormonal or cytokine systems will now be discussed.

INHIBITORS OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM (See also Chap. 29)

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors were the first consistent and substantial success story for medical therapy to improve the natural history of chronic HF, and this class of neurohormonal inhibitors remains a mainstay in HF treatment. ACE inhibitors were originally developed within the vasodilator paradigm,[317] but when their clinical results proved to be out of proportion to their relatively weak vasodilator effects (see Table 18-3) , it became apparent that another mechanism was operative. That mechanism, as elucidated by the Pfeffers' laboratory in elegant studies in myocardial infarction animal models[333] [334] and humans[318] [319] and then confirmed in chronic HF,[335] is the prevention of angiotensin II-mediated remodeling.[108]

MECHANISMS OF ACTION.

Figure 18-5 shows the pathways for angiotensin II formation, which occurs systemically as well as locally in cardiac and vascular tissue. Note that generation of angiotensin II is accomplished by two pathways, one that uses converting enzyme found in high abundance in endothelium and one that uses the protease chymase, which is found in interstitial cells. Transmyocardial studies in the intact human heart have indicated that greater than 80 percent of the generation of angiotensin II is via the ACE pathway,[336] but studies in isolated human heart preparations[337] and in model systems[338] have emphasized the contribution of the chymase pathway. If the chymase pathway is important in producing ventricular remodeling in the failing heart, angiotensin receptor-blocking agents (ARBs) would be more effective than ACE inhibitors in decreasing angiotensin II signaling. If, on the other hand, ACE inhibitors are just as effective clinically as ARBs, by inference, the ACE pathway is the dominant mechanism for generating angiotensin II in the failing heart. Finally, if ACE inhibitors are superior to ARBs, additional properties of

Figure 18-5 Pathways of angiotensin II formation. ACE=angiotensin-converting enzyme; Ang-1=angiotensin I; AT$_1$ R=angiotensin II type 1 receptor; NE=norepinephrine.

TABLE 18-7 -- BIOLOGICAL RESPONSES MEDIATED BY ANGIOTENSIN II RECEPTORS IN THE HUMAN CARDIOVASCULAR SYSTEM

BIOLOGICAL RESPONSE	RECEPTOR MEDIATION
Cardiac myocyte growth	AT$_1$
Positive inotropic response (minimal)	AT$_1$
Myocyte apoptosis	AT$_1$, AT$_2$
Aldosterone release	AT$_1$
Norepinephrine release	AT$_1$
Cardiac myocyte toxicity	Beta-adrenergic via norepinephrine release
Fibroblast proliferation	AT$_1$
Smooth muscle proliferation	AT$_1$
Vasoconstriction	AT$_1$

ACE inhibitors, such as increasing bradykinin,[339] are presumably responsible. Based on the results of the Evaluation of Losartan in the Elderly Study II (ELITE-II, see below), at present it would seem that the ACE pathway is the predominant means of generating angiotensin II in the human heart and that enhancement of bradykinin levels may well be important.

Studies in the failing human heart indicate that ACE gene[340] [341] and protein[341] expression and enzyme activity [336] [341] are increased, but chymase gene expression is not.[340] Systemically increased renin is taken up by failing human ventricles in larger amounts than by nonfailing ventricles,[342] and failing human hearts also exhibit lower angiotensinogen protein levels compatible with substrate depletion.[342] Finally, angiotensin II type 1 (AT$_1$) receptors are selectively downregulated in the failing human heart at the protein[343] and mRNA[344] levels, probably as a result of increased exposure to angiotensin II. These data indicate that the local myocardial renin-augiotensin system (RAS) is induced in the failing human heart, which adds to the increased systemic activation. No such induction seems to occur with the chymase system.

As shown in Table 18-7 , increased levels of angiotensin II have several adverse effects on the cardiovascular system, including cardiac myocyte hypertrophy, myocyte

apoptosis, presynaptic facilitation of norepinephrine release, and mitogenic effects on fibroblasts. Most, if not all of these effects are mediated via the AT_1 subtype. In addition, most of these biological effects of angiotensin II contribute to the development of hypertrophy and remodeling.

CLINICAL OBSERVATIONS.

Two types of studies demonstrate the consistent efficacy of ACE inhibitors in HF: post-myocardial infarction studies and clinical trials in chronic HF. As shown in Table 18-8 , more of the former studies than the latter have been conducted. All placebo-controlled chronic HF trials, with the exception of the "asymptomatic" Studies of Left Ventricular Dysfunction (SOLVD) Prevention Study,[345] demonstrated a reduction in mortality. As can be observed in Table 18-8 , the Class IV Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS I) had a much larger effect size than did the SOLVD Treatment Trial (Fig. 18-6) , which in turn had a larger effect size than the SOLVD Prevention Trial did. Although only these three placebo-controlled mortality trials have been conducted in patients with chronic HF, it seems obvious that ACE inhibitors reduce mortality in direct relation to the degree of severity of chronic HF. Although not placebo controlled, the V-HeFT-II Trial provided evidence that ACE inhibitors improve the natural history of HF through mechanisms other than vasodilation, inasmuch as subjects treated with enalapril had significantly lower mortality than did subjects treated with the nonneurohormonal inhibitor-vasodilator combination of hydralazine plus isosorbide dinitrate.[103]

Although only one ACE inhibitor, enalapril, has been used in placebo-controlled mortality trials in chronic HF, as can be observed in Table 18-8 , multiple ACE inhibitors have proved to be more or less equally effective when administered in oral form within the first week of the ischemic event in post-myocardial infarction trials.[346] [347] [348] This observation leads to the conclusion that the effects of ACE inhibition on the natural history of chronic HF or post-myocardial infarction left ventricular dysfunction are class effects.

In summary, an ACE inhibitor is considered mandatory treatment in chronic HF or in asymptomatic left ventricular systolic dysfunction. The doses employed should be at least the average dose used to lower mortality in heart failure or post-myocardial infarction trials. The only consistent adverse effect noted with ACE inhibitors is a low-level (5 percent greater than placebo) increase in cough. In such patients, an angiotensin II AT_1 receptor-blocking agent can be substituted.

Aldosterone Antagonists

It has been shown in numerous studies that ACE inhibitors do not completely inhibit tissue-based RAS systems[349] [350] [350A] and that after several months of treatment, "escape" can

occur with an increase in systemic angiotensin II[351] or aldosterone[352] levels. These observations set the stage for additional RAS inhibitor strategies, and one of them was addition of the competitive nanomolar-affinity aldosterone antagonist spironolactone[18] to ACE inhibitor therapy. This combination was used in the Randomized Aldactone Evaluation Study (RALES) Trial, which evaluated the addition of 25 mg of spironolactone vs. placebo to standard HF therapy

Figure 18-7 Results of the RALES Trial. (Reprinted, by permission, from Pitt B, Zannad F, Remme WJ, et al: The effect of spironolactone on morbidity and mortality in patients with severe heart failure. Randomized Aldactone Evaluation Study Investigators. N Engl J Med 341:709-717, 1999.)

in stage C (New York Heart Association [NYHA] Class III or IV) patients, with a primary endpoint of all-cause mortality.[23] As can be observed in Figure 18-7 , in RALES, spironolactone produced a 31 percent reduction in total mortality when compared with placebo (p=0.001). The beneficial effect of spironolactone appeared to be on both sudden and pump failure deaths. Although the mechanism behind the benefit of spironolactone has not been elucidated, prevention of extracellular matrix remodeling[353] and/or prevention of increasing potassium levels are leading contenders. In RALES, serum potassium levels were 0.3 mEq/liter higher in the spironolactone group than in the placebo group (p=0.001), [23] which could have played a major role in reducing sudden or even pump failure deaths.

Although spironolactone was well tolerated in RALES, it is associated with a small incidence of gynecomastia, which may lead to discontinuation. Some newer-generation aldosterone antagonists have a much lower incidence of this adverse effect, and one of them, eplerenone, is currently being evaluated in a large-scale post-myocardial infarction clinical trial.

Angiotensin II AT_1 Receptor-Blocking Agents

Six angiotensin receptor blockers (ARBs) approved for the treatment of hypertension are now on the market in the United States. However, none of them has received approval for the treatment of HF. The rationale for the use of these agents is derived from information presented in Table 18-7 , which is that virtually all the adverse

biological effects relevant to a failing, remodeled heart are mediated by the AT_1 receptor. Moreover, ARBs antagonize the effects of

angiotensin II regardless of its origin (via the ACE or chymase pathway). All these compounds are selective, high-affinity antagonists of AT_1 receptors.

Hemodynamic studies and studies with ARBs in HF have demonstrated effects that are similar to those of ACE inhibitors; that is, these agents reduce pulmonary wedge and pulmonary artery pressure moderately, are mild preload reducers, and increase cardiac output.[354] [355] [356] The heart rate is not affected unless baroreflexes are excessively activated by hypotension. Maximum exercise time is also improved to a similar degree with each type of RAS inhibitor.[356A] [357] [358]

Clinical trial data on ARBs are emerging, but the results thus far are limited and mixed. The initial comparison of an ARB (losartan) to an ACE inhibitor (captopril) was in ELITE (or ELITE-I); no difference in the primary endpoint of renal function was found in an elderly HF population, but unexpectedly, a 46 percent reduction in mortality (p=0.035) was noted in losartan-treated patients.[359] These results led to a mortality trial, ELITE-II, to test the hypothesis that losartan reduces mortality in comparison to captopril-treated patients. The results of ELITE-II are *not* consistent with ELITE-I in that losartan tended to *increase* mortality when compared with captopril.[359A] At this juncture, there is no reason to believe that ARBs will prove superior to ACE inhibitors in patients with HF, with the exception of the side effect of cough (4 percent with captopril, 0 percent with losartan in ELITE-I).[359] Moreover, based on bradykinin enhancement by ACE inhibitors, it is possible that ARBs will, in fact, be inferior to ACE inhibitors.

The future of ARB treatment in chronic HF would appear to be in combination with ACE inhibitors (and potentially spironolactone) to provide more complete inhibition of the RAAS. This view is supported by the observation that the combination of an ACE inhibitor and an ARB produces additive hemodynamic effects.[360] [361] Recently reported clinical trial data also support this concept. The Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD) Trial[362] compared enalapril, the ARB candesartan, and a combination of the two for their effects on remodeling and clinical parameters. In this trial, the combination of an ACE inhibitor plus an ARB produced the greatest degree of inhibition of remodeling.[362] Other studies investigating the combination of an ACE inhibitor and an ARB that have clinical primary endpoints (such as the Valsartan in Heart Failure Trial[363] [Val-HeFT]) are under way, and they will yield a definitive answer regarding ARBs in combination with ACE inhibitors.

For the time being, recommendations for the use of ARBs in chronic HF are limited to patients who are ACE inhibitor intolerant, particularly those with an ACE inhibitor-induced cough.

ANTIADRENERGIC AGENTS

Beta-Adrenegic Receptor-Blocking Agents (See also Chap. 37)

The failing human heart is adrenergically activated[364] [365] to maintain cardiac performance over the short term by increasing contractility[366] and heart rate. In contrast, in the resting state, no adrenergic support occurs in normally functioning human left ventricles.[366] Multiple lines of evidence[367] [368] [369] indicate that it is increased cardiac adrenergic drive rather than an increase in circulating norepinephrine that is both initially supportive and then ultimately damaging to the failing human heart.

BETA-ADRENERGIC RECEPTORS.

As shown in Table 18-9 , human cardiac myocytes have three adrenergic receptors ($beta_1$, $beta_2$, and $alpha_1$) that are coupled to a positive

TABLE 18-9 -- BIOLOGICAL RESPONSES MEDIATED BY ADRENERGIC RECEPTORS IN THE HUMAN HEART

BIOLOGICAL RESPONSE	ADRENERGIC RECEPTOR MEDIATION
Cardiac myocyte growth	$beta_1$, $beta_2$, $alpha_1$
Positive inotropic response	$beta_1$, $beta_2$, $alpha_1$ (minimal)
Positive chronotropic response	$beta_1$, $beta_2$
Myocyte toxicity	$beta_1$, $beta_2$ (?<$beta_1$)
Myocyte apoptosis	$beta_1$

inotropic response and cell growth.[162] [163] [177] [370] [371] Beta-adrenergic receptors are coupled via the "stimulatory" G protein G_s to the effector enzyme adenylyl cyclase, which converts the substrate Mg-ATP to cAMP. cAMP is a positive inotropic and chronotropic second messenger and is also strongly growth promoting. In younger (<50 years) nonfailing human left or right ventricles, the $beta_1$ /$beta_2$ ratio is 70 to 80/30 to 20,[313] but in failing[162] [370] [371] or older[372] human ventricles, 35 to 40 percent of the total number of beta receptors are $beta_2$ as a result of selective downregulation in the $beta_1$ subtype. $Alpha_1$ receptors are coupled via a different G protein (G_q) to the effector enzyme phospholipase C, which through the second messenger diacylglycerol activates the growth-promoting protein kinase C family. Because $alpha_1$ receptors are upregulated in the failing heart, [373] [374] the cardiac myocyte adrenergic receptor profile changes from predominantly (>70 percent of the total adrenergic receptor population) $beta_1$ to more of a mixed, 2:1:1 ratio in end-stage HF.[162] [163] [177] $Beta_2$ receptors are also present on adrenergic nerve terminals in the heart, where they facilitate norepinephrine release.[375] The $beta_3$ receptor may also be present in the human heart as a counterregulatory receptor coupled to the "inhibitory" G protein G_i ,[376] and evidence also exists for a "$beta_4$ " receptor.[377]

CARDIAC DAMAGE INDUCED BY RECEPTOR ACTIVATION.

Norepinephrine is an exceptionally cardiotoxic substance that produces cardiac myocyte injury[378] in concentrations found in the failing human heart. Norepinephrine is mildly (10- to 30-fold when compared with the binding affinity to $beta_2$ receptors) $beta_1$ receptor selective, and its cytotoxicity appears to be mediated through beta- rather than alpha-adrenergic receptors.[378] In transgenic mice, cardiac overexpression of human $beta_1$ receptors,[379] [380] [381] $beta_2$ receptors,[382] G_{alpha} s, [383] or G_{alpha} q[384] produces an overtly cardiomyopathic phenotype and, ultimately, chamber dilatation and systolic dysfunction. Although direct comparisons have yet to be made, it appears that higher levels of expression of human $beta_2$ versus $beta_1$ receptors are required to produce histopathology.[379] [380] [381] [382] Overexpression of G_{alpha} s is also associated with increased markers of apoptosis,[385] which can be produced in cardiac myocytes by norepinephrine exposure.[386] [387] [388] Norepinephrine-mediated apoptosis is mediated through $beta_1$ receptors,[388] and apoptosis is prominent in cardiac $beta_1$ receptor-overexpressing mice.[389] Finally, cardiac expression of a constitutively activated $alpha_1$ receptor produces concentric hypertrophy. [70] These data from model systems incontrovertibly indicate that chronic adrenergic signaling is a harmful compensatory mechanism in the failing human heart. The data are extremely convincing for chronic $beta_1$ receptor signaling and less convincing, but likely for chronic $beta_2$ and $alpha_1$ receptor pathway activation. The compensatory as well as adverse effects of adrenergic signaling pathways are summarized in Figure 18-1 and Table 18-9 .

Interestingly, when components of the beta-adrenergic-adenylyl cyclase-phospholamban phosphorylation pathway are transgenically manipulated beyond the level of G_{alpha} s, no overt pathology is apparent despite marked and sustained

increases in contractility.[207] [390] This finding may mean that G_{alpha} s-coupled cAMP-independent pathways mediate the majority of myocardial damage in beta-adrenergic receptor- and G_{alpha} s-overexpressing animals.

In the failing heart, beta-adrenergic signal transduction is reduced secondary to desensitization changes at the level of $beta_1$ and $beta_2$ receptors, the inhibitory G protein (G_i), and an enzyme responsible for modulating receptor activity by phosphorylation (beta-adrenergic receptor kinase), as well as by changes in expression of the adenylyl cyclase enzyme itself.[162] [177] [227] [228] [229] [370] [371] [391] [392] In an end-stage failing heart, 50 to 60 percent of the total signal transducing potential is lost, but

substantial signaling capacity remains.[165] These and other data from model systems[378] [393] suggest that the beta-adrenergic receptor pathway desensitization changes present in the failing human heart are adaptive changes and that a potentially effective therapeutic strategy would be to add to this endogenous antiadrenergic strategy by inhibiting receptor signal transduction.[163] [177] [313] [394] [395] [396]

Thus, the chronically increased adrenergic drive present in the failing human heart delivers adverse biological signals to the cardiac myocyte via $beta_1$ -, $beta_2$ -, and possibly $alpha_1$ -adrenergic receptors. Elimination of these adverse signals is the fundamental reason for using antiadrenergic agents in the treatment of chronic HF.

TREATMENT OF HEART FAILURE.

Because of their availability, beta-adrenergic blocking agents were the first antiadrenergic agents used to treat chronic HF.[314] Although three classes of beta blockers are now available for clinical use, only the "second-generation," $beta_1$ receptor-selective antagonists or the "third-generation," beta blocker-vasodilators are tolerated to an acceptable degree by subjects with chronic HF.[397] Second-generation compounds are tolerated because they do not block cardiac presynaptic or postsynaptic $beta_2$ receptors,[177] [375] [397] [398] while third-generation compounds are tolerated because their afterload-reducing properties mitigate the cardiac output-reducing effects of beta-adrenergic withdrawal.[177] [397] [399] The receptor-binding profiles of beta-blocking agents that have been used successfully to treat HF are given in Table 18-10 .

Regardless of the type of beta-blocking agent used, the treatment approach that must be taken in subjects with chronic HF is to start with extremely low (one-eighth to one-sixteenth of the target dose) doses and gradually increase the dose every 1 to 2 weeks to full beta-blocking doses.[397] [397A] When this approach is taken, over 90 percent of subjects with mild to moderate or stage B HF can tolerate beta blockade.[397]

The general mechanism of action of beta blockade in the failing, remodeled heart has been extensively reviewed.[108] [163] [177] [401] Both second- and third-generation beta-blocking agents improve intrinsic systolic function and reverse remodeling in primary or secondary cardiomyopathy in a time-dependent fashion that begins after an initial period of myocardial depression related to withdrawal of beta-adrenergic support.[108] [163] [177] However, these effects are not uniform across all treated subjects, and some subjects may deteriorate and have an adverse clinical response to beta blockade.[402]

The various beta blockers that have had substantial clinical trial experience in chronic HF or that are in development will now be reviewed.

Metoprolol

As can be observed in Table 18-10 , metoprolol is a second-generation, $beta_1$ receptor-selective blocking agent with an approximately 75-fold higher affinity for human $beta_1$ versus $beta_2$ receptors. Metoprolol is not yet approved for the treatment of HF in the United States but is approved for hypertension and ischemic heart disease indications. Metoprolol is approved in some European countries for an HF indication. The first placebo-controlled multicenter trial with a beta-blocking agent was the Metoprolol in Dilated Cardiomyopathy (MDC) Trial.[325] The MDC Trial compared metoprolol tartrate with placebo in subjects with symptomatic HF caused by idiopathic dilated cardiomyopathy. The sample size estimate was based on an expected 50 percent reduction by metoprolol in the combined endpoint of all-cause mortality and deterioration of the patient to the point of requiring listing for heart transplantation. The MDC Trial also had numerous prespecified secondary endpoints, including mortality alone, number of hospitalizations, left ventricular function, quality of life, and exercise tolerance.[325] In the MDC Trial, metoprolol at an average dose of 108 mg/d reduced the prevalence of the primary endpoint by 34 percent, which was not quite statistically significant (p=0.058). [325] The benefit was entirely due to a reduction by metoprolol in the morbidity endpoint (a reduction of 90 percent), inasmuch as a greater trend toward all-cause mortality was in fact seen in the metoprolol-treated group.[326] In addition, when compared with placebo, metoprolol improved left ventricular function, quality of life, number of hospitalizations, and exercise tolerance at 12 months.[325]

CLINICAL TRIALS.

The encouraging results of the MDC Trial led to a more traditional placebo-controlled mortality

$K(alpha_1)$=dissociation constant determined from ^{125}I-BE2254 competition curves in human ventricular myocardial membranes. $K(beta_1)$=average of the high-affinity dissociation constant determined from ^{125}I-CYP competition curves in human ventricular myocardial membranes, the dissociation constant determined from competition curves in transfected cells expressing recombinant human $beta_1$ receptors, and the dissociation constant determined from inhibition of isoproterenol-mediated stimulation of muscle contraction in preparations of nonfailing human heart. $K(beta_2)$=average of the low-affinity dissociation constant determined from ^{125}I-CYP competition curves, the dissociation constant determined from simple curve fitting in transfected cells expressing recombinant human $beta_2$ receptors, and the dissociation constant determined from inhibition of isoproterenol-mediated stimulation of adenylyl cyclase in membrane preparations of human heart.

*Beta receptors are the average of data from radiological binding data in myocardial membranes and recombinant receptors and inhibition in functional assays; $alpha_1$ receptors are from myocardial membranes. Metoprolol and bisoprolol data are from radiological binding data in myocardial membranes. Nebivolol data are from another laboratory in guinea pig receptor preparations.[400]

Based on an $alpha_1$ K_i of 69 nM in human saphenous vein ring segments (Tackett RL, personal communication, 1999).

trial, the Metoprolol CR/XL Randomized Interventional Trial in Congestive Heart Failure (MERIT-HF), which was stopped prematurely because of a 34 percent reduction in mortality in the metoprolol arm[329] (Fig. 18-8). The MERIT-HF Trial enrolled 3991 subjects with ischemic and nonischemic dilated cardiomyopathy who had Class II to IV HF, and the metoprolol preparation used was a continuous-release (CR), single-daily dose formulation of coated metoprolol succinate pellets.[329] Importantly, the average dose of metoprolol achieved in MERIT-HF was larger than in the MDC Trial, 159 versus 108 mg. The majority (97 percent) of patients enrolled in MERIT-HF were categorized as having Class II or III HF, and based on the annualized mortality of 11 percent in the placebo group and the baseline left ventricular ejection fraction of 28 percent, this landmark clinical trial enrolled subjects with mild to moderate HF and moderate to severe systolic dysfunction. Importantly, in the MERIT-HF, mortality from sudden death or progressive pump failure was reduced.[326] In addition, mortality was reduced across most demographic groups, including older versus younger subjects, nonischemic versus ischemic etiology, and lower versus higher ejection fractions.[329] However, almost no mortality reduction was noted in the relatively small number of female subjects enrolled (23 percent of the total),[329] which suggests that gender may influence the response to beta blockade in HF populations.

The CR preparation used in MERIT-HF produces a relatively constant blood level of metoprolol for 24 hours.[403] The bioavailability of the CR preparation is approximately 70 percent of the conventional formulation.[403] However, when compared with 50 mg twice daily of the conventional formulation, 100 mg/day of the CR preparation produces similar trough levels and degrees of reduction in the exercise heart rate, thus indicating bioequivalence of the two preparations.[403] The reduced fluctuation in blood levels for the CR versus the conventional formulation provides the potential for improved tolerability of the CR formulation in patients with HF, but no direct comparison studies have been performed. In addition, the much more shallow slope of the CR plasma concentration curve at the end of the dosing interval would theoretically reduce the potential of producing a beta blocker withdrawal effect[404] if doses are missed or dosing intervals are prolonged. Although these differences in pharmacokinetics could account for a greater efficacy of the CR preparation in reducing mortality, in the absence of direct comparison data demonstrating superiority of the CR formulation in HF populations, it is reasonable to assume that twice-daily dosing of the conventional tartrate metoprolol preparation is clinically equivalent to the

same daily dose of the CR formulation. Indeed, recent data comparing metoprolol tartrate with the CR succinate preparation in subjects with chronic HF indicate no obvious difference in efficacy between the two preparations.[405] However, therapy can be initiated with 12.5 or 25 mg of metoprolol succinate

Figure 18-8 Kaplan-Meier curves of the cumulative percentage of total mortality *(A)*, sudden deaths *(B)*, and deaths from worsening heart failure *(C)* in the MERIT-HF Trial. CR by simply halving the scored 50-mg tablet,[405] which is an advantage when compared with specially preparing 6.25-mg capsules of the tartrate.

Bisoprolol

Bisoprolol is a second-generation, $beta_1$ receptor-selective blocking agent with an approximately 120-fold higher affinity for human $beta_1$ versus $beta_2$ receptors (Table 18-10) . Bisoprolol is approved for the treatment of hypertension but not HF in the United States; however, it was recently approved for HF treatment in Europe. The first trial performed with bisoprolol was the Cardiac Insufficiency Bisoprolol Study I (CIBIS-I) Trial, which was a placebo-controlled trial of the effects of bisoprolol on mortality in symptomatic ischemic or nonischemic cardiomyopathy subjects treated for an average follow-up of 22.8 months[406] (Fig. 18-9) . This trial, sample-sized on an unrealistically high expected event rate in the control group, ended up with a statistically insignificant, 20 percent mortality reduction.[406] In addition, the benefit in this trial was confined to subjects with nonischemic cardiomyopathy, who had a 47 percent reduction (p=0.01) in mortality in comparison to placebo.[406] Despite the lack of overall statistical significance in CIBIS-I, the reduction in mortality was similar to what has been accomplished with ACE inhibitors and was viewed as encouraging. The results prompted a follow-up trial, CIBIS-II,[328] with more conservative effect size estimates and sample size calculations.

The CIBIS-II Trial was stopped by the Data and Safety Monitoring Committee 18 months early because of a 32 percent reduction ($p < 0.001$) in all-cause mortality (see

Figure 18-9 *A,* Survival curves in the CIBIS-II Trial. *B,* Relative risk of treatment effect on mortality by etiology and functional class at baseline in the CIBIS-II Trial. Horizontal bars represent 95% confidence intervals. (From CIBIS-II Investigators and Committees: The Cardiac Insufficiency Bisoprolol Study II [CIBIS II]: A randomized trial. Lancet 353:9-13, 1999. © by The Lancet Ltd., 1999.)

Table 18-4) in the bisoprolol-treated group.[328] CIBIS-II enrolled 2647 patients with Class III or IV HF caused by ischemic and nonischemic cardiomyopathy; the median follow-up was 1.3 years. In addition to the reduction in mortality, bisoprolol also reduced the number of hospitalizations (by 20 percent) and cardiovascular deaths (by 29 percent).[328] In CIBIS-II,[328] deaths classified as sudden were statistically reduced (by 44 percent) in the bisoprolol group, whereas pump failure deaths were nonsignificantly reduced by 26 percent.

This trend toward a greater reduction in sudden versus pump failure deaths was opposite that obtained in CIBIS-I.[406] Another difference between CIBIS-I and CIBIS-II was the effect on ischemic versus nonischemic cardiomyopathy, which also demonstrated opposite trends. In CIBIS-I,[406] the reduction in mortality in the nonischemic group was 47 percent (p=0.01), whereas in patients with a history of myocardial infarction, a trend toward an increase in mortality (by 11 percent) was noted in the bisoprolol group. One possible explanation for the differences between the CIBIS-I and CIBIS-II trials is the average dose of bisoprolol used; in CIBIS-II the target dose was 10 mg/day,[328] whereas in CIBIS-I it was 5 mg/day.[406]

Although CIBIS-II enrolled patients with Class III (>90 percent of the total) or Class IV symptoms, the annualized placebo mortality was only 13.2 percent[328] (Table 18-11) . This mortality rate is similar to that found in the enalapril arm of the SOLVD Treatment Trial,[324] which was composed of 68 percent Class I and II patients. In addition, the average blood pressure of patients enrolled in CIBIS-II was 130/80, which is higher than the blood pressures of the SOLVD patients[324] or the patients enrolled in the U.S. Carvedilol Trials, who were approximately 50/50 Class II/III.[326] A relatively large proportion of CIBIS-II patients were enrolled in Eastern Europe and Russia, where practice patterns, HF etiology, or symptom interpretation may not be comparable to that in Western Europe and the United States. Nevertheless, the results of CIBIS-II were internally consistent through all major demographic groups,[328] and the impressive results constitute a landmark clinical trial in the development of beta blockade as therapy for chronic HF.

Carvedilol

As may be noted in Table 18-10 , carvedilol is a minimally $beta_1$ receptor-selective beta-blocking agent that also has high affinity for $alpha_1$ receptors and antioxidant action.[406A] Because carvedilol is a potent vasodilator, its side effect profile on initiation of therapy and during uptitration is different from that of highly $beta_1$ -selective second-generation agents, with orthostatic symptoms being more prominent.[397] At low doses (
6.25 mg twice daily) carvedilol may exhibit some $beta_1$ selectivity in humans with HF. [407] At higher target doses, carvedilol blocks all three adrenergic receptors coupled to hypertrophy and other adverse biological effects (see Table 18-9) that contribute to remodeling and myocardial dysfunction in the failing human heart. The idea that a comprehensive antiadrenergic profile is desirable is supported by the results of the Multicenter Oral Carvedilol Heart Failure Assessment (MOCHA) Trial, which demonstrated left ventricular functional and clinical superiority of 25 mg carvedilol twice daily over 6.25 mg twice daily.[327] In addition, because it blocks presynaptic $beta_2$ receptors, carvedilol mildly reduces cardiac adrenergic drive.[408] Because of its potent, comprehensive antiadrenergic action, the beneficial effects of carvedilol on myocardial function and reversal of remodeling tend to be greater than for $beta_1$ -selective compounds.[408] [409] [410] [411] [412] [412A] [412B] However, it is not yet clear whether this superiority translates into better clinical results in view of the excellent results of $beta_1$ -selective compounds in the MERIT-HF[329] and CIBIS-II[328] trials. The answer to this question will be given by the outcome of the Carvedilol and Metroprolol European Trial (COMET) which is comparing the effects of metoprolol and carvedilol on all-cause mortality.

Carvedilol is currently the only beta blocker approved for the treatment of chronic HF in the United States, and it is also approved in most other countries. The controlled clinical trial data base for carvedilol is extensive. To date, 1748 patients have been enrolled in eight randomized, placebo-controlled phase II and III clinical trials with carvedilol. [326] [327] [413] [414] [415] [416] [417] [418] [419] [420] Although data on carvedilol are not yet

Effect size at 2 years.

available from prospectively designed placebo-controlled mortality trials (one such trial, the Carvedilol Prospective Randomized Cumulative Survival Trial (COPERNICUS), is in progress), the phase III U.S. Carvedilol Trials Program was stopped prematurely by the Data and Safety Committee monitoring all four trials because of a highly significant ($p < 0.0001$) 65 percent reduction in mortality by carvedilol versus placebo.[326] In addition, one individual trial (MOCHA) demonstrated a highly statistically significant 73 percent reduction in mortality.[327] However, because these trials were relatively short-term and the number of events was small, the data from MOCHA or the rest of the U.S. Carvedilol Trials Program were not considered by the FDA to be conclusive for an indication of mortality reduction. Carvedilol has been approved by the FDA for delaying progression of the myocardial disease process and lowering the combined risk of morbidity plus mortality.[421] Approval was based on (1) results from the "Mild" HF trial,[417] which demonstrated that carvedilol reduced the probability of development of the combined endpoint of mortality, cardiovascular hospitalization, or an increase in associated HF medical treatment when compared with placebo, and (2) grouped analysis of all four U.S. trials[327] [416] [417] [418] and one conducted in Australia-New Zealand[420] in which carvedilol reduced the combined endpoint of mortality or cardiovascular hospitalization.

To date, all the reported trials demonstrating unequivocal efficacy with carvedilol have been in stage A (asymptomatic to mild symptoms) or B (mild to moderate symptoms) HF. The two trials conducted in more advanced HF either had too many subjects eliminated up-front by carvedilol challenge[415] or were too small to reach conclusions.[418] The COPERNICUS mortality trial is investigating Class III to IV (stage C) HF, and this trial plus the Beta-Blocker Evaluation Survival Trial (BEST, see below) will provide the answer to whether beta blockers are indicated in patients with more advanced HF.

BUCINDOLOL

Bucindolol is a completely nonselective third-generation beta-blocking agent with mild vasodilator activity that is probably due to weak $alpha_1$ receptor-blocking properties.[177] The mild vasodilator properties of bucindolol coupled with its low "inverse-agonist" profile[177] [422] [423] make this beta blocker extremely well tolerated in HF subjects,[397] including those with advanced HF.[424] Inverse agonism is the ability of a receptor antagonist to inactivate "active-state" receptors that are precoupled to G proteins and capable of transducing signals without agonist occupancy.[163] In the human heart, the percentage of such precoupled beta-adrenergic receptors identified by high-affinity agonist binding is on the order of 10 to 30 percent of the total. Antagonists such as metoprolol and to a lesser extent carvedilol have a greater ability than bucindolol to inactivate these active-state receptors, which is probably why bucindolol is associated with less intrinsic myocardial depression and lowers 24-hour Holter-monitored heart rates less than metoprolol or carvedilol does.[399] The latter property translates into less symptomatic bradycardia with bucindolol, which is why the BEST Trial had a much lower heart rate exclusion criterion (50 beats/min)[425] than other beta blocker HF trials did (typically 68 beats/min). Thus, a low inverse-agonist profile is a property that increases the tolerability of a beta blocker in subjects with HF.

Although bucindolol has intrinsic sympathomimetic activity in some smaller animal species,[426] [427] because of differences in the stoichiometry of receptor-G protein coupling between animal models and humans, bucindolol has no intrinsic sympathomimetic activity in failing[315] [399] [428] [429] or nonfailing[430] human hearts. Finally, because of its potent $beta_2$ receptor-blocking properties coupled with only mild vasodilation, bucindolol is the only beta-blocking agent that has been shown to lower systemic adrenergic activity in subjects with HF.[315] [424] Thus, the unique pharmacological profile of bucindolol allows an agent with comprehensive antiadrenergic activity to be given to patients with advanced, stage C HF.[424] [425]

CLINICAL OBSERVATIONS.

The third-generation nonselective compound bucindolol was the first beta-blocking agent shown to improve left ventricular function in a placebo-controlled trial,[315] and it was the first beta-blocking agent shown to improve load-independent, intrinsic systolic function.[316] In those[315] and subsequent phase II trials, [431] [432] bucindolol was well tolerated, in marked contrast to previous[433] [434] and subsequent[435] experience with the nonselective first-generation agent propranolol. Bucindolol was the second beta-blocking agent to be evaluated in a multicenter trial in which bucindolol produced a dose-related improvement in left ventricular function and a dose-unrelated prevention of deterioration in left ventricular function in subjects with symptomatic ischemic and nonischemic cardiomyopathy treated for a 12-week period.[432] Based on these data, doses of bucindolol with very high degrees of beta blockade[432] (100 mg twice daily for subjects heavier than 75 kg, 50 mg twice daily for subjects less than 75 kg) were chosen for use in phase III trials.

THE BEST TRIAL.

The largest of these phase III trials, the recently completed BEST Trial[419] randomized 2708 subjects with advanced (Class III and IV) HF to placebo or bucindolol. As can be observed by the 12-month placebo mortality rates in Table 18-11 , the BEST Trial was conducted in subjects with much more advanced HF than the subjects enrolled in other beta blocker trials where mortality was reported. A 12-month mortality of 17 percent was observed in comparison

to 10 percent for the U.S. Carvedilol Trials, for example. Note in Table 18-11 that the CIBIS-II Trial, which purported to enroll subjects with NYHA Class III or IV symptoms, had a 12-month placebo mortality that is substantially less than that in BEST, which had internal controls to ensure that subjects with advanced HF were being enrolled.

In the BEST subject population as a whole, bucindolol produced a statistically nonsignificant (p=0.10), 10 percent reduction in total mortality that was heterogeneous with respect to race.[424] That is, the 76 percent of subjects in BEST who were not black had a statistically significant (p=0.01), 19 percent reduction in mortality, whereas the 24 percent who were black had a nonsignificant trend for an increase (by 17 percent) in mortality (interaction p value <0.05). Since BEST was the first beta blocker mortality trial to enroll a substantial percentage of black patients and it is the first reported beta blocker study in advanced HF, it is uncertain whether the demographically heterogeneous findings can be extrapolated to other beta-blocking agents or to less advanced HF. Of note is that in the U.S. Carvedilol Trials conducted in mild to moderate HF, an agent with a similar pharmacological profile produced a similar degree of improvement in left ventricular function and clinical parameters in blacks and nonblacks.[436] In addition, in a small single-center experience, metoprolol appeared to improve left ventricular function in blacks with HF similar to that produced in whites.[437] Therefore, the apparent lack of favorable effect of bucindolol in blacks in BEST may be due to the more advanced nature of HF investigated in BEST or the unique characteristics of the black patient population in this trial. However, there are also potential drug-specific explanations for the bucindolol versus carvedilol or metoprolol data in blacks, including the greater degree of vasodilation in carvedilol being beneficial in an HF population with a high

incidence of a history of hypertension, the beta$_1$ selectivity of metoprolol, or the norepinephrine-lowering property of bucindolol producing too much withdrawal of adrenergic support (see below for moxonidine) in the black population of BEST. Norepinephrine lowering is a beta$_2$ receptor blockade-mediated response, and the black population of BEST had higher baseline systemic norepinephrine levels than the other subjects did.[424]

From previous trials it is known that black hypertensives respond less well to beta-blocking agents or ACE inhibitors[438] than do nonblacks and that blacks with HF also do not respond well to ACE inhibitors.[439] Thus, the most beneficial therapy for favorably affecting the natural history of HF, ACE inhibitors and beta-blocking agents, may be less effective or even ineffective in a population group that represents 12 percent of the U.S. population. This obviously major problem will be commented on further below.

In the BEST population as a whole, bucindolol produced statistically favorable effects on multiple secondary endpoints, including cardiovascular deaths, heart failure hospitalizations, the combined endpoint of mortality plus hospitalization, the need for cardiac transplantation, left and right ventricular function, and the incidence of myocardial infarction.[424] Despite the advanced nature of the HF patients enrolled in BEST, bucindolol was well tolerated and slightly more subjects were receiving active drug than placebo when the trial was concluded.[424] The BEST Trial therefore demonstrates that a comprehensive antiadrenergic beta-blocking agent can be used in patients with advanced HF to lower morbidity but that beta-blocking agents should be used with caution or not at all in black patients who have advanced HF with the demographic characteristics of those enrolled in BEST. When the COPERNICUS Trial is completed, drug-specific versus degree-of-HF issues can, it is hoped, be determined.

NEBIVOLOL

Nebivolol is another third-generation beta-blocker-vasodilator with limited but favorable experience[440] [441] in HF trials. As can be observed in Table 18-10 , nebivolol is markedly beta$_1$ -selective,[442] and as such it is unique among third-generation compounds available or in development for HF. Another unique feature of nebivolol is its vasodilatory action appears to be due to the generation of nitric oxide.[443] Interestingly, in a small study comparing nebivolol and placebo, nebivolol improved intrinsic systolic function and resulted in regression of hypertrophy in South African blacks with mild to moderate HF.[440] Although it is likely that the patient populations differ substantially (such as more subjects with a history of hypertension in the carvedilol/U.S. data), it is worth noting that carvedilol and nebivolol, both of which have substantial vasodilator properties, have shown some success in black populations with mild to moderate HF. Nebivolol will be starting one phase II and then two phase III trials in 2000-2001.

Conclusions Regarding Beta Blockers as a Class

As can be observed in Table 18-11 , based on comparison of clinical trial data between ACE inhibitors and beta blockers, it appears that in mild to moderate HF (stage B; see p. 562) placebo annual mortality of 5 to 15 percent), beta blockers produce a much larger effect size than ACE inhibitors do (respective average mortality reduction of 36 vs. 21 percent). On the other hand, in stage C or D HF, ACE inhibitors[323] or aldosterone inhibition plus ACE inhibition[23] may produce a greater reduction in mortality than achieved with beta blockade[424] (respective mortality reduction of 31 vs. 10 percent). In other words, the effect size (degree of mortality reduction) increases with increasing severity of HF for agents acting by inhibiting the renin-angiotensin-aldosterone system (RAAS), and it decreases with increasing degree of HF for beta-blocking agents. The likely explanation for this difference is that patients with more advanced HF have a greater dependency on beta-adrenergic support of myocardial function; it becomes increasingly difficult to withdraw them from it, or withdrawal of adrenergic support may even be undesirable in many stage C patients. ACE inhibitors, on the other hand, have overall favorable effects on hemodynamics when administered to patients with advanced HF, which allows this type of treatment to take therapeutic advantage of inhibition of the high degree of activation of the RAAS in advanced HF.

Summary Recommendations for the Use of Beta-Blocking Agents

Patients with mild to moderate compensated HF from nonischemic or ischemic dilated cardiomyopathy and NYHA Class II to III symptoms (stage B subjects) who are receiving standard treatment, including diuretics and ACE inhibitors, and who do not have a contraindication to beta blockade are candidates for treatment with a beta-blocking agent.[397A] [424A] For the present, this group would include black patients, although the data supporting use in such patients are confined to carvedilol. Patients who are treated with beta-blocking agents should not have decompensated HF because the myocardial depression that accompanies initiation of therapy can be life threatening in such individuals. At present, the only FDA-approved agent is carvedilol, but metoprolol and bisoprolol are approved for other cardiovascular indications. For now, patients with advanced, Class III or IV (stage C) HF should not be routinely treated with beta-blocking agents pending the availability of bucindolol (in nonblack populations), demonstration of a favorable effect of carvedilol in the COPERNICUS Trial, or demonstration of benefit by metoprolol, bisoprolol, or nebivolol in such patients. Until a trial has demonstrated efficacy and safety, blacks with Class III or IV HF fitting the demographic characteristics of the BEST Trial population should not be treated with a beta-blocking agent. For patients in Class IV, beta blockers remain contraindicated, but this position could change pending the outcome of current trials such as Enoximone Plus Metoprolol in Subjects With Advanced Chronic Heart Failure (EMPOWER), which are combining PDEIs with beta blockers on the basis of encouraging phase II data.[253]

Once patients with HF reach a maintenance dose of a beta blocker, treatment should be maintained indefinitely because of the risk of deterioration after drug withdrawal.[444] As discussed in the section Positive Inotropic Agents, if it is necessary to treat a decompensated patient receiving maintenance beta blockade with a positive inotropic agent, a PDEI rather than a beta-agonist should be used because the hemodynamic effects of PDEIs are not antagonized by beta blockade.[231] [252] [254]

Limitations of Beta Blocker Therapy in Chronic Heart Failure

Despite their proven efficacy in mild to moderate HF in patients with primary or secondary dilated cardiomyopathy, it is important to emphasize that beta blockers have limitations to general application in HF populations. First and foremost is that many HF patients have contraindications to beta blockade, such as reactive airway disease, sinus node or conduction system disease with bradycardia,

and advanced HF with hemodynamic decompensation. Another problem is that even in mild to moderate HF, initiation of therapy and uptitration of beta-blocking agents can be difficult and require both persistence and a knowledge of management maneuvers[397] that allow target doses to be achieved. A third problem is that for reasons that are not yet clear, some patients do not respond to beta blockade in terms of favorable effects on myocardial function, and these individuals may have a worse outcome than patients treated with placebo.[402] Some, but not all of these problems might be overcome by the development of more efficacious or better-tolerated compounds, the use of other, more effective types of antiadrenergic therapy, or the use of a combination of beta blockers with positive inotropic agents.[252] [253] The importance of the beta blocker data set is not that it demonstrates a "cure" for chronic HF, but rather that it has now been shown that in some patients, the prognosis can be substantially improved by medical therapy. This observation should provide an impetus to develop further types of treatment that improve the biological properties of the failing heart.

Other Antiadrenergic Agents

The success of beta-blocking agents and the realization that many subjects have contraindications to them has prompted attempts to develop other antiadrenergic agents. Two of them, the dopamine beta-hydroxylase inhibitor nepicastat[445] and the imidazoline receptor agonist moxonidine,[446] * have had clinical trials conducted in chronic HF patients. A phase III trial of moxonidine (MOXCON) was recently stopped because of an increase in mortality, indicating that a drug that powerfully lowers adrenergic activity in a potentially irreversible manner is not a good strategy in the treatment of chronic stable heart failure.

Endothelin Antagonists

Endothelin-1, a peptide synthesized in endothelium and secreted on the abluminal side of the vascular wall, acts as an autocrine or paracrine substance[447] [448] (see also Chap. 21) . Although circulating endothelin levels are increased in patients with HF,[449] the half-life of endothelin is only a few minutes because of its rapid clearance by the lung.[450] Therefore, endothelin is an autocrine or paracrine cytokine, not a hormone.

Endothelin has powerful biological effects that are mediated through two receptors, ET_A and ET_B .[451] In human ventricular myocardium, the ET_A receptor gene is expressed in vascular endothelial and smooth muscle media and in cardiac myocytes, where expression is increased in myocardial failure.[452] The ET_A receptor is G_q and protein kinase C-coupled to vasoconstriction, a weak positive inotropic effect, as well as coupled to the indication of cardiac myocyte hypertrophy and fibroblast or smooth muscle cell hyperplasia.[447] [448] These biological/physiological effects are similar to those of the angiotensin II AT_1 receptor. The ET_B receptor is expressed in

human ventricular myocardium in endothelium, cardiac myocytes, and fibroblasts, but not in vascular smooth muscle.[452] The ET_B receptor is coupled to nitric oxide generation and vasodilation and possibly to antiproliferative responses in cardiac myocytes and fibroblasts.[447] [448] The ET_B receptor is also a clearance receptor in the lung[453] and probably in myocardium. [454] In human myocardial failure, tissue concentrations of endothelin are increased,[452] [455] the ET_A receptor population is upregulated from 60 to 80 percent of the total,[452] and the ET_B population is downregulated from 40 to 20 percent of the total. [452] These data suggest that the endothelin-1 system is quite activated in the failing human heart and that it contributes to the progression of remodeling. This hypothesis is strongly supported by data from HF animal models, where nonselective ET_A /ET_B [442] or selective ET_A [456] [458] antagonists prevent remodeling.

CLINICAL OBSERVATIONS.

Clinical experience with ET receptor antagonists in HF is limited to acute hemodynamic studies, where both nonselective[459] and ET_A -selective[460] [461] compounds produce the expected vasodilator effects with an increase in cardiac output and little or no increase in heart rate, as well as one clinical trial with clinical endpoints.[461] The one reported phase II trial[462] was stopped early for hepatotoxicity, but in the evaluable patients, clinical improvement was observed more frequently with the nonselective antagonist bosentan than with placebo. Bosentan continues in development at a lower dose in an attempt to mitigate its adverse effects on liver function. Hepatotoxicity has also been observed for some other members of this class, and teratogenicity is a general problem with all ET antagonists. Another potential issue with this class of compounds is that endothelin gene expression is stimulated by both angiotensin II[463] and norepinephrine,[464] and in the presence of full inhibition of the RAS and adrenergic systems, it is not clear how much additional benefit will be conferred by endothelin antagonists. Nevertheless, endothelin receptor antagonists remain a very promising potential treatment of HF.

Tumor Necrosis Factor-Alpha Inhibitors

Another promising treatment of HF that is entering phase III trials is TNF-alpha inhibition.[465] [466] The hypertrophic/remodeling response of failing myocardium incorporates features of a generalized inflammatory response, with increased systemic[467] and/or myocardial levels[468] [469] of the proinflammatory cytokines TNF-alpha and interleukin-1 (IL-1) contributing to growth signaling. TNF-alpha is a 17-kDa protein that acts through two distinct receptors, TNFR1 and TNFR2. TNF-alpha produces a series of powerful biological effects, including immunostimulation, mediation of host resistance to bacteria, activation of protein kinase C, and activation of expression of a wide variety of genes generally involved in inflammation or cell growth.[470] In an acute or subacute setting, most of these biological effects of TNF-alpha are helpful in combating infection or responding to injury.

TNF-alpha[471] as well as IL-1beta[472] can produce an increase in cardiac protein synthesis and cardiac myocyte hypertrophy. Moreover, Mann's laboratory has shown that in the failing human heart, TNF-alpha production is induced in cardiac myocytes[473] and that chronic infusion of TNF-alpha in rats produces left ventricular contractile dysfunction and dilatation.[474] Therefore, local myocardial production of TNF-alpha becomes, along with neurotransmitter-derived norepinephrine, autocrine- or paracrine-produced endothelin and hormonally or cytokine-derived angiotensin II, a serious candidate for mediation of the progression in myocardial dysfunction and remodeling that is part of the natural history of chronic HF. As is the case for angiotensin II, endothelin-1, and norepinephrine, the maladaptive aspect of TNF-alpha in the failing heart is the sustained production and chronic cell signaling. Finally, transgenic models of cardiac overexpression of TNF-alpha have unequivocally demonstrated that this cytokine can produce a dilated cardiomyopathy phenotype.[475] [476] Therefore, TNF-alpha appears to be involved in the progression of remodeling and myocardial dysfunction that characterizes the natural history of HF.

CLINICAL OBSERVATIONS.

On this impressive pathobiological background, inhibitors of TNF-alpha are just beginning to be evaluated in chronic HF. The first compound to enter phase III trials is etanercept, a soluble TNF-alpha receptor fusion protein that binds to and inactivates TNF-alpha. This compound was recently reported to improve left ventricular function and ameliorate symptoms and exercise intolerance in subjects with chronic HF.[477] In addition, a small-molecule TNF-alpha inhibitor[478] that is used to treat other disorders, pentoxifylline, was recently shown to increase left ventricular function in a controlled clinical trial.[479] Etanercept has recently entered phase III testing in a subcutaneous, twice-per-week dosing regimen that has been shown to be effective in rheumatoid arthritis.[480] This approach to the treatment of chronic HF is obviously quite rational and promising.

THE NEXT GENERATION OF HEART FAILURE TREATMENT

As can be observed by the effects of ACE inhibitor and beta blocker therapy (see Table 18-11) , medical therapy of HF has improved substantially since 1990. Moreover, as discussed above, in the near future there will likely be additional neurohormonal/cytokine inhibitors that will further improve the natural history of chronic HF. New drug classes, such as compounds that improve myocardial metabolism, may be added to the HF armamentarium in the next several years. In addition, because of the potential market size, the full force of the "high-technology revolution" of drug development is being applied to HF. Gene therapy, drugs designed to specifically reverse abnormalities in gene expression, and novel targets identified by transcriptomics and proteomics will probably emerge as effective HF therapies. Accordingly, we look forward to substantial expansion of Table 18-1 in the next edition of this textbook.

Chapter 19 - Treatment of Heart Failure: Assisted Circulation

WAYNE E. RICHENBACHER
WILLIAM S. PIERCE

Up to 4.9 million Americans suffer from congestive heart failure, with over 400,000 new cases diagnosed each year.[1] [2] The incidence of advanced heart failure rises dramatically with increasing age, accounting for approximately 80 percent of hospital discharges in patients older than 60 years of age.[2] Patients with New York Heart Association (NYHA) functional Class IV heart failure have a reported 1-year mortality of 33 to 37 percent.[3] According to the Framingham Heart Study, the 5-year mortality rate for patients with congestive heart failure is 75 percent in men and 62 percent in women.[4] Two hundred thousand patients with heart failure die annually at a cost estimated at $8 to $20 billion per year.[1] [2] Standard medical and surgical therapies benefit only a small percentage of patients with ventricular dysfunction. Cardiac transplantation (see Chap. 20) , the therapeutic mainstay for end-stage cardiomyopathic patients, has been performed with decreasing frequency worldwide for each of the past 4 years.[5] The decline in heart transplant volume is attributed to limited donor heart availability.

Two distinct patient populations benefit from mechanical circulatory support. Potential cardiac transplant recipients with hemodynamic instability may receive temporary mechanical circulatory support as a bridge to transplantation. The second patient group includes patients with reversible ventricular dysfunction. Two to 6 percent of patients who undergo an open-heart operation develop postcardiotomy cardiogenic shock.[6] Aggressive medical management, including intraaortic balloon (IAB) counterpulsation, allows 75 to 85 percent of these patients to be weaned from cardiopulmonary bypass. Thus, approximately 1 percent of patients who undergo an open-heart procedure would benefit from interval support with a mechanical blood pump.[7]

An evolving, third indication for blood pump insertion is as a permanent form of mechanical circulatory support. Best estimates suggest that 17,000 to 66,000 patients in the United States each year may benefit from a permanent implantable blood pump.[8] Not only will mechanical blood pumps be immediately accessible, but they will ultimately provide a cost-effective alternative to cardiac transplantation or long-term medical treatment of patients in NYHA functional Class III or IV.[9]

Patients with cardiovascular disease whose condition deteriorates hemodynamically first receive conventional medical therapy. Conventional management is directed toward correction of any electrolyte or acid-base imbalance, hypoxemia, rhythm disturbance, or hypovolemic state. Cardiogenic shock, as defined in Table 19-1 , is next treated with inotropes and, if systemic blood pressure permits, afterload reducing agents (see also Chap. 35) . Patients who manifest ongoing hemodynamic instability, and who fulfill the selection criteria outlined in Table 19-2 , may qualify for an advanced form of mechanical circulatory support.

Mechanical circulatory support devices can be divided into three major groups. The IAB is a readily available, catheter-mounted intravascular device designed to improve the balance between myocardial oxygen supply and demand while increasing systemic perfusion to a modest degree. The ventricular assist device (VAD) is a blood pump that is designed to assist or replace the function of either the right or left ventricle. A right VAD supports the pulmonary circulation, whereas a left VAD provides systemic perfusion, in the absence of adequate right or left ventricular ejection, respectively. Implantable VADs are positioned intracorporeally, under the anterior abdominal wall or within the thorax or abdomen. Extracorporeal VADs may be located in a paracorporeal position, on the patient's anterior abdomen, or externally, at the patient's bedside. Five pulsatile VAD systems have approval by the U.S. Food and Drug Administration (FDA) for clinical use. The total artificial heart (TAH) is an orthotopically positioned cardiac replacement device. The pneumatic TAH is used infrequently, and only with FDA approval, as a mechanical bridge to cardiac transplantation. Completely implantable electric VADs and artificial hearts that do not employ a percutaneous drive line have been successfully implanted in experimental animals and are expected to reach the clinical arena in the near future.

HISTORY

Extracorporeal counterpulsation was introduced by Clauss and coworkers in 1961.[10] The concept was modified by Moulopolous and colleagues, who described an intravascular counterpulsation balloon in 1962.[11] The first successful clinical application of balloon counterpulsation was reported by Kantrowitz and associates in 1968.[12] IAB insertion originally required a surgical procedure. In 1980, Bregman and coworkers described percutaneous IAB insertion using a sheath and dilators.[13] The IAB is now a standard form of therapy for a variety

TABLE 19-1 -- DEFINITION OF CARDIOGENIC SHOCK

Cardiac output index	<2.0 liters/min/m^2
Systolic blood pressure	<90 mm Hg
Left or right atrial pressure	>20 mm Hg
Urine output	<20 ml/hr
Systemic vascular resistance	>2100 dynes-secccm^{-5}

TABLE 19-2 -- MECHANICAL CIRCULATORY SUPPORT SELECTION CRITERIA

Patient fulfills hemodynamic criteria (see Table 19-1)
Maximal inotropic support and intraaortic balloon counterpulsation
Exclude patient if:
Blood urea nitrogen >100 mg/dl
Serum creatinine >5.0 mg/dl
Chronic lung disease
Chronic liver disease
Metastatic cancer

Systemic sepsis
Neurological deficit
Technically incomplete cardiac operative procedure (if postcardiotomy cardiogenic shock)
Age >65 yr (if bridge to transplant)

of patients with cardiovascular disease. In 1993, nearly 100,000 IABs were inserted in the United States alone.[14]

The dawn of complete, clinical mechanical circulatory support occurred on May 6, 1953, when Gibbon successfully closed a secundum atrial septal defect in a patient supported with cardiopulmonary bypass.[15] The majority of patients with ventricular dysfunction, however, do not require pulmonary support with an in-line oxygenator. Roller pump left ventricular assistance using atrial transseptal uptake and femoral arterial return was introduced by Dennis and colleagues in 1962.[16] Subsequently, DeBakey successfully employed left atrial to aortic bypass in patients who could not be weaned from cardiopulmonary bypass.[17] By the late 1970s, a variety of intracorporeal and extracorporeal mechanical blood pumps were being tested for both "support to weaning"[18] and "bridge to transplant"[19] indications. Patient selection and hemodynamic criteria were developed, and cannulation techniques, blood-biomaterial interactions, and control strategies were evaluated. During the 1980s, patient management techniques were refined and clinical results improved. Advances in myocardial preservation resulted in fewer blood pumps being required for postcardiotomy cardiogenic shock. However, a disparity in the ratio of cardiac donors to recipients increased the need for long-term circulatory support in patients requiring a bridge to cardiac transplantation. Results in this patient population proved gratifying, with survival statistics approaching those achieved with conventional cardiac transplantation.[20] The 1990s saw research efforts focus on the development of implantable VADs suitable for permanent implantation in patients with end-stage cardiomyopathy.

While IAB and VAD development were in their infancy, investigators also initiated laboratory efforts to develop a cardiac replacement device. In 1958, Akutsu and Kolff described an experiment in which a pneumatic TAH was implanted in a dog.[21] By the mid 1960s, Nose and coworkers had achieved 24-hour survival with sac-type hearts implanted in calves.[22] By the end of the decade survival times approached 3 to 5 days.[23] Experimental animals with TAHs have now lived for up to 1 year. The TAH entered the clinical arena in 1969 when Cooley and associates introduced the concept of staged cardiac replacement.[24] Joyce and coworkers were the first to implant a TAH as a permanent cardiac replacement.[25]

INTRAAORTIC BALLOON COUNTERPULSATION

The design and function of the IAB has not changed substantially during the past three decades. The IAB is an intravascular, catheter-mounted, counterpulsation device with a balloon volume between 30 and 50 ml. A central lumen allows passage of the balloon catheter over a small diameter guidewire and subsequent monitoring of central blood pressure. The IAB is attached to a small bedside console and timed to the patient's arterial pressure curve or electrocardiogram. The shuttle gas is helium, as its viscosity allows rapid balloon inflation and deflation, which facilitates counterpulsation in patients with tachyarrhythmias.

The IAB is positioned in the descending thoracic aorta and set to inflate at the dicrotic notch of the arterial pressure waveform when monitoring the aortic pressure (Fig. 19-1) . The diastolic rise in aortic root pressure augments coronary blood flow and myocardial oxygen supply. The increase in systemic perfusion may be less than 0.5 liter/min. The IAB is deflated during the isovolumetric phase of left ventricular contraction. The reduction in the afterload component of cardiac work decreases peak left ventricular pressure and myocardial oxygen consumption. The net effect is a favorable shift in the myocardial oxygen supply/demand ratio, with a small increase in systemic perfusion.

Indications and Results of Clinical Use

Traditional indications for IAB counterpulsation include refractory cardiogenic shock after cardiac surgery or acute myocardial infarction (Table 19-3) . The latter indication includes patients suffering from primary pump failure in addition to those with mechanical complications, such as acute mitral regurgitation or a postinfarction ventricular septal defect.

Five to 10 percent of patients who suffer an acute myocardial infarction develop cardiogenic shock.[26] Seventy-five percent of patients with an acute myocardial infarction who develop cardiogenic shock not amenable to conventional medical therapy will improve hemodynamically with IAB

Figure 19-1 The intraaortic balloon is inserted through the common femoral artery and positioned in the descending thoracic aorta. The tip is located just distal to the left subclavian artery. The balloon is inflated during cardiac diastole thereby increasing coronary artery perfusion *(A).* Left ventricular afterload is decreased as the balloon is deflated during cardiac systole *(B).* Proper balloon timing improves the ratio between myocardial oxygen supply and demand. (From Richenbacher WE: Intraaortic balloon counterpulsation. *In* Richenbacher WE [ed]: Mechanical Circulatory Support. Georgetown, TX, Landes Bioscience, 1999, p 33.).

TABLE 19-3 -- INDICATIONS FOR INTRAAORTIC BALLOON COUNTERPULSATION

Cardiogenic shock
Postcardiotomy
Associated with an acute myocardial infarction
Mechanical complication of an acute myocardial infarction
Mitral regurgitation
Ventricular septal defect
In association with coronary artery bypass surgery
Preoperative insertion
Patients with severe left ventricular dysfunction
Patients undergoing repeat bypass surgery
Postoperative insertion
Postcardiotomy cardiogenic shock
In association with nonsurgical revascularization
Hemodynamically unstable infarct patients
High-risk coronary angioplasty
Patients with severe left ventricular dysfunction
Complex coronary artery disease
Stabilization of cardiac transplant recipient before insertion of ventricular assist device
Postinfarction angina
Ventricular arrhythmias related to ischemia

counterpulsation.[27] Although it has been suggested that prolonged IAB support in such patients may improve hospital and long-term survival rates,[28] the role of IAB counterpulsation in this patient population is to facilitate early catheterization and reperfusion strategies. Patients with an acute myocardial infarction complicated by cardiogenic shock have a hospital survival rate of 5 to 21 percent.[26] If such patients can be revascularized either by coronary artery bypass or by thrombolysis and percutaneous transluminal coronary angioplasty, survival rates improve dramatically. Patients with an acute myocardial infarction and cardiogenic shock who are treated with early IAB counterpulsation and coronary artery bypass grafting achieve an early survival rate of 88 to 93 percent.[26] [29]

Patients who develop a mechanical complication after an acute myocardial infarction are best managed with IAB counterpulsation, urgent cardiac catheterization, and immediate surgical repair. IAB counterpulsation reduces the left-to-right shunt and maintains coronary perfusion in patients with a postinfarction ventricular septal defect. Hospital mortality in patients managed with an IAB and urgent operation is 25 to 47 percent.[30] [31] [32] Patients with postinfarction mitral regurgitation secondary to papillary muscle dysfunction or rupture also benefit from IAB insertion. IAB counterpulsation increases coronary perfusion and reduces ischemic ventricular dysfunction, mitral regurgitation, and the pulmonary capillary wedge pressure. Outcome is related to the extent of cardiac dysfunction, with surgical mortality approaching 55 percent.[33]

POSTCARDIOTOMY CARDIOGENIC SHOCK.

IAB counterpulsation is employed in association with coronary artery bypass surgery in up to 13 percent of cases.[34] Preoperative IAB insertion is thought to be efficacious in patients with profound left ventricular dysfunction and in certain patients who have had previous bypass surgery.[35] [36] Refractory postcardiotomy cardiogenic shock is related to preoperative left ventricular dysfunction, inadequate myocardial preservation, intraoperative myocardial infarction, prolonged cardiopulmonary bypass and intraoperative ischemic times, or technical difficulties with the conduct of the operation. With maximal medical support and IAB counterpulsation, survival rates average 52 to 66 percent.[37] Predictors of death with intraoperative or postoperative IAB use include age, mitral valve replacement, urgent or emergent operation, preoperative renal dysfunction, complex ventricular ectopy, right ventricular failure, and transthoracic IAB insertion.[38]

IAB counterpulsation has also been used in conjunction with nonsurgical revascularization. In addition to the use of the IAB in hemodynamically unstable infarct patients just described, IAB counterpulsation has been employed prophylactically in patients requiring high-risk coronary angioplasty.[39] Prophylactic IAB support has been used in patients with severe left ventricular dysfunction and complex coronary artery disease, a population that comprises 1 to 2 percent of the total number of angioplasty procedures. Using this management algorithm, successful angioplasty has been performed in 86 to 100 percent of patients, with a hospital mortality of 6 to 19 percent.[39]

HEART FAILURE.

The use of IAB counterpulsation in heart failure patients awaiting cardiac transplantation has decreased as the waiting time for donor hearts has increased. The rationale for IAB counterpulsation in this clinical setting is to maintain systemic perfusion and preserve end organ function until cardiac transplantation occurs. Long-term IAB use is, however, impractical because patients are not afforded an opportunity for rehabilitation and the IAB represents a significant ongoing infection risk. VAD support is now the standard of care in the patient requiring a bridge to transplantation. The role of IAB counterpulsation in this patient population has now been reduced to stabilization of the occasional patient with marked hemodynamic instability to allow time for VAD insertion.

UNSTABLE ANGINA (See also Chap. 36) .

IAB support has also been offered to patients who do not fulfill hemodynamic selection criteria but who suffer from unstable angina or malignant ventricular tachyarrhythmias. Although nonrandomized trials suggest that IAB counterpulsation and subsequent myocardial revascularization may be of some benefit in patients with unstable angina,[40] aggressive preoperative medical management and a judicious cardiac anesthetic may eliminate the need for an IAB with equally good results. The role of IAB counterpulsation in patients with postinfarction angina is equally controversial.[41] In general, IAB support is reserved for patients with deteriorating hemodynamics or ongoing ischemia, as evidenced by rest pain or electrocardiogram changes in the region of the infarct, prior to myocardial revascularization. IAB counterpulsation may be beneficial in patients with ventricular tachyarrhythmias, particularly when the ventricular tachyarrhythmias are related to ischemia.[42] Ectopic impulses originate in the ischemic area surrounding an infarct zone, and the IAB may reduce the frequency of such arrhythmias by increasing myocardial perfusion and oxygenation in the ischemic zone.

The use of IAB counterpulsation in the pediatric patient population remains problematic. Balloon catheters and consoles have been modified for use in children. However, the complex anatomy associated with congenital cardiac anomalies often results in biventricular failure for which IAB counterpulsation is not particularly effective. Even so, survival rates exceeding 50 percent in children supported with an IAB after a cardiac operation have been reported.[43]

CONTRAINDICATIONS.

Absolute contraindications to IAB counterpulsation include aortic insufficiency and aortic dissection (Table 19-4) . Contraindications to IAB insertion through the femoral arterial route include the presence of an abdominal aortic aneurysm or severe calcific aortoiliac or femoral arterial disease. The percutaneous insertion technique should not be employed in patients who have a recent groin incision with violation of the subcutaneous tissue at the proposed puncture site. The percutaneous insertion technique should be used with caution in the morbidly obese patient because the peritoneal reflection may be quite caudad, resulting in transperitoneal passage of the balloon catheter.

INSERTION TECHNIQUE

The IAB is most commonly inserted in a percutaneous fashion through the common femoral artery.[44] Preinsertion evaluation of the

TABLE 19-4 -- CONTRAINDICATIONS TO THE USE OF INTRAAORTIC BALLOON COUNTERPULSATION

Absolute Contraindications
Aortic valve insufficiency
Aortic dissection
Relative Contraindications
Femoral arterial insertion
Abdominal aortic aneurysm
Severe calcific aortoiliac or femoral arterial disease
Percutaneous insertion
Recent ipsilateral groin incision
Morbid obesity

patient's femoral arterial and pedal pulses facilitates rapid recognition of limb ischemia after balloon insertion. With the use of strict aseptic technique the femoral artery is accessed using the Seldinger technique. The femoral arterial puncture should occur below the inguinal ligament, to avoid a transperitoneal puncture, and above the profunda femoris artery, to reduce the potential for superficial femoral arterial cannulation.

The common femoral artery is dilated, and the final dilator and sheath are advanced over a guidewire into the descending thoracic aorta. The final dilator is withdrawn, and the IAB is inserted into the introducer sheath. The radiopaque tip of the IAB is positioned just distal to the left subclavian artery. The balloon is unwound, purged, connected to the bedside console, and pulsed. Proper augmentation is best accomplished with the IAB synchronized 1:2 with the patient's arterial pressure trace. Once inflation and deflation times are determined, augmentation is set at 1:1. Postinsertion anticoagulation is usually accomplished with a continuous heparin sodium infusion (1000 U heparin sodium in 500 ml normal saline, 3 ml/hr). Heparin sodium administration is not necessary in postcardiotomy patients.

Alternatively, the IAB may be inserted into the femoral artery using an open technique. The femoral artery is exposed, and a 5-cm segment of an 8- to 10-mm diameter vascular graft is anastomosed, at a 45-degree angle, to the common femoral artery. The IAB is passed through the vascular graft and into the artery and positioned as described previously. The IAB is fixed in position by tying umbilical tapes around the vascular graft.

When an abdominal aortic aneurysm or severe peripheral vascular disease precludes femoral arterial insertion, the IAB may be inserted directly into the ascending aorta or transverse arch.[45] Access is obtained through a median sternotomy, usually at the time of cardiotomy. The balloon is inserted through a vascular graft in a

manner identical to that described in the open femoral arterial technique. The balloon is advanced across the transverse arch into the descending thoracic aorta. Alternatively, the IAB can simply be inserted through two concentric pursestring sutures.

A "sheathless" insertion technique may be employed in the nonanticoagulated patient. With this technique, the IAB is inserted into the common femoral artery after dilation with the small diameter dilator. The large dilator and sheath assembly are not employed. This technique minimizes the obstruction to blood flow in the common femoral artery facilitating IAB use in patients with a small body habitus and in those with known or suspected peripheral vascular disease.

REMOVAL TECHNIQUE

As the patient's hemodynamic status improves, balloon augmentation is serially decreased. If the patient tolerates augmentation of every third to eighth cardiac cycle (1:3 to 1:8), the IAB can be safely withdrawn.[44] Balloon inflation is discontinued and the balloon aspirated to ensure deflation is complete. The balloon is withdrawn until it touches the sheath. Manual pressure is applied to the femoral artery distal to the insertion site, and the balloon and insertion sheath are withdrawn as a single unit. Blood is permitted to eject from the insertion site for one or two heartbeats to clear any thrombotic debris from the vascular space. Pressure is then applied to the insertion site: manually for 30 minutes and with a sandbag for an additional 8 hours. One must make certain the limb is adequately perfused during IAB removal. Withdrawal of an IAB inserted by the open technique requires surgical groin exploration, balloon and vascular graft removal, and femoral artery repair, usually with a vein patch. Open removal is also recommended when there has been a high (proximal) percutaneous insertion in morbidly obese patients, and in patients who develop limb ischemia after percutaneous insertion.

Balloons inserted into the ascending aorta can be removed under local anesthesia if the side arm graft is brought into the subcutaneous space.[46] The authors, however, recommend a repeat sternotomy with direct visualization of the insertion site.

COMPLICATIONS OF IAB USE

The complication rate from IAB counterpulsation ranges from 5 to 47 percent.[47] [48] Major complications, including limb ischemia necessitating thrombectomy or amputation, aortic dissection, aortoiliac laceration or perforation, and deep wound infection requiring debridement, occur in 4 to 17 percent of patients.[49] Major complications lead to an additional operative procedure, prolonged hospitalization, long-term morbidity, or death. Minor complications, including bleeding at the insertion site, superficial wound infections, asymptomatic loss of peripheral pulse or lymphocele, occur in 7 to 42 percent of patients.[49] Minor complications are usually self-limited or resolve after IAB removal. Although the overall complication rate has not changed appreciably in the recent past, it appears that the severity of complications and the mortality directly attributable to IAB insertion have decreased significantly.[50]

The most common complications related to femoral IAB use are vascular.[47] [48] [50] [51] [52] [53] [54] Vascular complication rates vary from 8 to 20 percent and are related to mechanical trauma to the vessel wall during IAB insertion, flow obstruction by the balloon catheter, and low cardiac output with peripheral vasoconstriction.[47] [50] [51] [52] [53] Risk factors for developing a major vascular complication after femoral IAB insertion are controversial but generally include peripheral vascular disease, diabetes mellitus, female gender, and small body surface area. In the past few years there has been a trend toward a lower incidence of limb ischemia associated with IAB use. This trend may be explained by an increased use of small-diameter balloon catheters. When percutaneous IAB insertion was introduced, a sheath as large as 12.5F was employed. Currently, sheaths as small as 8.5F to 9.5F are used, whereas sheath pull-back insertion techniques reduce the cross-sectional area of the catheter within the vascular space. These improvements in catheter design and insertion technique should have a significant positive impact on the vascular complication rate. Unfortunately, some series report no improvement in the vascular complication rate when a smaller catheter is employed[54] or when a sheathless insertion technique is used.[53]

LEG ISCHEMIA.

When a patient develops leg ischemia after femoral IAB insertion, the IAB should be removed. Persistent limb ischemia after IAB removal requires emergent femoral arterial exploration, thrombectomy, and vein patch angioplasty. Balloon-dependent patients with limb ischemia benefit from moving the IAB to the contralateral leg or undergoing a femoral-femoral crossover graft.[55]

The reported complication rate of transthoracic IAB counterpulsation is 0 to 13 percent.[49] [56] Complications associated with IAB insertion in the ascending aorta include bleeding at the insertion site, mediastinitis, transient ischemic attack, cerebrovascular accident, and an inability to close the sternum secondary to mechanical tamponade. Proponents of this route for IAB insertion note that the problem with leg ischemia is eliminated and placement of the IAB under direct vision reduces the potential for vessel perforation and risk of aortic dissection.[56]

VENTRICULAR ASSIST DEVICES

Unlike the IAB, which is designed to improve the ratio between myocardial oxygen supply and demand while supporting systemic perfusion to only a modest degree, ventricular assist devices (VADs) are designed to effectively unload either the right or left ventricle while completely supporting the pulmonary or systemic circulation. The term VAD describes any of a variety of mechanical blood pumps that are employed singly to replace the function of either the right or the left ventricle. Two blood pumps can be used for biventricular support. For right ventricular assistance, blood is withdrawn from the right atrium and returned to the main pulmonary artery. For left ventricular assistance, blood is withdrawn from either the left atrium or the apex of the left ventricle. The blood passes through the left VAD and is returned to the ascending aorta.

There is a wealth of information in the literature regarding the advantages and disadvantages of left atrial versus left ventricular inflow (with respect to the VAD) cannulation.[57] [58] In general, left atrial inflow cannulation is technically easier to perform, may employ cannulas readily available to any open-heart surgical team, but is thought to provide incomplete ventricular decompression. Left ventricular inflow cannulation requires a custom-designed cannula but provides very effective left ventricular decompression. The reduction in myocardial oxygen demand is offset by the fact that left ventricular apical cannulation damages the myocardium, an important consideration in a patient with marginal ventricular function. A left ventricular apex cannula is, however, ideally suited to patients who receive

TABLE 19-5 -- COMPARISON OF VENTRICULAR ASSIST PUMPS

VAD Type	Advantage	Disadvantage
Centrifugal	Readily available Simple to use Relatively inexpensive	Nonpulsatile Systemic anticoagulation Constant supervision required Not FDA approved as a VAD
Pneumatic pulsatile	No blood trauma ±anticoagulation Pulsatile flow Minimal supervision required	Limited patient mobility with current approved drive consoles Expensive

VAD=ventricular assist device; FDA=Food and Drug Administration.

mechanical circulatory support as a bridge to cardiac transplantation. In this patient population, ventricular recovery is not expected and the apical cannula is removed in its entirety at the time of recipient cardiectomy.

REGULATORY AFFAIRS

To better understand the enormous amount of effort that has been expended developing mechanical blood pumps, and limitations imposed on clinicians who desire access to a VAD, it is important to become familiar with the process by which medical devices are evaluated and approved for clinical use.[59] [60] The Medical Device Amendment of 1976 amended the federal Food, Drug and Cosmetic Act to require the FDA to approve clinical investigation of new medical devices and to approve new medical devices before they could be sold for general use. To prove that a new medical device is both safe and effective, the device must be the subject of a

carefully controlled clinical trial.

An investigator/manufacturer first conducts extensive in vitro device testing followed by in vivo animal experimentation. The data derived from the preclinical evaluation are submitted to the FDA along with results, if any, from foreign clinical trials. The investigator must also submit a formal clinical protocol and informed consent material that have been approved by the Institutional Review Board at the site of the proposed clinical trial. If the application for clinical investigation of the device is deemed satisfactory by the FDA, an Investigational Device Exemption (IDE) is granted to the investigator. It is expected that the clinical protocol will answer specific questions concerning the proposed indications and contraindications for use of the device.

Because of the inordinate expense of device research and development, and the cost incurred during the conduct of a clinical trial (under an approved IDE), most investigators have an industrial partner. Assuming the clinical trial shows the device to be safe and effective for a well-defined set of indications, the next step will be to seek approval from the FDA for commercial sale of the device. In general, the industrial partner will submit a Pre-Market Approval (PMA) request to the FDA. The focus of the PMA application is to provide more extensive durability testing, an important consideration in devices intended for long-term clinical use.

Durability testing is most often accomplished by accelerated in vitro experimentation, frequently performed under conditions more severe than those experienced when the device is in actual clinical use. Approval of a PMA by the FDA allows the manufacturer to release the medical device for commercial sale.

Description of Devices

Mechanical blood pumps capable of replacing the function of a single ventricle can be divided into three categories. The advantages and disadvantages of each category of blood pump are summarized in Table 19-5 . Representative members of each class of VAD are listed in Table 19-6 . Specific design features and functional characteristics of each VAD are described here. Specific details regarding implantation and explantation technique are described in the section entitled Management Considerations.

Centrifugal Pumps

Centrifugal pumps are simple to use and readily available to most cardiac surgeons.[61] [62] [63] [64] Standard cardiopulmonary bypass atrial and arterial cannulas are connected to the centrifugal head by short lengths of medical grade polyvinyl chloride tubing. The centrifugal head imparts forward flow to blood by creating a vortex with a rapidly spinning series of cones or impeller blades that are located within the rigid pump housing. The nonocclusive pump head has excellent blood handling characteristics, and the system is pressure limited, virtually eliminating the potential for air embolus or tubing disruption.[63] [65] Centrifugal blood pumps provide nonpulsatile blood flow and require full systemic anticoagulation and constant driver supervision.[66] The centrifugal pump can provide left- or right-sided heart support, or two pumps can be used for biventricular assistance. Centrifugal pumps entered the clinical arena before the Medical Device Amendment of 1976. However, centrifugal blood pumps are considered a Class III medical device, subject to the constraints imposed by this amendment to the federal Food, Drug and Cosmetic Act. Currently, the three centrifugal blood pumps available in the United States are approved by the FDA for only up to 6 hours of use, which makes them suitable for cardiopulmonary bypass but not

VAD=ventricular assist device.

for short-term temporary ventricular assistance (see Table 19-6) .

Pneumatic Pulsatile Blood Pumps

Complex, air-driven, pulsatile VADs are considerably more expensive than a centrifugal pump but are capable of producing pulsatile flow with no trauma to formed blood elements. Furthermore, integral sophisticated control systems are largely self regulating, and beyond the first few days after device insertion minimal supervision is required. As drive units become more refined and portable drivers are developed, patient mobility and lifestyle will improve dramatically.

ABIOMED BVS 5000 BIVENTRICULAR SUPPORT SYSTEM.

The Abiomed BVS 5000 Biventricular Support System (Abiomed, Inc., Danvers, MA) received PMA approval from the FDA for the treatment of patients with postcardiotomy cardiogenic shock.[67] [68] [69] The BVS 5000 blood pump is an external, dual-chamber device that is capable of providing short-term univentricular or biventricular circulatory support. Each chamber contains a 100-ml polyurethane blood sac. Trileaflet polyurethane valves are located at the inlet and outlet side of the ventricular chamber. The atrial chamber fills passively throughout pump systole and diastole while the ventricular chamber is intermittently pulsed with air from the drive console. Custom-designed cannulas provide right or left atrial inflow. The distal portion of the outlet cannula is a coated vascular prosthesis that is anastomosed to either the pulmonary artery or aorta. The cannulas traverse the skin subcostally. The drive unit functions asynchronously with respect to the patient's native cardiac rhythm. The control system maintains a constant 80-ml stroke volume by automatically adjusting the duration of pump systole and diastole in response to changes in preload and afterload.

HEARTMATE 1000 IP LVAS.

The Heart.Mate 1000 IP LVAS (Thermo Cardiosystems, Inc., Woburn, MA) has received PMA approval from the FDA for use as a mechanical bridge to cardiac transplantation.[70] [71] [72] [72A] This implantable blood pump is connected to an external drive unit by a percutaneous air drive line. The titanium VAD housing contains a flexible segmented polyurethane diaphragm that is bonded to a rigid pusher plate. The unique, textured blood contacting surface promotes the formation of a stable neointima.[73] Patients do not require systemic anticoagulation and instead receive only antiplatelet agents. Intermittent air pulses from the external drive console actuate the pusher-plate diaphragm, and eject blood from the VAD housing. The pump has a maximum stroke volume of 83 ml and a maximum pump output of 10 liters/min. Valved conduits containing 25-mm porcine valves are located at the inlet and outlet ports of the VAD housing. The VAD is only designed for left ventricular support, withdrawing blood from the left ventricular apex. Blood is returned to the ascending aorta. The device may be implanted intraperitoneally, but more typically it is positioned preperitoneally, in the patient's abdominal wall.[74] When the blood pump is placed in a preperitoneal position, the potential visceral complications associated with peritoneal implantation are avoided. The drive console runs on standard alternating current, as well as internal rechargeable batteries. The batteries provide up to 40 minutes of support. The control system allows the VAD to function in a fixed rate or pump-on-full mode. The latter is a rate-responsive mode in which the VAD is automatically pulsed when the pump chamber is approximately 90 percent filled.

THORATEC VAD SYSTEM.

The Thoratec VAD System (Thoratec Laboratories Corp., Berkeley, CA, Fig. 19-2) is the only VAD approved by the FDA both for the treatment of postcardiotomy cardiogenic shock and as a bridge to cardiac transplantation.[75] [76] [77] [77A] This versatile paracorporeal blood pump can be used for right, left, or biventricular assistance. In the case of left ventricular assistance, custom-designed cannulas allow blood to be withdrawn from either

Figure 19-2 The paracorporeal Thoratec ventricular assist device is located on the patient's anterior abdominal wall. The inlet and outlet cannulas traverse the skin in the subcostal region. The biventricular assistance configuration shown here would be used in a patient requiring a bridge to cardiac transplantation. The left ventricular assist device inflow cannula is inserted into the left ventricular apex. The left ventricular assist device outflow graft is sutured to the ascending aorta. The right ventricular assist device withdraws blood from the right atrium. Right ventricular assist device outflow is to the main pulmonary artery. (From Richenbacher WE: Ventricular assistance as a bridge to cardiac transplantation. *In* Richenbacher WE [ed]: Mechanical Circulatory Support. Georgetown, TX, Landes Bioscience, 1999, p 125.)

the left atrium or the apex of the left ventricle. The blood pump consists of a machined polycarbonate housing that contains a polyurethane blood sac and Bjork-Shiley monostrut inlet and outlet valves (Shiley, Inc., Irvine, CA). Patients are maintained on sodium warfarin. The blood pump has a stroke volume of 65 ml with a dynamic ejection fraction of approximately 0.75. Air pulses from the drive unit intermittently compress the flexible blood sac ejecting blood from the VAD housing. The control system allows the device to function in one of three modes: a manual fixed-rate mode, a synchronized mode in which the R-wave of the patient's electrocardiogram serves as an electronic trigger, and an asynchronous full-to-empty mode in which the VAD enters systole each time the blood sac fills. The latter mode maximizes cardiac output by allowing the VAD pump rate to be determined by preload.

Electric Pulsatile Blood Pumps

In the past few years great progress has been made in the development and clinical application of electric VADs. The current generation of electric blood pumps are intracorporeal devices that are capable of providing months, or even 1 or 2 years, of ventricular support. These devices provide left ventricular apex-to-aortic left ventricular assistance and are not designed for right ventricular assistance. Electric VADs are powered by a highly portable external controller and battery pack. In 1998, two electric VAD systems were approved by the FDA for the bridge to transplant application. Both approved systems employ a percutaneous drive line that connects the intracorporeal blood pump to the external electronics. Patients may now be discharged from the hospital to await their cardiac transplant at home.[78] [79] The conversion from a bulky external pneumatic drive unit to a small portable battery pack, with the possibility of hospital discharge, represents a dramatic improvement in the quality of life experienced by the patients who require mechanical circulatory support as a bridge to cardiac transplantation.

The next-generation electric VAD will be completely implantable and capable of providing years of tether-free left ventricular support. The electric VAD system will have an implantable controller and backup battery. An external, portable battery pack will serve as the primary power source. The external battery pack will be carried in a shoulder bag and transfer energy to the implantable controller and blood pump using transcutaneous energy transmission.[80] Energy will be passed from an external primary coil located on the surface of the skin to a subcutaneous secondary coil by inductive coupling. There will be no break in the integument, eliminating the potential for an ascending drive line infection. The internal, rechargeable battery will allow brief periods of entirely tether-free VAD function. Because these systems will be completely sealed, air displaced from the blood pump housing during VAD diastole will move to an implanted reservoir known as a compliance chamber.[81] As the final technological barriers to the development of implantable electric VADs are overcome, these systems will be permanently implanted in patients with unreconstructable coronary artery disease or end-stage cardiomyopathy not amenable to cardiac transplantation.

Recently, a clinical trial (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure [REMATCH]) was initiated.[82] The trial seeks to enroll patients with NYHA functional Class IV heart failure who are not candidates for cardiac transplantation. Patients are randomized to one of two treatment arms: medical therapy or permanent electric VAD insertion. The purpose of the study is to evaluate the efficacy, safety, and cost effectiveness of wearable VADs versus optimal medical therapy in the treatment of end-stage heart failure. As implantable VAD systems reach the clinical arena the goal of using mechanical blood pumps as an alternate to transplant will be realized.[83]

NOVACOR N100 LVAS.

The Novacor N100 LVAS (Novacor Medical Division, Baxter Healthcare Corporation, Oakland, CA) was approved by the FDA for the bridge to transplant application (Fig. 19-3) . This ventricular assist system contains a polyurethane blood sac that is compressed by dual, symmetrically opposed pusher plates.[84] The pump is actuated by a spring-decoupled solenoid energy converter. The blood pump and energy converter are contained within a lightweight fiberglass/epoxy housing that is implanted in a preperitoneal position in the left upper quadrant of the patient's abdomen.[84] [85] The inflow and outflow conduits each contain a bioprosthetic, pericardial valve. Patients require full anticoagulation with sodium warfarin.

The Novacor blood pump has a maximum stroke volume of 67 ml. The tethered configuration employs a percutaneous vented tube containing power and control wires.[84] The external console-based controller typically allows the device to function in a fill-rate trigger mode that provides synchronized counterpulsation to the native heart. The device may also be powered by a wearable, microprocessor-based controller and external batteries.[86] [87] [88] The compact controller and rechargeable batteries are worn as a belt and can support the blood pump for up to 6 hours.

HEARTMATE VE LVAS.

The HeartMate VE LVAS (Thermo Cardiosystems, Inc., Woburn, MA) has been approved by the FDA for the bridge to transplant application (Fig. 19-4) . This left ventricular assist system utilizes a

Figure 19-3 The implantable Novacor N100 LVAS. The blood pump is located in the preperitoneal position in the left upper quadrant of the patient's abdomen. The device is designed to provide left-sided heart support. Blood is withdrawn from the left ventricular apex and is returned to the ascending aorta. The percutaneous drive line connects the blood pump to the external controller and primary and reserve power packs. (Courtesy of the Novacor Division, Cardiovascular Group, Baxter Healthcare Corporation, Oakland, CA.)

Figure 19-4 The implantable Thermo Cardiosystems VE LVAS. The blood pump is positioned preperitoneally in the left upper quadrant of the patient's abdomen. The device is configured for left ventricular assistance with a left ventricular apex inflow cannula and an aortic outflow graft. The percutaneous drive line exits the skin in the right upper quadrant. The external controller is clipped to a belt. The two batteries are worn in shoulder holsters. (From Richenbacher WE: Ventricular assistance as a bridge to cardiac transplantation. *In* Richenbacher WE [ed]: Mechanical Circulatory Support. Georgetown, TX, Landes Bioscience, 1999, p 123.)

blood pump similar to that employed in the pneumatically powered ventricular assist system produced by the same manufacturer.[71] [72] [89] In the vented electric version, however, the diaphragm pusher-plate mechanism is pulsed by a low-speed high-torque motor. The percutaneous electrical leads connect the blood pump to the external controller and batteries. The rechargeable batteries, capable of providing 4 to 6 hours of tether-free operation, are carried in a shoulder holster, or the device may be connected to a stationary power base unit.

ARROW LIONHEART LVAS.

The completely implantable, sealed system being developed at The Pennsylvania State University and Arrow International (Arrow International, Inc, Reading, PA) contains a segmented polyurethane blood sac that is contained in a rigid housing.[90] [91] Bjork-Shiley monostrut inlet and outlet valves provide unidirectional blood flow. The blood sac is compressed by a pusher plate driven by a brushless direct current motor. Air displaced from the pump housing during VAD diastole is managed by a polyurethane compliance chamber.[81] Control electronics and a 30-minute battery pack are contained in an implantable cannister that receives power from a subcutaneous energy transmission coil. The external battery pack carried by the patient transfers energy to the implanted coil using transcutaneous energy transmission.[80] The device has a stroke volume of 62 ml and can pump up to 8.5 liters/min. The controller adjusts the VAD beat rate in response to physiologic conditions, ensuring that the blood pump functions in a full-to-empty mode.

The Pennsylvania State University electric VAD has run continuously for more than 1 year on a mock circulatory system.[90] The system has been tested in vivo for up to 90 days.[92] Clinical implants began in Europe in the fall of 1999. An IDE has been submitted to the FDA in preparation for the initial feasibility study in the United States.

Indications and Results of Clinical Use

POSTCARDIOTOMY CARDIOGENIC SHOCK.

The original indication for VAD support was postcardiotomy cardiogenic shock. Approximately 1 percent of patients cannot be separated from cardiopulmonary bypass after an open-heart operation despite maximum medical therapy and IAB counterpulsation.[7] [93] [94] These patients are considered potential candidates for VAD insertion. The goal of mechanical circulatory support in this clinical setting is to alter the balance between myocardial oxygen supply and demand to create a milieu that favors myocardial recovery. At the same time, systemic perfusion is maintained. The end point in this scenario is a return of ventricular function, with the expectation that following a few days of mechanical circulatory support the VAD(s) could be removed.

The results achieved with mechanical blood pump support for postcardiotomy cardiogenic shock are summarized in Table 19-7 . The Combined Registry for the Clinical Use of Mechanical Ventricular Assist Devices and the Total Artificial Heart was developed in 1988 under the auspices of the International Society for Heart Transplantation and the American Society for Artificial Internal Organs.[7] The responsibility for the Registry was transferred to the Society of Thoracic Surgery in 1993. Clinicians from 62 centers worldwide voluntarily submit data to this registry.

Postcardiotomy cardiogenic shock remains the most frequent indication for mechanical circulatory support, although the number of blood pumps implanted for this clinical indication has declined steadily during the past decade.[7] Whether this reflects more strict implantation criteria, advances in myocardial preservation, improved medical

management of postcardiotomy heart failure, or underreporting to the voluntary registry is unknown. Mechanical circulatory support for postcardiotomy cardiogenic shock is most frequently required after coronary revascularization. The duration of support is brief, varying between 1.4 and 5.7 days.[7] [64] [98] Recent trends suggest that the duration of support required is independent of the need for left, right, or biventricular assistance.[7]

In general, lower survival is associated with an unsuccessful operation,[93] perioperative myocardial infarction,[93] advanced age,[7] renal failure,[7] [93] [95] neurologic complications,[7] biventricular failure,[7] [95] multisystem organ failure,[98] and sepsis.[98] Patients who are subjected to prolonged cardiopulmonary bypass times or who require late VAD insertion (hemodynamic collapse after having been moved out of the operating room) have very poor survival rates.[7] [93] Survival does not appear to be influenced by the type of operation performed before VAD insertion, the need for right versus left versus biventricular support, or the type of device used.[7] Survival is similar regardless of whether the patient receives a centrifugal or pulsatile blood pump. Although an overall salvage rate of approximately 25 percent seems low, it must be understood that without mechanical circulatory support, patients with refractory postcardiotomy cardiogenic shock would die. Although registry data show that weaning and survival rates have not improved in the past decade, Curtis and colleagues have shown that there is a trend toward increased hospital survival when an early versus recent cohort of patients at a single institution are compared.[64] Recently, Korfer and associates described 50 patients who received mechanical circulatory support for postcardiotomy cardiogenic shock with a hospital discharge rate of 50 percent.[98] Of note, the survival curve levels off after hospital discharge. The Registry reports a 24 percent 6-month survival and a 22 percent 5-year survival.[7] The majority of long-term survivors achieve NYHA functional Class II or better.[64]

ADJUNCT TO CARDIAC TRANSPLANTATION (See alsoChap. 20) .

With the introduction of cyclosporine-based immunosuppressive regimens, and the resurgence of interest in cardiac transplantation in the early 1980s, a second patient population that could potentially benefit from mechanical ventricular assistance was identified. The number of patients with end-stage cardiomyopathy quickly exceeded the number of donor hearts available. The list of approved cardiac transplant candidates grew, and the time a patient spent waiting for a donor heart increased. At year-end 1998, 4185 potential cardiac transplant recipients were listed with the United Network for Organ Sharing (UNOS).[99] During the same year, 767 potential cardiac transplant recipients died while on the UNOS waiting list.[99] Cardiac transplant recipients who decompensate hemodynamically before the availability of a donor heart are potential candidates for VAD implantation. The role of mechanical circulatory support in this clinical setting is to maintain systemic perfusion and end organ function until a donor heart is available. The recipient's heart and VAD are removed at the time of cardiac transplantation.[99A]

Results of mechanical blood pump support as a bridge to cardiac transplantation are summarized in Table 19-8 . Although the length of time a cardiac transplant candidate waits for a suitable donor heart varies with UNOS status, blood type, and weight, the average waiting time is a number of months and can be as long as 1 to 2 years. Pulsatile devices, in particular implantable VADs, are designed to provide long-term support. The average duration of support for the series summarized in Table 19-8 varied between 41 and 108 days.[71] [72] [76] [98] [103] Fifty-five percent of patients who receive support with a pulsatile device that is approved by the FDA for the bridge application survive to hospital discharge after cardiac transplantation.[76] [97] [98] [101] [102] [103] Some would question the wisdom of allocating hearts to this critically ill patient population when the 1-year survival after conventional heart transplantation now exceeds 80 percent.[5] It has been suggested that VAD support intensifies the donor shortage by including recipients who otherwise would not have survived to transplantation.[104] The Registry of the International Society for Heart and Lung Transplantation notes that VAD support before transplantation is a recipient factor that has a significant negative impact on 1-year patient survival after transplantation.[5] If the cumulative experience of the bridge patients is reviewed, approximately two thirds of patients requiring VAD support survive to transplantation. More importantly, 86 percent of patients who require VAD support, and who are successfully transplanted, will survive to hospital discharge.[76] [97] [98] [101] [102] [103] Others have shown that posttransplant survival in bridge patients meets,[101] [102] [104] or exceeds,[105] the survival rate in non-bridge patients.

Risk factors associated with reduced survival in patients requiring VAD support as a bridge to cardiac transplantation include a preoperative need for mechanical ventilation; significant end organ dysfunction as evidenced by an elevated blood urea nitrogen, creatinine (with or without the need for dialysis), or bilirubin level; the need for a reoperation for bleeding after VAD insertion; right-sided heart failure requiring mechanical right ventricular assistance in addition to left VAD insertion; infection; and device failure.[71] [103] [106] The incidence of device failure is low, a tribute to extensive preclinical device testing. Technical refinements in device design have largely eliminated the causes of device malfunction that appeared in the early clinical experience. [71] [107] [108]

The benefits of an extended period of VAD support are well defined. Patients undergo vigorous nutritional and physical rehabilitation.[109] Hemodynamic parameters, exercise tolerance, and end organ function improve.[110] [111] [112] [113] The recent approval by the FDA of two intracorporeal, electric VAD systems now allows VAD supported patients to be

*= Survived to successful transplanatation;

= survived to hospital discharge after transplantation.

discharged from the hospital. Home-based care has significant psychological and emotional benefits for patients and their families.[114] [115] Outpatient VAD care also has a positive impact on health care economics.[116]

Mechanical circulatory support has been employed in two additional subpopulations of patients requiring cardiac transplantation: both after donor heart implantation. According to the Registry, 40 patients have been treated with circulatory support during a rejection episode complicated by hemodynamic compromise.[117] Only 23 of the patients (58 percent) underwent a second cardiac transplant. Eight of the 23 patients (35 percent) were discharged from the hospital. This represents an absolute salvage rate of 20 percent. Sixty-eight other posttransplant patients suffered from presumed reversible cardiogenic shock unrelated to rejection.[117] VAD support in this patient population resulted in an absolute salvage rate of 19 percent, statistically equal to the survival rate when ventricular assistance was employed in patients with postcardiotomy cardiogenic shock after other types of procedures.

ACUTE MYOCARDIAL INFARCTION (See also Chap. 35) .

Patients in cardiogenic shock after acute myocardial infarction treated with mechanical circulatory support alone have a mortality rate of 80 percent, the same as patients treated medically.[118] Ventricular assistance has been used in this patient population to stabilize the patient's condition to allow cardiac catheterization and emergent revascularization, treat cardiogenic shock after urgent revascularization, or support patients with irreparable cardiac damage until cardiac transplantation can be performed.[119] Mortality in certain subsets of patients may be reduced to 25 to 40 percent.[118] [119] [120] Because the therapeutic end point is unknown, proper device selection can be problematic. If ventricular apex cannulation is employed, the surgical technique must be modified when dealing with necrotic myocardium.[121] In general, less than optimal results leave the role for mechanical circulatory support in this clinical setting poorly defined.

LONG-TERM BRIDGE TO RECOVERY.

Most large series in which a pulsatile VAD has been inserted as a bridge to cardiac transplantation include patients who have recovered ventricular function after a protracted period of mechanical circulatory support.[72] [76] [89] [122] [123] [123A] In this situation the VAD is removed, obviating the need for cardiac transplantation. In most instances the VAD is removed when the patient develops a contraindication to transplantation or device malfunction. Observational studies describe a variety of morphological and physiological changes that are associated with chronic ventricular unloading.[124] [125] Indicators of ventricular recovery, however, are unknown. It is also unclear if the improvement in left ventricular function is sustained after VAD explantation. At this time, the role of ventricular assistance in the management of the patient with chronic heart failure, other than as a bridge to transplantation, must be considered experimental.

Complications Associated with VAD Use

Hemorrhage, usually defined as the need for a reexploration for bleeding, occurs in 14 to 50 percent of patients who require mechanical ventricular assistance.[64] [71] [76] [77] [89] [98] [103] Postimplant bleeding occurs more frequently in patients who receive a VAD for postcardiotomy cardiogenic shock versus a VAD as a bridge to transplant.[126] There is also a device-related prevalence in that bleeding occurs more frequently in the patients supported with a centrifugal pump for postcardiotomy cardiogenic shock than in patients supported with a pulsatile device for the same indication.[7] The etiology of bleeding associated with VAD implantation is multifactorial and includes preoperative hepatic failure or coagulopathy, technical surgical ability, hematologic abnormalities related to a prolonged cardiopulmonary bypass time, hypothermia, hemodilution, and platelet activation or disseminated intravascular coagulation secondary to blood-biomaterial interaction in the heart-lung machine or VAD.[126] [127] Use of the bovine serine protease inhibitor aprotinin has reduced blood loss associated with VAD implantation.[128]

Stasis of blood within the blood pump and inadequate anticoagulation may lead to thrombus deposition.[129] Thromboembolic complications occur in 6 to 47 percent of patients.[64] [72] [76] [98] [103] [130] Not all thromboembolic events result in a neurological deficit, and, in fact, many thromboembolic events are not clinically evident.[64] [130] [131] Multisystem organ failure is usually related to preimplantation end organ hypoperfusion but may be exacerbated by postimplantation low-flow states. Renal failure, in most instances defined as the need for dialysis, occurs in 5 to 29 percent of patients.[64] [76] [77] [98] [103] After left VAD insertion, systemic hypoperfusion is most often related to right ventricular failure and inadequate left VAD filling. Right ventricular dysfunction secondary to pulmonary hypertension is most effectively treated with inhaled nitric oxide.[132] [133] Medically refractory right-sided heart failure requiring right VAD insertion occurs in 11 to 37 percent of patients.[71] [72] [77]

Infection occurs in up to 59 percent of patients receiving mechanical circulatory support.[64] [71] [72] [76] [98] [103] Infection is often attributed to prolonged hospitalization, indwelling lines and catheters, and percutaneous drive lines or cannulas. Device-related infections occur in 11 to 27 percent of patients.[71] [72] [76] Device-related infections include percutaneous drive line colonization, intracorporeal VAD pocket infections, and VAD endocarditis. VAD endocarditis, best treated with chronic antibiotic therapy and early VAD removal, is associated with a poor outcome.[134] [135] Septic complications in the patient receiving VAD support as a bridge to transplantation should not influence the decision to proceed with transplantation. Transplantation in the face of infection is the most effective treatment option because survival rates are not significantly different in patients who are transplanted with or without an infectious complication during the period of VAD support.[134] [136]

Management Considerations

POSTCARDIOTOMY CARDIOGENIC SHOCK.

Patients who have preexisting ventricular dysfunction and who are at risk for intractable heart failure after an open-heart procedure have a femoral arterial line placed before the initiation of cardiopulmonary bypass. The presence of a femoral arterial line facilitates subsequent IAB insertion. Selected patients also undergo a cursory pretransplant evaluation. Of 965 postcardiotomy cardiogenic shock patients reported to the Registry for Mechanical Circulatory Support, 43 patients (4.5 percent) were activated as potential cardiac transplant recipients when they developed device dependency and had no contraindication to transplant.[6]

On completion of the cardiac operation, acid-base balance and electrolyte abnormalities are corrected. A functional cardiac rhythm is restored utilizing temporary cardiac pacing, if necessary. A patient is considered a candidate for VAD insertion when he or she fulfills the hemodynamic criteria outlined in Table 19-1 , has no contraindication to VAD insertion as outlined in Table 19-2 , and cannot be weaned from cardiopulmonary bypass despite moderate inotropic support and IAB counterpulsation. It is imperative that operative decision-making be performed rapidly, and VAD insertion undertaken expeditiously, to avoid the complications associated with a prolonged cardiopulmonary bypass time.[137]

Standard cardiopulmonary bypass cannulas are employed for centrifugal VAD support.[138] [139] [140] Custom-designed cannulas are used with pulsatile VADs. For left ventricular

TABLE 19-9 -- HEMODYNAMIC STATUS DURING MECHANICAL LEFT VENTRICULAR ASSISTANCE

CVP (mm Hg)	LAP (mm Hg)	Systolic AoP (mm Hg)	CI (liters/min/m [2])	Diagnosis
15-20	<15	>90	>2.0	Satisfactory pumping
<15	<15	<90	<2.0	Hypovolemia
15-20	>20	<90	<2.0	Inlet cannula obstruction
>20	<15	<90	<2.0	Right ventricular failure

CVP=central venous pressure; LAP=left atrial pressure; AoP=aortic pressure; CI=cardiac output index.

assistance, left atrial cannulation is preferred as myocardium is spared and decannulation, after a return of ventricular function, can be performed without cardiopulmonary bypass. With a left VAD in place, cardiopulmonary bypass is discontinued. Simultaneous monitoring of left and right atrial pressures aids in the distinction between inflow cannula obstruction, hypovolemia, and right ventricular failure should left VAD filling be less than satisfactory (Table 19-9) . Right ventricular failure is managed with judicious volume loading, intravenous isoproterenol, or inhaled nitric oxide. Intractable right-sided heart failure mandates insertion of a right VAD. The goal is to achieve a cardiac index greater than 2.2 liters/min/m[2] . The IAB may be left in place to impart a degree of pulsatility to nonpulsatile centrifugal left ventricular assistance. To avoid septic complications, however, the IAB is usually withdrawn in the immediate postoperative period.

Postoperatively, abnormal coagulation studies are aggressively corrected with protamine sulfate and blood product administration. When mediastinal tube drainage slows, patients are anticoagulated with continuous intravenous heparin sodium. Sodium warfarin is not usually employed as the time course for ventricular recovery is measured in days. A variety of weaning protocols have been employed.[141] In general, ventricular support is periodically decreased to assess a patient's native ventricular function. This can be accomplished with pulmonary arterial catheter measurements of cardiac output or observations of wall motion using transesophageal echocardiography.[142] When ventricular recovery is complete, the patient is returned to the operating room for device explantation. Management is conventional thereafter.[142A]

BRIDGE TO CARDIAC TRANSPLANTATION.

To be considered for mechanical circulatory support before cardiac transplantation, patients must not only fulfill VAD selection criteria but must also meet cardiac transplant selection and exclusion criteria (see Chap. 20) . The timing of VAD insertion is critical. When an inotrope-dependent cardiac transplant candidate deteriorates to the point where IAB counterpulsation is required, VAD implantation should follow within 24 to 48 hours. VAD insertion as a bridge to transplant is rarely an emergent procedure. However, inordinate delays in device implantation only result in progressive end organ deterioration and an increased risk of infectious complications.

Pulsatile devices are most frequently employed in this clinical setting. Implantation techniques are highly specialized but well documented.[74] [85] [140] [141] [143] [144] Cardiopulmonary bypass times are often brief, but postoperative bleeding can be troublesome. Aprotinin is used routinely.[128] Because aprotinin may have been used during a previous open heart operation, appropriate precautions should be taken as the patient may have been sensitized during the previous exposure. Should a right VAD be necessary, device selection is limited. The versatile Thoratec device can be employed for either right- or left-sided support.[76] [77] [140] If an implantable device is employed on the left, right ventricular support can only be provided with a hybrid pump configuration using a paracorporeal Thoratec VAD. The Abiomed BVS 5000, or a nonpulsatile pump, may also be used for right-sided heart support, although neither is approved by the FDA as a bridge to cardiac transplantation.

Postoperatively, the patient should be rapidly extubated and all invasive monitoring lines and tubes removed as soon as medically allowed to avoid nosocomial infection.[135] Fastidious cannula/drive line care and immobilization of the drive line reduces the potential for tract colonization.[145] Blood transfusions should be minimized and only leukocyte-depleted blood administered. Interval panel reactive antibody determinations will detect the presence of preformed antibodies to human lymphocyte antigens and determine the need for a prospective crossmatch with the cardiac donor or perioperative plasmapheresis at the time of transplant.[146] Aggressive nutritional and physical rehabilitation will prepare the patient for the subsequent cardiac transplant.[109] [147] Cardiac transplantation should be delayed for at least 2 to 4 weeks after VAD insertion to allow time for the patient to convalesce from the VAD implant, rehabilitate, and recover end organ function.[110] [111] [148] The VAD is explanted at the time of recipient cardiectomy.[149]

THE ARTIFICIAL HEART

The total artificial heart (TAH) is a biventricular device capable of supporting both the pulmonary and systemic circulations. The TAH is implanted within the patient's pericardium (orthotopic position) in a manner very similar to donor heart implantation at the time of cardiac transplantation. The TAH must be compact and possess a control system capable of balancing the output of the two prosthetic ventricles, while varying cardiac output with physiological need.

Pneumatic Total Artificial Heart

At least 11 different TAHs have been employed clinically worldwide.[150] All possess similar design characteristics. Each prosthetic ventricle contains a flexible blood sac that is housed in a rigid case. Air pulses generated by a bedside drive unit are transmitted through small diameter percutaneous drive lines and periodically compress the flexible blood sacs. Inlet and outlet valves ensure a unidirectional flow of blood through the prosthetic ventricle. Cardiac output and output balance between the ventricles are achieved with a sophisticated control system. A manual, fixed rate control system functions using the Starling mechanism. The prosthetic ventricles completely empty during systole but heart rate and diastolic fill time are modified to limit diastolic filling. Any increase in preload results in more complete ventricular filling, a higher stroke volume, and increased cardiac output. An automatic control system employs two negative feedback servomechanisms.[151] The left ventricle pumps a full stroke with each beat, varying the rate to maintain systemic pressure within normal limits. The right ventricular beat rate varies to maintain a left atrial pressure of 5 to 12 mm Hg.

TAH implantation is carried out using cardiopulmonary bypass, with bicaval venous and aortic cannulation.[152] The patient's heart is excised by transecting the great vessels just distal to the semilunar valves and the atria along the atrioventricular groove. Prosthetic atrial cuffs are sutured to the atrial remnants. Vascular grafts are anastomosed to the aorta and pulmonary artery. The prosthetic ventricles are attached to the atrial cuffs and outlet grafts with snap-on quick connects or a threaded union nut. The ventricles are de-aired, pumping initiated, and cardiopulmonary bypass discontinued.

The pneumatic TAH has been employed extensively as a mechanical bridge to transplantation. Patient selection criteria are identical to those outlined in the VAD section. The sole exception is patient size. Patients must weigh at least 150 pounds and have an adequate anteroposterior thoracic dimension to avoid atrial compression and inflow obstruction at the time of sternal closure. The most recent Registry report includes 191 patients who received TAH support as a bridge to cardiac transplantation.[103] One hundred and thirty-five patients (71 percent) underwent transplantation, of whom 66 (49 percent) were discharged from the hospital. The posttransplant discharge rate is 49 percent (66/135 patients). Transplantation rates were statistically equal regardless of whether the patient was supported with a left VAD, two VADs, or the TAH.[103] However, there was a highly statistically significant difference in posttransplant discharge rate, with the best outcome seen with left-sided heart support and least favorable outcome with the TAH. The only pneumatic TAH still employed as a bridge to transplantation under an IDE in the United States is the CardioWest (Jarvik) Total Artificial Heart (CardioWest, Tucson, AZ). Since 1993 the CardioWest TAH has been implanted in 100 patients.[153] [154] Sixty-seven patients subsequently underwent a cardiac transplant. Sixty-one patients (61 percent) were discharged to home, for a posttransplant discharge rate of 91 percent.

Of historical interest, four patients received the Jarvik-7-100 TAH under an FDA-approved protocol as a permanent form of circulatory replacement.[155] The longest survivor lived for 620 days, whereas all four patients succumbed to hematologic, thromboembolic, and infectious complications. Currently, infectious complications secondary to percutaneous drive lines and lifestyle issues related to the requisite bulky external drive unit preclude the use of pneumatic TAHs as a permanent form of circulatory support. Although the TAH can provide safe and effective hemodynamic support to a precardiac transplant patient, the TAH is more expensive and technically more difficult to implant than a VAD. Furthermore, univentricular support will suffice in the majority of patients who require a mechanical bridge to cardiac transplantation. We believe that transplant recipients who decompensate hemodynamically before cardiac transplantation are best served by VAD insertion. The TAH,

if available, should be reserved for selected patients with a postinfarction ventricular septal defect, valvular heart disease, or intractable arrhythmias.

Electric Total Artificial Heart

When available for clinical use, the electric TAH will serve as a readily available cardiac replacement for patients with irreparable acute or chronic heart failure (Fig. 19-5) . The electric TAH is designed for permanent use and, as such, will be completely implantable. Size constraints represent the most significant hurdle to device development. Two blood pumps are located within the pericardium and, unlike the pneumatic TAH that employs a separate external drive unit for each ventricle, the electric TAH uses a single implantable energy converter to drive both ventricles, greatly increasing the complexity of device control. The electric TAH has a minimum energy requirement of 14 watts. Implantable batteries cannot provide the power required. Thus, currently available electric TAHs will rely on an external power source and transcutaneous energy transmission, with a small rechargeable implantable backup battery capable of serving as a power source for 30 to 60 minutes. In the future, higher-energy density batteries may reduce or eliminate the need for a primary external power source altogether.[156]

Two research teams are developing an electric TAH under a contract program established by the National Heart, Lung, and Blood Institute in 1988.[157] The Abiomed TAH

Figure 19-5 The completely implantable electric motor-driven artificial heart being developed at The Pennsylvania State University. The artificial heart is positioned within the pericardium. The implanted controller and rechargeable reserve battery are powered by an external battery pack. Energy passes from the superficial primary coil to the subcutaneous secondary coil using inductive coupling (TETS). Air displaced from the blood pump housing enters the intrathoracic compliance chamber. Air that diffuses out of the compliance chamber over time is replenished using the subcutaneous access port. SVC=superior vena cava, PA=pulmonary artery, Ao=aorta. (From Corry DC, Richenbacher WE: Mechanical circulatory support: Past, present and future. Surgical Rounds 21:426, 1998.)

(Abiomed, Inc., Danvers, MA) is an electrohydraulically actuated device capable of providing a cardiac output in excess of 10 liters/min.[158] [159] An atrial flow balancing chamber is used to control the left-right blood flow balance.[160] Preclinical device testing is in progress with the expectation that the device will be implanted clinically within the next year.

The Pennsylvania State University/Benecor Heart Systems (Benecor Heart Systems, Inc., Ann Arbor, MI) TAH employs a dual pusher plate rollerscrew energy converter.[161] Left-right output balance is achieved with an implanted control algorithm that adjusts the left pump diastolic fill time and speed of systole, to just barely allow complete left pump filling while maximizing pump rate.[151] Extensive mock loop testing is being performed at this time as required by the FDA before clinical trials. The completely implanted system has been tested in vivo in 5 acute and 37 chronic studies.[162] The blood pump has now functioned in a calf for over 1 year without evidence of thromboembolic complications.

Chapter 20 - Heart and Heart-Lung Transplantation

DOUGLAS N. MINIATI
ROBERT C. ROBBINS BRUCE A. REITZ

Although cardiac transplantation in humans was first carried out in 1967, it is only since the early 1980s that it has been established as an accepted treatment for end-stage heart disease. The advances in immunosuppression and management that have made this possible also have led to successful heart-lung and lung transplantation. The increasingly widespread application of thoracic organ transplantation has brought this therapy to many centers around the world and to an ever-increasing patient population.

The Registry of the International Society for Heart Transplantation in 1999 listed a cumulative total of 48,541 cardiac transplantation procedures performed in 304 transplant centers.[1] The expansion of heart transplantation is emphasized by the fact that before 1980, fewer than 360 transplantations had been performed. The 30-year cardiac transplantation experience with approximately 1000 patients at Stanford University was reviewed and published.[2] The management philosophies and strategies discussed in this chapter are based in part on this experience.

HISTORY

There are several mentions of heart transplantation in ancient Chinese mythology and biblical reference, but not until the pioneering work of Alexis Carrel at the beginning of the 20th century did surgeons have the ability to transplant organs such as the heart.[3] In a number of imaginative experiments, Carrel demonstrated that a heart could be transplanted and resume functioning in the new host. Carrel not only transplanted hearts but also suggested and performed the en bloc transplantation of heart and lungs,[4] both of these procedures being heterotopic transplants into the necks of recipient dogs.

With the advent of techniques for successful cardiac surgery in the 1950s, major attention was finally directed to the problem of transplantation of the heart in the chest in the normal, or orthotopic, position. The current most commonly used surgical technique for heart transplantation originated with the work of Lower and Shumway in 1959.[5] A number of important questions about transplants, including protocols for immunosuppression,[6] correlation of the surface electrocardiogram with allograft rejection,[7] and reversal of these changes with augmented immunosuppression, were subjects of early laboratory study. Despite this prior laboratory work, many were surprised when the first human heart transplant was performed by Christiaan Barnard in Capetown, South Africa, in December 1967.[8] This transplant initiated a great amount of interest at other centers around the world, and 170 transplants were performed by 65 surgical teams between December 1967 and March 1971. The 1-year survival was only 15 percent, and because of this, enthusiasm for heart transplantation rapidly waned by the end of 1971.

Only at Stanford University and the Medical College of Virginia did surgical teams continue with programs in heart transplantation. Working virtually alone through the decade of the 1970s, these investigators refined recipient selection criteria,[9] saw the development of the transvenous endomyocardial biopsy for diagnosing rejection,[10] developed rabbit antithymocyte globulin as an effective treatment of acute rejection,[11] and defined many of the late posttransplant complications and management principles.[12]

IMMUNOSUPPRESSIVE THERAPY.

Widespread application of heart transplantation depended on the development of better immunosuppressive therapy (see pp. 178 , 179 , and 180). This goal was reached with the discovery that cyclosporin A (cyclosporine), a novel cyclic undecapeptide of fungal origin, could selectively block the effect of interleukin 2 (IL-2) in stimulating T cells.[13] [14] [15] [16] [17]

Heart and lung transplantation has been extended to a large number of additional recipients, including neonates with hypoplastic left heart syndrome, the elderly (age 60 to 70), and patients with primary lung disease, such as emphysema, cystic fibrosis, or primary pulmonary hypertension.

ORGANIZATION OF A TRANSPLANT PROGRAM

In 1999, there were 304 centers performing cardiac transplantation worldwide. Experience has shown that a successful program depends on both institutional commitment and participation of many professional groups within the institution that must work together in caring for patients. Careful attention to detail in organizing a transplant program is crucial in obtaining and sustaining good outcomes in transplant recipients.

The development of an effective cardiac transplant program requires careful organization and cooperation from both clinical and nonclinical personnel. Some but not all states require a certificate of need to initiate a new program of heart transplantation. The National Organ Transplantation Act of 1984 established certain minimum criteria for transplant programs to enroll in the nationwide computerized matching system.[18] To encourage excellent patient care and to discourage transplantation in centers with suboptimal results, the act established the United Network for Organ Sharing (UNOS), with membership limited to those centers that perform a minimum of 12 transplant procedures per year and that obtain a 1-year survival rate of at least 70 percent. In addition to these performance criteria, the center must have adequate operating room facilities and trained physicians and nursing personnel and must be a participating member in a local organ procurement organization. The program must have established protocols and procedures for the selection of patients, the evaluation and distribution of donor organs, postoperative management, and long-term follow-up. Both surgeons and physicians involved in the care of patients must meet certain criteria in terms of training and prior experience. The ability of an individual center to obtain funding from Medicare depends on similar criteria.[19]

RECIPIENT SELECTION

With improved outcomes in both quality of life and percentage of patients surviving, cardiac transplantation has become accepted therapy for many patients with end-stage

Figure 20-1 Adult heart transplantation indications. (From Hosenpud JD, Bennett LE, Keck BM, et al: The Registry of the International Society for Heart and Lung Transplantation: Sixteenth Official

heart disease. A fairly rigid selection process is required in order to obtain excellent results in individual patients. Although a tendency has been to relax these criteria in an effort to extend the benefits of transplantation to a larger number of patients, this has heightened the problem of donor scarcity. The number of potential recipients rises exponentially with an extension of the upper age accepted. The indications for heart transplantation are listed in Figure 20-1 . The most frequent indications are equally divided between ischemic heart disease and cardiomyopathy. Contraindications (Table 20-1) vary somewhat by program.

An important aspect of evaluation is a comprehensive psychosocial evaluation by a clinical social worker or psychologist. Patients' ability to follow a complex medical regimen is extremely important, as is family support necessary to help patients through numerous medical procedures and evaluations and to maintain the essential medical regimen after transplantation.

All conventional medical or surgical therapies should be used before consideration of transplantation. Evaluation might reasonably include endomyocardial biopsy to rule out other treatable causes of cardiomyopathy, especially for patients without ischemic heart disease. Unsuspected sarcoidosis or myocarditis is occasionally detected and might respond favorably to an alternative therapy, and some patients with recurrent life-threatening arrhythmias may be best treated initially by placement of an automatic implantable cardiac defibrillator.

Although it may be easy to identify the most severely ill

TABLE 20-1 -- CONTRAINDICATIONS TO HEART TRANSPLANTATION

Advanced age (>70 yr)
Irreversible hepatic, renal, or pulmonary dysfunction
Severe peripheral vascular or cerebrovascular disease
Insulin-requiring diabetes mellitus with end-organ damage
Active infection
Recent cancer with uncertain status
Psychiatric illness, poor medical compliance
Systemic disease that would significantly limit survival or rehabilitation
Pulmonary hypertension with pulmonary vascular resistance
>6 Wood units or 3 Wood units after treatment with vasodilators

patients with a poor prognosis for 6-month survival, for a large group of patients with symptomatic cardiomyopathy and ominous objective findings (ejection fraction <20 percent, stroke volume
40 ml, severe ventricular arrhythmias), timing may be somewhat difficult. A further consideration may be the quality of life, which is a judgment made by patients and the physicians caring for them. This comes into play in patients with intractable angina and coronary vessels that cannot be bypassed.

Clinical Considerations

The selection of a candidate for heart transplantation ultimately results from a clinical assessment that a patient free of established contraindications (see Table 20-1) suffers severe cardiac disability refractory to expert management. The pathophysiology usually encompasses congestive heart failure but is occasionally dominated by recurrent lethal arrhythmias or intolerable ischemic symptoms. Consideration based solely on a low (<20 percent) ejection fraction has become less reliable since the introduction of aggressive vasodilator therapy. Some patients with extensive left ventricular dysfunction are remarkably symptom free. Even symptomatic patients, when using the appropriate selection criteria, can experience 1- and 4-year survivals of 98 and 84 percent when treated medically,[20] and patients who are removed from the list of candidates because of clinical improvement have been shown to have similar symptoms and survival data as those going on to transplantation.[21]

INITIAL SCREENING.

The fine line between medical therapy and transplantation is often drawn with the help of physiological data that numerous studies have proved to be adequate predictors of short- and long-term survival. Several authorities have noted the value of peak exercise oxygen consumption (dot$(V)_{O_2}$) and cardiac output response to exercise in delineating which patients should be listed for transplantation.[22] [23] [24] [25] In considering peak dot$(V)_{O_2}$, however, it has been noted that many patients may terminate exercise for reasons other than a cardiopulmonary limitation (e.g., leg fatigue). As such, provided that the patient has reached the anaerobic threshold, there is near consensus that either a peak dot$(V)_{O_2}$ of less than 15 ml/kg/min or less than 55 percent of predicted peak dot$(V)_{O_2}$ should result in strong consideration of listing for transplantation. A peak dot$(V)_{O_2}$ of less than 12 ml/kg/min augurs a very poor 1-year survival rate and warrants listing in nearly all contraindication-free cases.[26]

UPPER AGE LIMIT.

One of the most controversial aspects of patient selection is the upper age limit for cardiac transplantation. The initial Stanford University criteria considered an upper age limit of 50 years. This was modified to include patients older than 55 and then up to age 60 during the era of improving results because of cyclosporine therapy in the early 1980's. Sufficient additional experience has now been reported in patients older than 60 to indicate that a strict chronological age criterion is not appropriate.[27] [28] In fact, one study used organs considered marginal for an alternate list of patients who would not have otherwise been considered for transplantation owing to age or need for a third transplant. The investigators found no significant difference in early and medium-term outcomes in comparison with patients on the standard list.[29] At Stanford, 65 years currently is considered the general upper age limit, although successful cardiac transplantations have been performed in patients up to 70 years old. Some evidence has suggested that older patients experience less rejection than younger patients.[30] Patients older than 50 years may warrant additional screening for comorbid conditions, and the concurrent relative contraindications of diabetes or other systemic disease, such as chronic pulmonary disease, probably would eliminate most patients older than 60 years as potential candidates.

PULMONARY VASCULAR DISEASE.

This is an important consideration. Orthotopic cardiac transplantation requires that the pulmonary vascular resistance be low, so that the normal right ventricle of the donor heart can adequately support the recipient's circulation after transplantation. A great deal of controversy has developed over the optimal measure of pulmonary vascular resistance. Most programs use the measurement of the traditional Wood unit and limit the value to 6 units or less at rest or less than 3 with maximal vasodilation. Other centers use the pulmonary vascular resistance index (Wood units × body surface area) or transpulmonary pressure gradient (mean pulmonary artery pressure minus mean pulmonary capillary wedge pressure) of 15 mm Hg or less.[31] Whatever measure of resistance is used, in those patients with values toward the upper limits, it is imperative to demonstrate in the catheterization laboratory that the resistance can be manipulated with oxygen, vasodilators, inhaled nitric oxide, or intravenous or inhaled prostacyclin.[32] [33] [34] If the pulmonary vascular resistance measurements remain elevated, strong consideration should be given to heart-lung transplantation. Because patients may remain on a waiting list for more than 6 months, repeat cardiac catheterization may be necessary semiannually to determine if the pulmonary vascular resistance has increased. Significantly elevated pulmonary vascular resistance and right-sided heart failure remain problems after orthotopic cardiac transplantation and are major causes of early postoperative mortality.

COEXISTING DISEASES.

Patients with involvement of other organs that precluded selection in the past but that now respond to transplantation may be considered candidates for *dual organ transplantation.* In addition to heart-lung, these include heart-kidney (notably for retransplantation in heart transplant recipients who have developed cyclosporine nephrotoxicity) and heart-liver (for homozygous familial hypercholesterolemia). Dual organ candidacy does not change a patient's status or position on the waiting list, but when patients become eligible for a heart or liver based on standard criteria, the second required organ may be allocated from the same donor.[35] The ethical dilemma of improving one life instead of two remains unresolved.

Patients with infective endocarditis (without metastatic infection) and patients with malignancy without evidence of recurrence (often with anthracycline cardiomyopathy) have successfully received heart transplants. All patients, however, should have at least several stool guaiac tests; mammograms, and Papanicolaou (PAP) smears, or prostate-specific antigen tests; and chest radiographs, to screen for cancer. Obesity (>140 percent of ideal body weight), which carries risks of worse graft coronary disease, hypertension, and wound infection, is a relative contraindication. Osteoporosis may contribute to spontaneous fractures associated with prednisone use, so candidates at risk should be evaluated with a bone density study. Sarcoidosis and some types of muscular dystrophy are considered a contraindication to transplantation. Systemic amyloidosis, because of its frequent multiorgan involvement as well as documented recurrence in the allograft, remains an unlikely condition

for permitting transplantation at most centers.

All programs inevitably exercise some subjectivity in the selection process, determined by the prior experience of the transplant team with the many clinical, physiological, and social variables involved. Although the evaluation of potential candidates for cardiac transplantation is difficult, these established criteria have led to certain predictable outcomes in terms of quality of life and actuarial survival. Deviations from these protocols usually produce less favorable results. As with any medical or surgical procedure, the final decision ultimately rests with the patient, in accordance with the concept of informed consent.

TREATMENT OF PATIENTS AWAITING TRANSPLANTATION

Because a number of patients are awaiting transplantation at any point in time, their management is important. The UNOS patient waiting list for needed organs in October 1998 totaled nearly 4000 patients awaiting heart transplantation worldwide.[26] Because approximately 3400 procedures were performed per year during 1997 to 1999, a number of awaiting recipients will not survive to receive a needed organ. Most centers experience between 10 and 20 percent mortality of patients on the waiting list. Worldwide heart-lung transplantations, after peaking at 241 in 1990, have declined to an average of 130 per year 1997 to 1999, while lung transplantations have steadily risen and stabilized at an annual rate of close to 1200.[1]

The management of end-stage congestive heart failure is described in Chapter 18 . Although digitalis remains the only generally available oral inotropic agent, the use of intravenous low-dose dopamine or dobutamine has been a helpful tool for treating some of these patients.[36] Some controversy surrounds the use of outpatient inotrope infusion, because some studies have noted increased mortality,[37] especially with higher doses. [38] More recent reports, however, have demonstrated safe and effective use of these agents.[39] [40] [41] With brief hospitalizations for hemodynamic monitoring to optimize use of vasodilators, diuretics, and intravenous inotropes, patients often sustain improvement lasting for weeks or even months. The use of anticoagulants as prophylaxis against systemic or pulmonary thromboembolism is practiced routinely at some centers. Finally, beta blockers have produced hemodynamic and symptomatic improvement in chronic heart failure and have been demonstrated to decrease mortality in patients who are also taking digoxin, diuretics, and an angiotensin-converting enzyme (ACE)-inhibitor (see Chap. 18).[42]

MECHANICAL DEVICES FOR BRIDGING.

Patients in whom conventional medical therapy fails may require intraaortic balloon counterpulsation or possibly a mechanical assist device for bridging to transplantation (see Chap. 19). The major devices currently being used all have been recently reviewed and include the total artificial heart (TAH, CardioWest, Tucson, AZ),[43] [44] Thoratec (Thoratec Laboratories, Pleasanton, CA),[45] TCI Heartmate (Thermo Cardiosystems, Woburn, MA),[46] [47] [48] [49] and Novacor Left Ventricular Assist System (Baxter Healthcare, Oakland, CA).[50] [51] In addition, the Arrow Lionheart and the Abiomed Abiocor will soon be clinically available as destination therapy for patients who are not candidates for cardiac transplantation. More than 2000 ventricular assist devices have been implanted,

TABLE 20-2 -- ADULT THORACIC TRANSPLANTATION CANDIDATE STATUS

STATUS	CRITERIA
1A	Inpatient+ MCS (VAD 30 d; TAH; IABP; ECMO) *or* MCS >30 days+significant device-related complications *or* Mechanical ventilation *or* Continuous infusion of one high-dose or multiple IV inotropes*or* Life expectancy <7 d without transplant
1B	VAD>30 d *or* Continuous infusion of IV inotropes *or* Justified exceptional case
2	Does not meet status 1A or 1B criteria
7	Temporarily unsuitable to receive organ

MCS=mechanical circulatory support; VAD=ventricular assist device; TAH=total artificial heart; IABP=intraaortic balloon pump; ECMO=extracorporeal membrane oxygenation; IV=intravenous.

and more than 500 have been used as a bridge to transplantation.[52] Although bleeding and thromboembolism remain important complications, 69 percent of intention-to-bridge patients go on to successful transplantation. For patients requiring only left-sided support, the short- and long-term transplantation survival is comparable to that of nonbridged transplant recipients. Over time, more compact systems for outpatient management have developed, and the use of all of these devices as portable bridges to transplantation, to recovery, or as permanent replacement therapy has become a more real possibility.

Once selected, patients are categorized on the basis of size, ABO blood group, time on the waiting list, and clinical status. Clinical status divisions include IA, IB, 2, and 7 and are described in Table 20-2 . Patients are "delisted" if they improve or if they suffer complications (e.g., cerebral or pulmonary embolism) or superimposed illnesses (e.g., infections, gastrointestinal bleeding), which increase the risk of operation and immunosuppression or which compromise rehabilitation or survival. They are reactivated when clinically appropriate. Current UNOS policy allows for all time accumulated on the waiting list to be held forever by a patient and to be accrued if the patient is delisted and reactivated.

EVALUATION AND TREATMENT OF THE HEART DONOR

The factor limiting the number of heart transplant performed is the availability of donor organs. Thus, it is imperative to obtain as high a percentage of potential donor organs as possible by increasing the donation rate and to consider all donor organs that might possibly be suitable for transplantation. Cardiologists frequently are asked to take part in the donor evaluation process so that the adequate function of the graft can be predicted before transplantation.

Brain death has been accepted as the legal definition of death throughout the United States.[53] The diagnosis should not involve physicians caring for a potential candidate, and it requires the absence of hypothermia (core temperature >32.5°C) or drugs capable of altering neurological or neuromuscular function.[54]

The specific neurological catastrophe that has resulted in brain death may include blunt traumatic injury to the head, intracranial hemorrhage, or penetrating traumatic injury. The characteristics of all organ donors are listed in Table 20-3 . Heart and heart-lung transplant donor criteria once were very selective. The upper age limit was usually 35 years, and there were a number of other criteria. With the need to increase the number of transplants, these criteria have been modified. Most centers evaluate any potential donor up to as old as 55 years of age. Especially with older or suboptimal donors, a careful cardiac history must be obtained from the next of kin and adequate cardiac function ensured, including potential evaluation with coronary arteriography for men older than 40 or women older than 45 years. Sweeney and colleagues reported on the use of hearts from donors who did not meet the standard criteria.[55] Recipients received grafts from older donors (> age 40) or from patients with a history of prolonged cardiac arrest or septicemia. Their results indicate that selective use of such donors is possible, with reasonable outcomes. In addition, Drinkwater and associates[56] demonstrated similar early and late outcomes when using organs with a mean donor age of 51 years compared with younger donors. In some cases, the older donor organs simultaneously received bypass grafts, and incidence of rejection, infection, and graft coronary artery disease were similar between the two groups.[56] The most recent Registry of the International Society of Heart and Lung Transplantation, however, includes increasing donor age among risk factors for 1- and 5-year mortality and demonstrates a significant interaction between ischemic time and donor age.[1] Hearts from older donors should, whenever possible, be reserved for older recipients because of inherent loss of function with age.

The evaluation of potential donors includes obtaining adequate background data, a physical examination, a 12-lead electrocardiogram, and an echocardiogram. Brain death and increased intracranial pressure often result in nonspecific ST and T wave changes. These also may be seen with hypothermia. The echocardiogram has assumed an even greater role in evaluating cardiac function. This evaluation should be done at a time when doses of intravenous inotropic agents have been lowered to as low as is compatible with adequate blood pressure and cardiac output, and after adequate fluid resuscitation.

Current matching criteria of donors and recipients include only ABO compatibility and appropriate size match. A prospective specific crossmatch between donor and

recipient is performed only where recipients have been identified as having more than 5 percent of reactivity when evaluated against a panel of random donors. A recent large multicenter retrospective analysis showed modest predictive value of HLA mismatch on survival of cardiac allografts.[56A]

With respect to size, fairly wide limits are acceptable, although donors who weigh less than 80 percent of the recipient's weight should not be accepted for those patients who have higher levels of pulmonary vascular resistance.

Vital signs in patients with brain death frequently are unstable, and close attention to fluid balance is required, owing to diabetes insipidus. This necessitates monitoring of central venous pressure and adequate fluid resuscitation, administration of vasopressin, and replacement of fluid lost

TABLE 20-3 -- CALIFORNIA TRANSPLANT DONOR NETWORK DONOR CHARACTERISTICS (1995-1998)*

CAUSE OF DEATH	NUMBER OF DONORS	%
Intracranial bleed	356	44.3

*Mean age 36.7 years (0.3-78.0); 59.5% male, 40.5% female.

through urine output. If hypotension occurs despite adequate volume replacement, a vasopressor is infused. Dopamine is the standard inotropic agent used, but some donors are better maintained on an alpha-adrenergic agent.

Donor evaluation currently also includes various serology results. These are for human immunodeficiency virus (HIV), hepatitis B antigen, cytomegalovirus (CMV), and toxoplasmosis. The finding of HIV antibody rules out a potential donor, and the presence of CMV antibody may disqualify a potential heart-lung donor for a CMV-negative recipient at some centers. Present consensus also excludes donors with carbon monoxide-hemoglobin levels above 20 percent, arterial oxygen saturation less than 80 percent, previous myocardial infarction, or severe coronary or structural heart disease. The presence of metastatic malignancy is also an exclusion at many centers, although those with primary brain tumors and skin cancers may be excepted. Relative contraindications include sepsis, prolonged (>6 hours) severe (<60 mm Hg) hypotension, noncritical coronary disease, hepatitis B surface antigen or hepatitis C antibodies (unless the organs are destined for recipients with the same serology), repeated resuscitations, severe left ventricular hypertrophy, or the need for inotropic support (dopamine >20 mug/kg/min) for 24 hours.[53]

Distant procurement of the heart and heart-lung for transplantation is now routine in almost all transplant centers. The technique for heart preservation remains simple, with cold crystalloid or blood cardioplegia infusion combined with topical cold for extended preservation. Average ischemic times are between 3 and 4 hours, with excellent function in most cases. Data from the Registry of the International Society for Heart Transplantation show some relation between ischemic time and survival, although most experienced centers see no particular relation for up to 6 hours of ischemia.[1]

Techniques for distant heart-lung procurement and preservation of isolated lung grafts include flush solutions in the pulmonary artery with potent pulmonary vasodilators,[57] the use of cold blood for flush, [58] placing the donor on cardiopulmonary bypass,[59] and the use of an autoperfusing heart-lung preparation for maintaining the organs at normothermia in a working state.[60] Again, distant procurement is limited to 6 hours or less, with most procurements having an ischemic period between 3 and 4 hours.

This length of allowable ischemic time has usually kept procurement between centers of not more than 1000 miles distance. The tendency to use donor organs within the local region also has limited times.

Allocation of organs begins with status 1 patients in ever-widening zones. It is offered first to candidates in the local Organ Procurement Organization (OPO) and then to patients within a 500-mile and then 1000-mile radius. If no recipient is found, the process is repeated for the status 2 list.

Regional OPOs are available to assist doctors and hospitals with all medical and legal considerations involved in organ donation. A listing of OPOs with contact information can be found via the Association of Organ Procurement Organizations (website *www.aopo.org*).

OPERATIVE TECHNIQUE

The current technique for orthotopic heart transplantation was described in 1960 by Lower and Shumway.[5] The method involves retaining a large portion of the posterior wall of the right and left atrium in the recipient and implanting the donor heart with relatively long suture lines in the atria, together with direct end-to-end anastomoses of the aorta and the pulmonary artery. Modification of this technique with venous anastomoses at the level of the cavae and the pulmonary veins permits a more physiological atrial contribution to ventricular fitting and causes less distortion of the mitral and tricuspid annuli, with less tendency to atrioventricular valve regurgitation and rhythm disturbances.[61] [62] In addition, Blanche and colleagues demonstrated significantly greater short- and long-term survival using this total reimplantation technique.[63] This technique is reviewed by Trento and associates[64] and is illustrated in Figure 20-2 .

Many types of congenital anomalies have been dealt with during cardiac transplantation. For example, absence of the right superior vena cava or persistent left superior vena cava can easily be accommodated.[65] Corrected transposition of the great vessels requires extra length of the donor aorta and pulmonary artery.[66]

The operation is performed by way of a median sternotomy incision, with routine cannulation of the aorta and both venae cavae. Cardiopulmonary bypass is usually performed with moderate hypothermia of between 28° and 30°C. The implantation procedure usually requires from 45 to 80 minutes, and after careful attention to de-airing maneuvers and resuscitation of the heart, cardiopulmonary bypass is weaned. The incision is closed after placement of temporary pacing wires and chest drainage catheters.

PHYSIOLOGY OF THE TRANSPLANTED HEART

The transplanted heart initially is completely denervated. It is generally believed that partial reinnervation of the transplanted

Figure 20-2 Total heart replacement by pulmonary venous anastomoses on right or left and caval anastomosis at the superior and inferior vena cava. Aorta and pulmonary artery attached as in the previous biatrial transplantation technique.

heart begins within 1 year. Evidence exists for both sympathetic[67] [68] and parasympathetic[69] function, but most authorities agree that these phenomena are incomplete and variable from patient to patient, and the data are less clear for the parasympathetic system in particular.[70] [71] Various studies document the transplanted cardiac response to exercise or stress, which is less than normal but adequate for almost all activities (Fig. 20-3) . The heart rate accelerates slowly during the first stages of exercise, accompanied by an immediate increase in filling pressures as a result of augmented venous return from exercising muscles and decreased compliance. The latter may result from rejection, arteriopathy, arterial hypertension, small donor heart size, or cyclosporine use. Atrial contribution to end-diastolic filling is compromised

by the dissociation between host and donor atrial contractions. The midatrial anastomosis may partially deform the atrioventricular annuli, leading to mitral and tricuspid regurgitation. In the absence of hypertension or rejection, ventricular ejection fractions are normal to high.[72] [73]

Incomplete innervation abolishes or blunts the heart's anatomically mediated reflexes while enhancing its sensitivity to circulating norepinephrine. The resting heart rate is generally higher owing to absence of vagal tone. Respiratory sinus arrhythmia and carotid sinus-mediated reflex bradycardia are absent. The more gradual increase of heart rate with exercise parallels the rise in circulating catecholamines, which also leads to an increase in the inotropic state of the myocardium. With augmented venous return and higher filling pressures, the stroke volume increases, contributing to the necessary increase in cardiac output during exercise.

Figure 20-3 The relationship between cardiac output (C.O.) and oxygen consumption in seven patients 1 year after cardiac transplantation (*dots and solid line*) and in 27 normal subjects ages 14 to 41 (*dashed line*). (From Hosenpud JD, Novick RJ, Breen TJ, Daily OP: The Registry of the International Society for Heart and Lung Transplantation Eleventh Official Report--1994. J Heart Lung Transplant 13:561, 1994. Reprinted with permission from Mosby-Year Book.)

Cardiac denervation results in an increase in beta-adrenergic receptor density.[74] In laboratory animals, denervation results in increased responsiveness to noradrenaline and isoproterenol. This supersensitivity appears to be due both to upregulation of beta receptors and to a loss of norepinephrine uptake in postganglionic sympathetic neurons. In a study by Borow and associates, the heart rate response to dobutamine was compared with that of normal subjects pretreated with atropine and found to be greater in the group of transplant recipients.[75] In other studies, infusions of isoproterenol produced a greater increase in heart rate than in normal controls.[76] This slight supersensitivity of the chronically denervated heart may be important in maintaining the necessary inotropic and chronotropic response to exercise and other stresses. All of the mechanisms underlying this supersensitivity have not been fully defined. Denervation of the allograft also blunts systemic responses to volume changes. Failure to reduce sympathetic tone during hypervolemia may contribute to hypertension and persistence of edema,[77] and blunted rate response to hypovolemia may predispose to orthostatic hypotension.

Arrhythmias are uncommon. Sinus node dysfunction occurs in 10 to 20 percent of patients in the immediate perioperative period but is readily repaired in most cases with theophylline.[78] When this falls, permanent pacing may be necessary. With the adoption of the bicaval anastomosis technique there has been a trend toward decreased requirements for permanent pacemaker insertions.

Pronounced sinus tachycardia (<120) at rest in an a febrile patient without obvious cause suggests physiological distress and warrants a search for hypovolemia, hypoglycemia, rejection, silent myocardial infarction, pulmonary emboli, adrenal insufficiency, tamponade, or abdominal catastrophe masked by corticosteroids.

Atrial arrhythmias--particularly atrial flutter--may signal rejection and are a sufficient indication for heart biopsy. Ventricular arrhythmias are uncommon except with ischemic disease or severe rejection. Ventricular fibrillation is often refractory to resuscitation.

With respect to the coronary circulation, the coronary vasodilator reserve of the transplanted heart is normal in the absence of rejection, hypertrophy, or regional wall motion abnormalities. During periods of acute rejection, coronary flow reserve is impaired.

EARLY POSTOPERATIVE RECOVERY

Much of the early postoperative treatment is similar to that of other patients recovering from cardiac surgical procedures. Strict isolation precautions are no longer considered mandatory. Patients are weaned from the ventilator and from inotropic drugs, as tolerated. Mobilization and use of physical therapy are begun as soon as tolerated.

RIGHT VENTRICULAR FAILURE.

Because the pulmonary vascular resistance of the recipient may be elevated, acute right ventricular failure is a frequent cause of early morbidity and mortality. The normal donor right ventricle may be unable to meet the elevated resistance, and there may be a high degree of both pulmonary and tricuspid valve regurgitation in the early posttransplant period.[79] This problem may be exacerbated by a relatively long ischemic time or by a donor heart somewhat smaller than that of the recipient. Therapy for right ventricular failure has included ventricular assist devices,[80] [81] intravenous or inhaled prostacyclin, inhaled nitric oxide,[82] [83] and extracorporeal membrane oxygenation. [84] [85]

IMMUNOSUPPRESSION.

The most important feature of early management is the institution of the immunosuppressive regimen, which will be continued throughout the patient's lifetime. Numerous protocols exist for maintenance immunosuppression and evolve continually. Most patients receive cyclosporine in combination with several other medications. The most common protocol currently involves triple-drug therapy of cyclosporine or tacrolimus, azathioprine or mycophenolate mofetil (MMF), and prednisone. They are usually given in higher doses in the early posttransplant period, with weaning to lower and less toxic levels for long-term administration. A typical protocol for immunosuppression is shown in Table 20-4 .

Withdrawal or marked reduction of corticosteroids is of particular benefit in diabetic patients and in the presence of severe osteoporosis or aseptic necrosis of bone. In children, a corticosteroid-free regimen permits normal axial growth and prevents the development of the cushingoid features and acne that contribute to noncompliance in adolescents.[86]

Figure 20-4 represents an overview of the site and mechanism of action of immunosuppressive agents based

TABLE 20-4 -- IMMUNOSUPPRESSION FOR HEART TRANSPLANTATION PROTOCOLS

DRUG	EARLY	LATE
Methylprednisolone	500 mg IV intraoperatively then 125 mg IV q8hr×3	
OKT3 induction	5 mg/d IV×7	
Cyclosporine	6-10 mg/kg/d PO* or 0.5-2 mg/kg/d IV	3-6 mg/kg/d PO

on the immune response signals of antigen recognition, co-stimulation, and T-cell activation. Corticosteroids have many potential immunosuppressive effects, including suppressing activation of the transcriptional regulator nuclear factor kappa B (NF-kappaB). By regulating the promoter of the inhibitory factor intracellular kappa B

(IkappaB) and increasing IkappaB levels, steroids reduce transcription of many genes involved in inflammation and immunity.[87] In addition, steroids can alter the transcription of some cytokine genes, inhibiting cytokine production.[88]

Cyclosporine binds to cyclophilin, which inhibits IL-2 expression by blocking calcium-dependent signal transduction via calcineurin. Cyclosporine also inhibits IL-2 receptor expression on T-helper and cytotoxic T lymphocytes. These two actions limit the differentiation into and proliferation of cytotoxic T lymphocytes. Although the advent of cyclosporine significantly improved transplantation outcomes, major toxicities mandated the search for better agents. These toxicities include renal dysfunction, neurotoxicity, hypertension, gingival hyperplasia, hirsutism, and others. Renal dysfunction is the most frequent side effect, occurring in 40 to 70 percent of patients. The microemulsion formulation of cyclosporine, Neoral, has increased bioavailability and has more favorable pharmacokinetics.[89] [89A]

Tacrolimus (FK-506) also inhibits calcineurin but by forming a complex with an FK-binding protein distinct from cyclophilin. Randomized trials indicate that tacrolimus prophylaxis is comparable to cyclosporine in survival and incidence of rejection but may have more severe side effects, in particular nephrotoxicity and hyperglycemia.[89]

Azathioprine, one of the first agents used for immunosuppression, blocks proliferation of replicating cells, including lymphocytes, by inhibiting synthesis of inosinic acid, a precursor of purine synthesis. Although an effective component of triple-drug therapy together with cyclosporine and steroids, azathioprine can cause important side effects. These unwanted actions include hepatotoxicity and severe myelosuppression, especially in patients deficient in thiopurine methyltransferase, an enzyme important in azathioprine metabolism.[90]

MMF inhibits inosine monophosphate dehydrogenase and guanylate synthetase, enzymes in the de novo pathway of purine synthesis. Because proliferating B and T lymphocytes rely primarily on this pathway for purine synthesis, MMF more specifically inhibits cells of these lineages. This drug may also reduce recruitment of monocytes and lymphocytes by reducing guanosine triphosphate (GTP) production, which slows the transfer of saccharide moieties to the glycoproteins expressed on some adhesion molecules.[91] Comparison studies have shown that MMF prophylaxis reduced

Figure 20-4 Overview of the site and mechanism of action of immunosuppressive agents based on signals required for the immune response. 1-year mortality and the need for antirejection therapy but also was associated with an increased incidence of opportunistic infections compared with azathioprine.[92] Additional studies have indicated that MMF causes little renal, hepatic, and bone marrow toxicity. The most common side effects are gastrointestinal and include nausea, diarrhea, and abdominal cramping.[91]

OKT3 is used as induction therapy for heart transplantation recipients at Stanford University and has also been used as treatment for severe rejection. This monoclonal murine antibody against the CD3 antigen causes T-lymphocyte cell lysis, which can cause severe systemic effects due to release of multiple cytokines. Premedication including acetaminophen, diphenhydramine, and hydrocortisone can ameliorate these effects. OKT3 induction can be advantageous, especially in cases of critically ill patients with renal dysfunction, by allowing for a delay in the initiation of cyclosporine therapy.

Interleukin-2 receptor antagonism with a monoclonal antibody has shown reduction in the frequency and severity of rejection in early post-cardiac transplantation.[91A]

ACUTE REJECTION

Immunosuppression to prevent allograft rejection continues from the time of implantation. Although a number of strategies, including those described earlier, are being developed to enhance immunosuppression and to maximize development of tolerance in recipients, virtually every patient experiences some acute allograft rejection during the first transplant year.

According to a report from the Cardiac Transplant Research Database, risk of acute rejection in patients receiving heart transplants in 30 institutions from January 1990 to July 1993 peaked at approximately 1 month after transplantation then rapidly decreased.[93] That study found a mean of 1.25 episodes of rejection per patient during the first year, 0.18 episodes per patient in the second year, and 0.13 and 0.02 episodes per patient in the third and fourth years, respectively. Risk factors for recurrent rejection included female gender, black race, recipient positive CMV serology and CMV infection, shorter time since previous rejection, and more prior rejection episodes.

Acute rejection continues to contribute significantly to early morbidity and mortality of heart transplant recipients. Detection and treatment of acute rejection remain crucial aspects of transplant management.

Detection of Acute Rejection

NONINVASIVE TECHNIQUES

The most reliable and frequently used technique to assess allograft rejection is endomyocardial biopsy. Many less invasive modalities have been suggested but have yet to be developed for use in humans. Noninvasive techniques reported to have clinical potential include intramyocardial electrograms, serum troponin measurement, radionuclide scanning, and antimyosin antibody binding.

HIGH-RESOLUTION INTRAMYOCARDIAL ELECTROGRAMS.

In a multiinstitutional U.S. study, measurement of the ventricular evoked response during ventricular pacing using epimyocardial leads and high-resolution telemetry pacemakers allowed detection of significant rejection, with a negative predictive value of 98 percent.[94] In another study of pediatric patients, intramyocardial electrograms successfully indicated acute rejection and allowed for improvement in long-term survival.[95]

SERUM TROPONIN.

Cardiac troponin T is detectable in the circulation only after myocyte damage, which is likely to occur in acute rejection. Dengler and colleagues demonstrated that serum troponin T concentrations increased in parallel with severity of graft rejection in endomyocardial biopsy samples and that severe rejection would have been detected before the development of clinical symptoms.[96]

RADIONUCLIDE SCANNING.

Technetium 99m-labeled annexin V has been shown to concentrate at sites of apoptotic cell death and to correlate with acute rejection in animal studies.[97] [98] [99] [99A] A multiinstitutional clinical trial using annexin V imaging to detect acute heart transplant rejection in humans is currently under way.

ANTIMYOSIN ANTIBODIES.

These monoclonal Fab fragments directed against myosin can be used to evaluate myosin exposure during the cell death associated with cardiac rejection.[100]

Endomyocardial Biopsy

With the inadequacy of these noninvasive tests, the endomyocardial biopsy remains the standard method for the detection of rejection and its effective treatment with augmented immunosuppression. The technique was introduced for cardiac transplantation by Caves and associates in 1973.[10] The relatively diffuse interstitial infiltrate associated with rejection renders the focal biopsy a useful reflection of events throughout the myocardium.[101] Although an invasive procedure, endomyocardial biopsy seems relatively well tolerated and can be performed sequentially. Complications are usually mild and include pneumothoraces, transient rhythm disturbances, a rare

instance of myocardial perforation, or tricuspid regurgitation due to chordal interruption.

A study at Stanford University showed that severe tricuspid regurgitation can occur after repeated biopsies and entails substantial morbidity. In this series, 6 of 336 patients required tricuspid valve replacement.[102] Because endomyocardial biopsy is a percutaneous and transvenous technique, it requires only local anesthetic. The procedure is rapidly performed, usually through the right internal jugular vein, and can be repeated on many occasions through the same access site. It can also be accomplished from the left jugular vein, the subclavian vein, or the femoral veins, as shown in Figure 20-5 . Fluoroscopy is usually used, although

Figure 20-5 Positioning of the bioptome for endomyocardial biopsy. (1) Bioptome is inserted with the tip pointed toward the lateral wall of the right atrium. (2) At the level of the mid-right atrium, the bioptome is rotated anteriorly about 180 degrees and is advanced through the tricuspid valve apparatus toward the right ventricle. (3) The bioptome is advanced to the interventricular septum with the jaws opened. the use of echocardiography for bioptome guidance is increasing.

To get an adequate sample for examination, four to six biopsy specimens are taken at each examination.[101] A typical posttransplant biopsy schedule is shown in Table 20-5 . Based on our experience with OKT3 induction therapy, the need for endomyocardial biopsy during the first week after transplantation has been eliminated. Patients who demonstrate allograft rejection are treated with an appropriate immunosuppressive regimen (discussed later), and repeat endomyocardial biopsy is performed again after an interval of 10 to 14 days. The effect of treatment during this time is usually monitored by echocardiographic and clinical assessment.

The variety and significance of the observed histological changes in cardiac allografts have now been reasonably well defined. Many grading systems have been advocated by different transplant groups, but the International Society for Heart and Lung Tranplantation has used uniform criteria since 1989.[103] The tissue fragments are embedded together in a single block, processed, and sectioned. Most specimens are assessed using standard hematoxylin and eosin stains, but other special stains may be useful for gaining additional information, such as the amount of collagen present or identification of specific subtypes of infiltrating lymphocytes.

The most important feature of most posttransplant biopsy specimens is the detection of lymphocyte infiltration and the presence of myocyte necrosis. The continuum of histological findings from a normal specimen to one showing severe acute rejection includes various subtle findings (Table 20-6) . Figure 20-6 shows examples of acute rejection of various grades.

A certain number of confusing histopathological changes can be seen in some biopsy specimens and can be unrelated to rejection. For example, specimens taken early after

TABLE 20-6 -- STANDARDIZED CARDIAC BIOPSY GRADING (ISHLT SCALE)

GRADE	FINDINGS
0	No rejection
1	A Focal (perivascular or interstitial) infiltrate without necrosis B Diffuse but sparse infiltrate without necrosis
2	One focus only with aggressive infiltration and/or focal myocyte damage
3	A Multifocal aggressive infiltrates and/or myocyte damage B Diffuse inflammatory process with necrosis
4	Diffuse aggressive polymorphous infiltrate, ±edema, ±hemorrhage, ±vasculitis, with necrosis

transplantation may reveal necrotic myocytes undergoing macrophagic removal because of ischemia at the time of the transplant procedure itself. Necrosis may also be secondary to infectious agents, such as CMV and toxoplasmosis. Occasional infections with these agents have been first diagnosed by endomyocardial biopsy. Perhaps the most frequent abnormality is a sample taken from a previous biopsy site that may contain contraction bands and evidence of inflammation and collagen formation as a result of healing of the previous biopsy site. The findings associated with

Figure 20-6 Composite photomicrograph showing different stages of acute cardiac rejection: *A,* Mild acute rejection, with a sparse interstitial lymphocytic infiltrate (grade 1B, ISHLT) (hematoxylin and eosin, original magnification × 200). *B,* Moderate acute rejection with islands of lymphocytes replacing myocardial tissue (grade 3A, ISHLT) (hematoxylin and eosin, original magnification ×200). *C,* Severe acute rejection with marked myocyte damage and a mixed inflammatory infiltrate (grade 4, ISHLT) (hematoxylin and eosin, original magnification × 300). (Courtesy of Dr. Margaret Billingham).

previous biopsy site histology are described in more detail elsewhere.[104]

In addition to classical cell-mediated rejection, occasional cases of hyperacute rejection due to preformed circulating antibodies from prior transfusion, pregnancy, or ABO incompatibility may occur within hours of surgery and require prompt retransplantation. In established allografts, vascular damage in the absence of lymphocytic infiltration has been accompanied by deposition of complement and IgG on endothelial cells that are swollen or disrupted.[105] The specificity of these findings remains controversial[106] ; however, when they are accompanied by clinical deterioration, treatment with an augmented immunosuppressive regimen and plasmapheresis has been used successfully.[107]

Treatment of Acute Rejection

Although a number of new immunosuppressive agents have become available, acute rejection episodes are still treated by a relatively small number of standard

therapies.

The timing and severity of rejection episodes dictate the appropriate therapy. A representative algorithm for treatment is shown in Figure 20-7 . Episodes that occur within the first 3 months or that are moderate to severe are best treated by pulse therapy with methylprednisolone. Methylprednisolone sodium succinate is administered intravenously at a dose of 1000 mg/d for 3 consecutive days. Rejection that occurs after more than 1 month may be treated by augmenting oral steroid intake to 100 mg of prednisone per day for 3 consecutive days, tapered gradually back to baseline over 2 weeks. Several studies have demonstrated that an equivalent oral dose of prednisone may be as effective as intravenous methylprednisolone in early acute rejection.[108] In children or small adults, the dose of methylprednisolone and prednisone should be decreased in proportion to body size. Because of the side effects of increased corticosteroid therapy, patients should be carefully monitored for infections, increased fluid retention. glucose intolerance, and psychological or mood changes.

SEVERE REJECTION.

When prednisone treatment is ineffective or in particularly severe cases of rejection associated with hemodynamic changes, more aggressive therapy is given. The use of ATGAM (horse antithymocyte globulin), rabbit ATG, or OKT3 monoclonal antibody constitutes rescue therapy after unsuccessful use of prednisone or methylprednisolone. Unfortunately, the availability of commercial preparations of ATGAM is limited. Similarly, the availability of rabbit ATG preparations is erratic because such preparations are not commercially available and require special local arrangements for preparation. Consequently, OKT3 therapy is probably the most frequent type of rescue therapy being used and is an effective treatment for most resistant rejection episodes.[109] Treatment with OKT3 is costly ($3000 for a 10-day coure). Precautions to limit OKT3 toxicity are described later (see p. 183).

MILD REJECTION.

Additional strategies for treatment of early or mild rejection have been advocated. Kobashigawa and associates treated patients with mild acute rejection with increases in oral cyclosporine, treating 40 episodes in 28 patients.[110] In their study of those patients with an actual increase in serum cyclosporine levels, 90 percent had no progression of rejection or clearing of rejection, whereas 37 percent of those who had no increase in levels had increasing evidence of acute rejection requiring treatment. An alternative approach is simply to observe patients in cases of grade IA or IB rejection and rebiopsy in 2 weeks, because almost two thirds of patients with stable cyclosporine levels reverted to normal spontaneously.

PERSISTENT OR RECURRENT REJECTION.

For patients with persistent recurrent rejection episodes despite repeated courses of conventional therapy, Hunt and colleagues at Stanford University[111] and Kirklin's group at Alabama[112] have supported the use of total lymphoid irradiation (TLI). It was administered according to standard protocols. Total doses varied from 240 to 1200 cGy (rads) over 5 to 10 weeks and were adjusted in response to leukopenia and thrombocytopenia. Measurement of absolute T-cell counts may also be helpful. The frequency of rejection episodes eventually fell to 5 percent of the pretreatment rate. Azathioprine and MMF should be discontinued or diminished

Figure 20-7 Algorithm for treating acute allograft rejection. EMB = endomyocardial biopsy; ATG = antithymocyte globulin.

during TLI. Olsen and coworkers from the University of Utah reported using methotrexate in the treatment of persistent low-grade rejection.[113] Methotrexate was given three times a week for an average of 8 weeks to 16 patients. All rejections were reversed, and the dose of prednisone could be reduced. Although there were no infections, azathioprine dose had to be reduced in 10 patients because of leukopenia. Methotrexate has also been advocated for recurrent acute, as well as refractory rejection in doses up to 15 mg/wk.[114]

In addition to these therapies, if a patient is receiving a traditional triple-drug regimen, consideration should be given to switching from cyclosporine to tacrolimus and from azathioprine to MMF.[115] [116] Finally, some authorities have advocated plasmapheresis in refractory cases.[117] [118] [119]

NEW AND FUTURE IMMUNOSUPPRESSIVE AGENTS

The availability of many agents for selective immunosuppression will almost certainly enhance the early and late acceptance of cardiac allografts, minimize toxicities, and increase the safety of cardiac transplantation.

SIROLIMUS.

Like tacrolimus, this investigative compound of fungal origin also binds to the FK-binding protein; however, its mode of action is not linked to calcineurin. Instead, it interferes with the action of growth factors on T cells. It selectively targets only those cells responsive to IL-2 and similar lymphokines and does not inhibit the replication of other rapidly dividing cells. Its mechanism complements that of cyclosporine and tacrolimus.[120]

Sirolimus (rapamycin) has been studied in a randomized trial of heart transplant recipients with acute moderate rejection. The investigators concluded that this agent effectively treats rejection in a dose-dependent manner and that adverse events, including thrombocytopenia, neutropenia, infection, and nausea/vomiting, were also dose related.[121] Ongoing clinical trials will define the use of sirolimus as maintenance immunosuppression with or without cyclosporine.

IL-2 RECEPTOR (CD25) MONOCLONAL ANTIBODIES.

Daclixiimab (humanized monoclonal) and basiliximab (chimeric, murine variable region and human constant region) are anti-IL-2 receptor antibodies that have been efficacious in treating acute rejection in renal tranplant recipients.[122] [123] Their effectiveness in heart transplantation has recently been demonstrated.[91A]

HYDROXYMETHYLGLUTARYL-COENZYME A REDUCTASE INHIBITORS.

Kobashigawa and colleagues found that the lipid-lowering agent pravastatin not only lowered mean cholesterol levels compared with no treatment controls but also reduced cardiac rejection with hemodynamic compromise and graft coronary artery disease and improved 1-year survival (94 vs. 78 percent).[124] Other HMG-CoA reductase inhibitors have been shown to inhibit natural killer cells in vitro,[125] so it is possible that these agents have some unexpected immunosuppressive effect that remains to be elucidated.

OTHERS.

Additional promising approaches to the treatment of acute rejection include strategies for blockade of costimulation such as CTLA4Ig and monoclonal antibodies to B7 or CD40 ligand, and antisense oligonucleotides, in particular to intercellular adhesion molecule-1, all of which have shown success in animal models.

COMPLICATIONS OF IMMUNOSUPPRESSION

Along with the benefits of immunosuppressive drugs come numerous complications. All of the commonly used drugs cause side effects, increase the risk of infection, and are associated with neoplasia.

DRUG-SPECIFIC TOXICITIES

CYCLOSPORINE TOXICITY.

Cyclosporine is associated with a number of complications. The most clinically significant effect of cyclosporine involves the kidneys. Almost all patient groups receiving cyclosporine have a fall in creatinine clearance, an increase in serum creatinine level, and hypertension.[126] [127] Histopathological changes after long-term administration are found in the proximal convoluted tubule and in the distal tubules and consist of vacuotion of cells, epithelial swelling, hydropic degeneration, and

necrosis, increasing clinical and experimental evidence shows that cyclosporine produces a derangement in the prostaglandin system in the renal tubules. Indomethacin exacerbates renal dysfunction after cyclosporine administration.

Cyclosporine may act by increasing urinary thromboxane B_2 levels in a dose-dependent manner, with local vasoconstriction, platelet aggregation, and release of platelet-produced thromboxane. This may explain the development of hypertension, renal ischemia, and the dysfunction that is seen clinically, although azotemia and hypertension are occasionally independent of each other.[128] Acute elevation of cyclosporine to three to four times customary maintenance levels may cause acute oliguria and rapid decline in renal function. This is probably due to vasoconstriction and is promptly reversible with adjustment of dose or removal of drugs hindering cyclosporine catabolism. Chronic interstitial fibrosis and nephron loss is common but is usually stable, it may be intermittently exacerbated by nephrotoxins used for therapy (e.g., amphotericin B, nonsteroidal antiinflammatory drugs) or diagnosis (radiographics contrast agents).

Early after transplant, many patients have oliguria. Thus, many transplant groups restrict the use of cyclosporine to continuous intravenous administration with careful control of circulating levels during the early posttransplant period, or they omit cyclosporine altogether and use induction therapy with OKT3 until serum creatinine level is normal and the patient has recovered from the effects of cardiopulmonary bypass.[127] [129] [130]

Hepatotoxicity, although uncommon, is usually acute and secondary to exceptionally high levels of cyclosporine. It is evidenced by an increase in bilirubin and by increases in serum liver enzyme levels. There are no characteristic cellular pathological alterations except for centrilobular fatty changes. The hepatotoxicity is dose related and reverts to normal after the dose of cyclosporine is lowered or eliminated. In general, hepatotoxicity is uncommon after cardiac transplantation, and so far, no long-term sequelae of cyclosporine on liver function have been reported.

Neurotoxic reactions are manifested by a fine tremor, paresthesias, and occasionally seizures. Most of these events are dose related and reversible. Other unusual side effects include the development of hirsutism or hypertrichosis, observed in almost all patients who receive cyclosporine. These effects tend to regress as the dose of cyclosporine is lowered. Similarly, gingival hyperplasia has been observed. A combination of cyclosporine and nifedipine has resulted in an increased rate of gingival hyperplasia (51 percent) when compared with cyclosporine alone (8 percent).[131] Because cyclosporine is metabolized almost exclusively by the liver, hepatic dysfunction can cause abrupt elevations of blood levels of cyclosporine, precipitating renal dysfunction. Many commonly used compounds can influence the hepatic P450 cytochrome system, which is responsible for cyclosporine catabolism. Drugs that raise cyclosporine levels include the antimicrobials erythromycin, doxycycline, imipenem, cilastatin, ticarcillin, norfloxacin, ketoconazole, and itraconazole; the calcium channel blockers diltiazem, verapamil, nifedipine, and nicardipine; hormone products such as danazol, androgens, estradiol, and oral contraceptives, as well as other commonly used medications such as cimetidine, ranitidine, warfarin, acetazolamide, metoclopramide, and amiodarone. (Diltiazem and ketoconazole have been used adjunctively to lower the dose and cost of cyclosporine maintenance.[132])

Conversely, a decline in circulating cyclosporine levels, with the danger of causing rejection, may be precipitated by omeprazole, by the antibiotics rifampin and nafcillin, and by the anticonvulsants phenytoin, carbamazepine, valproic acid, primidone, and methsuximide.[133] [134] The use of lovastatin to control hypercholesterolemia in patients receiving cyclosporine has rarely been associated with rhabdomyolysis.[135]

CORTICOSTEROID TOXICITY.

Perhaps the most troublesome side effects of immunosuppressive therapy are associated with long-term administration of corticosteroids. In patients who require relatively high doses of steroids, these can be especially severe and include adrenal cortical atrophy, cushingold appearance, cataracts, skin fragility, severe osteoporosis, peptic ulcers, aseptic necrosis of bone, weight gain, psychiatric effects, diabetes, elevated serum lipid levels, and heightened susceptibility to infection of all types. In children, axial growth may be impaired. Perhaps the major advance in transplantation will come when corticosteroid therapy can be completely eliminated, a strategy under investigation.[136]

AZATHIOPRINE TOXICITY.

The major morbidity of long-term azathioprine administration is bone marrow suppression. Severe granulocytopenia has resulted from inadvertent coadministration of allopurinol for the treatment of CyA-induced hyperuricemia and gout and has been life threatening. In some patients, azathioprine also causes hepatotoxicity that may be so severe that the drug must be discontinued with substitution of an alkylating agent, such as cyclophosphamide.

TACROLIMUS TOXICITY.

Tacrolimus is nephrotoxic and should not be used simultaneously with cyclosporine. In addition, mild to severe hyperkalemia has been noted with its use. Serum potassium levels should be monitored, and potassium-sparing diuretic therapy should be avoided. Hyperglycemia requiring insulin therapy has also been noted with its use. Neurotoxicity, including tremor, headache, coma, and delirium have been associated with high blood levels of tacrolimus. The most commonly associated neoplasms are lymphomas and skin carcinomas.

MYCOPHENOLATE MOFETIL TOXICITY.

MMF has been most frequently associated with gastrointestinal adverse events, from dyspepsia and diarrhea to gastrointestinal tract ulceration and hemorrhage. In addition, up to 2 percent of patients receiving MMF can develop severe neutropenia, and mild to moderate hypertension has been reported. Finally, lymphoproliferative (approximately 1 percent) and skin malignancies can also occur.

OKT3 TOXICITY.

Many patients develop cytokine release syndrome 30 to 60 minutes after administration OKT3, with frequency and severity increased with the first dose. The syndrome ranges from a mild, self-limited flulike illness to a less frequently reported severe, life-threatening

---

shocklike reaction. Most patients experience fever and chills, and fewer report rash, pruritus, and noncardiac pulmonary edema. Transient rise in serum creatinine and hepatic transaminases may also be noted with the initial doses. Premedication with acetominophen 650 mg orally, ranitidine 100 mg intravenously, diphenhydramine 25 mg intravenously, and hydrocortisone 100 mg intravenously given 30 minutes before the OKT3 dose during the first 3 days of therapy serves as cytokine release syndrome prophylaxis.

Infection

In most centers, infectious complications are the most common cause of death after transplantation. Despite the fact that more effective immunosuppressive therapy has reduced the incidence and severity of infections, they still remain a major problem.[137] The overall incidence of infections ranges from 41 to 71 percent in various series, and repeated infections are frequent. In a multicenter analysis of 814 consecutive patients undergoing primary heart transplantation between 1990 and 1991, approximately half suffered acute infection at 6 months. This rose to almost two thirds by 1 year.[138]

With the extensive experience now available from both kidney, liver, and heart transplant recipients, certain typical infection patterns can be described. Infections in the first postoperative month tend to involve bacterial pathogens encountered in surgical patients in general. Infections in the time from 1 to 4 months after surgery usually involve opportunistic pathogens, especially CMV. After this period, both conventional and opportunistic infections occur.

In contrast to renal transplant recipients, cardiac recipients must receive somewhat higher levels of pharmacological immunosuppression, which cannot be reduced appreciably at the time of infectious complications, hence the need for early diagnosis and aggressive therapy for any type of infection.

The role of immunization in preventing posttransplant infections is too often overlooked. If given before the institution of immunosuppressive regimens, immunization is more likely to be successful. Pretransplant inoculation with pneumococcal and hepatitis B vaccines, boosters for diphtheria-pertussis-tetanus, and, for young people not previously immunized, measles-mumps-rubella and polio vaccines are recommended. Because these last two are live virus vaccines, they should be avoided by patients (and immediate family members) after transplantation, when immunosuppression may enhance their virulence. Regular use of influenza vaccine every 2 years is controversial but has been advocated for HIV-infected patients and may be useful in transplant recipients as well.

EARLY INFECTION.

Infections in the first month after transplantation are commonly bacterial and most frequently pulmonary. This is especially true of patients with lung transplants in addition to heart. Nosocomial organisms, such as *Legionella, Staphylococcus epidermidis, Pseudomonas aeruginosa, Proteus, Klebsiella,* and *Escherichia coli* are typically encountered. The incidence of significant mediastinitis is between 0.4 and 4.5 percent in heart transplant recipients. Treatment includes prolonged courses of antibiotics, debridement of devitalized bone, and the use of vascularized muscle flaps for subsequent wound closure. Other typical causes of early postoperative infection, such as urinary tract infections, bacteremias, and pneumonia, should be suspected. The clinical diagnosis of pneumonia is made on the basis of typical clinical features, including cough, fever, sputum production, and chest radiographs showing a new pulmonary infiltrate. An aggressive approach to early diagnosis is recommended. This may include bronchoscopy with washings and culture. The results of these cultures will determine specific antibiotic therapy, but early broad-spectrum coverage started immediately after obtaining appropriate cultures is recommended.

LATE INFECTION.

Late posttransplant infections are more diverse. These are frequently of the opportunistic variety, including viruses (CMV, herpes), *Pneumocystis carinii,* and other fungi (e.g., *Candida* and *Aspergillus*), as well as more exotic varieties. *Nocardia* or *Toxoplasma gondii* is occasionally encountered. The variety of late posttransplant pneumonias may vary from center to center, depending on local prevalences and the use of prophylactic treatments. For example, in some series, *P. carinii* is the most common late pulmonary infection, whereas in other series it is absent. Regular prophylactic administration of trimethoprim-sulfamethoxazole (TMP-SMZ) three times per week on a long-term basis is now routinely recommended by most transplant programs to prevent *P. carinii* pneumonia (PCP) and *Toxoplasma* infection (or if TMP-SMZ is not tolerated, monthly pentamidine aerosol inhalation for PCP prophylaxis).[139]

CYTOMEGALOVIRUS INFECTION.

CMV infection is the most frequent and important viral infection in transplant recipients, with an incidence in cardiac recipients of between 73 and 100 percent.[140] [141] CMV is the single most frequent infecting organism, accounting for 26 percent of all infections in a large cooperative study.[137] This can be minimized in CMV-negative patients by the use of CMV-negative blood products, but a CMV-positive donor almost invariably transmits infection. It may be detected in some patients only by seroconversion or, if they are seropositive preoperatively, by a rise in IgG titers or the appearance of an IgM antibody. Some infections remain subclinical. When clinical disease is present, it may present as leukopenia, pneumonia, gastroenteritis, hepatitis, or retinitis in various combinations. Of these, pneumonia is the most lethal (13 percent mortality), whereas retinitis is the most refractory and requires indefinite maintenance therapy. Most cases are responsive to ganciclovir (DHPG) or foscarnet. The addition of hyperimmune globulin has further improved therapeutic outcome and decreased mortality, particularly from CMV pneumonia. Although seronegative recipients who accept allografts from CMV-positive donors are the most vulnerable, prior seropositivity does not offer protection from infection (15 percent disease frequency), and late reactivation, reflecting the persistence of this member of the herpesvirus family, may occur.

Unfortunately, results of diagnostic tests are not always positive. Viral cultures may be negative in the presence of infection, and serological responses may be diminished owing to immunosuppression. The addition of polymerase chain reaction (PCR) technology for the detection of CMV viremia has added a more sensitive diagnostic method.[142] Because of these limitations, CMV should always be suspected in the event of unexplained fevers, gastroenteritis, or culture-negative interstitial pneumonitis. Endoscopy with biopsy may establish the diagnosis promptly in these latter cases.[143] Early prophylaxis with ganciclovir in the setting of positive CMV graft into a negative recipient includes the use of ganciclovir and hyperimmune globulin for 6 to 8 weeks after transplantation. Prophylaxis against CMV infection decreased the incidence of CMV disease in recipients who were seropositive before transplantation but not in those who were seronegative.[144]

The importance of CMV infection cannot be overemphasized because of its relation to the development of late graft arteriosclerosis. The availability of newer antiviral treatments may help to minimize the complications of this particular infection in the future.

FUNGAL INFECTIONS.

Although less common than viral and bacterial infections, fungal infections are more serious, less responsive to therapy, and more likely to be lethal. (*P. carinii,* originally thought to be a protozoan, has now been reclassified as fungus). *Candida* and *Aspergillus* are the most commonly encountered pathogens. Treatment with imidazoles is often effective for *Candida* and coccidioidomycosis,

but their use may raise cyclosporine levels. Infections of vital organs usually require amphotericin B and flucytosine, which compromise renal function and potentiate leukopenia, respectively.

Toxoplasmosis is uncommon but responds to pyrimethamine.[145]

NEOPLASMS

Chronic immunosuppression can predispose to certain malignancies. In general, transplant recipients have a threefold increase in the incidence of various cancers when compared with age-matched controls. Some specific cancers are more than 100 times more frequent in immunosuppressed patients than in the general population. For all tumors, the average time of appearance of the cancer after transplantation is 58 months, although some tumors may characteristically appear at other intervals. Cardiac transplant recipients have a somewhat higher incidence of cancer than do renal transplant recipients, perhaps because of the higher levels of immunosuppression. The most common tumors among transplant recipients are those of the skin and lips, non-Hodgkin lymphomas, Kaposi sarcomas, and uterine, cervical, vulval, and perineal neoplasms. The frequency of common adenocarcinomas, such as those of breast, lung, prostate, and colon, does not exceed that in the general population.[146]

Perhaps the most important neoplasms are the lymphoproliferative tumors that occur early after transplantation, more frequently in younger recipients. Most of these tumors are thought to be the result of Epstein-Barr viral infection and consist of B-cell proliferation that is unchecked because of T-cell suppression or depletion.[147] The recurrent use of OKT3 has been identified as a risk factor in some programs,[148] but this has not been confirmed by others.[149] Approximately 15 percent are of T-cell origin, and some of these tumors also carry Epstein-Barr virus markers.[146] [150]

The tumors typically arise in extranodal sites, such as lung, gut, or central nervous system. Treatment has included diminishing immunosuppression, adding antiviral therapy with acyclovir or ganciclovir,[151] and irradiation or surgical removal for monofocal tumor. Closer surveillance by cardiac echocardiography and biopsy is essential during this period. If rejection occurs or if the tumor is refractory, additional therapy with alfa-interferon chemotherapy, and monoclonal B-cell antibodies have been used with success.[152] Roughly one-third of patients will respond, and recurrence is uncommon.

GRAFT CORONARY ARTERY DISEASE

The major long-term problem after cardiac transplantation, assuming greater importance as the number of survivors increases, is the development of coronary artery disease in the transplanted heart. Graft coronary artery disease was first observed by Thomson in 1969 in the first long-term survivor reported from South Africa.[153] Nineteen months after transplantation for ischemic cardiomyopathy, the patient died with extensive coronary artery disease. Various reports describe an incidence of between 20 and 50 percent at 5 years.[154] [155] [156] [157] [158] [158A]

With the advent of protocols using cyclosporine for immunosuppression, there has been no significant decline in the incidence of this disease.[159]

Graft coronary artery disease has been observed as an incidental finding at autopsy as early as 3 months after transplantation. Significant coronary disease may produce arrhythmias, myocardial infarction, sudden death, or impaired left ventricular function with congestive heart failure.[160] Angina pectoris is rare because the cardiac allograft remains essentially denervated, so patients may present with sudden and severe cardiac dysfunction. The disease tends to be diffuse and concentric, and coronary angiograms must be closely inspected and compared with previous studies to appreciate the reduction in coronary diameter. The introduction of intravascular ultrasound to assess thickness and composition of the coronary arterial wall, as well as to provide precise measurement of lumen diameter, has demonstrated the presence of disease that was not visible angiographically (Fig. 20-8 *B*). Definite intimal thickening was present in one quarter of patients at Stanford University at 1 year, and its prevalence increased to approximately 80 percent at 5 years after transplantation. Multivessel intracoronary ultrasound interrogation increases the sensitivity for detection of graft coronary disease.[160A] Calcification was uncommon (<10 percent) up to 5 years but approached 25 percent at 6 to 10

years and 50 percent at 11 to 15 years.[161] Electron beam computed tomography may aid detection of coronary calcification in this context.[161A]

Noninvasive stress imaging with thallium and sestaMIBI scans has been generally disappointing, probably because of the diffuse nature of the vascular lesion, which affects the intramyocardial as well as epicardial coronary arteries.

PATHOGENESIS.

The cause of graft coronary artery disease remains controversial and is probably multifactorial (see also Chap. 30) . Vascular endothelium is known to be immunologically active, and similar vascular changes are seen late after kidney and liver transplantation. The early stages of cardiac allograft rejection are characterized by lymphocytic perivascular infiltration, and vasculitis frequently is a prominent part of moderate to severe allograft rejection. Vascular changes with deposition of immunoglobulin, complement, and fibrin occur in both patients and animals. Current data strongly support a complex immune mechanism for the development of graft coronary artery disease. Histological features of graft arteriopathy demonstrate extensive concentric intimal proliferation (Fig. 20-9) with hyperplasia of smooth muscle and lipid-laden macrophages. [162] Grossly, the vessels show diffuse disease extending symmetrically into distal branches with few collateral

Figure 20-8 *A,* Intravascular ultrasound examination of the left anterior descending coronary artery in a transplant recipient at the site shown at A in the middle panel depicting the coronary angiogram. *B,* Intravascular ultrasound in the proximal circumflex coronary artery at the point marked in the coronary angiogram in the central panel at B. Reprinted with permission from the American College of Cardiology.)

vessels. Proximal stenoses occur rarely.[163] Angiography may not be sensitive enough to show this disease (see Fig. 20-9 *B*).

RISK FACTORS.

Both alloantigen-dependent and alloantigen-independent factors contribute to coronary artery endothelial damage, which results in graft coronary artery disease. The association of episodes of acute rejection with later development of the graft coronary artery disease points toward immune-mediated mechanisms.[164] Additional alloantigen-independent risk factors could contribute to the progression of graft coronary artery disease. Recipient characteristics (age, gender, obesity, hypertension, hyperlipidemia, insulin resistance, and CMV infection) and donor characteristics (age, gender, preexisting coronary disease, and donor ischemic time) may have such a role.[165] Chang and colleagues, for example, have demonstrated increased recipient triglyceride levels and older donor age, but not lipoprotein(a) levels, to significantly predict development of the disease.[166] In addition, the ischemia-reperfusion injury inherent to the transplantation procedure activates the microvascular endothelium, leading to release of reactive oxygen species and inflammatory mediators, which may have long-term consequences.[167]

CYTOMEGALOVIRUS INFECTION.

Several reports emphasize the possible role of CMV infection in graft coronary artery disease. CMV may contribute to the pathogenesis of graft coronary artery disease by inducing molecular events that serve to promote mononuclear adhesion, activation, and transendothelial migration within the allograft vasculature.[168] In addition, intimal proliferation has been linked to the inactivation of p53 (a tumor suppressor) by CMV, permitting enhanced proliferation of smooth muscle cells.[169] Hosenpud has shown that CMV infection alters the expression of major histocompatibility complex type I molecules as well as cytokine gene transcription in smooth muscle cells, favoring a proinflammatory milieu.[170] Finally, a study from Stanford has shown a decreased incidence of graft coronary artery disease in patients treated with ganciclovir (CMV prophylaxis) when not concurrently taking a calcium channel blocker.[171] The mechanistic implications of this investigation have yet to be elucidated.

PREVENTION.

Most centers use some preventive measures in the hope of reducing the incidence of graft arteriosclerosis. In addition to measures to limit CMV, strategies have been directed toward limiting the amount of steroid administered. Hypercholesterolemia is a known risk factor for the development of coronary artery disease in general, and the use of prednisone[172] and cyclosporine[173] is correlated with elevated serum cholesterol levels in cardiac transplant recipients. Other modifications of known risk factors include maintenance of ideal body weight through dietary restriction, reduced intake of cholesterol and saturated fats, the use of lipid-lowering agents such as pravastatin or simvastatin,[173A] [173B] cessation of smoking, regular exercise, and the use of an antiplatelet agent such as low-dose aspirin. Doses of statins should be chosen recognizing the potential for interaction with cyclosporine. The addition of diltiazem to the posttransplant regimen has retarded progression of allograft coronary disease, and its cyclosporine-sparing effect has also reduced costs.[174]

TREATMENT.

The existence of more discrete proximal lesions has been treated by percutaneous transluminal coronary angioplasty in some cases, and even coronary artery bypass grafting has been reported.[175] [176] [177] [178] However, retransplantation is the major alternative once diffuse graft atherosclerosis develops. The results of retransplantation are worse than for the primary procedure, with a reported patient survival rate of approximately 48 percent at 1 year (n = 449) reported by the International Society for Heart and Lung Transplantation. Uncontrolled rejection and an interval of less than 6 months between operation and the need for pretransplant mechanical support were listed as risk factors.[179]

LATE FOLLOW-UP

Late follow-up of cardiac transplant recipients requires a coordinated and systematic approach. The drug regimen for late follow-up is shown in Table 20-7 . MMF therapy is supplanting azathioprine use in some centers, including Stanford University. The two leading causes of early morbidity

TABLE 20-7 -- DRUG REGIMEN FOR LONG-TERM RECIPIENT

Prednisone 0.1-0.2 mg/kg/d
Cyclosporine 3-6 mg/kg/d
Diltiazem 120-240 mg/kg/d
Sulfamethoxazole-trimethoprim b.i.d. 3 d/wk
Azathioprine 1-2 mg/kg/d
Pravastatin 20 mg/d
Miscellaneous
Furosemide
Potassium supplements
Antacids
Aspirin
Additional antihypertensives p.r.n.

and mortality are rejection and infection. Later surveillance should focus also on graft arteriosclerosis and cancer. The frequency and timing of transplant follow-up visits are determined by the general condition of the patient and the time after transplant. Endomyocardial biopsy remains a necessity and is performed every 3 to 4

months indefinitely. We currently recommend performing coronary arteriography on a yearly basis, although some programs alternate this with noninvasive studies of myocardial function or ischemia.

In addition to the objective laboratory data, a detailed interval history and physical examination are important to detect other complicating illnesses at an early stage. Patients may minimize new symptoms, and physicians must be constantly alert to the possibility of an occult but potentially life-threatening infectious complication. A detailed inquiry into all medications that the patient is taking should be performed to avoid errors of omission, dosage misunderstanding, or unexplained additions that might alter the metabolism or excretion of immunosuppressive drugs, potentially causing rejection (e.g., rifampin), nephropathy (e.g., erythromycin), or bone marrow suppression (e.g., allopurinol). A sampling of other late problems routinely encountered includes aseptic necrosis of bone, azotemia, cataracts, cholelithiasis, gout, heart failure, herpes zoster, impotence, obesity, rejection, vertebral compression fractures, and an assortment of skin lesions.

SURVIVAL EXPECTATIONS

Long-term survival and complete rehabilitation can be attained by most patients currently undergoing heart transplantation. Three-year actuarial survival data from the Registry of the International Society of Heart and Lung Transplantation, broken down by four time periods, is shown in Figure 20-10. From 1991 onward, even though significant changes in donor and recipient characteristics such as increased age in both have occurred, overall survival is maintained at approximately 82 percent for 1 year and 74 percent for 3 years.[1] At Stanford, patients receiving a cardiac transplant in the past year had a 1-year survival of 91 percent.

Longer-term data are given by the recent Stanford 30-year report. For patients receiving transplants in the past decade (1988 to 1998), the 1-, 5-, and 10-year survival is 85, 68, and 46 percent. With improved immunosuppression, deaths due to rejection and infection have declined

Figure 20-10 Heart transplantation actuarial survival by era for all patients reported to the Registry of the International Society for Heart and Lung Transplantation from 1980 to 1998. (From Hosenpud JD, Bennett LE, Keck BM, et al: The Registry of the International Society for Heart and Lung Transplantation: Sixteenth Official Report--1999. J Heart Lung Transplant 18:614, 1999. Reprinted with permission from Elsevier Science Ltd.)

and freedom from graft coronary artery disease has increased. These improvements occurred despite older organ donors, longer graft ischemic times, and longer waiting periods on the transplantation list for the group in the later treatment era.[2]

Quality-of-life studies, both short and long term, indicate overall good physical status and well-being in the majority of patients.[180] [181] The majority of heart transplant recipients report no activity limitations, but less than 40 percent are working. This may reflect planned early retirement, unwillingness to give up disability and insurance benefits, or the employer's resistance to hiring someone with a chronic disorder, rather than any real physical limitation.[1] Structured cardiac rehabilitation programs are common and can improve exercise capabilities.[182]

COST CONSIDERATIONS

The cost of care has been divided into pretransplantation, evaluation and candidacy, transplantation, and posttransplantation by Evans.[183] Pretransplantation costs derive from the care needs of patients with end-stage heart disease and are multiplied by the steadily increasing time spent on waiting lists, which reached a median in 1993 of 208 days (22 percent waited 6 to 12 months and 42 percent waited more than a year).[184] Depending on the need for hospitalization, intensive care, or mechanical support, such costs easily exceed $100,000. These costs are considerably higher for status I patients.[185]

The cost of candidacy, including catheterization, myocardial biopsy, social service evaluation, special studies,[186] and professional fees, totals $10,000 to $20,000.

The median charge for a heart transplant in 1993 dollars was $123,000, with a median length of hospital stay of 23 days (range 1 to 554). The charge, when separated into its components, was distributed as follows: hospital charges $84,000, donor organ acquisition $17,000, surgeons' fees $13,000, and other professional fees $9000. The extremes for these figures varied by factors of 5 to 10.[183] In 1993, charges for the entire first year were estimated at $209,000. Efforts to reform the health care system have focused on cost, quality, and access, and growing involvement of managed care has reduced this expenditure to less than $100,000.[187] Yearly follow-up thereafter, including angiography and regular biopsies (three to four per year), probably exceeds $15,000, with immunosuppressive drugs alone costing $4000 to $6000 annually.[188]

The majority of private insurers[189] and, by 1990, 78 percent of state Medicaid programs[190] cover heart transplantation. Medicare also pays for care at designated centers that meet federal operational criteria.[19]

Reimbursement is usually less than 80 percent of charges, and long-term medication costs are not always recovered.[190] Insurance contracts that pay ongoing costs only when linked to claims of continued disability necessarily inhibit return to work.

HEART TRANSPLANTATION IN CHILDREN

The annual number of pediatric heart transplantations performed worldwide peaked at 395 in 1993 and since then has averaged approximately 340 per year. Overall, congenital heart disease and cardiomyopathy are the most common indications for transplantation in children younger than 1 year and 1 year and older, respectively. Various other indications have included failed Fontan procedure, severe Ebstein anomaly, single ventricle, and tricuspid and pulmonary atresia with coronary artery sinusoids.[191]

International Society of Heart and Lung Transplantation Registry data indicate an actuarial 1- and 5-year survival of approximately 78 and 65 percent. Children ages 11 to 17 have survival nearly identical to adults, whereas those younger than 1 year fare worse.[1] Some evidence

shows that rejection complications are less frequent in children in whom transplantation occurs before 1 month of age. After that time, rejection is clearly common and appears to be no less than in adult patients.

A major drawback to transplantation in children is the need for invasive endomyocardial biopsy to monitor the function of the transplanted heart. A report by Braunlin and colleagues suggests that episodes of rejection are relatively uncommon with triple-drug immunosuppression and that surveillance biopsies more than 6 months after transplantation are unlikely to show rejection in the absence of symptoms or an abnormal echocardiogram.[192] Rejection in neonatal patients may be associated with fever, irritability, and difficulty feeding. Emerging noninvasive techniques of detecting rejection were discussed earlier in this chapter and may someday greatly benefit the management of pediatric patients.

With continual improvements in immmunosuppression, the consequence of long-term administration of these drugs may be lessened, and the need for retransplantation later in life may also be alleviated. These issues, together with limited donor resources, remain the major stumbling blocks to more widespread use of transplantation in infants and children.

RETRANSPLANTATION

An important consideration in cardiac transplantation is the question of retransplantation. The major indications are (1) the development of graft coronary artery disease, (2) treatment of severe acute early rejection, and (3) treatment of early acute right-sided heart failure. All of these patient groups are less desirable potential recipients than are primary transplant candidates, either because of chronic immunosuppression or the circumstances surrounding early graft failure.

These patients should meet the same standard criteria as initial candidates. These include a lack of evidence of systemic infection, no other irreversible major organ system failure, and the potential for adequate rehabilitation. Recipients should be screened for the presence of preexisting cytotoxic antibodies. If a sufficient percentage is determined against a panel of random donor cells, a specific crossmatch will be required for the retransplantation procedure.

Although some reports demonstrate worse survival after retransplantation, others indicate that long-term survival and survival after an interval between procedures of at least 2 years approximate that of primary transplantation.[1] [193] [194] [195] In the largest report, 67 patients underwent 69 retransplantations out of 954 total procedures at

the Stanford University

Figure 20-11 Adult heart retransplantation actuarial survival based on length of time since primary transplantation, as reported to the Registry of the International Society for Heart and Lung Transplantation. (From Hosenpud JD, Bennett LE, Keck BM, et al: The Registry of the International Society for Heart and Lung Transplantation: Fifteenth Official Report--1998. J Heart Lung Transplant 17:658, 1998. Reprinted with permission from Elsevier Science Ltd.)

Medical Center. Twenty-three patients received retransplantation for early rejection and 43 patients for development of coronary artery disease. Causes of death were similar to those for other transplant recipients, and survival was 49, 27, and 15 percent at 1, 5, and 10 years after operation.[2] Actuarial survival of patients undergoing retransplant procedures reported to the Registry of the International Society of Heart and Lung Transplantation is shown in Figure 20-11. A clear benefit is seen in patients undergoing retransplantation more than 9 months after the initial transplantation. Because of the scarcity of donor organs and experiences with worse outcomes, most authorities agree that candidates for retransplantation must be carefully selected.

HEART-LUNG TRANSPLANTATION

Transplantation of the entire cardiopulmonary axis was accomplished experimentally even before orthotopic heart transplantation.[196] Despite early experimental attempts, it was a difficult clinical endeavor because of problems inherent in lung transplantation. The nonspecific immunosuppression available before cyclosporine therapy led to major problems with pulmonary infections and delayed healing of the trachea or bronchus, such that no truly therapeutic and extended lung transplant had been reported.[197] The availability of cyclosporine-based protocols led to success in primate allografts in the laboratory[198] and then a clinical series initiated at Stanford University Medical Center. The first reported therapeutic success in heart-lung transplantation was reported in 1981.[16]

The indications for heart-lung transplantation initially were severe pulmonary vascular disease, either primary or secondary to congenital heart disease. Later, heart-lung transplantation was extended to patients with various diffuse pulmonary diseases, such as emphysema, lymphangioleiomyomatosis, diffuse pulmonary atriovenous fistulas, and cystic fibrosis. Heart-lung transplantation currently is mainly performed for patients with complex congenital heart disease and Eisenmenger syndrome. Patients with cystic fibrosis and primary pulmonary hypertension are preferentially treated with bilateral lung transplantation; in cases of these conditions complicated by severe right or left ventricular failure, heart-lung transplantation may be indicated. Long-term survival figures for heart-lung transplantation (Fig. 20-12) are not as favorable as for heart transplantation (see Fig. 20-10).

Figure 20-12 Survival of patients receiving heart-lung transplants, as reported to the Registry of the International Society for Heart and Lung Transplantation. Chapter 21 - Management of Heart Failure

MICHAEL R. BRISTOW

INTRODUCTION

DEFINITION OF HEART FAILURE AND RELATED DISORDERS (see also Chaps. 16 and 18).

Heart failure (HF) is a specific term used to define the clinical syndrome that ensues when the heart is unable to pump enough blood to supply the metabolic needs of the body. The clinical syndrome of HF is caused by *cardiac failure*, a term used to define the various types of pump dysfunction that may cause HF. Cardiac failure may be produced by processes involving the pericardium, heart valves, coronary circulation, or myocardium (Table 21-1) . Of these etiologies, the most common cause of chronic HF is myocardial dysfunction, termed *myocardial failure*. Myocardial failure is usually divided into two general types, *systolic dysfunction* and *diastolic dysfunction,* to reflect the dominant abnormalities of contraction and relaxation, respectively. Subjects with myocardial failure can have symptomatic HF or asymptomatic ventricular dysfunction.

As typically used, HF generally refers to the chronic syndrome, or *chronic HF*. The qualifier "congestive" should not be used in association with HF inasmuch as many HF patients receiving modern medical treatment do not manifest congestive symptoms or signs. Rather, HF symptoms usually relate to impaired exercise tolerance, plus or minus symptoms related to fluid overload. Symptoms of exercise intolerance are typically assessed by the New York Heart Association (NYHA) functional classification,[1] where I=no symptoms, II=symptoms with moderate or marked levels of activity, III=symptoms with mild activity, and IV=symptoms at rest (see also Chap. 3).

CLINICAL IMPORTANCE (see also Chap. 17).

Because of its high prevalence (1 to 2 percent of the adult population)[2] and frequent hospitalizations, the clinical syndrome of HF is among the most costly medical problems in the United States.[3] Despite improvements in the treatment of HF introduced since the early 1980s, including the general availability of cardiac transplantation and better medical treatment, clinical outcome following the onset of symptoms remains characterized by high mortality, morbidity, and progression of symptoms. For example, even in recent clinical trials showing benefit of new agents superimposed on successful older treatment, annualized mortality (percent) and hospitalization rates (number of hospitalizations per patient per year) in the active treatment groups have been respectively 5 to 9 percent and 0.3 to 0.4 in Classes II and III[4] [5] [6] and 14 to 18 percent and 0.6 to 0.8 in Classes III and IV HF.[7] [8] Furthermore, HF is the only cardiovascular disorder in the United States that is increasing in prevalence,[9] and since the prevalence is directly related to age,[10] the incidence and prevalence of HF will continue to increase on the basis of population demographics (Fig. 21-1) . At present, an estimated 4.5 million patients have HF in the United States,[9] plus at least as many additional subjects with asymptomatic left ventricular dysfunction.[11] As can be observed in Figure 21-1 , by 2050 the number of subjects with symptomatic HF will increase to over 7 million on the basis of an increase in the number of persons older than 65 years,[12] in whom the prevalence of HF is 6 percent.[10]

PHENOTYPIC CLASSIFICATION OF HEART MUSCLE DISEASE (see also Chap. 48)

Heart muscle disease, or cardiomyopathy, is classified by a system developed by a World Health Organization/International Society and Federation of Cardiology (WHO/ISFC) task force. This committee recently revised the original classification,[13] which dealt with only "unknown cause" cardiomyopathies, and included all cardiomyopathies regardless of whether the cause is known.[14] The reasons for this change were the desire to be able to classify all cardiomyopathies within one classification and the developing reality that many previously unknown types of cardiomyopathy, such as hypertrophic cardiomyopathies, now have known molecular causes.

Within the current WHO/ISFC classification[14] (see Table 48-1) of cardiomyopathy, the most common cause of the clinical syndrome of chronic HF is a secondary (e.g., ischemic, valvular, hypertensive) or a primary (e.g., idiopathic or familial) dilated cardiomyopathy, defined as a ventricular chamber exhibiting increased diastolic and systolic volume and a low (<0.40) ejection fraction. However, all types of cardiomyopathy listed in Table 48-1 can cause chronic HF.

As shown in Table 48-1 , the WHO/ISFC cardiomyopathy classification[14] uses two separate methods to define the individual categories. The first is based on the global anatomical description of chamber dimensions in systole and diastole. Thus, the dilated and restrictive

TABLE 21-1 -- GENERAL ETIOLOGIES OF CARDIAC FAILURE

GENERAL CAUSE	SPECIFIC EXAMPLES
Pericardial	Tamponade, pericardial constriction
Valvular	Aortic or mitral regurgitation
Myocardial	Idiopathic dilated cardiomyopthy, familial dilated cardiomyopathy, ischemic cardiomyopathy, valvular cardiomyopathy
Coronary vascular	Acute ischemic episodes
Rhythm disturbances	Tachycardia-induced heart failure

Figure 21-1 Effect of the aging population on the prevalence of heart failure. *(Based on data from Phase I of the National Health and Nutrition Examination Survey III 1980 and U.S. Bureau of the Census data and projections appearing in Hayflick L: How and Why We Age. New York, Ballantine, 1994.)*

categories have definitions based on left ventricular dimension or volume, which also defines function via the calculated ejection fraction. The justification for classification is that these two groups have distinct natural histories and may respond differently to medical treatment. The second method of creating individual categories within the WHO/ISFC classification is for cardiomyopathies that are genetically based, have unique myocardial phenotypic features, and do not exhibit

extracardiac phenotypes. Thus, hypertrophic cardiomyopathy caused by mutations in sarcomeric proteins and manifested as a unique phenotype (see Chap. 48) merits a separate category. The same is true for arrhythmogenic right ventricular dysplasia, which also has a unique phenotype and will probably turn out to be completely genetic in basis, as has hypertrophic cardiomyopathy. On the other hand, genetic cardiomyopathies without unique phenotypes, such as the X-linked dilated cardiomyopathy of Becker-Duchenne muscular dystrophy (see Chap. 71), are included as one type of the anatomical/chamber dimension category (category I).

SECONDARY (SPECIFIC) CARDIOMYOPATHIES.

The WHO/ISFC classification includes another assignment of nomenclature in "secondary" cardiomyopathies, i.e., those associated with known cardiac or systemic processes. These conditions are referred to as "specific cardiomyopathies" and are named for the disease process with which they are associated. Thus, an ischemic cardiomyopathy would be a specific cardiomyopathy related to previous myocardial infarctions and the subsequent remodeling process and would usually fall within the dilated class. On the other hand, a hypertensive cardiomyopathy might be classified as either dilated or restrictive, depending on chamber dimensions. Therefore, the correct term for these cardiomyopathies would be "ischemic dilated cardiomyopathy" and "hypertensive dilated (or restrictive) cardiomyopathy."

PATHOPHYSIOLOGY OF HEART FAILURE DUE TO PRIMARY OR SECONDARY DILATED CARDIOMYOPATHIES (see also Chap. 16)

HF caused by pericardial, valvular, and acute coronary circulation problems is discussed elsewhere. The discussion here is confined to the pathophysiology of primary and secondary dilated cardiomyopathy, the cause of the majority of cases of HF, as it may relate to medical therapy. More detailed discussion of the pathophysiology of myocardial failure is given in Chapter 16 .

As depicted in Figure 21-2 , two interrelated processes, chamber remodeling and myocardial systolic dysfunction, are thought to play critical roles in the development and progression of primary and secondary dilated cardiomyopathy.[15] [16] Although both are the products of changes that occur at the cardiac myocyte level, changes in the interstitium also contribute.[17] In the remodeling process, cardiac myocytes become longer without a proportional increase in transverse diameter, which explains the increase in chamber diameter without an increase in wall thickness.[18] [19] Although this adjustment does increase the number of contractile elements as new sarcomeres are laid down in series, the law of Laplace dictates that diastolic wall stress will be markedly increased (see also Chap. 14). Also, the elongated and remodeled cardiac myocyte is poorly contractile.[20] The end result of these processes is a poorly contractile, dilated ventricular chamber that at some point can no longer adequately support the circulatory requirements of daily living.

As originally described in rat models,[21] the process of hypertrophy is accompanied by a qualitative change in the expression of genes regulating cell growth and contractile function. This constellation of changes in myocardial gene expression resembles the prenatal pattern of expression, and hence the term *induction of fetal gene expression* is used to describe these changes. Some of the specific changes are shown in Table 21-2 . Several of the fetal gene program changes can depress contractile function, such as the decrease in alpha-myosin heavy chain (alpha-MyHC) and sarcoplasmic reticulum Ca^{2+} ATPase and the increase in beta-MyHC. For many years, human ventricular myocardium

Figure 21-2 Relationship between remodeling and dysfunction.

TABLE 21-2 -- FETAL GENE PROGRAM INDUCTION IN HYPERTROPHIED, FAILING HUMAN VENTRICULAR MYOCARDIUM, DEGREE OF EXPRESSION (0-4+)

GENE EXPRESSED	ADULT PATTERN	FETAL PATTERN	HYPERTROPHY/FAILURE	BIOLOGICAL EFFECT IN HYPERTROPHY
alpha-MyHC	++	0-+	0-+	Contractile function
beta-MyHC	+++	++++	++++	Contractile function Contractile function Cell growth
SR Ca^{2+} ATPase	+++	++	++	Contractile function
Natriuretic peptides (ANP, BNP)	0-+	+++	+++	? Cell growth
Skeletal actin	+++	++++	?	--
Cardiac actin	+	0-+	?	--

ANP=atrial natriuretic peptide; BNP=brain natriuretic peptide; MyHC=alpha-myosin heavy chain; SR=sarcoplasmic reticulum.

was not thought to undergo the full pattern of fetal induction, but recent data indicate that failing human ventricular myocardium qualitatively resembles rodent models of fetal gene induction.[22] [23] [24] [25] Hypertrophied and failing human ventricular myocardium undergoes changes in expression of MyHC isoforms and sarcoplasmic reticulum Ca^{2+} handling proteins that summate to decrease systolic and diastolic function; on the basis of work done in rodent models,[21] [26] [27] it is likely that this mechanism of fetal gene induction contributes to the development of myocardial failure in the context of pathological hypertrophy, as depicted in Figure 21-2 .

VENTRICULAR REMODELING AND SYSTOLIC DYSFUNCTION.

These processes are progressive in most patients with established chronic HF,[28] and the pace [29] and degree[30] of this progression are directly related to the prognosis. It is therefore not surprising that two of the most effective treatments for chronic HF, inhibition of the renin-angiotensin and adrenergic nervous systems, act by attenuating or partially reversing these processes.[16] This mechanism implies that activation of the renin-angiotensin and adrenergic nervous systems is in part responsible for progressive remodeling and myocardial dysfunction, as depicted in Figure 21-3 and Table 21-3 . As shown in Figure 21-3 , after a myocardial insult sufficient to reduce pump function, only a limited number of compensatory options are available to stabilize cardiac output. As described in Table 21-3 , these options are an increase in heart rate and contractility, volume expansion to increase preload and thereby reach a higher position on the Frank-Starling curve, and an increase in the number of contractile elements through cell and chamber hypertrophy. As can be observed in Table 21-3 , the renin-angiotensin and adrenergic mechanisms are involved

Figure 21-3 Activation of compensatory mechanisms leads to a decrease in intrinsic and modulatable myocardial function.

TABLE 21-3 -- COMPENSATORY MECHANISMS ACTIVATED WHEN THE HEART BEGINS TO FAIL

PROCESS	MECHANISM PRIMARILY RESPONSIBLE
Heart rate	Beta-adrenergic
Contractility	Beta-adrenergic
Preload	Renin-angiotensin, beta-adrenergic
Hypertrophy	Renin-angiotensin, alpha- and beta-adrenergic, endothelin, cytokines (TNF-alpha, interleukin-1 beta) stretch-activated pathways

TNF=tumor necrosis factor.

in several of these mechanisms. The compensatory adjustments listed do stabilize myocardial pump performance in most subjects for a period. However, as implied in Figure 21-3 , ultimately, continuous activation of compensatory mechanisms produces additional myocardial damage in the context of the remodeling process. Some of the ways in which this additional damage occurs are given in Figure 21-4 .

The heart is unique among critical organs in that it has the ability to rapidly and markedly increase its performance

Figure 21-4 Harmful effects of neurohormonal, cytokine, and wall stress (mechanical stretch) signaling in the failing heart.

above a basal level of function. This specialized property, termed "modulatable function" in Figure 21-3 , can account for a twofold to fivefold increase in cardiac output in response to stress or exercise, which allows normal individuals to routinely increase workloads in the course of their daily activities. The specialized mechanisms that are responsible for modulatable function are the beta-adrenergic pathways, or the same mechanisms used as compensatory mechanisms when the heart begins to fail.[31] As shown in Figure 21-3 , because these mechanisms are continuously used to support the failing heart, some of their signal transduction capacity is lost through desensitization changes, thereby resulting in attenuation of exercise responses. [31] [32]

Thus, activation of compensatory neurohormonal/cytokine mechanisms contributes to progression in myocardial dysfunction and remodeling, as well as the HF syndrome, including fluid retention and loss of exercise capacity. Therefore, the most effective therapies in HF associated with primary or secondary dilated cardiomyopathy are neurohormonal antagonists.

DIAGNOSIS OF HEART FAILURE: DETERMINATION OF ETIOLOGY AND PROGNOSIS (see also Chap. 17)

One of the major problems in HF is its initial diagnosis, since the earliest symptoms of HF are often mistaken for other medical problems, including reactive airway disease, chronic obstructive pulmonary disease, pneumonia, and other pulmonary and nonpulmonary problems. Numerous studies have documented the lack of sensitivity and specificity of HF signs and symptoms,[33] [34] and the initial diagnosis is often first made by the radiologist from a chest radiograph demonstrating pulmonary edema and cardiomegaly. Because of these realities, alternative means of initially diagnosing HF are needed, such as a point-of-care blood test. One such test, brain natriuretic peptide, is promising in this regard.[35]

ECHOCARDIOGRAPHY.

If HF is suspected because of symptoms (dyspnea, dyspnea on exertion, paroxysmal nocturnal dyspnea, orthopnea, peripheral edema, easy fatigability, or other radiographic or biochemical data), an echocardiogram needs to be obtained. In the limited number of subjects who cannot be imaged by ultrasound for technical reasons, radionuclide ventriculography or magnetic resonance imaging (MRI) can be used to detect ventricular systolic dysfunction. An echocardiogram is the initial test of choice because it evaluates valvular and pericardial causes of HF, as well as being able to detect systolic dysfunction, and it may also be able to detect diastolic dysfunction. An echocardiogram (see Chap. 7) provides immediate information about whether the etiology is a pericardial, valvular, or myocardial process. It is important to emphasize that HF needs to be diagnosed as early as possible so that mortality- and morbidity-lowering treatment can be initiated.

If impaired left ventricular systolic function is detected by echocardiography, more precise measurement of the function of both ventricles may be indicated via radionuclide ventriculography (see Chap. 9). This imaging modality is able to measure left ventricular systolic function more precisely, which is important from a prognostic standpoint,[29] [30] and for monitoring the response to beta-blocker therapy, a treatment that favorably affects systolic function (see below).[16] Radionuclide ventriculography can also measure right ventricular function, which is another prognostic index in chronic HF.[36] As shown in Table 21-4 , when right ventricular structural abnormalities are suspected, cardiac MRI is indicated (see Chap. 10) because this modality is currently the best available imaging method for visualizing right ventricular pathology and function.

DIASTOLIC DYSFUNCTION (see Chaps. 15 and 16).

The diagnosis of diastolic dysfunction is largely one of exclusion. That is, to make the diagnosis of diastolic dysfunction, two pieces of data are required: documentation of normal or near-normal systolic function and unequivocal evidence of HF. The latter may be provided by unambiguous documentation of acute episodes of decompensation (e.g., pulmonary edema on a chest radiograph plus symptoms of breathlessness or right-sided failure) or chronic myocardial dysfunction resulting in high filling pressure, decreased cardiac output, and impaired functional capacity. Although echocardiographic and radionuclide ventriculographic data can contribute to a diagnosis of diastolic dysfunction, neither are considered sufficiently definitive to establish the diagnosis on the basis of isolated measurements. Finally, diastolic dysfunction as the cause of HF in a relatively young (<60 years) patient suggests an infiltrative process, and an endomyocardial biopsy may be indicated.

Once the diagnosis of HF has been established, additional data need to be gathered. In general, the goals of this additional work-up are to determine the etiology and establish a general prognosis. The diagnostic work-up of HF should seek to determine the etiology, as outlined in Table 21-1 , unless the patient is so infirm that no form of intervention would be possible. Figure 21-5 gives an algorithm for a work-up of confirmed or suspected cases of HF. Cardiac catheterization is often indicated, as discussed in Table 21-4 .

ENDOMYOCARDIAL BIOPSY.

Perhaps the most controversial diagnostic test in the work-up of heart muscle disease is endomyocardial biopsy (see Chap. 11). This procedure in inexperienced hands can be associated with complications, including death in rare cases (
1 percent). On the other hand, recent data indicate that in the presence of

TABLE 21-4 -- INDICATIONS FOR CARDIAC CATHETERIZATION AFTER EVALUATION FOR HEART FAILURE AND PERFORMANCE OF AN ECHOCARDIOGRAM

ECHOCARDIOGRAPHY, CLINICAL FINDINGS	CARDIAC CATHETERIZATION OR OTHER PROCEDURE
Significant pericardial effusion, evidence of tamponade	Right-heart catheterization, pericardiocentesis
Thickened pericardium, evidence of cardiac compression	Right- and left-heart catheterization, with or without endomyocardial biopsy if restriction suspected
Severe aortic or mitral regurgitation, LV enlargement with decreased systolic function	Right- and left-heart catheterization, coronary angiography in anticipation of possible surgery
Aortic stenosis	Right-heart catheterization, coronary angiography in anticipation of surgery
Mitral stenosis	Right- and left-heart catheterization, coronary angiography in anticipation of possible surgery
LV enlargement, decreased systolic function with valvular abnormalities less than severe	Right- and left-heart catheterization, coronary angiography, possible endomyocardial biopsy if coronaries normal
Normal LV size, function	Right- and left-heart catheterization, coronary angiography, possible endomyocardial biopsy if coronaries normal to rule out an infiltrative process
Hypertrophic cardiomyopathy with ASH, with or without mitral regurgitation	Coronary angiography if surgery (myectomy with or without mitral valve replacement) contemplated
Normal LV size, decreased systolic function, no history of anthracycline use	Right- and left-heart catheterization, coronary angiography, endomyocardial biopsy if coronaries normal to rule out inflammatory heart disease
RV dysfunction, arrhythmia	MRI (to rule out ARVD)
RV dysfunction, isolated	Right-heart catheterization (to rule out PPH)

ARVD=arrhythmogenic right ventricular dysplasia; ASH=asymmetrical septal hypertrophy; LV=left ventricular; MRI=magnetic resonance imaging; PPH=primary pulmonary hypertension; RV=right ventricular

Figure 21-5 Algorithm for establishing the diagnosis of heart failure and determining etiology and prognosis. LV=left ventricular; MR=magnetic resonance imaging; RV=right ventricular.

unexplained heart muscle disease, endomyocardial biopsy yields important diagnostic/prognostic information in 11 percent of patients,[37] a figure high enough to justify biopsy provided that experienced personnel are available to perform it and interpret the results.

In cases of systolic dysfunction caused by a primary or secondary dilated cardiomyopathy, precise determination of the degree of left and right ventricular dysfunction will have important prognostic value. Additional clinical characteristics that may have an impact on the prognosis are the degree of pulmonary hypertension, the presence or absence of high-grade ventricular arrhythmia, and the extent of coronary artery disease. Importantly, valuable prognostic information can be gained by measuring peak oxygen consumption (V_{O_2}), which in chronic HF correlates with prognosis independently of left ventricular function.[38]

MANAGEMENT OF ACUTE, NEW-ONSET HEART FAILURE

TRANSIENT HEART FAILURE.

Although chronic HF is the most commonly encountered form of symptomatic myocardial dysfunction, HF may also be acute and not superimposed on chronic pump dysfunction (see also Chap. 18). Such manifestations can occur in the postoperative state following cardiac surgery,[39] in the setting of severe brain injury,[40] secondary to ischemic insults, or after the sudden onset of an inflammatory process or any pathophysiological mechanism that rapidly produces myocardial injury. The general pathophysiological mechanism involved is either some form of "stunning" of functional myocardium (see Chap. 14) or abrupt loss of functioning tissue that occurs before compensatory mechanisms can stabilize function. In both of these situations, myocardial function is adequate to support the circulation once recovery has occurred, and in the case of mechanisms that may produce stunning, such as cardiopulmonary bypass, other ischemic insults, and severe brain injury (where the stunning is probably related to massive release of catecholamines[40]), myocardial function may be completely normal on recovery.

Treatment.

Management of episodes of acute HF caused by an evanescent process depressing myocardial function is support of pump function with positive inotropic agents (see Chap. 18) and/or, if extremely severe, with mechanical devices (see Chap. 19) to the extent necessary to provide adequate perfusion of critical organs. Once function has recovered, no further treatment may be necessary. In the case of ischemia caused by coronary artery disease or another mechanism that may persist to cause recurrent problems, treatment of the underlying process is the management goal. Further details of the treatment of transient myocardial failure are given below under the treatment of decompensated chronic HF.

NEW-ONSET, PERSISTENT HEART FAILURE.

The most common manifestation of acute, new-onset HF is superimposition on a chronic process that has previously been subclinical and in which myocardial function has been supported by the compensatory mechanisms described in Table 21-3 . Therefore, most episodes of new-onset HF are actually the first episode of decompensation, similar to what occurs in established chronic HF.

How much myocardial functional loss can be countered by compensatory mechanisms? The quantitative relationship between degree of myocardial loss and development of myocardial pump dysfunction has been examined in two settings, following myocardial infarction[41] [42] and after individual cardiac myocyte "dropout" from anthracycline cardiotoxicity.[43] The experimental model data from acute myocardial infarction[41] [42] are more relevant to acute-onset HF superimposed on previously normal cardiac function, while the anthracycline data generated in patients represent decompensation superimposed on a chronic myocardial process that has previously been stabilized by compensatory mechanisms. The conclusion from the myocardial infarction studies conducted in animal models was that loss of 30 percent or less of the left ventricle in rats[41] and 25 percent or less in dogs[42] is relatively well tolerated, whereas in rats,[41] infarcts in excess of 46 percent were associated with severe hemodynamic compromise.

Investigation of the structure-function relationship in anthracycline-induced cardiomyopathy (see Chap. 69) was conducted in the intact human heart in patients receiving

---

Figure 21-6 Relationship of the degree of myocardial damage to myocardial dysfunction in anthracycline-induced cardiomyopathy in 15 subjects who underwent serial biopsy. Myocardial damage is assessed semiquantitatively by the Billingham scale according to the percentage of cells exhibiting an anthracycline effect on endomyocardial biopsy (biopsy score).[43] [44] [45] Myocardial dysfunction is assessed by a "catheterization score" based on abnormalities detected by right-heart catheterization with exercise.[43] [44] [45]

the antitumor agent doxorubicin (Adriamycin). Myocardial damage in this unique form of drug-induced heart disease consists of vacuolization and myofibrillar loss in individual cardiac myocytes, which are typically surrounded by myocytes that are unaffected.[43] By morphometrically counting the number of affected myocytes relative to the total in a field of endomyocardial biopsy material, it is possible to determine the percentage of cells that are nonfunctional because of the anthracycline process.[44] [45] The percentage of affected cells is converted to a semiquantitative score, as described in Figure 21-6 . The degree of myocardial damage can then be related to the degree of myocardial dysfunction, as assessed by right-heart catheterization performed at rest and with exercise.[43] [44] [45] As shown in Figure 21-6 , it is not until more than 15 percent of cells are damaged that detectable myocardial dysfunction develops, and moderate dysfunction (grade 2 catheterization abnormalities in Fig. 21-6) does not develop until more than 25 percent of cardiac myocytes are involved. In other words, as in myocardial infarction, in anthracycline-associated cardiomyopathy a certain amount of myocardial damage can be tolerated with the aid of compensatory mechanisms. In anthracycline cardiomyopathy, these compensatory mechanisms rely heavily on adrenergic stimulation, since hypertrophy is inhibited by the effects of anthracyclines on myocardial protein synthesis.[46] [47]

Therefore, data from these model systems suggest that the initial, sudden onset of HF will occur when compensatory mechanisms can no longer sustain normal myocardial function. Consequently, myocardial function and structure usually indicate a chronic remodeling process at the initial evaluation for HF.

Treatment of acute, new-onset myocardial failure does not differ from that of decompensated chronic HF, which is discussed in detail below.

MANAGEMENT OF CHRONIC HEART FAILURE

Pharmacological Therapy for Chronic Heart Failure Caused by Systolic Dysfunction

The pharmacological treatment of chronic HF is best understood by subdividing the patient population into four groups as described in Table 21-5 . This "HF stage" classification system reflects the average symptomatic status of the patient inasmuch as patients typically move from one NYHA class to another within the stage groups. In general, the average symptomatic status is directly related to hospitalization frequency and is also related to mortality risk as demonstrated in Figure 21-7 and described in Table 21-5 . Important differences between the HF stage-ordered classification and the NYHA functional class are that the stage classification (1) begins with some level of disability as opposed to asymptomatic status, (2) ends with a more advanced level of disability than is generally reflected by the NYHA Class IV category, and (3) recognizes the reality that patients with HF often move from one level of symptoms to another, for example, typically exhibiting Class III symptoms that transiently increase to Class IV depending on medical management and other factors.

As outlined in Table 21-6 , the goals of treatment for chronic HF are to (1) relieve symptoms, (2) improve functional capacity and reduce disability, (3) decrease the intensity of medical care and reduce economic cost, (4) delay progression of or reverse remodeling and myocardial dysfunction, and (5) reduce mortality. Depending on the stage that a particular HF patient is in, one or more of these goals may be more important than the others and dictate the type of agent to be developed or used once efficacy and safety are established.

TABLE 21-5 -- CLINICAL STAGES OF CHRONIC HEART FAILURE ASSOCIATED WITH SYSTOLIC DYSFUNCTION BASED ON SYMPTOMS AND HOSPITALIZATION REQUIREMENT

STAGE	DESCRIPTION	NYHA CLASS	ANNUALIZED MORTALITY (%)*	HOSPITALIZATIONS/YEAR
A (asymptomatic-mild)	Asymptomatic or only minimal symptoms, rare hospitalizations	I-II	2-5	<0.25
B (mild-moderate)	Mild-moderate symptoms, infrequent hospitalizations	II-III	5-15	0.25-0.75
C (advanced)	Moderate-severe symptoms, frequent hospitalizations	III-IV	15-25	0.75-2
D (severe)	Persistent, severe symptoms; frequent prolonged or continuous hospitalizations	IV	>25	>2

*Risk also depends on the degree of myocardial dysfunction and other factors.

Figure 21-7 Plot of the relationship between survival or hospitalization frequency and New York Heart Association Class in chronic heart failure.

STAGE A (NO OR MILD HEART FAILURE, NYHA CLASS I/II SYMPTOMS).

As for any chronic disease process, the most effective way to deal with the HF problem is to treat it early, before irreversible damage has developed. The goals of treatment of stage A HF (see Table 21-6) are to prevent progression of the underlying pathophysiological processes of remodeling and dysfunction and thereby prevent disease progression and overt development of the HF syndrome. However, only limited data actually support this generally accepted belief. Clinical trial experience is confined to one study, the Studies of Left Ventricular Dysfunction (SOLVD) Prevention Trial.[48] That trial demonstrated that the angiotensin-converting enzyme (ACE) inhibitor enalapril reduced the probability of development of overt HF by 37 percent and reduced the combined endpoint of mortality plus HF hospitalizations by 20 percent.[48]

TABLE 21-6 -- GOALS AND PHARMACOLOGICAL TREATMENT FOR VARIOUS STAGES OF HEART FAILURE

STAGE	GOALS (IN ORDER OF IMPORTANCE)	TREATMENT
A (asymptomatic-mild)	Reverse or prevent progressive remodeling and dysfunction	ACE inhibitors ? Beta-blocking agents ? Other neurohormonal or cytokine antagonists
	Prevent overt heart failure or progressive symptoms	ACE inhibitors ? Beta-blocking agents ? Other neurohormonal or cytokine antagonists
B (mild-moderate)	Reverse or prevent progressive remodeling and dysfunction	ACE inhibitors Beta-blocking agents ? Other neurohormonal or cytokine antagonists
	Improve symptoms and functional capacity	Diuretics ACE inhibitors Beta-blocking agents ? Other neurohormonal or cytokine antagonists Digoxin Reduce dietary Na
	Reduce disability and hospitalizations	Diuretics ACE inhibitors Beta-blocking agents ? Other neurohormonal or cytokine antagonists ? Digoxin Reduce dietary Na
	Reduce mortality	ACE inhibitors Beta-blocking agents ? Other neurohormonal or cytokine antagonists
C (advanced)	Reduce mortality	ACE inhibitors Spironolactone ? Beta-blocking agents ? Other neurohormonal or cytokine antagonists
	Reduce disability and hospitalizations	Reduce dietary Na Diuretics ACE inhibitors Beta blockers Spironolactone ? Other neurohormonal or cytokine antagonists ? Positive inotropic agents
	Improve symptoms and functional capacity	Reduce dietary Na Diuretics ACE inhibitors Spironolactone ? Other neurohormonal or cytokine antagonists ? Positive inotropic agents

ACE=angiotensin-converting enzyme.

TABLE 21-7 -- CLINICAL TRIALS OF MEDICAL THERAPY FOR MILD TO MODERATE HEART FAILURE

TRIAL (YEAR OF PUBLICATION)	ENTRY CRITERIA	n	THERAPY	FOLLOW-UP	PRIMARY ENDPOINT	COMMENTS
ANTIARRHYTHMICS						
GESICA[142] (1994)	NYHA II-IV LVEF <35%	516	Amiodarone vs. placebo	--	Amiodarone decreased mortality	In contrast to CHF-STAT (see below), this study included sicker patients with a high event rate and more nonischemic etiology. Results should be viewed carefully, because this was an open-label study
CHF-STAT[143] (1995)	History of CHF PVC 10/hr EF 40%	674	Amiodarone vs. placebo	45 mo	Neutral for mortality	Largely patients with ischemic etiology in whom no benefit was noted. Nonischemic patients had a trend (p=0.07) for a survival benefit. LVEF was increased in amiodarone-treated patients
BETABLOCKERS						
U.S. Carvedilol Program[4] (1996)	NYHA II-IV LVEF <35%	1094	Carvedilol vs. placebo	6 mo		Combined morbidity and cardiovascular hospitalization were decreased in the overall trial. Combining the four individual phase III trials demonstrated at 65% reduction in mortality
CIBIS-II[5] (1999)	NYHA III-IV	2647	Bisoprolol vs. placebo	16 mo	Favorable for mortality	Larger trial with a sicker population and higher bisoprolol dosing than in CIBIS-I; 34% reduction in mortality, particularly sudden death; favorable for hospitalization
MERIT-HF[6] (1999)	NYHA II-IV	3991	Metoprolol CR/XL vs. placebo	12-mo mean	Favorable for mortality and morbidity/mortality combined	34% reduction in mortality and a similar reduction in combined mortality and HF hospitalization
COPERNICUS (ongoing)	NYHA IIIB-IV LVEF <25%	1800	Carvedilol vs. placebo	--	Mortality	An important trial testing beta blockade in population with advanced HF
VASODILATORS						
V-HeFT-1[144] (1986)	NYHA II-III LVEF <45% CTR >0.55	642	Hyd-Isdn vs. placebo, prazosin vs. placebo	2.5-yr mean	Decreased mortality (Hyd-Isdn); no mortality effect with prazosin	Provided strong evidence of the hypothesis that a vasodilator (Hyd-Isdn) improved prognosis in HF
V-HeFT-II[145] (1991)	NYHA II-III LVEF <45% CTR >0.55	804	Enalapril vs. Hyd-Isdn	2.5-yr mean	Decreased mortality with enalapril	Demonstrated that an ACE inhibitor was superior to a proven vasodilator regimen. First evidence that an ACE inhibitor decreased sudden death
CALCIUM ANTAGONISTS						
PRAISE-I[146] (1996)	NYHA III-IV LVEF <30%	1094	Amlodipine. vs. placebo (background ACE inhibitors, digitalis, diuretics)	14.5-mo mean	Neutral for mortality and life-threatening hospitalization	Overall, suggests safety with amlodipine in advanced HF; PRAISE-II will assess the unexpected benefit seen in nonischemic patients
PRAISE-II (ongoing)	NYHA III-IV Nonischemic cardiomyopathy	1800	Amlodipine vs. placebo (background ACE inhibitors, diuretics, digoxin)	--	Mortality	Designed to prospectively test the finding of PRAISE-I that amlodipine decreased mortality in nonischemic cardiomyopathy
RENIN-ANGIOTENSIN INHIBITORS						
CONSENSUS[59] (1987)	NYHA IV	253	Enalapril vs. placebo	Early termination	Decreased mortality	Established ACE inhibitors as the standard of therapy for severe HF
SOLVD Treatment[49] (1991)	NYHA II-III LVEF <35%	2569	Enalapril vs. placebo	41.4-mo average	Decreased mortality	Established that an ACE inhibitor was the standard of therapy in mild to moderate HF
SOLVD Prevention[48] (1992)	Asymptomatic LVEF <35%	4228	Enalapril vs. placebo	37.4 mo	Equivocal mortality; decreased progression of HF or hospitalization combined with deaths	Mortality effect hampered by open-label ACE inhibitor use. Trial established that ACE inhibitors could decrease progression of HF in asymptomatic patients
ATLAS[50] (1998)	NYHA II-IV LVEF <30%	3000	High-dose lisinopril vs. low-dose lisinopril	3 yr	Neutral for mortality	High-dose ACE inhibitors modestly decreased combined HF hospitalization and mortality, as well as HF hospitalization alone
VALHeFT (ongoing)	NYHA II-IV LVEF <40%	5000	Valsartan vs. placebo+standard therapy	--	Mortality/morbidity and mortality	Designed to test the effect of angiotensin II receptor blockade added to standard therapy
CHARM (ongoing) Preserved systolic function Additive therapy ACE inhibitor intolerant	NYHA II-IV LVEF >40% LVEF <40% LVEF <40%	6500 2800 2700 1000	Candesartan vs. placebo	--	HF mortality and HF hospitalization	Ambitious trial testing angiotensin II receptor blockade across the spectrum of HF. These investigations are the only ones to date evaluating HF patients who are intolerant of ACE inhibitors and HF patients with preserved systolic function
INOTROPIC AGENTS						
DIG[147] (1997)	NYHA II-IV, stratified LVEF <45% LVEF >45%	7788	Digoxin vs. placebo	37 mo	Neutral mortality; decreased HF and hospitalization	Long-awaited results indicated that digoxin did not alter mortality but improved morbidity in HF
RALES[7] (1999)	NYHA III-IV LVEF <35%	1663	Spironolactone vs. placebo	34 mo	Decreased mortality and cardiovascular morbidity	Surprising result with dramatic decrease in both mortality and HF hospitalization

ACE=angiotensin-converting enzyme; CTR=cardiothoracic ratio; EF=ejection fraction; HF=heart failure; Hyd-Isdn=hydralazine-isosorbide dinitrate; LVEF=left ventricular EF; NYHA=New York Heart Association; PVC=premature ventricular contractions.

Adapted from Carson P: Current review of heart failure trials. Cardiology, Vol 5, 1999.

Although it is likely that beta-adrenergic blocking agents will reduce mortality in stage A HF, because of the sample size and therefore the cost considerations of performing placebo-controlled trials in this patient population, to date no beta blocker clinical trial has examined this patient population. Similarly, trials with other neurohormonal antagonists will probably not be performed until efficacy has been demonstrated in later stage HF.

STAGE B (MILD TO MODERATE HEART FAILURE, NYHA CLASS II/III SYMPTOMS).

This stage of HF is the stage in which the majority of clinical trial data are available because of the prevalence, relative stability, and sample size considerations in these patients (Table 21-7) . As a result, recommendations for medical therapy for Class II to III or stage B HF can be given with a high degree of certainty. The goals of therapy in this stage are, similar to stage A, centered around reversal or prevention of progression of remodeling and dysfunction because the potential for reversibility of the dilated cardiomyopathy phenotype still exists. As remodeling/dysfunction is attenuated or reversed, the other treatment goals outlined in Table 21-6 will be realized, and all are important in stage B HF.

ACE inhibitors[49] and beta-blocking agents[4] [6] [50] have been shown to reduce mortality and hospitalizations in patients with stage B HF (see Figs. 18-6 , 18-8 , and 18-9). ACE inhibitors also improve symptoms and tend to improve functional capacity in this stage of HF,[51] while beta-blocking agents have produced variable results on symptoms and functional capacity.[52] On balance, digoxin has generally improved symptoms and functional capacity in mild to moderate HF,[53] and other, nonapproved positive inotropic agents have as well.[54] [55] [56] However, positive inotropic agents other than digoxin are associated with increased mortality when used chronically in HF, and it is unclear whether newer strategies such as low-dose administration[56] [57] or combination with beta-blocking agents [58] will mitigate theses adverse effects.

Although never subjected to large-scale trials, diuretics are a cornerstone of symptomatic HF treatment beginning in stage B.[58A] The goals of diuretic therapy are to reduce congestive symptoms, reduce wall stress, and attenuate the harmful signaling of remodeling/dysfunction mechanisms outlined in Figure 21-2 . In stage B, a loop diuretic alone will usually suffice, along with potassium replacement to maintain serum levels well into the normal range. Diuretics should be used in conjunction with dietary salt restriction, initially avoiding added salt and then avoiding foods prepared with salt such as canned foods and processed foods.

The majority of patients in stages B and C (described next) should be treated with an ACE inhibitor, a beta-adrenergic blocker, digoxin, a diuretic, and sodium restriction.

STAGE C (ADVANCED HEART FAILURE, NYHA CLASS III/IV SYMPTOMS).

As shown in Figure 21-7 , in this stage of HF the hospitalization rate and mortality begin to markedly increase. Therefore, the main goal of therapy in advanced, stage C HF is to lower the probability of HF-related hospitalization and mortality. ACE inhibitors[59] and the aldosterone antagonist spironolactone[7] have been shown to be effective in this regard. Beta-blocking agents, which are quantitatively more effective than ACE inhibitors in stage B HF, appear to be less effective in reducing mortality and hospitalizations in more advanced HF.[8] However, in a recent trial conducted in stage C patients, the third-generation beta blocker bucindolol did reduce mortality by 10 percent and HF-associated hospitalizations by 14 percent[8] (see also Chap. 18).

In terms of symptom relief and improvement of functional capacity in stage C patients, inhibitors of the renin-angiotensin system, diuretics, and possibly positive inotropic agents have had some success in controlled trials. For diuretics, in stage C HF it is often necessary to add the powerful thiazide diuretic metolazone plus a K^+ -sparing compound (spironolactone if it is tolerated) to control fluid retention. Dietary salt restriction should be intensified. Trials of inotropic agents in this patient population have not prolonged survival thus far,[60] [61] [62] but promising low-dose and combined beta blocker-inotrope approaches are currently being evaluated.[57] [58]

STAGE D (SEVERE HEART FAILURE, CLASS III/IV SYMPTOMS WITH FREQUENT OR SUSTAINED DECOMPENSATION).

When subjects progress to stage D, i.e., severe HF despite optimal medical management, the goals of therapy change to include palliation of symptoms, reducing rates of hospitalization, and in subjects who are eligible, bridging to cardiac transplantation (see also Chap. 20). In general, reversal of the intrinsic biological processes of remodeling and dysfunction are not possible in this stage. The only treatment shown to be effective in lowering mortality in this stage of HF is ACE inhibition,[59] but despite this treatment, when subjects reach stage D HF, the possibility of salvage by medical therapy is indeed remote.

Although for ethical reasons no randomized study has provided convincing proof, in subjects who periodically decompensate to incipient or overt cardiogenic shock, the administration of non-glycoside-positive inotropic agents is life saving. Currently, no orally administered positive inotropic agents are approved for palliation of advanced HF, but investigational agents[63] [64] have shown enough promise to instigate phase III clinical trials in this regard. Until an oral agent is available, the standard treatment for palliation of advanced HF will remain intermittent or continuous administration of intravenous inotropic agents such as dobutamine,[65] milrinone,[66] or enoximone.[67]

PHARMACOLOGICAL THERAPY IN SUBGROUPS.

Two HF demographic groups have exhibited a response to pharmacological treatment that appears to be different from that of other groups or the population as a whole. The first is American blacks, who in the beta-Blocker Evaluation of Survival Trial[8] (BEST) exhibited a worse response to beta blockade than did the rest of the population (see also Chap. 18). American blacks treated with bucindolol had a statistically insignificant 17 percent increase in mortality as compared with a statistically significant 19 percent reduction in mortality in the rest of the population.[8] A statistical test for interaction between blacks and the remainder of the population was significant, which suggests that this disparity in clinical response was not due to chance.[8] The poorer response of blacks to beta blockade in BEST is reminiscent of the reduced efficacy of beta blockers in treating hypertension in blacks[68] and less efficacy of ACE inhibitors in treating hypertension[68] or HF[69] in blacks.

However, blacks treated with carvedilol in the U.S. Carvedilol Trials fared as well as the rest of the population,[70] perhaps because they had only stage B HF as opposed to the stage C subjects in BEST. Another possibility for the difference in response to beta blockade in BEST and the U.S. Carvedilol Trials is that the more powerful vasodilator properties of carvedilol were beneficial in a population enriched in hypertensive heart disease.[8] [70] What is certain is that blacks with HF have very different associated demographics, including a lower prevalence of ischemic cardiomyopathy, more hypertension by history, a higher prevalence of diabetes, and a younger subject population.[8] [70] [71] Thus, it is not clear whether race per se or associated demographic modifiers account for the difference in response to beta blockers and ACE inhibitors that has been noted in clinical trials. The scientific basis for these differences needs to be elucidated, and more effective treatment of blacks with HF needs to be developed. For the present, it is prudent to avoid beta blockers in black patients with stage C HF and to consider the alternative of hydralazine/isosorbide dinitrate instead of ACE inhibitor treatment.[69]

Women with HF may also have special characteristics that can influence pharmacological treatment.[72] [73] [74] These characteristics include a better prognosis than men,[10] greater functional incapacity for the same degree of left ventricular dysfunction,[72] a higher prevalence of diastolic dysfunction,[73] and a higher percentage of elderly individuals.[73] Some or all of these factors may contribute to the tendency for lower effect sizes in women versus men in the few clinical trials that have enrolled enough women to report differences in response versus men.[6] [8]

Pharmacological Therapy for Chronic Heart Failure Caused by Diastolic Dysfunction(Table 21-8)

As many as 30 to 40 percent of patients with symptomatic HF exhibit diastolic rather than systolic dysfunction (see also Chaps. 15 , 16 , and 17).[74] [75] Diastolic dysfunction is much more common in women[73] and the elderly,[76] and in the latter it may be the dominant form of HF.[76] Additional risk factors for diastolic dysfunction include a history of hypertension[77] or diabetes mellitus.[78] Most studies indicate that that patients with diastolic dysfunction as the primary cause of HF have a better prognosis than do controls with systolic dysfunction.[74] Importantly, as discussed above, predominantly diastolic dysfunction in a younger (<60 years) patient suggests an infiltrative cardiomyopathic process.

Unlike systolic dysfunction, no definitive pharmacological therapy for diastolic dysfunction is available. The cornerstone of treatment is careful regulation of ventricular filling pressure by diuretics, in a range that prevents excessive dyspnea and liver congestion but allows for adequate cardiac output. ACE inhibitors and/or spironolactone may make diuretic management easier by preventing excessive activation of the renin-angiotensin-aldosterone system. In addition, in limited settings some evidence indicates that ACE inhibitors improve ventricular relaxation,[79] but this improvement does not seem to be translated into benefit in subjects with diastolic HF.[80] Beta blockers may be used to slow the heart rate and prolong filling time, and beta blockers or amiodarone may be required to control and prevent

TABLE 21-8 -- DIASTOLIC DYSFUNCTION: TREATMENT GOALS AND METHODS

Reduce the Congestive State
Salt restriction, diuretics, ACE inhibitors
Dialysis or plasmapheresis
Maintain Atrial Contraction
Direct-current or pharmacological cardioversion
Sequential atrioventricular pacing
Prevent Tachycardia and Promote Bradycardia
Beta blockers
Radiofrequency ablation and pacing
Treat and Prevent Myocardial Ischemia
Nitrates, beta blockers, calcium blockers
Bypass surgery, angioplasty
Control Hypertension and Promote Regression of Hypertrophy
Antihypertensive agents
Attenuate Neurohormonal Activation
Beta blockers, ACE inhibitors
Prevent Fibrosis and Promote Regression of Fibrosis
ACE inhibitors, spironolactone
Antiischemic agents
Improve Ventricular Relaxation
Phosphodiesterase inhibitors
Systolic unloading
Treat ischemia
Calcium blockers (in hypertrophic cardiomyopathy)
ACE=angiotensin-converting enzyme.
From Smith TW (ed): Cardiovascular Therapeutics: A Companion to Braunwald's Heart Disease. Philadelphia, WB Saunders, 1996, p 241.

supraventricular arrhythmias. Finally, phosphodiesterase inhibitors (PDEIs) have been shown to improve diastolic function acutely,[81] but there has been no controlled experience with these agents in chronic therapy.

Adjunctive Pharmacological Therapy

ANTIARRHYTHMIC AGENTS (see also Chap. 23).

In general, antiarrhythmic therapy in HF patients is reserved for symptomatic arrhythmias or for control of ventricular responses to atrial fibrillation. With regard to treatment of ventricular arrhythmias, the Cardiac Arrhythmia Suppression Trial (CAST),[82] [83] which was conducted not in an HF population but in subjects with left ventricular dysfunction after myocardial infarction, convincingly demonstrated that type 1 antiarrhythmic agents (i.e., Na channel blockers) increase mortality when used to suppress ventricular premature contractions. The Electrophysiological Study Versus Electrocardiographic Monitoring (ESVEM)[84] extended the evidence for adverse effects of type 1 agents in subjects with left ventricular dysfunction and Holter monitor-documented ventricular arrhythmias or inducible sustained ventricular tachycardia. In the ESVEM trial, sotalol, a beta-blocking agent with type III antiarrhythmic properties, was the most effective agent. However, ESVEM had no placebo control, so it was not possible to precisely measure the efficacy and adverse effects of sotalol.

The antiarrhythmic agent that has undergone the most extensive evaluation for efficacy and safety in populations with HF or left ventricular dysfunction is amiodarone. Similar to sotalol, amiodarone is a type III antiarrhythmic with antiadrenergic properties[85] (see Chap. 23). In controlled clinical trials in HF or asymptomatic left ventricular dysfunction, amiodarone either has been associated with reduced mortality[86] or has been equivalent to placebo. [87] In other words, amiodarone is the one antiarrhythmic agent that appears to be safe in patients with left ventricular dysfunction and HF. However, amiodarone has pulmonary, thyroid, liver, and other toxicities, and its use should be accompanied by careful surveillance for adverse effects. Additionally, as for all antiarrhythmic agents, amiodarone has negative inotropic effects and may be poorly tolerated by patients with advanced HF.

Treatment of arrhythmias has evolved to catheter-based ablation (see Chap. 23) and implantable defibrillators (see Chap. 24). Current indications for device therapy for ventricular arrhythmias are given below.

ANTICOAGULATION (see also Chap. 62).

An area of considerable controversy is the use of anticoagulation in the form of warfarin in patients with normal sinus rhythm and severe left ventricular dysfunction. In controlled clinical trials, the risk of arterial thromboembolic events, most of which are stroke, ranges from 0.9 to 5.5 per 100 patient-years.[88] [89] Since warfarin convincingly lowers thromboembolism and stroke risk in atrial fibrillation,[90] it is logical that this benefit would extend to subjects with severe left ventricular dysfunction. Such benefit may be particularly true in nonischemic cardiomyopathies, which are associated with a relatively high incidence of left ventricular thrombus.[91] On the basis of these considerations, many, but not all HF centers routinely administer anticoagulants to all patients with moderate or severe left ventricular dysfunction who do not have a contraindication. However, anticoagulation with warfarin is not without risk, and it must be carefully monitored. In chronic HF, a firm indication for anticoagulation can be made in patients with atrial fibrillation, those with a visualized left ventricular thrombus, and those with a history of a thromboembolic event.[92] Anticoagulation in left ventricular dysfunction with normal sinus

rhythm should be considered optional, with the issue to be settled by ongoing clinical trials.

Device Therapy

IMPLANTABLE CARDIAC DEFIBRILLATORS (see also Chap. 24).

Implantable cardiac defibrillators are now the treatment of choice in patients with left ventricular dysfunction who have survived sudden cardiac death,[93] have symptomatic sustained ventricular tachycardia,[93] or have asymptomatic nonsustained but inducible ventricular tachycardia.[94] [95] Data supporting these recommendations are derived from the Antiarrhythmic Versus Implantable Defibrillator Trial[93] (AVID), the Multicenter Automatic Defibrillator Implantation Trial[94] (MADIT), and the Multicenter Unsustained Tachycardia Trial[95] (MUSTT). At this point, the major question is whether implantable defibrillators can reduce mortality in other left ventricular dysfunction or HF populations, such as patients with nonsustained and noninducible ventricular tachycardia, large numbers of premature ventricular contractions, intraventricular conduction delays, and abnormal signal-averaged electrocardiograms, or even in subjects with no evidence of electrophysiological abnormalities.

BIVENTRICULAR PACING.

One of the more interesting developments in HF is the concept that left ventricular or biventricular pacing may be beneficial in a subset of subjects with intraventricular conduction delay, which may include 30 to 50 percent of subjects with advanced left ventricular dysfunction.[96] The biventricular pacing strategy is based on the fact

that most subjects with intraventricular conduction delay have asynchronous left ventricular contraction, which results in a reduction in ventricular performance and an increase in regional wall stress.[97] There is no question that, acutely, biventricular or left ventricular pacing can, by synchronizing left ventricular contraction, improve left ventricular dP/dT, ejection fraction,[97] and cardiac index[98] ; reduce wall stress[97] ; and decrease left ventricular filling pressure.[97] [98] These favorable myocardial functional effects contribute to a short-term reduction in neurohormonal activation.[99] If these salutary effects can be sustained in the long term, biventricular pacing would be expected to improve functional capacity and clinical outcomes. Such hypotheses are being tested by the Multicenter InSync Randomized Clinical Evaluation (MIRACLE) and the Comparison of Medical Therapy, Pacing and Defibrillation in Chronic Heart Failure (COMPANION) trials.

VENTRICULAR ASSIST DEVICES (see also Chap. 19).

Ventricular assist devices have emerged as a potential treatment of chronic HF, beyond their traditional role as a bridge to transplantation. A randomized, controlled clinical trial[100] (the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure [REMATCH] Trial) to test one device is under way in patients who are not transplant eligible. This trial has, as a control group, optimal medical therapy, and the endpoints are clinically meaningful. If the left ventricular assist device proves superior to medical therapy in this stage C to D HF population and is cost-effective, mechanical device implantation will have a role in the treatment of a subset of ultraadvanced HF patients.

OTHER INVESTIGATIONAL DEVICES.

Several other devices in development may have a role in the treatment of HF. For example, external pneumatic counterpulsation, shown to be effective in treating angina,[101] may have a role in treating HF.[102] One of the more interesting approaches to preventing progressive remodeling is a device (the "Acorn" device) that physically prevents ventricular dilatation in animal models.[103] Clearly, devices of various types will increasingly contribute to HF treatment in the future.

Surgical Therapy

CARDIAC TRANSPLANTATION (see also Chap. 20).

This procedure was the first definitive treatment developed for HF, that is, the first treatment that lowered mortality.[104] The treatment is so successful in advanced or severe stage C or D HF that to this point no randomized study could have been ethically justified. The current survival of severe HF stage D subjects from the enalapril arm of the Cooperative New Scandinavian Enalapril Survival (CONSENSUS) Trial,[59] a cohort of stage C subjects from 1980 prior to ACE inhibitor treatment, is shown in Figure 47-7 . Survival after transplantation is superior to that with medical therapy. However, survival with medical therapy is improving,[52] and with another incremental improvement it will rival transplantation for outcomes in stage C patients.

The biggest limitation of cardiac transplantation is not efficacy or safety, but rather the limited supply of donors available to apply the treatment. It has been estimated that less than 10 percent of subjects who would benefit from cardiac transplantation can actually receive it on the basis of the upward limit of 2000 to 3000 donors per year in the United States.[105] Therefore, transplantation is reserved for subjects who have reached stage D or late stage C HF and are progressing despite application of all medical therapy of proven benefit.

CORONARY ARTERY BYPASS GRAFTING (see also Chap. 37).

Over 15 years ago, the Coronary Artery Surgery Study (CASS)[106] demonstrated that coronary artery bypass grafting (CABG) is superior to medical therapy from a survival standpoint in subjects with symptomatic three-vessel coronary artery disease and reduced but not severely depressed left ventricular ejection fractions (LVEFs). In recent years, the benefit of CABG has been extended to patients with LVEFs lower than the 0.35 cutoff in CASS. Many centers have successfully extended CABG therapy to stage C HF subjects with LVEFs less than 0.30,[107] [108] but no large controlled trials have compared CABG with current recommended standard medical therapy, including beta blockers. Such trials need to be conducted.

MITRAL VALVE RECONSTRUCTION IN LEFT VENTRICULAR DYSFUNCTION (see also Chap. 46).

Mitral regurgitation occurs to a greater or lesser degree in the remodeled, dilated ventricle. Recently, surgical approaches to correction of mitral regurgitation without valve replacement have been applied to the failing, remodeled ventricle with low operative mortality and impressive early clinical outcomes.[109] However, no prospective controlled/randomized studies have compared mitral valve reconstruction with the best available medical therapy, which itself can reverse remodeling.[16] Thus, the role of mitral valve reconstruction in the setting of remodeling and mitral regurgitation is somewhat unclear and at the moment should be conservatively confined to cases of severe mitral regurgitation with some preservation of left ventricular function, i.e., with ejection fractions over 0.30.

VENTRICULAR REDUCTION SURGERY.

The most controversial treatment of HF developed in recent years is ventricular reduction surgery, originally known as the Batista procedure after the surgeon who developed and popularized it.[110] This procedure involves a direct, surgical approach to reversing remodeling by simply removing a large (20 to 40 percent) amount of the left ventricle and reshaping it.[110] Later approaches have also included mitral valve reconstruction.[111] Despite the considerable initial fanfare of this approach to HF, enthusiasm quickly waned when it was appreciated that the combined rate of mortality, cardiac transplantation, or need for a left ventricular assist device was on the order of 30 percent.[111]

The basic flaw with this approach is represented in Figure 21-2 . Ventricular remodeling is caused by cardiac myocyte lengthening as part of the hypertrophic response. Much of the signaling for myocyte hypertrophy and sarcomeric assembly in series derives from myocardial dysfunction, which in most cases of primary or secondary dilated cardiomyopathy precedes the remodeling process. For example, after myocardial infarction, gradual ventricular dilatation and shape change, i.e., remodeling, take place in a subset of patients over several months to years. This response, which occurs more frequently in patients who have had a large anterior infarction, serves the compensatory role of increasing stroke volume by increasing end-diastolic volume. When a substantial amount of functioning myocardium is surgically removed, even though the ejection fraction may temporarily rise because end-diastolic volume is reduced, on average, stroke volume will not increase and may even decrease to the point of circulatory compromise in many subjects.[111] This process leads to further activation of the signaling mechanisms responsible for remodeling and myocyte dysfunction outlined in Figure 21-2 . Therefore, clinical results with ventricular reduction surgery indicate that in most patients, the bioenergetic benefit of reducing ventricular size does not outweigh the deleterious consequences of removing functioning myocardium.

The latest direct surgical approach to ventricular remodeling is to not remove functioning myocardium, but to surgically reshape the ventricle off bypass in a minimally invasive approach.[112] While this procedure is more rational than removing functioning myocardium, no controlled data have yet documented its usefulness.

Health Care Delivery Strategies

HEART FAILURE CENTERS.

The number of therapeutic options for the care of HF patients is extensive, and access to investigational agents or complex approaches limited to specialized centers, such as transplantation, are often required. Numerous outcomes studies[113] [114] [115] have documented the utility of such centers, and there is good argument[116] for federal support of such a mechanism analogous to what was done in the United States in the early 1970s for cancer. However, it must be appreciated that the majority of patients are cared for by primary care physicians rather than HF specialists or general cardiologists.[117] The sheer number of HF patients dictates that primary care physicians will continue to care for these patients, but it is likely that specialized centers will have an increasing role as treatment becomes even more complex.

HEART FAILURE CLINICS.

It is evident that a substantial and perhaps a majority of HF patients are not being optimally treated with the most basic medications, much less given more aggressive treatment options such as some of the surgical approaches described above. For example, the latest estimates on the number of HF patients being treated with ACE inhibitors are between 50 percent[118] and 71 percent,[119] whereas on the basis of what is achieved in controlled clinical trials, it should be over 90 percent.[4] [7] [8] For beta blockers, the results are even more dismal, with estimates of 5 percent of the HF population receiving therapy (Kwasha D, personal communication, 1999) as compared with the ideal figure of greater than 25 percent. Inadequate medical treatment of HF no doubt extends beyond the appropriate use of ACE inhibitors or beta blockers and probably includes failure to consistently adhere to a low-salt diet, suboptimal use of diuretics, failure to maintain digoxin levels lower than 1.0 ng/ml,

inadequate interval follow-up, and numerous other important factors.

The failure to deliver optimal medical care to HF patients is multifactorial. As for other medical conditions, optimal care includes a health care provider with knowledge and the ability to communicate that knowledge, a method of ensuring that the patient has received and understood the knowledge, a system of encouraging adherence to the recommended regimen, and patient compliance. The elderly nature of many HF patients and the incapacitating nature of the disease syndrome present special challenges to caregivers in this setting. However, many of the challenges to delivering optimal care to HF patients can be met through an integrated specialized clinic approach that uses nurse and physician extender personnel to deliver and ensure the implementation of care. This approach has been shown to reduce hospitalizations and increase the percentage of patients receiving ideal, guideline-recommended therapy.[120] The end result is lowered cost of HF treatment and probably improved survival.

The biggest challenge to this obvious solution to the delivery of HF care is how to support the additional personnel required in the "HF clinic" model. In specialized centers, the costs are usually supported by sponsored research, and in the community, some health care maintenance organizations or hospitals have seen the wisdom of this cost-reducing approach. This model will probably be adopted in direct relation to the availability of support for it, which in turn is dependent on the health care system.

Exercise

Until recently, HF patients were instructed to avoid exercise, and at one point, bed rest was offered as a treatment of HF.[121] Bed rest is no longer prescribed, and in fact, exercise now appears to be promising as a treatment of HF. It is not surprising that an exercise regimen can increase functional capacity in subjects with HF, as documented in numerous studies.[122] [123] [124] [125] [126] [127] What is surprising is that in small controlled studies, various other aspects of HF thought to be important in prognosis, such as neurohormonal activation,[122] [125] symptoms,[126] resting cardiac function,[127] and quality of life,[122] appear to be improved by exercise. What is lacking is a large, well-controlled clinical outcomes trial to test the hypothesis that moderate levels of exercise improve the natural history of HF. Until such a trial is available, it seems prudent to suggest to patients that they maintain at least some level of conditioning with mild to moderate regimens of aerobic exercise in view of the lack of evidence that such exercise is harmful and the potential beneficial effect on symptoms and individual psychology.

Treatment of Episodes of Decompensation

As discussed above, acute manifestations of HF can either be in the context of new onset or be in subjects with established chronic HF. Treatment of acute episodes of HF are similar in these two scenarios, with the exception that a diagnostic work-up potentially leading to definitive therapy should be done in new cases. Since multiple treatment modalities may be brought to bear on acute HF episodes, the discussion will be divided into pharmacological and nonpharmacological forms of therapy.

Pharmacological Therapy (see also Chap. 18)

Table 21-9 gives the standard treatment modalities typically used to treat acute episodes of HF with advanced,

TABLE 21-9 -- PHARMACOLOGICAL THERAPY FOR ACUTE, DECOMPENSATED HEART FAILURE

TREATMENT MODALITY	SPECIFIC EXAMPLES
Intravenous diuretics	Furosemide, bumetanide, torsemide
Intravenous positive inotropic agents	Dobutamine, milrinone, enoximone
Intravenous afterload reducers	Nitroprusside, nitroglycerin, brain natriuretic peptide*
Blood pressure, renal perfusion support	Intravenous dopamine

*Not yet approved in the United States.

Class IV symptoms. In general, treatment begins with intravenous diuretics, which in subjects with adequate organ perfusion often suffice to produce diuresis accompanied by a prompt drop in preload and relief of symptoms related to pulmonary edema. If peripheral perfusion is compromised or diuresis does not ensue, intravenous dobutamine, an inotropic beta/alpha-adrenergic agonist that produces an increase in cardiac output without substantially dropping preload or blood pressure,[128] can be added via a well-secured peripheral line. A PDEI such as milrinone[129] [130] or enoximone[131] [132] can also be used to treat decompensated HF, but a PDEI should not be administered without pulmonary artery pressure monitoring unless it is certain that left ventricular filling pressure is high (>16 mm Hg). The reason for this precaution is that PDEIs are such potent venodilators that in patients with normal or low filling pressure, they can drop preload to undesirably low levels. Finally, in decompensated subjects who are still receiving beta-blocking agents, a PDEI rather than a beta blocker is the treatment of choice because PDEIs retain full or even have enhanced activity in the presence of beta blockade.[133]

If the situation has not stabilized, additional inotropic support with or without supplemental afterload reduction is indicated and best delivered with the aid of pulmonary artery catheter monitoring (Table 21-10) . The combination of dobutamine and a PDEI is additive for effects on cardiac output and, via the PDEI, will produce a reduction in pulmonary artery and left ventricular filling pressure.[134] [135] The latter may provide welcome unloading of the right ventricle inasmuch as high pulmonary artery pressure can produce limiting right ventricular dysfunction in some patients.

Once optimal inotropic therapy is being delivered, pure vasodilators can be additionally administered to subjects with persistently high systemic or pulmonary vascular resistance.

TABLE 21-10 -- SUGGESTED INDICATIONS FOR HEMODYNAMIC MONITORING DURING THERAPY FOR DECOMPENSATED HEART FAILURE

PRESENCE OF HYPOPERFUSION SUSPECTED FROM :
Narrow pulse pressure
Mental obtundation
Declining renal function with high volume status
INTENSE NEUROHORMONAL ACTIVATION SUGGESTED BY :
Serum sodium below 133 mEq/L
Persistent systemic hypotension with low doses of ACE inhibitors
SYMPTOMS OF CONGESTION AT REST IN THE PRESENCE OF :
Frequent angina or other evidence of ischemia
Frequent symptomatic ventricular arrhythmias
Baseline impairment in renal function
Severe intrinsic pulmonary disease
PERSISTENT OR RECURRENT SYMPTOMS OF CONGESTION AT REST OR DURING MINIMAL EXERTION DESPITE :
Administration of high doses of loop diuretics
Addition of metolazone or hydrochlorothiazide
Salt and fluid restriction
ACE=angiotensin-converting enzyme.
Modified from Smith TW (ed): Cardiovascular Therapeutics: A Companion to Braunwald's Heart Disease. Philadelphia, WB Saunders, 1996, p 201.

Vasodilators such as nitroprusside or nitroglycerin can also be used in lieu of a positive inotropic agent, particularly in patients with higher systemic vascular resistance. In addition to more traditional vasodilators, brain natriuretic peptide is a novel, mild vasodilator with the unique property of preferentially increasing renal blood flow.[136] [137] However, brain natriuretic peptide is still undergoing clinical trials and is not yet approved by the Food and Drug Administration.

Finally, in patients with blood pressure so low that renal perfusion is compromised, dopamine may be added to increase perfusion pressure and renal blood flow via this agent's alpha-adrenergic and dopaminergic properties. However, dopamine should not be considered an effective positive inotropic agent because the majority of its weak, partial beta-agonist effect is mediated by norepinephrine release,[138] which results in tachyphylaxis within 12 hours of administration.[139]

Nonpharmacological Therapy

Table 21-11 lists some nonpharmacological therapies that can be used to treat acute episodes of HF. In general, nonpharmacological therapy is used only if drug therapy does not stabilize the patient. Although its effectiveness has never been demonstrated in a controlled clinical trial, use of an intraaortic balloon pump (IABP) can increase cardiac output modestly while increasing effective coronary perfusion pressure (see Chap. 19). This benefit and the ease of use of this device make it an attractive adjunct in myocardial failure occurring in the context of ischemia. The IABP is also helpful in nonischemic myocardial failure. However, contraindications to IABP use include significant aortic regurgitation and severe peripheral vascular disease. If pharmacological therapy plus IABP does not stabilize the patient, a ventricular assist device should be used in selected individuals, as discussed in Chapter 19 .

Because of the success of treating acute myocardial infarction by primary angioplasty[140] with stenting [141] (see Chap. 35), percutaneous coronary intervention techniques (see Chap. 38) have assumed an important role in treating the most common cause of new-onset acute HF, that arising in the setting of myocardial infarction. In general, the primary goal of treating myocardial failure in the setting of infarction is to establish and maintain patency of the infarct artery in the most expeditious manner possible. The catheterization laboratory is also an ideal setting in which to initiate adjunctive treatment such as an IABP, mechanical ventilation, and optimal pharmacological support guided by hemodynamic monitoring. Other catheterization techniques used in acute HF treatment include pericardiocentesis for tamponade (see Chap. 50) and relief of severe mitral stenosis by balloon valvuloplasty (see Chap. 46) (see Table 21-11).

Occasionally, urgent cardiac surgery is required for the treatment of acute HF. As outlined in Table 21-11 , these procedures include CABG in acute ischemic disorders involving left main disease or in patients in whom percutaneous coronary intervention is not a technical option, acute aortic or mitral valve surgery, and on rare occasion, transplantation. In general, it is neither desirable nor feasible to perform cardiac transplantation on someone during their initial experience with HF.

TABLE 21-11 -- NONPHARMACOLOGICAL THERAPY FOR ACUTE, DECOMPENSATED HEART FAILURE

TREATMENT MODALITY	SPECIFIC EXAMPLES
Oxygenation	Supplemental oxygen, mechanical ventilation
Balloon counterpulsation	Intraaortic balloon pump
Ventricular assist device	Pulsatile-flow LVAD
Pacing	AV sequential pacemaker
Urgent cardiac catheterization	PTCA, mitral valvuloplasty, pericardiocentesis
Urgent cardiac surgery	CABG, AVR, MV repair or replacement, transplantation

AV=atrioventricular; AVR=aortic valve replacement; CABG=coronary artery bypass grafting; LVAD=left ventricular assist device; MV=mitral valve; PTCA=percutaneous transluminal coronary angioplasty.

Investigational Treatment and Future Directions

In the last 10 years, major progress has been made in the medical treatment of HF. In mild to moderate stage B HF, the use of ACE inhibitors and beta-adrenergic blocking agents has reduced mortality by nearly 50 percent.[52] The degree of the remaining challenge and the size of the pharmaceutical market will ensure that medical therapy will continue to improve for all degrees of HF. However, to attain such progress, subjects with HF will need to continue to be enrolled in investigational protocols, typically available at larger, well-organized HF centers. In addition, left ventricular assist devices will continue to become more practical and economical and will probably soon become standard treatment of advanced HF in selected individuals.

GUIDELINES
MANAGEMENT OF HEART FAILURE

Thomas H. Lee

Heart failure guidelines were published by the Agency for Health Care Policy and Research (AHCPR) in 1994,[1] by an American College of Cardiology/American Heart Association (ACC/AHA) task force in 1995,[2] and by a task force of the Heart Failure Society of America in 1999.[3] These guidelines preceded research on new strategies for heart failure, such as beta-blockers, spironolactone, angiotensin receptor blockers, and left ventriculoplasty, and therefore do not comment on their role. The guidelines are consistent and, in some ways, complementary. The ACC/AHA guidelines contain detailed information on management of acute syndromes, such as cardiogenic shock. In contrast, a focus of the AHCPR guidelines is improving care by reducing common errors in diagnosis and chronic management.

Among the common errors in management and testing cited by the AHCPR panel are

- Overuse of testing technologies
- Inadequate treatment of coexistent hypertension
- Inadequate education for patient, family, and caregivers
- Inappropriate treatment of heart failure not due to systolic dysfunction
- Suboptimal patient involvement in care and compliance
- Delayed referral for transplantation
- Underutilization of exercise prescriptions
- Underutilization of angiotensin-converting enzyme (ACE) inhibitors
- Inadequate dosing of diuretics in patients with persistent volume overload
- Failure of clinicians to appreciate adverse effects of medications

To reduce the frequency of these errors, the AHCPR panel formulated recommendations for a wide range of topics (excerpted in Table 21-G-1). [1] The multidisciplinary group that developed these guidelines used an A-B-C system to grade the strength of evidence in support of their recommendations. The focus of the AHCPR guidelines were patients with left ventricular systolic dysfunction leading to volume overload or inadequate tissue perfusion, but one of their most specific recommendations was aimed at preventing this syndrome: The guidelines recommend use of ACE inhibitors in patients with moderately or severely reduced left ventricular systolic function even if they are asymptomatic.

TABLE 21--G-1 -- SELECTED RECOMMENDATIONS FROM GUIDELINES FOR HEART FAILURE

Topic	Recommendation	Strength of Evidence
Prevention in asymptomatic patients	Asymptomatic patients with moderately or severely reduced left-ventricular systolic function (ejection fraction <35--40 percent) should be treated with an angiotensin-converting enzyme (ACE) inhibitor to reduce the chance of developing clinical heart failure.	A
Initial evaluation	Patients with symptoms that are highly suggestive of heart failure should undergo echocardiography or radionuclide ventriculography to measure left ventricular function even if physical signs of heart failure are absent.	C
Diagnostic testing	Practitioners should perform a chest x-ray; electrocardiography (ECG); complete blood count (CBC); serum electrolytes, serum creatinine, serum albumin, liver function tests; and urinalysis for all patients with suspected or clinically evident heart failure. A T4 and thyroid-stimulating hormone (TSH) level should also be checked in all patients over the age of 65 with heart failure and no obvious etiology and in patients who have atrial fibrillation or other signs of symptoms of thyroid disease. Routine use of myocardial biopsy is not recommended.	C
Screening for arrhythmias	Screening evaluation for arrhythmias such as ambulatory ECG is not routinely warranted.	A
Hospital admission criteria	Presence of suspicion of heart failure and any of the following findings usually indicates a need for hospitalization: Clinical or ECG evidence of acute myocardial ischemia. Pulmonary edema or severe respiratory distress. Oxygen saturation below 90 percent (not due to pulmonary disease). Severe complicating medical illness (e.g., pneumonia). Anasarca. Symptomatic hypotension or syncope. Heart failure refractory to outpatient therapy. Inadequate social support for safe outpatient management	C

Hospital discharge criteria	Patients with heart failure should be discharged from the hospital only when: Symptoms of heart failure have been adequately controlled. All reversible causes of morbidity have been treated or stabilized. Patients and caregivers have been educated about medications, diet, activity and exercise recommendations, and symptoms of worsening heart failure. Adequate outpatient support and follow-up care have been arranged.	C
Activity recommendations	Regular exercise should be encouraged for all patients with stable NYHA Class I-III heart failure.	B
Cardiac rehabilitation	There is insufficient evidence at this time to recommend the routine use of supervised rehabilitation programs for patients with heart failure.	C
Diet	Dietary sodium should be restricted to as close to 2 grams per day as possible.	C
	People who drink alcohol should be advised to consume no more than one drink per day.	C
Discussion of prognosis	All patients should be encouraged to complete a durable power of attorney for health care or another form of advanced directive.	N/A
Initial pharmacological management	Patients with heart failure and signs of significant volume overload should be started immediately on a diuretic. Patients with mild volume overload can be managed adequately on thiazide diuretics, whereas those with more severe volume overload should be started on a loop diuretic.	C
ACE inhibitors	Patients with heart failure due to left-ventricular systolic dysfunction should be given a trial of ACE inhibitors unless specific contraindications exist: (1) history of intolerance or adverse reactions to these agents, (2) serum potassium greater than 5.5 mEq/liter that cannot be reduced, or (3) symptomatic hypertension. Patients with systolic blood pressure less than 90 mm Hg have a higher risk of complications and should be managed by a physician experienced in utilizing ACE inhibitors in such patients. Caution and close monitoring are also required for patients who have a serum creatinine level greater than 3.0 mg/dL or an estimated creatinine clearance of less than 30 mL/min; half the usual dose should be used in this setting.	B
Digoxin	Digoxin should be used routinely in patients with severe heart failure and should be added to the medical regimen of patients with mild or moderate heart failure who remain symptomatic after optimal management with ACE inhibitors and diuretics.	C
Hydralazine/isosorbide dinitrate	Isosorbide dinitrate and hydralazine is an appropriate alternative in patients with contraindications for intolerance to ACE inhibitors.	B
Anticoagulation	Routine anticoagulation is not recommended.	C
Patient follow-up	Patients should be instructed to call if they experience an unexplained weight gain greater than 3--5 pounds since their last clinical evaluation.	C

Strength of Evidence: A = strongest, B = intermediate; C = weakest on consensus of expert opinion.

From Konstam M, Dracup K, Baker D, et al: Heart Failure: Evaluation and Care of Patients with Left-Ventricular Systolic Dysfunction. Clinical Practice Guidelines No. 11. AHCPR Publication No. 94-0612. Rockville, MD, Agency for Health Care Policy and Research, NHLBI Public Health Service, U.S. Department of Health and Human Services, June 1994.

INITIAL EVALUATION

The AHCPR guidelines identify symptoms that should trigger consideration of an evaluation for heart failure, the most critical of which are paroxysmal nocturnal dyspnea, orthopnea, or new-onset dyspnea on exertion. Unless the patient has clear evidence of a noncardiac cause for these symptoms, the AHCPR guidelines indicate that echocardiography or radionuclide ventriculography should be used to evaluate left ventricular function, even if physical signs of heart failure are not present. Other symptoms that suggest this diagnosis are lower extremity edema, decreased exercise tolerance, unexplained confusion or fatigue, and abdominal symptoms associated with ascites, hepatic engorgement, or both.

Similar recommendations are given for tests in the initial evaluation of heart failure in both the AHCPR and the ACC/AHA guidelines (Table 21-G-2); also see Table 21-G-1). The goals of this testing include assessment of severity and identification of causes of the myocardial dysfunction. However, both sets of guidelines emphasize that screening evaluation, such as ambulatory electrocardiography, for arrhythmias should not be performed routinely for all patients with heart failure; instead, this test should be reserved for patients with histories of syncope, near syncope, or other symptoms suggestive of arrhythmia.

One arrhythmia that may be *undertreated* in this population is atrial fibrillation. The AHCPR guidelines recommend attempting cardioversion for patients with left atrial diameters less than 50 mm and with less than a 1-year history of atrial fibrillation. No recommendations are offered on the drug of choice, although the guidelines comment that amiodarone may emerge as the preferred agent. The ACC/AHA guidelines do not address this issue.

Routine use of myocardial biopsy is not supported by either set of guidelines because of a lack of evidence that the information from this procedure leads to improved management or outcomes.

INPATIENT AND OUTPATIENT MANAGEMENT

The AHCPR guidelines give specific criteria for admission to the hospital and also offer standards for outcomes to be achieved before patients with heart failure are discharged to home (see Table 21-G-1). These recommendations reflect the importance of discharge planning and an adequate system of outpatient care, including patient and family education and counseling. Many of these interventions, such as support groups, have not been part of the traditional focus of physicians; hence, these guidelines imply close collaboration of a team of providers for patients with heart failure. Among the topics for patient education specifically cited are

Nature of heart failure

Drug regimens

Dietary restrictions

What to do if symptoms occur

Prognosis

Completion of advanced directives

Smoking and chewing of tobacco

Importance of influenza and pneumococcal vaccination

Sexual activity

Alcohol use

Regular physical activity programs are recommended for all patients except those with New York Heart Association (NYHA) Class IV heart failure, but the guidelines do not explicitly endorse the use of cardiac rehabilitation programs for all patients with heart failure.

MANAGEMENT

Both the AHCPR and the ACC/AHA guidelines provide a strong endorsement of the use of ACE inhibitors for patients with left ventricular systolic dysfunction in the absence of specific contraindications (see Tables 21-G-1 and 21-G-2) and make recommendations regarding several other medications. Diuretic use for patients with signs of volume overload should be immediate, according to the guidelines, which also suggest that patients with mild volume overload can be managed adequately on thiazide diuretics, which cause less acute diuresis than does furosemide. For patients without volume overload, ACE inhibitors may be considered as the sole initial therapy. The prominent roles of ACE inhibitors and diuretics in the AHCPR guidelines are reflected in its flowsheet summarizing pharmacological management.

TABLE 21--G-2 -- ACC/AHA GUIDELINES FOR MANAGEMENT OF CONGESTIVE HEART FAILURE

INDICATION	CLASS I (INDICATED)	CLASS II (PROBABLY/POSSIBLY INDICATED)	CLASS III (NOT INDICATED)
Initial Diagnostic Evaluation of Acute Pulmonary Edema	1. Focused history/physical examination 2. Twelve-lead ECG 3. Continuous ECG monitoring 4. Blood--serum studies: complete blood count (CBC); electrolytes, blood urea nitrogen (BUN), creatinine and cardiac enzyme levels 5. Digital pulse oximetry/arterial blood gases 6. Chest radiography 7. Transthoracic Doppler--two-dimensional echocardiography 8. Cardiac catheterization/coronary arteriography for suspected coronary artery disease (1) if acute intervention for myocardial injury/infarction is anticipated; (2) to determine the cause(s) of refractory acute pulmonary edema	1. Indwelling arterial cannula 2. Transesophageal echocardiography 3. Tabulation of fluid volume intake and urine output	1. Extensive evaluation (e.g., cardiac catheterization and coronary arteriography) in a patient with a concomitant terminal illness or who would not be considered a candidate for the necessary major cardiovascular intervention
Therapeutic Management of Acute Pulmonary Edema	1. Oxygen therapy 2. Nitroglycerin, sublingually or intravenously 3. Intravenous administration of a diuretic (e.g., furosemide) 4. Morphine sulfate 5. Administration of cardiovascular support drugs to attain and stablize clinical-hemodynamic status (e.g., intravenous infusion of nitroprusside, dobutamine, dopamine) 6. Thrombolytic therapy or urgent revascularization (angioplasty or coronary artery bypass surgery) for acute myocardial injury/farction 7. Intubation and mechanicaSl ventilation for severe hypoxia that does not respond rapidly to therapy and for respiratory acidosis 8. Definitive correction of the underlying cause (e.g., mitral valve replacement or repair of acute severe mitral regurgitation) when indicated and clinically feasible		
Initial Diagnostic Evaluation of Cardiogenic Shock/Near Shock	1. Focused history--physical examination 2. Twelve-lead ECG (plus occasional right-sided leads) 3. Continuous ECG monitoring 4. Blood--serum studies; complete blood count, platelet count, clotting studies, electrolytes, BUN, creatinine, glucose, and cardiac and liver enzymes 5. Arterial blood gases and lactate concentration 6. Chest radiograph 7. Transthoracic Doppler--two-dimensional echocardiography 8. Indwelling arterial cannula for continuous monitoring of systemic blood pressure and for arterial blood gas sampling 9. Tabulation of fluid volume intake, urine output, and other fluid volume loss 10. Cardiac catheterization/coronary arteriography if acute revascularization for acute myocardial injury/infarction is anticipated	1. Transesophageal echocardiography	1. Extensive evaluation in a patient with a concomitant terminal illness or who is not a candidate for cardiovascular intervention

Therapeutic Management of Cardiogenic Shock/Near Shock	1. Oxygen therapy 2. In the absence of obvious intravascular volume overload, brisk intravenous administration of fluid volume 3. In the presence of intravascular volume overload or after adequate intravenous fluid volume therapy, intravenous administration of cardiovascular support drugs (e.g., dopamine, dobutamine, norepinephrine) to attain and maintain stable clinical-hemodynamic status 4. Urgent coronary artery revascularization for acute myocardial injury/infarction, if readily available	1. Thrombolytic therapy in the setting of acute myocardial injury/infarction if a cardiac catheterization/coronary arteriography/revascularization procedure is not readily available 2. Ventricular assist device in patients who respond inadequately to the aforementioned interventions and who are reasonable candidates for heart transplantation	1. Extensive evaluation and major intervention in patients with a concomitant terminal illness, those afflicted with an irreversible underlying cause, or those who are not candidates of corrective intervention or heart transplantation
Recommendations for Intraaortic Balloon Counterpulsation in Heart Failure	1. Cardiogenic shock, pulmonary edema and other acute heart failure conditions not responding to the proper administration of fluid volume or pharmacological therapy, or both, in patients with potentially reversible heart failure or as a bridge to heart transplantation 2. Acute heart failure accompanied by refractory ischemia, in preparation for cardiac catheterization/coronary arteriography and definitive intervention 3. Acute heart failure complicated by significant mitral regurgitation of rupture of the ventricular septum, to obtain hemodynamic stabilization for definitive diagnostic studies or intervention, or both	1. Progressive, chronic heart failure, if necessary to allow for a proper diagnostic approach, time to consider treatment options and definitive intervention (e.g., cardiac surgery, heart transplantation)	1. Significant aortic insufficiency 2. Aortic dissection 3. Patients unresponsive to therapy in whom the cause is known to be uncorrectable or irreversible and who are not candidates for transplantation 4. Patients in the end stage of a terminal illness 5. Bleeding diathesis or severe thrombocytopenia
Recommendations for Placement of Pulmonary Artery Balloon Catheter in Heart Failure	1. Cardiogenic shock or near shock that does not respond promptly to the proper administration of fluid volume 2. Acute pulmonary edema that does not respond to appropriate intervention or is complicated by systemic hypotension or shock/near shock 3. As a diagnostic tool to resolve any uncertainty of whether pulmonary edema is cardiogenic or noncardiogenic in origin	1. Assessment of the status of intravascular volume, ventricular filling pressures, and overall cardiac function in a patient whose decompensated chronic heart failure is not responding appropriately to standard therapy 2. Evaluation of overall cardiachemodynamic status and exclusion of left heart failure in a patient with decompensated chronic lung disease 3. As a diagnostic tool to assess the origin and clinical and hemodynamic significance of a new systolic murmur in acute heart failure	1. As a routine approach to the assessment, diagnosis, or treatment of heart failure
Recommended Routine Diagnostic Studies for Adult Patients With Chronic Heart Failure or Stabilized Acute Heart Failure Not Previously Performed	1. CBC and urinalysis 2. Blood--serum: electrolytes, BUN, creatinine, glucose, phosphorus, magnesium, calcium and albumin levels 3. Thyroid-stimulating hormone levels in patients with atrial fibrillation and unexplained heart failure 4. Chest radiograph and ECG 5. Transthoracic Doppler--two-dimensional echocardiography 6. Noninvasive stress testing to detect ischemia in patients without angina but with a high probability of coronary artery disease who would be candidates for revascularization 7. Noninvasive testing to detect ischemia and assess myocardial viability or coronary arteriography in patients with a previous infarction but with no angina who would be candidates for revascularization 8. Cardiac catheterization/coronary arteriography in patients with angina or large areas of ischemic or hibernating myocardium; also in patients at risk for coronary artery disease who are to undergo surgical correction of noncoronary cardiac lesions	1. Serum iron and ferritin 2. Noninvasive stress testing to detect ischemia in all patients with unexplained heart failure who are potential candidates for revascularization 3. Coronary arteriography in all patients with unexplained heart failure who are potential candidates for revascularization 4. Endomyocardial biopsy in patients (a) with recent onset of rapidly deteriorating cardiac function or other clinical indications of myocarditis; (b) receiving chemotherapy with Adriamycin or similar myocardial toxic agents; (c) with a systemic disease and possible cardiac involvement (hemochromatosis, sarcoid, amyloid, Loeffler endocarditis, endomyocardial fibroelastosis) 5. Thyroid-stimulating hormone levels in patients with sinus rhythm and unexplained heart failure	1. Repeat cardiac catheterization/coronary arteriography or stress testing in patients in whom coronary artery disease as a cause of left ventricular dysfunction has been excluded previously and no objective evidence of intercurrent ischemia or infarction has occurred 2. Endomyocardial biopsy in the routine evaluation of patients with chronic heart failure 3. Multiple echocardiographic or radionuclide studies in the routine follow-up of patients with heart failure responding to therapy 4. Routine Holter monitoring or signal-averaged electrocardiography 5. Cardiac catheterization/coronary arteriography in patients who are not candidates for revascularization, valve surgery, or heart transplantation
Recommendations for Assessment of Functional Capacity in Heart Failure	1. Patient interview or questionnaire at each clinic visit 2. Exercise testing, usually with respiratory gas analysis, to determine potential candidacy for heart transplantation	1. Exercise testing to more definitively assess functional capacity and symptomatic limitations in patients in whom a disparity exists between symptoms expressed and clinical assessment 2. Exercise testing to address specific clinical questions and issues. Examples include: (a) ventricular rate changes and control during atrial fibrillation or after pacemaker placement; (b) blood pressure control in a patient with heart failure with a history of hypertension; (c) exercise-induced arrhythmias; (d) quantitative evaluation of degree of disability; and (e) assessing a change in functional capacity or response to therapy	1. Exercise testing as a routine serially performed procedure following chronic ventricular dysfunction that is clinically stable, unless used to assess candidacy

Pharmacologic Treatment of Left Ventricular Systolic Dysfunction	1. ACE inhibitors for all patients with significantly reduced left ventricular ejection fraction unless contraindicated 2. Hydralazine and isosorbide dinitrate in patients who cannot take ACE inhibitors 3. Digoxin in patients with heart failure due to systolic dysfunction not adequately responsive to ACE inhibitors and diuretic drugs 4. Digoxin in patients with atrial fibrillation and rapid ventricular rates 5. Diuretic drugs for patients with fluid overload 6. Anticoagulation in patients with atrial fibrillation, or a previous history of systemic or pulmonary embolism 7. Beta blockers for high-risk patients after an acute myocardial infarction	1. 1. Digoxin for all patients with heart failure due to left ventricular systolic dysfunction 2. Addition of hydralazine and isosorbide dinitrate for patients who do not respond adequately to ACE inhibitors 3. Beta blockers for patients with dilated cardiomyopathy 4. Anticoagulation in patients with sinus rhythm with a very low eject fraction or intracardiac thrombi 5. Outpatient low-dose dobutamine infusion for refractory heart failure	1. Calcium channel blockers in the absence of coexistent angina or hypertension 2. Treatment of asymptomatic ventricular arrhythmias
Pharmacologic Treatment of Left Ventricular Diastolic Dysfunction	1. Diuretic drugs 2. Nitrates 3. Drugs suppressing AV conduction to control ventricular rate in patients with atrial fibrillation 4. Anticoagulation in patients with atrial fibrillation or previous systemic or pulmonary embolization	1. Calcium channel blockers 2. Beta blockers 3. ACE inhibitors 4. Anticoagulation in patients with intracardiac thrombus	1. Drugs with positive inotropic effect in the absence of systolic dysfunction 2. Treatment of asymptomatic arrhythmias
Recommendations for Hospital Admission of Patients with Heart Failure	1. Patients experiencing moderate to severe heart failure for the first time 2. Patients with recurrent heart failure complicated by acutely threatening events of clinical situations (e.g., recent myocardial ischemia/infarction, acute pulmonary edema, hypotension, pulmonary or systemic embolus, symptomatic arrhythmias, or other severe medical illnesses)	1. Mild to moderate decompensation of chronic heart failure 2. Patients experiencing mild heart failure for the first time	

From Williams JF Jr, Hlatky MA, Bristow MR, et al: Guidelines for the Evaluation and Management of Heart Failure. Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Evaluation and Management of Heart Failure). J Am Coll Cardiol 26:1376--1398, 1996.

ECG = electrocardiogram; ACE = angiotensin-converting enzyme.

The guidelines also support use of digoxin, despite the uncertainty regarding its impact on mortality.[4] [5] [6] Because of data demonstrating that digoxin can improve physical function and decrease symptoms in at least some patients with heart failure, the guidelines recommend that it be used routinely for patients with severe heart failure and added to the regimen of patients with mild or moderate heart failure that remain symptomatic despite the use of diuretics and ACE inhibitors.

The AHCPR task force concluded that anticoagulation was not justifiable as part of routine therapy for heart failure but should be reserved for patients with thromboembolic disease, atrial fibrillation, or mobile left ventricular thrombi. The guidelines also do not clearly support use of beta-adrenergic blockers, despite the promising findings from studies. This recommendation can be expected to change in future revisions.

Revascularization of ischemic myocardium either by percutaneous transluminal coronary angioplasty (PTCA) or by coronary artery bypass grafting (CABG) does not directly improve heart failure in most patients, but this strategy can improve survival, inasmuch as patients with severe coronary disease and left ventricular dysfunction have a poor prognosis with medical therapy alone. Therefore, the guidelines support performance of coronary angiography in patients with heart failure and with exercise-limiting angina, rest angina, or recurrent episodes of acute pulmonary edema.

Should left ventricular function be irreversibly and severely damaged, patients may be considered for cardiac transplantation. The AHCPR guidelines do not provide recommendations for the evaluation of this patient population.

OUTCOMES ASSESSMENT AND FOLLOW-UP

The most important judge of whether therapeutic interventions have led to improvement is the patient, not a noninvasive test. Therefore, the AHCPR guidelines emphasize the importance of follow-up of patient data such as physical functioning, mental health, sexual function, and ability to perform usual work and social activities. Between visits to their physicians, patients should keep track of their own weights, and contact their provider if their weight goes up more than 3 to 5 pounds.

More recent guidelines for management of heart failure that reflect findings from randomized trials in the late 1990s were published by the Heart Failure Society of America (HFSA) in 1999.[3] These guidelines focus on issues related to the use of pharmaceutical agents and use the same approach for evaluating the strength of evidence in support of recommendations (A, B, and C).

BETA ADRENERGIC BLOCKERS

The most prominent differences in the HFSA statement in comparison with prior guidelines are regarding use of beta-adrenergic receptor blockers. Whereas the AHCPR and ACC/AHA guidelines consider this strategy experimental, the HFSA statement recommends that beta-blocker therapy be *routinely administered to stable patients with left ventricular systolic dysfunction and mild-to-moderate symptoms* and considered for asymptomatic patients. The guidelines recommend that physicians initiate beta blockers cautiously, and this therapy is not endorsed in patients with symptoms of heart failure at rest.

The HFSA guidelines acknowledge some unresolved therapeutic issues related to use of beta blockers in patients with heart failure. These issues include the safety of combining beta-blocking agents with amiodarone therapy, because both may induce bradycardia; implantation of cardiac pacemakers to provide protection from symptomatic bradycardia; and whether therapy with beta blockers should be continued indefinitely.

DIGOXIN

Use of digoxin for patients with symptomatic heart failure is endorsed by the HFSA guidelines, which reflects evidence of efficacy from trials unavailable to committees developing prior guidelines.[4] [5] [6] [7] Evidence for digoxin's use is considered stronger for patients with NYHA Classes II and III (strength of evidence=A) than for NYHA Class IV patients (strength of evidence=C). The HFSA committee recommends dosages of digoxin of 0.125 to 0.25 mg per day in most patients without use of a loading dose. (Patients with abnormal renal function should begin on 0.125 mg per day.) Higher dosages for patients with atrial fibrillation are not supported; instead, if necessary, rate control should be achieved with amiodarone or beta-blocker therapy.

WARFARIN

The HFSA guidelines[3] support use of warfarin therapy for anticoagulation in patients with heart failure and atrial fibrillation who do not have contraindications, and they urge consideration of warfarin for patients with a left ventricular ejection fraction of 35% or less. The committee did not consider evidence for potentially negative interactions between ACE inhibitors and acetylsalicylic acid sufficiently strong to advise against their use in combination.

ANGIOTENSIN II RECEPTOR BLOCKERS

The HFSA committee emphasized that angiotensin II receptor blockers (ARBs) were not first-line therapies for heart failure and that ACE inhibitors should be used if at all possible. The guidelines indicate that the strength of evidence supporting ARBs as an alternative to ACE inhibitors is less than that for use of the combination of hydralazine and isosorbide dinitrate. The impact of combined use of ACE inhibitors and ARBs was considered an unresolved issue.

ANTIARRHYTHMIC THERAPY

For patients with life-threatening ventricular arrhythmias, implantable cardioverter defibrillators were recommended. Amiodarone therapy was not recommended for primary prevention of sudden death in patients with heart failure except in patients who were not candidates for implantable cardioverter-defibrillators. However, amiodarone was considered the preferred drug for supraventricular tachycardia not controlled with digoxin or beta blockers.

OTHER

The HFSA guidelines were able to reflect the results of the Randomized Aldactone Evaluation Study trial[8] and recommended that spironolactone be considered for patients with severe heart failure. Cautions regarding the danger of hyperkalemia are included in the recommendations.

Finally, these guidelines do not support use of immunosuppressive therapy for patients with myocarditis.

Chapter 22 - Genesis of Cardiac Arrhythmias: Electrophysiological Considerations

MICHAEL RUBART
DOUGLAS P. ZIPES

ANATOMY OF THE CARDIAC CONDUCTION SYSTEM

Sinus Node

In humans, the sinus node is a spindle-shaped structure composed of a fibrous tissue matrix with closely packed cells. It is 10 to 20 mm long, 2 to 3 mm wide, and thick, tending to narrow caudally toward the inferior vena cava. It lies less than 1 mm from the epicardial surface, laterally in the right atrial sulcus terminalis at the junction of the superior vena cava and right atrium (Figs. 22-1 and 22-2). The artery supplying the sinus node branches from the right (55 to 60 percent of the time) or the left circumflex (40 to 45 percent) coronary artery and approaches the node from a clockwise or counterclockwise direction around the superior vena caval-right atrial junction.

CELLULAR STRUCTURE.

Cell types in the sinus node include nodal cells, transitional cells, and atrial muscle cells. *Nodal cells,* also called "P cells" and thought to be the source of normal impulse formation, are small (5 to 10 mum), ovoid, primitive-appearing cells with relatively few organelles, mitochondria, and myofibrils. They are grouped in elongated clusters located centrally in the sinus node. No transverse tubular system exists. Contact between nodal cells appears to occur via nexus connections.

TRANSITIONAL CELLS.

Also known as "T cells," these elongated cells are intermediate in size and complexity between nodal cells and atrial muscle cells. T cells near nodal cells have simple intercellular connections, while more fully developed intercalated discs exist between T cells and atrial myocardium. Since nodal cells make contact only with each other or T cells, the latter may provide the only functional pathway for distribution of the sinus impulse formed in the nodal cells to the rest of the atrial myocardium.

ATRIAL MYOCARDIAL CELLS.

These cells extend as peninsulas into the nodal boundaries, with overlapping zones of sinus and atrial cells most prominent on the nodal surface that abuts the crista terminalis.

GAP JUNCTIONS.

Gap junctional channels (see p. 669) formed by connexin 45, 43, and 40, depending on the species and tissue type, electrically couple sinus node cells and probably account for their synchronized electrical activity.[1] [2] [3] [4] [5] [14A] [43A] [43B] [48A] [154A] [157A] [157B] [159A] The relative paucity and small size of gap junctions may account for slow conduction in the sinus node.[3] Few gap junctions may be required for frequency entrainment.[4] Although most gap junctions contain connexin 40, 43, and 45, the sinus and atrioventricular (AV) nodes are virtually devoid of connexin 43 but contain connexin 40 and connexin 45.[5] [6] [7] [61A] Abnormalities in gap junctions can cause arrhythmias.[8]

FUNCTION.

Very probably, no single cell in the sinus node serves as *the* pacemaker. Rather, sinus nodal cells function as electrically coupled oscillators that discharge synchronously because of mutual entrainment. Thus, faster-discharging cells are slowed by cells firing more slowly, while they themselves are sped so that a "democratically derived" discharge rate occurs.[9] In humans, sinus rhythm may result from impulse origin at widely separated sites, with two or three individual wavefronts created that merge to form a single, widely disseminated wavefront.[10] Modulated parasystole can occur.[9]

Figure 22-1 The human sinus node. This photograph, taken in the operating room, shows the location of the normal cigar-shaped sinus node along the lateral border of the terminal groove at the superior vena cava-atrial junction *(arrowheads)*. (From Anderson RH, Wilcox BR, Becker AE: Anatomy of the normal heart. *In* Hurst JW, Anderson RH, Becker AE, Wilcox BR [eds]: Atlas of the Heart. New York, Gower, 1988, p 1.2.)

Figure 22-2 Histological section taken at right angles to the cigar-shaped sinus node shows how in short axis, the node is a wedge-shaped structure located between the wall of the superior vena cava and the terminal crest. Discrete boundaries between the sinus node and atrial muscle are noted *(arrowheads)*. The node is penetrated by the sinus nodal artery. (From Anderson RH, Wilcox BR, Becker AE: Anatomy of the normal heart. *In* Hurst JW, Anderson RH, Becker AE, Wilcox BR [eds]: Atlas of the Heart. New York, Gower, 1988, p 1.2.)

INNERVATION.

The sinus node is richly innervated with postganglionic adrenergic and cholinergic nerve terminals.[11] [12] [13] [14] [14A] [15] [16] [154A] [157A] [157B] [159A] Discrete vagal efferent pathways innervate both the sinus and AV regions of the dog and nonhuman primate. Most efferent vagal fibers to the atria appear to converge first at a single fat pad that is located between the medial portion of the superior vena cava and the aortic root, superior to the right pulmonary artery; the fibers then project onto two other fat pads found at the inferior vena cava-left atrial junction and the right pulmonary vein-atrial junction and subsequently project to both atria. Vagal fibers to the sinus and AV nodes also converge at the superior vena cava-aortic root fat pad before projection to the right pulmonary vein and inferior vena cava fat pads.[17] The concentration of norepinephrine is two to four times higher in atrial than in ventricular tissue in canine and guinea pig hearts. Although the sinus nodal region contains amounts of

norepinephrine equivalent to those in other parts of the right atrium, acetylcholine, acetylcholinesterase, and choline acetyltransferase (the enzyme necessary for the synthesis of acetylcholine) have all been found in greatest concentration in the sinus node, with the next highest concentration in the right and then the left atrium. The concentration of acetylcholine in the ventricles is only 20 to 50 percent of that in the atria.

Vagal stimulation, by releasing acetylcholine, slows the sinus nodal discharge rate and prolongs intranodal conduction time, at times to the point of sinus nodal exit block. Acetylcholine increases and norepinephrine decreases refractoriness in the center of the sinus node. Adrenergic stimulation speeds the sinus discharge rate. The phase (timing) in the cardiac cycle at which vagal discharge occurs and the background sympathetic tone importantly influence vagal effects on the sinus rate and conduction (see below). The negative chronotropic effects of acetylcholine are due to inhibition of the hyperpolarization-activated pacemaker current I_f ,[18] [19] [20] [21] [22] probably mediated by a G protein (see Chap. 14) . Acetylcholine also activates the muscarinic m_2 receptor in the pacemaker cell. The activated receptor in turn activates a specific G protein (G_1) that activates the K channel ($I_{K.G}$), which also modulates the discharge rate.[23] The m_2 receptor also inhibits adenylate cyclase via G_1 to antagonize adrenergic effects on the sinus node. After cessation of vagal stimulation, sinus nodal automatically may accelerate transiently (postvagal tachycardia).

INTERNODAL AND INTRAATRIAL CONDUCTION

Whether impulses travel from the sinus to the AV node over preferentially conducting pathways has been contested. Anatomical evidence has been interpreted to indicate the presence of three intraatrial pathways. The *anterior internodal pathway* begins at the anterior margin of the sinus node and curves anteriorly around the superior vena cava to enter the anterior interatrial band, called the *Bachmann bundle.* This band continues to the left atrium, with the anterior internodal pathway entering the superior margin of the AV node. the *Bachmann bundle* is a large muscle bundle that appears to conduct the cardiac impulse preferentially from the right to the left atrium. The *middle internodal tract* begins at the superior and posterior margins of the sinus node, travels behind the superior vena cava to the crest of the interatrial septum, and descends in the interatrial septum to the superior margin of the AV node. The *posterior internodal tract* starts at the posterior margin of the sinus node and travels posteriorly around the superior vena cava and along the crista terminalis to the eustachian ridge and then into the interatrial septum above the coronary sinus, where it joins the posterior portion of the AV node. Some fibers from all three tracts bypass the crest of the AV node and enter its more distal segment. These groups of internodal tissue are best referred to as *internodal atrial myocardium,* not tracts, because they do not appear to be histologically discrete specialized tracts, only plain atrial myocardium.

Preferential internodal conduction, i.e., more rapid conduction velocity between the nodes in some parts of the atrium than in other parts, does exist and may be due to fiber orientation, size, geometry, or other factors rather than to specialized tracts located between the nodes. Importantly, the atrial anterosuperior and posteroinferior inputs or approaches to the AV node may be the anatomical substrates constituting the fast and anterograde slow pathways of AV nodal reentry, the upper end of the retrograde fast pathway being located at the apex of the Koch triangle, near the His bundle, and the upper end of the anterograde pathway being located near the coronary sinus os.[24] [25] [26] The term "*triangle of Koch,*" however, has to be used with caution since recent histological studies of anatomically normal adult hearts demonstrated that the tendon of Todaro, which forms one side of the triangle of Koch, is absent in about two-thirds of hearts.[27]

The Atrioventricular Junctional Area and Intraventricular Conduction System

The normal AV junctional area (Figs. 22-3 and 22-4) can be divided into distinct regions: the transitional cell zone,

Figure 22-3 Photograph of a normal human heart showing the anatomical landmarks of the triangle of Koch. This triangle is delimited by the tendon of Todaro superiorly, which is the fibrous commissure of the flap guarding the openings of the inferior vena cava and coronary sinus, by the attachment of the septal leaflet of the tricuspid valve inferiorly, and by the mouth of the coronary sinus at the base. The stippled area adjacent to the central fibrous body is the approximate site of the compact atrioventricular node. (From Janse MJ, Anderson RH, McGuire MA, et al: "AV nodal" reentry: I. "AV nodal" reentry revisited. J Cardiovasc Electrophysiol 4:561, 1993.)

also called nodal approaches; the compact portion, or the AV node itself; and the penetrating part of the AV bundle (His bundle), which continues as a nonbranching portion.

TRANSITIONAL CELL ZONE.

In the rabbit AV node, the transitional cells or nodal approaches are located in posterior, superficial, and deep groups of cells. They differ histologically from atrial myocardium and connect the latter with the compact portion of the AV node. Some fibers may pass from the posterior internodal tract to the distal portion of the AV node or His bundle and provide the anatomical substrate for conduction to bypass AV nodal slowing. However, the importance of this structure is unclear.

THE AV NODE.

The compact portion of the AV node is a superficial structure lying just beneath the right atrial endocardium, anterior to the ostium of the coronary sinus, and directly above the insertion of the sepal leaflet of the tricuspid valve. It is at the apex of a triangle formed by the tricuspid annulus and the tendon of Todaro, which originates in the central fibrous body and passes posteriorly through the atrial septum to continue with the eustachian valve[24] [25] [28] [29] (Figs. 22-3 and 22-4; however, see comments on the triangle of Koch above). The compact portion of the AV node is divided from and becomes the penetrating portion of the His bundle at the point where it enters the central fibrous body. In 85 to 90 percent of human hearts, the arterial supply to the AV node is a branch from the right coronary artery that originates at the posterior intersection of the AV and interventricular grooves (crux). A branch of the circumflex coronary artery provides the AV nodal artery in the remaining hearts. Fibers in the lower part of the AV node may exhibit automatic impulse formation.

THE BUNDLE OF HIS, OR PENETRATING PORTION OF THE AV BUNDLE.

This structure connects with the distal part of the compact AV node, perforates the central fibrous body, and continues through the annulus fibrosis, where it is called the nonbranching portion as it penetrates the membranous septum (see Fig. 22-4) . Proximal cells of the penetrating portion are heterogeneous and resemble those of the compact AV node, while distal cells are similar to cells in the proximal bundle branches. Connective tissue of the central fibrous body and membranous septum encloses the penetrating portion of the AV bundle, which may send out extensions into the central fibrous body.[24] [25] [28] [29] However, large well-formed fasciculoventricular connections between the penetrating portion of the AV bundle and the ventricular septal crest are rarely found in adult hearts. Branches from the anterior and posterior descending coronary arteries supply the upper muscular interventricular septum with blood, which makes the conduction system at this site more impervious to ischemic damage unless the ischemia is extensive.

THE BUNDLE BRANCHES, OR BRANCHING PORTION OF THE AV BUNDLE.

These structures begin at the superior margin of the muscular interventricular septum, immediately beneath the membranous septum, with the cells of the left bundle branch cascading downward as a continuous sheet onto the septum beneath the noncoronary aortic cusp (Fig. 22-5) . The AV bundle may then give off other left bundle branches, sometimes constituting a true bifascicular system with an anterosuperior branch, in other hearts giving rise to a group of central fibers, and in still others appearing more as a network without a clear division into a fascicular system. The right bundle branch continues intramyocardially as an unbranched extension of the AV bundle down the right side of the interventricular septum to the apex of the right ventricle and base of the anterior papillary muscle. In some human hearts, the His bundle traverses the right interventricular crest and gives rise to a right-sided narrow stem origin of the left bundle branch. The anatomy of the left bundle branch system may be variable and may not conform to a constant bifascicular division. However, the concept of a trifascicular system remains useful to both the electrocardiographer and the clinician (Fig. 22-5)

TERMINAL PURKINJE FIBERS.

These fibers connect with the ends of the bundle branches to form interweaving networks on the endocardial surface of both ventricles that transmit the cardiac impulse almost simultaneously to the entire right and left ventricular endocardium. Purkinje fibers tend to be less concentrated at the base of the ventricle and at the papillary muscle tips. They penetrate the myocardium for varying distances depending on the animal species: In humans, they apparently penetrate only the inner third of the endocardium, while in the pig they almost reach the epicardium. Such variations could influence changes produced by myocardial ischemia, for example, since Purkinje fibers appear to be more resistant to ischemia than ordinary myocardial fibers are.

CELLULAR COMPOSITION OF THE AV JUNCTIONAL AREA.

Transitional cells in the rabbit are elongated and smaller than atrial cells, stain more palely, and are separated by numerous strands of connective tissue. They merge at the entrance of the compact portion of the AV node, where the cells are small and spherical, not separated by muscle or connective tissue, and have very few nexuses. They interweave in interconnecting whorls of fasciculi. The AV node is divided on the basis of electrophysiological characteristics into AN, N, and NH regions[30] (Fig. 22-6) .

In the rabbit, the AN region corresponds to the transitional cell groups of the posterior portion of the node, the NH region to the anterior portion of the bundle of lower nodal cells, and the N region to the small enclosed node where transitional cells merge with midnodal cells. *Dead-end pathways*--groups of cells that form an apparent

electrophysiological cul-de-sac that does not contribute to overall conduction in the node--are also found at several sites. Cells in the penetrating bundle remain similar to compact AV nodal cells. In the dog, P cells, similar to those found in the sinus node, and several types of transitional cells have been noted and related to the automaticity and conduction properties of the AV node.[24] [25]

Purkinje cells are found in the His bundle and bundle branches, cover much of the endocardium of both ventricles, and align to form multicellular bundles in longitudinal strands separated by collagen. They are large, clear cells (10 to 30mum in diameter, 20 to 50mum long) with loosely arrayed mitochondria distributed between few linearly aligned myofibrils that have few myofilaments. Round nuclei occupy the center of the cell. Although conduction of the cardiac impulse appears to be their major function, free-running Purkinje fibers, sometimes called *false tendons,* which are composed of many Purkinje cells in a series, are capable of contraction (Fig. 22-7). Extensive lateral and end-to-end gap junctions, made up primarily of connexin 43, apparently transform the individual Purkinje cells into functioning like a cable.[5] [6] [7] [31]

Innervation of the AV Node and His Bundle

PATHWAYS OF INNERVATION.

The AV node and His bundle region are innervated by a rich supply of cholinergic and adrenergic fibers with a density exceeding that found in the ventricular myocardium. Ganglia, nerve fibers, and nerve nets lie close to the AV node. Parasympathetic nerves to the AV node region enter the canine heart at the junction of the inferior vena cava and the inferior aspect of the left atrium, adjacent to the coronary sinus entrance. Nerves in direct contact with AV nodal fibers have been noted, along with agranular and granular vesicular processes, presumably representing cholinergic and adrenergic processes. Acetylcholine release may be concentrated around the N region of the AV node.[13] [14] [14A] [15]

In general, autonomic neural input to the heart exhibits some degree of "sidedness," with the right sympathetic and vagal nerves affecting the sinus node more than the AV node and the left sympathetic and vagal nerves affecting the AV node more than the sinus node. The distribution of the neural input to the sinus and AV nodes is complex because of substantial overlapping innervation. Despite the overlap, specific branches of the vagal and sympathetic nerves can be shown to innervate certain regions preferentially, and sympathetic or vagal nerves to the sinus node can be interrupted discretely without affecting AV nodal innervation. Similarly, vagal or sympathetic neural input to the AV node can be interrupted without affecting sinus innervation. Supersensitivity to acetylcholine follows vagal denervation.

Figure 22-6 Diagram showing the distribution of morphologically different cell types in the atrioventricular (AV) node. *Upper panel,* Transverse section showing the trilaminar appearance of the interior part of the node. The level of sectioning is indicated by the vertical dark line in the *lower panel. Lower panel,* Diagram of the AV node indicating the different sites identified histologically after recording typical action potentials. (From Janse MJ, van Capelle FJL, Anderson RH, et al: Electrophysiology and structure of the atrioventricular node of the isolated rabbit heart. *In* Wellens JHH, Lie KI, Janse MJ [eds]: The Conduction System of the Heart. Philadelphia, Lea & Febiger, 1976, p 296.)

Stimulation of the right stellate ganglion produces sinus tachycardia with less effect on AV nodal conduction, while stimulation of the left stellate ganglion generally produces a shift in the sinus pacemaker to an ectopic site and consistently shortens AV nodal conduction time and refractoriness but inconsistently speeds the sinus nodal discharge rate. Stimulation of the right cervical vagus nerve primarily slows the sinus nodal discharge rate, while stimulation of the left vagus primarily prolongs AV nodal conduction time and refractoriness when "sidedness" is present. While neither sympathetic nor vagal stimulation affects normal conduction in the His bundle, either can affect abnormal AV conduction.

Most efferent sympathetic impulses reach the canine ventricles over the ansae subclaviae, branches from the stellate ganglia. Sympathetic nerves then synapse primarily in the caudal cervical ganglia and form individual cardiac nerves that innervate relatively localized parts of the ventricles. On the right side, the major route to the heart is the recurrent cardiac nerve, and on the left, the ventrolateral cardiac nerve. In general, the right sympathetic chain shortens refractoriness primarily of the anterior portion of the ventricles, while the left affects primarily the posterior surface of the ventricles, although overlapping areas of distribution occur.

The intraventricular route of sympathetic nerves generally follows coronary arteries. Functional data suggest that afferent and efferent sympathetic nerves travel in the superficial layers of the epicardium and dive to innervate the endocardium, and anatomical observations support this conclusion. Vagal fibers travel intramurally or subendocardially and rise to the epicardium at the AV groove[13] [14] [14A] [15] [32] (see Fig. 22-7) .

EFFECTS OF VAGAL STIMULATION.

The vagus modulates cardiac sympathetic activity at prejunctional and postjunctional sites by regulating the amount of norepinephrine released and by inhibiting cyclic adenosine monophosphate (cAMP)-induced phosphorylation of cardiac proteins such as phospholamban.[23] The latter inhibition occurs at more than one level in the series of reactions constituting the adenylate cyclase-, AMP-dependent protein kinase system. Neuropeptides released from nerve fibers of both autonomic limbs also modulate autonomic responses. For example, neuropeptide Y released from sympathetic nerve terminals inhibits cardiac vagal effects.[11] [12]

Tonic vagal stimulation produces a greater absolute reduction in sinus rate in the presence of tonic background sympathetic stimulation, a sympathetic-parasympathetic interaction termed *accentuated antagonism.* In contrast, changes in AV conduction during concomitant sympathetic and vagal stimulation are essentially the *algebraic sum* of the individual AV conduction responses to tonic vagal and sympathetic stimulation alone. Cardiac responses to brief vagal bursts begin after a short latency and dissipate quickly; in contrast, cardiac responses to sympathetic stimulation commence and dissipate slowly. The rapid onset and offset of responses to vagal stimulation allow for dynamic beat-to-beat vagal modulation of heart rate and AV conduction, whereas the slow temporal response to sympathetic stimulation precludes any beat-to-beat regulation by sympathetic activity. Periodic vagal bursting (as may occur each time a systolic pressure wave arrives at the baroreceptor regions in the aortic and carotid sinuses) induces phasic changes in sinus cycle length and can entrain the sinus node to discharge faster or slower at periods that are identical to those of the vagal burst. In a similar phasic manner, vagal bursts prolong AV nodal conduction time and are influenced by background levels of sympathetic tone. Because the peak vagal effects on sinus rate and AV nodal conduction occur at different times in the cardiac cycle, a brief vagal burst can

slow the sinus rate without affecting AV nodal conduction or can prolong AV nodal conduction time and not slow the sinus rate.[9] [11] [12]

EFFECTS OF SYMPATHETIC STIMULATION.

Stimulation of sympathetic ganglia shortens the refractory period equally in the epicardium and underlying endocardium of the left ventricular free wall, although dispersion of recovery properties occurs, i.e., different degrees of shortening of refractoriness occur when measured at different epicardial sites. Nonuniform distribution of norepinephrine may, in part, contribute to some of the nonuniform electrophysiological effects since the ventricular content of norepinephrine is greater at the base than at the apex of the heart, with greater distribution to muscle than to Purkinje fibers. Afferent vagal activity appears to be greater in the posterior ventricular myocardium, which may account for the vagomimetic effects of inferior myocardial infarction.[13] [14] [14A] [15]

The vagi exert minimal but measurable effects on ventricular tissue: decreasing the strength of myocardial contraction and prolonging refractoriness. Under some circumstances, acetylcholine can cause a positive inotropic effect. It is now clear that the vagus (acetylcholine) can exert direct effects on some types of ventricular fibers, as well as exert indirect effects by modulating sympathetic influences.[14] [14A] [33]

ARRHYTHMIAS AND THE AUTONOMIC NERVOUS SYSTEM.

Alterations in vagal and sympathetic innervation can influence the development of arrhythmias.[14] [14A] [34] Damage to nerves extrinsic to the heart, such as the stellate ganglia, as well as to intrinsic cardiac nerves from diseases that may affect nerves primarily, e.g., viral infections, or secondarily, from diseases that cause cardiac damage, may produce cardioneuropathy. Such neural changes may create electrical instability via a variety of electrophysiological mechanisms. For example, myocardial infarction can interrupt afferent and efferent neural transmission and create areas of sympathetic supersensitivity that may be conducive to the development of arrhythmias.[13] [14]

Figure 22-7 *Left panel,* Intraventricular route of sympathetic and vagal nerves to the left ventricle. *Right panel,* Schematic of the transverse views of the right ventricular (RV) wall showing functional pathways of the efferent sympathetic and vagal nerves. *Top right,* Transverse view of the RV outflow tract at the upper horizontal line on the left. *Bottom right,* Transverse view of the anterolateral wall at the lower horizontal line on the left. The *vertical solid line* indicates the center of the RV anterolateral wall. Closed circles indicate positions of plunge electrodes labeled 1 to 6. IVS = interventricular septum; LAD = left anterior descending coronary artery; RA = right atrium; RCA = right coronary artery. Figure 22-8 Structure of ion channels. *A,* Subunit of a voltage-gated potassium channel containing six membrane-spanning domains (S1 through S6) linked by intracellular and extracellular sequences of hydrophilic amino acids. One of the subunits (S4) has positively charged lysine and arginine residues, and this region is thought to form the voltage sensor of the channel. Transmembrane segments S5 and S6, along with the intervening peptide chain (H), line the pore through which ions pass into the lipid bilayer. Voltage-dependent "fast" or N-type inactivation is mediated by an N-terminal particle that binds to the activated channel and plugs the permeation pathway. Both the COOH-terminus and the NH_2 -terminus have phosphorylation sites (P) that are potential targets for a variety of protein kinases and protein phosphatases. A change in phosphorylation status may then result in altered gating and/or permeation properties of the channel. *B,* Voltage-gated Na+ and Ca^{2+} channels are composed of a *single* tetramer consisting of four covalently linked repeats of the six-transmembrane-spanning motifs, whereas voltage-gated K+ channels are composed of four *separate* subunits, each containing a single six-transmembrane-spanning motif. (Modified from Katz AM: Molecular biology in cardiology, a paradigmatic shift. J Mol Cell Cardiol 20:355, 1988.)

BASIC ELECTROPHYSIOLOGICAL PRINCIPLES

Physiology of Ion Channels

Electrical signaling in the heart involves the passage of ions through ionic channels. The Na+, K+, Ca^{2+} , and Cl-- ions are the major charge carriers, and their movement across the cell membrane creates a flow of current that generates excitation and signals in cardiac myocytes. Ion channels are macromolecular pores that span the lipid bilayer of the cell membrane (Fig. 22-8). Conformational transitions change (gate) a single ion channel from closed to open, which allows selected ions to flow passively down the electrochemical activity gradient at a very high rate (>10^{6} ions per second). The high transfer rates and restriction to "downhill" fluxes not stoichiometrically coupled to the hydrolysis of energy-rich phosphates distinguish ionic channel mechanisms from those of other ion-transporting structures such as the sarcolemmal Na+, K+-adenosine triphosphatase (ATPase) or the sarcoplasmic reticular Mg^{2+} , Ca^{2+} -ATPase. Ion channels may be gated by extracellular and intracellular ligands, changes in transmembrane voltage, or mechanical stress. Gating of single ion channels can best be studied by means of the patch-clamp technique, as illustrated in Figure 22-9 , with the voltage-gated Ca^{2+} channel used as an example.

Ion channels are usually named after the strongest permeant ion--Na+, Ca^{2+} , K+, Cl----but some channels are less or not selective, as in gap junctional channels. Channels have also been named after neurotransmitters, as in acetylcholine-sensitive K+ channels, $I_{K.Ach}$.

The ionic permeability ratio is a commonly used quantitative index of a channel's selectivity. It is defined as the ratio of the permeability of one ion type to that of the main permeant ion type. Permeability ratios of voltage-gated K+ and Na+ channels for monovalent and divalent (e.g., Ca^{2+}) cations are usually less than 1:10.[34] Voltage-gated Ca^{2+} channels exhibit a more than thousand-fold discrimination against Na+ and K+ ions (e.g., P_K /P_{Ca} = 1/3000) and are impermeable to anions.

Because ions are charged, net ionic flux through an open channel is determined by both the concentration and electrical gradient across the membrane. According to the Goldman-Hodgkin-Katz (GHK) *current* equation, the current i carried by an ion S is equal to the permeability of the channel to that ion, P_S , multiplied by a nonlinear function of voltage, V.

Figure 22-10 demonstrates that the GHK theory predicts nonlinear single-channel current (i)-voltage (V) relationships whenever permeant ion concentrations are unequal on the two sides of the membrane; i.e., channel conductance (which equals the slope of the i-V curve) is larger when ions flow from the more concentrated side (rectification). The intercept of the i-V curve with the voltage axis indicates the reversal potential of the channel. At this point, the passive flux of ions along the chemical driving force is exactly balanced by the electrical driving force. In the case of a channel that is perfectly selective for one ion species (as illustrated in Fig. 22-10*A* for a K+-selective channel), the reversal potential equals the Nernst or thermodynamic equilibrium potential of that ion, E_S , which is given by the Nernst equation in the form

where S_i and S_o are the intracellular and extracellular concentrations of the permeant ion, respectively, z is the valence of the ion, R is the gas constant, F is Faraday constant, T is the temperature in Kelvin, and ln is the logarithm to the base *e*. If the current through an open channel is carried by more than one permeant ion, the reversal potential becomes a weighted mean of all Nernst potentials, as illustrated in Figure 22-10 (insert), with a Ca^{2+} channel weakly permeable to K+ used as an example.

As shown in Figure 22-15 and Table 22-2 , membrane voltages during a cardiac action potential are in the range of -95 to +30 mV. With physiological external K+ (4 mM; see Table 22-1) , E_K is approximately -91 mV, and passive K+ movement is out of the cell. K+ efflux through a single K+ channel, or the single-channel current i, *increases* with membrane depolarization over the range of physiological membrane potentials (Fig. 22-10 *A*). On the other hand, since the calculated reversal potential of a Ca^{2+} channel is +64 mV (P_K /P_{Ca} = 1/3000, K_i =150 mM, K_o =4 mM, Ca_i =100 nM, Ca_o =2 mM), passive Ca^{2+} flux is into the cell. Ca^{2+} influx through a single open Ca^{2+} channel *decreases* with membrane depolarization in a nonlinear fashion (see Fig 22-10 *A*). With physiological internal and external chloride concentrations (see Table 22-1) , E_{Cl} is -80 to -35 mV, and passive movement of Cl-- ions

Figure 22-9 Patch-clamp measurements of ion channel activity, with the voltage-dependent Ca^{2+} channel used as an example. *A,* Open-closed gating of a single L-type Ca^{2+} channel. A glass

pipette filled with an electrolyte solution is pressed against the cell surface, suction is applied, and a tight electrical seal is formed between the pipette rim and cell membrane. This high-resistance seal ensures that the recording circuit measures only ionic currents flowing through the 1 to 3 mum[2] of membrane that is encircled by the pipette tip. In this way, the ionic current passing through a single open channel can be measured ("cell-attached" mode). The pipette is filled with 5 mM Ca^{2+} . To activate the channel, step depolarization (500 milliseconds) to -40 mV from a holding potential of -70 mV is applied, followed by repolarization to -70 mV. (The square wave-shaped tracing at the top indicates voltage changes.) During the step depolarization, brief openings (downward current deflections) and closings of one channel appear as discrete changes in the record. At the -40-mV applied membrane potential, an open channel passes -0.25 pA, which corresponds to a flux of approximately 750,000 Ca^{2+} ions per second through a single open pore. Note that the depolarization causes the channel to open only occasionally, with seven brief openings of a single channel in this example. *B,* In the whole-cell mode, after a cell-attached patch has been formed, a brief pulse of suction disrupts the membrane underneath the pipette tip and creates low-resistance access to the entire intracellular space. While in this configuration, current passing through the whole cell can be measured. In this example, step depolarization to +20 mV from a holding potential of -40 mV causes an inward Ca^{2+} current of several hundreds of picoamperes that subsides upon repolarization to the holding potential.

through open chloride channels can be both inward and outward at membrane potentials typically occurring during a cardiac action potential. In more general terms, the direction and magnitude of passive ion flux through a single open channel at any given transmembrane voltage is governed by the reversal potential of that ion and its concentration on the two sides of the membrane, with the net flux being larger when ions move from the more concentrated side.

ION FLUX THROUGH VOLTAGE-GATED CHANNELS

Changes in transmembrane potential determine ion flux through voltage-gated channels not only through the voltage dependence of the electrochemical driving force on the permeant ion but also through the voltage dependence of the open-state probability of that channel. If the probability of a channel being activated, P_{act} (or the fraction of time that it permits ions to permeate), exhibits voltage-dependent activation, as is the case, for example, with the L-type Ca^{2+} channel or voltage-dependent K+ channels in cardiac myocytes, P_{act} would increase with membrane depolarization. Hypothetical examples

Figure 22-10 Relationship between channel properties and whole-cell ionic currents. *A,* Hypothetical single-channel current (i)-voltage (V_m) relationships of a potassium and a calcium channel. The relationships were generated from the Goldman-Hodgkin-Katz *current* equation (see the text), assuming that the K+ channel is perfectly selective for K+ and the Ca^{2+} is weakly permeable to K+ (P_K P_{Ca} = 1/3000). Intracellular and extracellular concentrations of Ca^{2+} and K+ are those given in Table 22-1 . The thermodynamic equilibrium potentials or Nernst potentials for Ca^{2+} (E_{Ca}) and K+ (E_K) were therefore +124 mV and -91 mV, respectively (at T = 294.16 K). P is a constant and was scaled so that i=0.3 pA (K+ channel) and -0.5 pA (Ca^{2+} channel) at -20 mV. Despite their low permeability, K+ ions generate a significant outward current through open Ca^{2+} channels, as reflected in the negative shift of the reversal potential in the single open channel i-V relationship. *B*, Hypothetical voltage dependence of single-channel current activation, measured as single-channel open-state probability or the probability of being activated, P_{act} . The relations were obtained from Boltzmann activation curves with the following parameters: Ca^{2+} channel: V_{half} =+5 mV, k=+7 mV; K+ channel: V_{half} =+5 mV, k=+13 mV. *C,* Hypothetical whole-cell current-voltage relationships. At each membrane potential, the whole cell current (I) equals the product of the single-channel current (i) and P_{act} multiplied by the number of channels (N): 5000 and 45,000 for the K+ and Ca^{2+} channel, respectively.

based on data from cardiac myocytes are shown in Figure 22-10 *B.* The dependence of the single-channel open-state probability (or the probability of being activated, P_{act}) on membrane potential is sigmoidal and usually described by a Boltzmann distribution equation of the form

where V_{half} is the membrane potential at which P_{act} is half-maximal and k is a steepness factor that indicates the sensitivity of channel activation to changes in membrane potential. Note that channels do not have a sharp voltage threshold for opening. The open probability of channels is a continuous function of voltage as formalized in the Boltzmann distribution equation above. Thus, even at membrane potentials well hyperpolarized to the midpoint of activation, voltage-gated Ca^{2+} (K+, Na+) channels would have a finite, albeit extremely small open probability. Cardiac myocytes, though, show a sharp threshold for firing an action potential. This characteristic, however, reflects reversal of net membrane current and not a threshold for channel opening. An action potential develops when a depolarizing stimulus increases the open-state probability of a sufficient number of Na+ channels (or Ca^{2+} channels in slow tissue) to generate an inward current that opposes the outward current carried by K+ or CI-- ions.

Whole-cell ionic currents, I, are related to the single-channel current i and the open state probability P_{act} by

where N is the number of functional channels in the plasma membrane. Whole-cell currents can be measured by using the patch-clamp technique (see Fig. 22-9 *B*).

TABLE 22-1 -- INTRACELLULAR AND EXTRACELLULAR ION CONCENTRATIONS IN CARDIAC MUSCLE

ION	EXTRACELLULAR CONCENTRATION (mM)	INTRACELLULAR CONCENTRATION	RATIO OF EXTRACELLULAR TO INTRACELLULAR CONCENTRATION	E_i (mV)
Na	145	15 mM	9.7	+60
K	4	150 mM	0.027	-94
Cl	120	5-30 mM	4-24	-83 to -36
Ca	2	10^{-7} M	2×10^4	+129

Although intracellular Ca content is about 2 mM, most of this Ca is bound or sequestered in intracellular organelles (mitochondria and sarcoplasmic reticulum).

E_1 =equilibrium potential for a particular ion at 37°C.

Modified after Sperelakis N: Origin of the cardiac resting potential. In Berne RM, Sperelakis N, Geiger SR (eds): Handbook of Physiology, The Cardiovascular System. Bethesda, MD, American Physiological Society, 1979, p 193.

The I-V relationships for hypothetical voltage-gated K+ and Ca^{2+} channels are illustrated in Figure 22-10 *C*. The voltage dependence of the macroscopic Ca^{2+} current has a different shape than that of the single-channel current (i) because it is determined by i N P_{act} . Thus, this relationship is bell shaped, i.e., near zero at threshold (large i but small P_{act}), maximal at V_{peak} (
+10 mV; intermediate i and large P_{act}), and smaller at more positive potentials (small i, maximal P_{act}). In contrast, the I-V relationship of the voltage-dependent K+ channel is similar to the single-channel current (i)-voltage (V) relationship because i increases with membrane depolarization.

As indicated in Figure 22-11 , open channels enter a nonconducting conformation after a depolarizing change in membrane potential, a process termed *inactivation.* Channel inactivation increases with membrane depolarization. The voltage dependence of channel inactivation is expressed by plotting the availability of the channel to open (equal to 1 - P_{inact} [the probability for a channel being in the inactivated state]) against membrane potential. The relationship between membrane potential and channel inactivation is sigmoidal and usually described by a Boltzmann equation of the same form as given above (Equation 2). Hypothetical Boltzmann activation and inactivation curves for a voltage-gated Ca^{2+} channel are shown in Figure 22-12 .

From overlap of the activation and inactivation curves it is predicted that a potential range exists where P_{act} (1 P_{inact}) 0, and a steady-state or noninactivating current with the approximate amplitude P_{act} (1 P_{inact}) I (V_{peak}) will flow. The existence of such a window current has been verified for both the voltage-gated Na+ current[35] and the L-type Ca^{2+} current.[36] A role of the L-type window current has been implicated in the genesis of early afterdepolarizations (EADs).

Channels recover from inactivation and then enter the closed state from which they can be reactivated (see Fig. 22-11) . Rates of recovery from inactivation vary among the different types of voltage-dependent channels and usually follow monoexponential or multiexponential time courses, with the longest time constants ranging from a few milliseconds, as, for example, for the fast sodium channel, to hundreds of milliseconds, as for the transient outward potassium current.

PRINCIPLES OF IONIC CURRENT MODULATION

According to Equation 3, modulation of whole-cell current amplitudes may be due to changes in i (e.g., changes in charge carrier concentration or temperature), number of functional channels in the cell membrane (e.g., changes in ion channel gene expression), and/or P_{act} (e.g., modulation of the voltage dependence of single-channel gating by

Figure 22-11 Simplest scheme for gating of voltage-gated ion channels.

intracellular second messengers). Changes in single-channel open-state probability underlie most of the second messenger effects on voltage-gated channels. Intracellular second messengers may act through (1) change in the channel's closed and open time, (2) shift in the membrane potential dependence of a channel's activation and/or availability curve, (3) modification of the sensitivity of channel activation/inactivation to changes in membrane potential, and (4) any combination of the above. An example of a second messenger-induced change in a channel's open and closed time is given in Figure 22-13 . The consequences of a negative shift in the channel's activation curve on the whole-cell Ca^{2+} current are simulated in Figure 22-13 *C*. At activating potentials below V_{peak} , the percent increase in macroscopic current is larger than at V_{peak} or more positive potentials, where P_{act} approaches its saturating value.

MOLECULAR STRUCTURE OF ION CHANNELS.

Voltage-gated potassium channels are composed of four *separate* subunits, each containing six regions of hydrophobic amino acids (S1 through S6) that are thought to form membrane-spanning domains, and these hydrophobic regions are linked by sequences of hydrophilic amino acids that are exposed to the intracellular or extracellular space (see Fig. 22-8 *A*). One of the membrane-spanning subunits (S4) is positively charged, having a cluster of basic amino acids (lysine or arginine), and this region is thought to be part of the voltage sensor. The peptide chain linking S5 and S6

Figure 22-12 Hypothetical Boltzmann activation and inactivation curves of a voltage-gated channel. Inactivation and activation curves were constructed by using the Boltzmann distribution equation (see the text), with midpoints of activation and inactivation (V_{half}) of +5 mV and -10 mV, respectively. The slope of each curve (k) was assumed to not be different and was 7 mV. Inactivation and activation curves overlap over a potential range from approximately -30 to about +30 mV. Over this range, the product of the probability of being activated and of not being inactivated is nonzero, P_{act} - (1 P_{inact}) 0, thus indicating that a steady-state or noninactivating current will flow.

Figure 22-13 On-cell recording from a guinea pig ventricular cell patch containing one L-type Ca^{2+} channel. Panels show currents during eight consecutive applications of a 190-millisecond depolarizing voltage-clamp pulse to +20 mV and the average current *(below)* of about 500 sweeps. Charge carrier: 70 mM Ba^{2+} . *A*, Control conditions. Many sweeps are blank or show brief openings. One sweep contains repeated openings. *B,* After bath application of a membrane-permeable cyclic adenosine monophosphate analog, the channel opens more often and the open times become longer. (From Yue DT, Herzig S, Marban E: beta-Adrenergic stimulation of calcium channels occurs by potentiation of high-activity gating modes. Proc Natl Acad Sci 87:753, 1990.) Simulation of the effects of a hypothetical Ca^{2+} current modulator on the channel's activation curve and the whole-cell Ca^{2+} currents, assuming that the effect is through a negative shift of the membrane potential dependence of single-channel open-state probability. *Dotted line* = presence of channel modulator; *solid line* = control conditions.

(H5 loop) lines the water-filled pore. Voltage-dependent "fast" inactivation of the channel is mediated by a tethered N-terminal particle ("inactivation ball") that binds to the activated channel and occludes the intracellular mouth of the permeation pathway (see Fig. 22-8 *A*). Voltage-gated Na+ and Ca^{2+} channels have a basic structure similar to voltage-dependent potassium channels, although unlike K+ channels, each Ca^{2+} or Na+ channel consists of a single (alpha) subunit containing the four repeats of the six transmembrane-spanning domains (Fig. 22-8 *B*).

A structurally different family of potassium channels is that containing the inwardly rectifying potassium-selective channels (Kir). Kir channels in cardiac myocytes, as in other cells, conduct inward current at membrane potentials negative to E_K and smaller outward currents at membrane potentials positive to E_K . The activity of Kir channels is a function of both the membrane potential and the extracellular K+ concentration ($[K+]_o$). As $[K+]_o$ changes, the channel conducts inward current at potentials negative to the new E_K while a small outward current within a certain potential range positive to the new E_K remains. Structurally, Kir channels resemble voltage-gated K+ channels, but the subunits lack the S1 to S4 domains, whereas the pore-forming domains and the H5 region are conserved. Kir channel subunits can form heteromultimeric complexes with other proteins, which adds considerable complexity to the behavior of Kir channels. For example, the ATP-sensitive K+ channel $I_{K.ATP}$ is a heteromeric complex of inwardly rectifying potassium channel subunits and the sulfonylurea receptor. Drugs such as nicorandil, pinacidil, and diaxozide open ATP-sensitive K+ channels, while sulfonylurea compounds (such as glibenclamide) inhibit the activity of $I_{K.ATP}$.

The molecular basis of the acetylcholine-activated potassium channel $I_{K.Ach}$ is a heteromultimer of two inwardly rectifying potassium channel subunits. This channel is activated after direct binding of the beta-gamma subunits of G protein. Stimulation of $I_{K.Ach}$ by vagally secreted acetylcholine decreases spontaneous depolarization in the sinus node and slows the velocity of conduction in the AV node.[37] Adenosine, via type 1 purinergic receptor-mediated G protein activation, also increases $I_{K.Ach}$ activity in atrial, sinus node, and AV node cells, thus making this compound a treatment of choice for AV reentry tachycardia.

INTERCALATED DISCS

Another family of ion channel proteins is that containing the gap junctional channels. These dodecameric channels are found in the intercalated discs between adjacent cells. Three types of specialized junctions make up each intercalated disc. The macula adherens or desmosome and fascia adherens form areas of strong adhesion between cells and may provide a linkage for the transfer of mechanical energy from one cell to the next. The *nexus,* also called the *tight* or *gap junction,* is a region in the intercalated disc where cells are in functional contact with each other. Membranes at these junctions are separated by only about 10 to 20 A and are connected by a series of hexagonally packed subunit bridges. Gap junctions provide low-resistance electrical coupling between adjacent cells by establishing aqueous pores that directly link the cytoplasm of these adjacent cells. Gap junctions allow movement of ions and small molecules between cells, thereby linking the interiors of adjacent cells.

Gap junctions permit a multicellular structure such as the heart to function electrically like an orderly, synchronized, interconnected unit and are probably responsible in part for the fact that conduction in the myocardium is *anisotropic,* i.e., its anatomical and biophysical properties vary according to the direction in which they are measured. Usually, conduction velocity is two to three times faster longitudinally, i.e., in the direction of the long axis of the fiber, than it is

Figure 22-14 Model of the structure of a gap junction based on results of x-ray diffraction studies. Individual channels are composed of paired hexamers that travel in the membranes of adjacent cells and adjoin in the extracellular gap to form an aqueous pore that provides continuity of the cytoplasm of the two cells. (*From Saffitz JE: Cell-to-cell communication in the heart. Cardiol Rev 3:86, 1995.*)

transversely, i.e., in the direction perpendicular to this long axis. Resistivity is lower longitudinally than transversely. Interestingly, the safety factor for propagation is greater transversely than horizontally. Conduction delay or block occurs more commonly in the longitudinal direction than it does transversely. Cardiac conduction is discontinuous because of resistive discontinuities created by the gap junctions, which have anisotropic distribution on the cell surface.[38] Because of anisotropy,

propagation is discontinuous and can be a cause of reentry.

Gap junctions may also provide "biochemical coupling" that might permit cell-to-cell movement of ATP on other high-energy phosphates. Gap junctions can also change their electrical resistance. When intracellular calcium rises, as in myocardial infarction, the gap junction may close to help "seal off" the effects of injured from noninjured cells. Acidosis increases and alkalosis decreases gap junctional resistance. Increased gap junctional resistance tends to slow the rate of action potential propagation, a condition that could lead to conduction delay or block.[5] [6] [7] [8] [61A] [39] [40] [41] [42] [43] [43A] [43B]

Connexins are the proteins that form the intercellular channels of gap junctions. An individual channel (connexin) is created by two hemichannels, each located in the plasma membrane of adjacent cells and composed of six integral membrane protein subunits (connexins). The hemichannels surround an aqueous pore and thereby create a transmembrane channel (Fig. 22-14). . Connexin 43, a 43-kp polypeptide, is the most abundant cardiac connexin, with connexin 40 and 45 found in smaller amounts. Gap junctions in the distal His bundle and proximal bundle branches have large amounts of connexin 40 and 43. Atrial gap junctions have large amounts of all three connexins, while ventricular gap junctions have large amounts of connexin 43 and 45 and much less connexin 40 (see p. 659) [3] [6]

Phases of the Cardiac Action Potential

The cardiac transmembrane potential consists of five phases: phase 0--upstroke or rapid depolarization; phase 1--early rapid repolarization; phase 2--plateau; phase 3 final rapid repolarization; and phase 4--resting membrane potential and diastolic depolarization (see Fig. 20-17). These phases are the result of passive ion fluxes moving down electrochemical gradients established by active ion pumps and exchange mechanisms. Each ion moves primarily through its own ion-specific channel. Impulses spread from one cell to the next without requiring neural input. The transplanted heart dramatically demonstrates this fact. The following discussion will explain the electrogenesis of each of these phases. For in-depth coverage, the reader is referred to other reference sources.[44] [45]

General Considerations

Having a basic understanding of how transmembrane voltage controls ionic fluxes through ionic channels, we now ask the question how ionic fluxes regulate membrane potential in cardiac myocytes. When only one type of ion channel opens, assuming that this channel is perfectly selective for that ion, the membrane potential of the entire cell would equal the Nernst potential of that ion. Solving the Nernst equation for the four major ions across the plasma membrane, one obtains the following equilibrium potentials: sodium, +60 mV; potassium, -94 mV; calcium, +129 mV; and chloride, -80 to -35 mV. Therefore, if a single K^+ -selective channel opens, such as the inwardly rectifying K^+ channel, the membrane potential will approach E_K (-94 mV). If a single Na^+ -selective channel opens, the transmembrane potential will become E_{Na} (+60 mV). A quiescent cardiac myocyte (phase 4) has many more open potassium than sodium channels, and the cell's transmembrane potential is close to E_K (Table 22-2) . When two or more types of ion channel open simultaneously, each type will try to make the membrane potential go to the equilibrium potential of that channel. The contribution of each ion type to the overall membrane potential at any

Figure 22-15 *Left,* Demonstration of action potentials recorded during impalement of a cardiac cell. The upper row of diagrams shows a cell (circle), two microelectrodes, and stages during impalement of the cell and its activation and recovery. *A,* Both microelectrodes are extracellular, and no difference in potential exists between them (0 potential). The environment inside the cell is negative and the outside is positive since the cell is polarized. *B,* One microelectrode has pierced the cell membrane to record the intracellular resting membrane potential, which is -90 mV with respect to the outside of the cell. *C,* The cell has depolarized and the upstroke of the action potential is recorded. At its peak voltage, the inside of the cell is about +30 mV with respect to the outside of the cell. *D,* Phase of repolarization, with the membrane returning to its former resting potential (*E*) (From Cranefield PF: The Conduction of the Cardiac Impulse. Mt Kisco, NY, Futura, 1975.)

given moment is determined by the instantaneous permeability of the plasma membrane to that ion. For example, deviation of the measured resting membrane potential from E_K (see Table 22-1) would predict that other ion types with equilibrium potentials positive to E_K contribute to the resting membrane potential in cardiac myocytes. If it is assumed that Na^+ , K^+ , and Cl^- are the permeant ions at resting potential, their individual contributions to the resting membrane potential V_r can be quantified by the GHK *voltage* equation of the form

where the symbols have the meanings as outlined above. With only one permeant ion, V_r becomes the Nernst potential for that ion. With several permeant ion types, V_r is a weighted mean of all the Nernst potentials.

Intracellular electrical activity can be recorded by inserting a glass microelectrode filled with an electrolyte solution and having a tip diameter less than 0.5 mum into a single cell. The electrode produces minimal damage, its entry point apparently being sealed by the cell. The transmembrane potential is recorded by using this electrode in reference to an extracellular ground electrode placed in the tissue bath near the cell membrane and represents the potential difference between intracellular and extracellular voltage (Fig. 22-15) . Alternatively, the patch-clamp technique in current clamp mode can be used to measure transmembrane potentials.

Phase 4--The Resting Membrane Potential

Intracellular potential during electrical quiescence in diastole is 50 to 95 mV, depending on the cell type (see Table 22-2) . Therefore, the inside of the cell is 50 to 95 mV negative relative to the outside of the cell because of the distribution of ions such as K^+ , Na^+ , and Cl^- .

Because cardiac myocytes have an abundance of open K^+ channels at rest, the cardiac transmembrane potential (in phase 4) is close to E_K . Potassium outward current through open, inwardly rectifying K^+ channels, I_{Kl} , mainly contributes to the resting membrane potential in atrial and ventricular myocytes, as well as in Purkinje cells, under normal conditions. Deviation of the resting membrane potential from E_K is due to movement of monovalent ions with an equilibrium potential greater than E_K , e.g. Cl^- efflux through activated chloride channels, such as $I_{Cl.cAMP}$, $I_{Cl.Ca}$, and $I_{Cl.swell}$. [46] Calcium does not contribute directly to the resting membrane potential, but changes in intracellular free calcium concentration can affect other membrane conductance values. For instance, an increase in sarcoplasmic reticulum Ca^{2+} load can cause spontaneous intracellular Ca^{2+} waves,[47] which in turn activate the Ca^{2+} -dependent chloride conductance $I_{Cl.Ca}$ and thereby lead to spontaneous transient inward currents and concomitant membrane depolarization. Increases in $[Ca^{2+}]_i$ may also stimulate the Na^+/Ca^{2+} exchanger $I_{Na/Ca}$. This protein exchanges three Na^+ ions for one Ca^{2+} ion, the direction being dependent on the sodium and calcium concentrations on the two sides of the membrane and the transmembrane potential difference. At resting membrane potential and during a spontaneous sarcoplasmic reticulum Ca^{2+} release event, this exchanger would generate a net Na^+ influx, possibly causing transient membrane depolarizations. [48] $[Ca^{2+}]_i$ has also been shown to activate the activity of I_{Kl} in cardiac myocytes, thereby indirectly contributing to cardiac resting membrane potential. Because of the Na-K pump, which pumps Na^+ out of the cell against its electrochemical gradient and simultaneously pumps K^+ into

the cell against its chemical gradient, the intracellular K^+ concentration remains high and the intracellular

Figure 22-16 Currents and channels involved in generating resting and action potentials. The time course of a stylized action potential of atrial and ventricular cells is shown on the left, and that of sinoatrial node cells is on the right. Above and below are the various channels and pumps that contribute the currents underlying the electrical events. See Table 22-3 for identification of the symbols and description of the channels or currents. Where possible, the approximate time courses of the currents associated with the channels or pumps are shown symbolically without an effort to represent their magnitudes relative to each other. I_K incorporates at least two currents, I_{K-R} and I_{K-S} . There appears to be an ultrarapid component as well, designated I_{K-UR} . The heavy bars for I_{Cl} , I_{pump} , and $I_{K(ATP)}$ indicate only the presence of these channels or pump without implying magnitude of currents since that would vary with physiological and pathophysiological conditions. The channels identified by brackets (I_{NS} and $I_{K(ATP)}$) imply that they are active only under pathological conditions. I_{NS} may represent a swelling-activated cation current. For the sinoatrial node cells, I_{NS} and I_{K1} are small or absent. Question marks indicate that experimental evidence is not yet available to determine the presence of these channels in sinoatrial cell membranes. Although it is likely that other ionic current mechanisms exist, they are not shown here because their roles in electrogenesis are not sufficiently well defined. (From Members of the Sicilian Gambit: Antiarrhythmic Therapy: A Pathophysiologic Approach. Mt Kisco, NY, Futura, 1994, p 13.)

Na^+ concentration remains low. This pump, fueled by an Na^+ , K^+ -ATPase enzyme that hydrolyzes ATP for energy, is bound to the membrane. It requires both Na^+ and K^+ to function and can transport three Na^+ ions outward for two K^+ ions inward. Therefore, the pump can be electrogenic and generate a net outward movement of positive charges. The rate of Na^+ -K^+ pumping to maintain the same ionic gradients must increase as the heart rate increases since the cell gains a slight amount of Na^+ and loses a slight amount of K^+ with each depolarization. Cardiac glycosides block this pump.

Phase 0--Upstroke or Rapid Depolarization

A stimulus delivered to excitable tissue evokes an action potential characterized by a sudden voltage change caused by transient depolarization followed by repolarization. The action potential is conducted throughout the heart and is responsible for initiating each "heartbeat." Electrical changes in action potential follow a relatively fixed time and voltage relationship that differs according to specific cell types (Figs. 22-16 and 22-17). In nerve, the entire process takes several milliseconds, while action potentials in cardiac fibers last several hundred milliseconds. Normally, the action potential is independent of the size of the depolarizing stimulus, if the latter exceeds a certain threshold potential. Small subthreshold depolarizing stimuli depolarize the membrane in proportion to the strength of the stimulus. However, once the stimulus is sufficiently intense to reduce membrane potential to a threshold value in the range of -70 to -65 mV for normal Purkinje fibers, more intense stimuli do not produce larger action potential responses, and an "all-or-none" response results. In contrast, hyperpolarizing pulses, i.e., stimuli that render the membrane potential more negative, elicit a response proportional to the strength of the stimulus.

MECHANISM OF PHASE 0.

The upstroke of the cardiac action potential in atrial and ventricular muscle and His-Purkinje fibers is due to a sudden increase in membrane conductance to Na^+ . An externally applied stimulus or a spontaneously generated local membrane circuit current in advance of a propagating action potential depolarizes a sufficiently large area of membrane at a sufficiently rapid rate to open the Na^+ channels and depolarize the membrane further. When the stimulus activates enough sodium channels, Na^+ rushes into the cell, down its electrochemical gradient. The excited membrane no longer behaves like a K^+ electrode, i.e., exclusively permeable to K^+ , but more closely approximates an Na^+ electrode, and the membrane moves toward the Na^+ equilibrium potential.

The rate at which depolarization occurs during phase 0, i.e., the maximum rate of change of voltage over time, is indicated by the expression dv/dtma or Vmax (see Table 22-2) , which is a reasonable approximation of the rate and magnitude of Na^+ entry into the cell and a determinant of conduction velocity for the propagated action potential. The transient increase in sodium conductance lasts 1 to 2 milliseconds. The action potential, or more properly the Na^+ current (I_{Na}), is said to be regenerative; that is, intracellular movement of a little Na^+ depolarizes the membrane more, which increases conductance to Na^+ more, which allows more Na^+ to enter, and so on. As this process is occurring, however, $[Na^+]_1$ and positive intracellular charges increase and reduce the driving force for Na^+ . When the equilibrium potential for Na^+ (E_{Na}) is reached, Na^+ no longer enters the cell; i.e., when the driving force acting on the ion to enter the cell balances the driving force acting on the ion to exit the cell, no current will flow. In addition, Na^+ conductance is time dependent, so when the membrane spends some time at voltages less negative than the resting potential, Na^+ conductance decreases (in activation). Therefore, an intervention that reduces membrane potential for a time--but not to threshold--partially inactivates Na^+ channels, and if threshold is now achieved, the magnitude and rate of Na^+ influx are reduced.

The probability of a voltage-gated channel not being inactivated, 1 - P_{inact} , is given by the Boltzmann distribution equation of the form

Figure 22-17 Action potentials recorded from different tissues in the heart (*left*) remounted along with a His bundle recording and scalar electrocardiogram from a patient (*right*) to illustrate the timing during a single cardiac cycle. In panels *A* to *F,* the top tracing is dV/dt of phase 0 and the second tracing is the action potential. For each panel the numbers (from left to right) indicate maximum diastolic potential (mV), action potential amplitude (mV), action potential duration at 90 percent of repolarization (milliseconds), and Vmax of phase 0 (V/sec). Zero potential is indicated by the short horizontal line next to the zero on the upper left of each action potential. *A,* Rabbit sinoatrial node; *B,* canine atrial muscle; *C,* rabbit atrioventricular node; *D,* canine ventricular muscle; *E,* canine Purkinje fiber; *F,* diseased human ventricle. Note that the action potentials recorded in *A, C,* and *F* have reduced resting membrane potentials, amplitudes, and Vmax when compared with the other action potentials. In the *right panel,* A = atrial muscle potential; AVN = atrioventricular nodal potential; HB = His bundle recording; II = lead II; PF = Purkinje fiber potential; SN = sinus nodal potential; V = ventricular muscle potential. Horizontal calibration on the left: 50 milliseconds for *A* and *C,* 100 milliseconds for *B, D, E,* and *F;* 200 milliseconds on the right. Vertical calibration on the left: 50 mV. Horizontal calibration on the right: 200 milliseconds (Modified from Gilmour RF Jr, Zipes DP: Basic electrophysiology of the slow inward current. *In* Antman E, Stone PH (Eds.) Calcium Blocking Agents in the Treatment of Cardiovascular Disorders. Mt Kisco, NY, Futura, 1983, pp 1-37.)

Figure 22-18 Schematic representation of membrane channels for rapid and slow inward currents at resting membrane potential *(top row)*, during the activated state *(middle row)*, and during the inactivated state *(bottom row)*. Vertically separated panels depict fibers with a normal resting potential of -90 mV *(left)*, with resting membrane potential reduced to less than -60 mV *(middle)*, and after stimulation of the cell with catecholamines *(right)*. The activation (m) and inactivation (h) gates of the fast channel and the activation (d) and inactivation (f) gates of the slow channel are depicted. During the resting state *(left panel)*, the activation gates of both channels are closed while the inactivation gates are open. When the cell is stimulated, the m gates of the fast channel open, and for a brief period, the open m gates and h gates allow inward sodium current to flow, depolarize the cell, and produce its upstroke. The action potential is depicted below. The h gates then close the channel and inactivate sodium conductance. Membrane depolarization also activates voltage-gated Ca^{2+} channels (d gates open), allowing influx of Ca^{2+} that contributes to the plateau phase of the action potential. The inactivation gates of the slow Ca^{2+} channel are both voltage and $[Ca^{2+}]_i$ dependent. High and low levels of intracellular free calcium ions respectively accelerate and slow inactivation, thereby functioning as a negative feed-back mechanism to control intracellular calcium content. When the upstroke of the action potential exceeds the threshold for activation of the slow inward current, the d gates open and allow ingress of the slow inward current that contributes to the plateau phase of the action potential. The f gates of the slow channel close more slowly than the h gates. Although the slow inward channel remains open longer than the fast channel does, less total current flows. When the resting membrane potential is reduced below -60 mV by increasing $[K]_o$ from 4.0 to 14.0 mm *(middle panel)*, the cell depolarizes to -60 mV and the fast channel becomes inactivated because the h gates remain closed. Even though the m gate may open during activation, the amount of sodium current is too small to elicit an action potential. The inactivation gates of the slow channel (f gates) remain open, and when the cell is excited after the addition of catecholamine *(right panel),* the d gates open and permit flow of a slow inward current that causes a slow-response action potential. This action potential resembles those in panels *A, C,* and *F* of Figure 22-17. (From Wit AL, Bigger JT Jr: Possible electrophysiological mechanisms for lethal arrhythmias accompanying myocardial ischemia and infarction. Circulation 52(Suppl 3):96, 1975. By permission of the American Heart Association, Inc.)

(for symbols see Equation 2). If it is assumed that the midpoint of half-inactivation is -60 mV and the steepness of the inactivation curve of the voltage-gated Na^+ channel is -3 mV, sustained membrane depolarization from -90 to -65 mV would decrease steady-state Na^+ channel availability from approximately 1 to 0.84.

In cardiac Purkinje fibers and to a lesser extent in ventricular muscle, two different populations of Na+ channels exist, or two different modes of operation of the same Na+ channel. One is responsible for the brief Na+ current of phase 0, while the other, which is longer lasting, participates in the action potential plateau (Steady-state or "window" current, see Fig. 22-12). Tetrodotoxin (TTX) and local anesthetics block both types of channels, thereby diminishing the rate of rise of phase 0 and shortening the action potential duration.[49] Furthermore, there may be a background Na+ current (I_{Na-B}) through a voltage-independent channel in sinus nodal cells that contributes

to pacemaker behavior.[50]

THE GATED SYSTEM--A HYPOTHETICAL MODEL.

In this hypothetical model, three m (activation) gates and one h (inactivation) gate can be considered to be lined up in series in the membrane Na+ channel (Fig. 22-18), , with the m gate on the extracellular side and the h gate on the intracellular side of the membrane. When the membrane is in a resting polarized state, the m gates are almost completely closed, the h gate is open, and no Na+ can cross the membrane. Although depolarization of the membrane opens the m gates and closes the h gate, the m gates open faster than the h gate closes; i.e., activation of the channel proceeds faster than inactivation can occur, and Na+ flows through the Na+ channel for about 1 millisecond while both gates are open simultaneously (Fig. 22-18*left panel,* red arrow).

When the membrane repolarizes to fairly high negative values, i.e., the membrane potential becomes more negative than about -60 mV, the m gates shut rapidly, the h gate opens more slowly (reactivation or recovery from inactivation), and the membrane is once again capable of depolarization. Until that time, the cell is absolutely refractory; i.e., no stimulus, regardless of intensity, can activate the cell. If the membrane is activated a second time before reaching a large negative value, all the h gates have not yet reopened and the maximum number of Na+ channels that can open is reduced. The

Figure 22-19 Mechanism of fast inactivation of sodium channels. The hinged-lid mechanism of sodium channel inactivation is illustrated. The intracellular loop connecting domains III and IV of the sodium channel is depicted as forming a hinged lid. The critical residue (Phe1489F) is shown as occluding the intracellular mouth of the pore. (From Catteral WA: Molecular analysis of voltage gated sodium channels in the heart and other tissues. *In* Zipes DP, Jalife J (eds): Cardiac Electrophysiology: From Cell to Bedside. 2nd ed. Philadelphia, WB Saunders, 1994, p 1.)

resulting action potential will have reduced Vmax, amplitude, duration, and conduction velocity. The state of the gates at any time depends on the membrane potential and the length of time that the potential has been maintained.[49]

A cluster of positively charged arginine and lysine residues in the S4 domain is thought to function as the voltage sensor (m gate), while the peptide loop connecting repeats S3 and S4 binds to the activated channel and occludes the intracellular mouth of the channel pore (h gate; see Fig. 22-19). This loop could be regarded as analogous to the N-terminal peptide chain of inactivating voltage-gated potassium channels (see Fig. 22-8*A*).

A Hodgkin-Huxley formalism has been used to describe the voltage dependence of single-channel permeability to sodium, with four hypothetical gating particles making independent transitions between conducting and nonconducting positions to control ion flux. Three m particles control activation and one h particle controls inactivation. The probability that they are all in a position where the channel conducts is m^3 h, and for the Na+ channel,

where P_{Na} is the permeability of the sodium channel at a given voltage, $P_{Na,max}$ is the maximal possible permeability of the channel, m^3 represents the probability that all three activation particles are in a position to make up an open channel (m = 1, gate is permissive; m = 0, gate is nonpermissive), whereas h represents the probability that the Na+ channel is not inactivated ([1 - P_{inact}], h = 1, gate is open; h = 0, gate is shut; see Fig. 22-12) . Since opening and closing of the gates are voltage *and* time dependent, the permeability of the channel (P_{Na}) will be some fraction of the maximum possible permeability ($P_{Na,max}$), depending on membrane potential and the period that the membrane has been at that voltage.

TABLE 22-3 -- SYNOPSIS OF IONIC CURRENTS IN MAMMALIAN CARDIAC MYOCYTES

I_{Na}	Tetrodotoxin-sensitive voltage-gated Na^+ current
I_{Na-B}	Proposed background Na^+ current through a voltage-independent channel in sinus nodal cells
$I_{Ca.L}$	L-type (*l*ong lasting, *l*arge conductance) Ca^{2+} currents through voltage-gated channels blocked by dihydropyridine-type antagonists (e.g., nifedipine), phenylalkylamines (e.g., verapamil), benzothiazepines (e.g., diltiazem), and a variety of divalent ions (e.g., Cd^{2+}), activated by dihydropyridine-type agonists (e.g., Bay K 8644), responsible for phase 0 depolarization and propagation in sinoatrial and AV nodal tissue, and contributing to the plateau of atrial, His-Purkinje, and ventricular cells; main trigger of Ca^{2+} release from the sarcoplasmic reticulum (Ca^{2+} -induced Ca^{2+} release); a noninactivating or "window" component may underlie early afterdepolarizations
$I_{Ca.T}$	T-type (*t*ransient current, *t*iny conductance) Ca^{2+} currents through voltage-gated channels blocked by mibefradil but insensitive to dihydropyridines; may contribute inward current to the later phase of phase 4 depolarization in pacemaker cells
I_f	Hyperpolarization-activated current carried by Na^+ and K^+ in sinoatrial and AV nodal cells and His-Purkinje cells and involved in generating phase 4 depolarization; increases rate of impulse initiation in pacemaker cells
I_{K1}	Inward rectifier K^+ current, voltage-dependent block by Ba^{2+} at micromolar concentrations; responsible for maintaining resting membrane potential in atrial, His-Purkinje, and ventricular cells; channel activity is a function of both membrane potential and $[K^+]_0$; inward rectification appears to result from depolarization-induced internal block by Mg^{2+}
$I_{K.G}$ ($I_{K.Ach}$, $I_{K.Ade}$)	Inwardly rectifying K^+ current activated by muscarinic (M_2) and purinergic (type 1) receptor stimulation via GTP regulatory (G) protein signal transduction; expressed in sinoatrial and AV nodal cells and atrial cells, where it causes hyperpolarization and action potential shortening; activation causes negative chronotropic and dromotropic effects
I_K	K^+ current carried by a voltage-gated K^+ channel (delayed rectifier K^+ channel); composed of the rapid (I_{Kr}) and slow (I_{Ks}) component. I_{Kr} is specifically blocked by dofetilide and sotalol in a reverse-use-dependent manner; inward rectification of I_{Kr} results from depolarization-induced fast inactivation; plays a major role in determining action potential duration
$I_{K,ur}$	K^+ current through a voltage-gated channel with ultrarapid activation, but ultraslow inactivation kinetics; expressed in atrial myocytes; determines action potential duration
I_{to} (I_{to1} , I_A)	Transient outward K^+ current through voltage-gated channels; exhibits fast activation and inactivation kinetics; blocked by 4-aminopyridine in a reverse-use-dependent manner; determines time course of phase 1 repolarization
$I_{Cl.Ca}$ (I_{to2})	4-Aminopyridine-resistant transient outward current carried by Cl^- ions; activated by rises in intracellular calcium; blocked by stilbene derivatives (SITS, DIDS); determines time course of phase 1 repolarization; may underlie spontaneous transient inward currents under conditions of Ca^{2+} overload
$I_{Cl.cAMP}$	Time-independent chloride current regulated by the cAMP/adenylate cyclase pathway; slightly depolarizes resting membrane potential and significantly shortens action potential duration; antagonizes action potential prolongation associated with beta-adrenergic stimulation of $I_{Ca.L}$
$I_{Cl.swell}$	Outwardly rectifying, swelling-activated Cl^- current; inhibited by 9-anthracene carboxylic acid; activation causes resting membrane depolarization and action potential shortening
$I_{K.ATP}$	Time-independent K^+ current through channels activated by a fall in intracellular ATP concentration; inhibited by sulfonylurea drugs, such as glibenclamide; activated by pinacidil, nicorandil, cromakalim; causes shortening of action potential duration during myocardial ischemia or hypoxia
$I_{Cir.swell}$	Inwardly rectifying, swelling-activated cation current; permeable to Na^+ and K^+ (P_{Na}/P_K =8); inhibited by Gd^{3+} ; depolarizes resting membrane potential and prolongs terminal (phase 3) repolarization
$I_{Na/Ca}$	Current carried by the Na/Ca exchanger; causes a net Na^+ outward current and a Ca^{2+} inward current (reverse mode) or a net Na^+ inward and Ca^{2+} outward current (3 Na^+ for 1 Ca^{2+}), the direction of Na^+ flux being dependent on membrane potential and intracellular and extracellular concentrations of Na^+ and Ca^{2+} ; Ca^{2+} influx mediated by $I_{Na/Ca}$ can trigger SR Ca^{2+} release; underlies I_{ti} (transient inward current) under conditions of intracellular Ca^{2+} overload
$I_{Na/K}$	Na^+ outward current generated by Na^+ , K^+ -ATPase (stoichiometry: 3 Na^+ leave and 2 K^+ enter); inhibited by digitalis

ELECTRONEUTRAL ION-EXCHANGING PROTEINS

Ca^{2+} -ATPase	Extrudes cytosolic calcium
Na/H	Exchanges intracellular H^+ for extracellular Na^+ ; cardiac myocytes express isoform NHE 1; specifically inhibited by the benzoylguanidine derivatives HOE 694 and HOE 642; inhibition causes intracellular acidification
Cl^{--} -HCO_3 --	Exchanges intracellular HCO_3 $^{--}$ for external Cl^{--} ; inhibited by SITS
Na^+ -K^+ -$2Cl^{--}$	Cotransporter blocked by amiloride

ATP=adenosine triphosphate; AV=atrioventricular; cAMP=cyclic adenosine monophosphate; DIDS=4,4 -diisothiocyanatostilbene-2,2 -disulfonic acid; GTP=guanosine triphosphate; SITS=4-acetamido-4 -isothiocyanatostilbene-2,2 -disulfonic acid; SR=sarcoplasmic reticulum.

UPSTROKE OF THE ACTION POTENTIAL.

In normal atrial and ventricular muscle and in fibers in the His-Purkinje system, action potentials have very rapid upstrokes with a large Vmax and are called *fast responses.* Action potentials in the normal sinus and AV nodes have very slow upstrokes with a reduced Vmax and are called *slow responses* [31] (see Fig. 22-17 and Table 22-3) . Upstrokes of "slow responses" are mediated by a slow inward, predominantly Ca^{2+} current (I_{Ca}) rather than the fast inward I_{Na} (Table 22-4) . These potentials received the name *slow response* because the time required for activation and inactivation of the slow inward current ($I_{Ca.L}$) is approximately an order of magnitude slower than that for the fast inward Na+ current (I_{Na}). Recovery from inactivation also takes longer. Calcium entry and $[Ca^{2+}]_i$ help promote inactivation. Thus, the slow channel opens (activation gates d) and closes (inactivation gates f) more slowly than the fast channel does, remains open for a longer time, and requires more time following a stimulus to be reactivated (see Fig. 22-18) . In fact, recovery of excitability outlasts full restoration of maximum diastolic potential, which means that even though the membrane potential has returned to normal, the cell has not recovered excitability completely because the latter depends on elapse of a certain amount of time (i.e., is time dependent) and not just on recovery of a particular membrane potential (i.e., voltage dependence).
