Heart Disease

A TEXTBOOK OF CARDIOVASCULAR MEDICINE

6th EDITION

Edited by

EUGENE BRAUNWALD M.D., M.D. (hon), Sc.D. (hon), F.R.C.P.
Vice President for Academic Programs, Partners HealthCare System
Distinguished Hersey Professor of Medicine
Faculty Dean for Academic Programs at Brigham and Women;cqs Hospital and
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

DOUGLAS P. ZIPES M.D.
Distinguished Professor of Medicine, Pharmacology, and Toxicology
Director, Krannert Institute of Cardiology
Director, Division of Cardiology
Indiana University School of Medicine
Attending Physician
University Hospital, Wishard Memorial Hospital, and Roudebush Veterans
Affairs Hospital
Indianapolis, Indiana

PETER LIBBY M.D.
Mallinckrodt Professor of Medicine
Harvard Medical School
Chief, Cardiovascular Medicine
Brigham and Women;cqs Hospital
Boston, Massachusetts

Contributors

DAVID H. ADAMS M.D.

Associate Professor of Surgery, Harvard Medical School; Associate Chief, Division of Cardiac Surgery, Brigham and Women's Hospital, Boston, Massachusetts
Medical Management of the Patient Undergoing Cardiac Surgery

JOSHUA ADLER M.D.

Assistant Clinical Professor of Medicine, University of California, San Francisco; Director, Ambulatory Practices, University of California, San Francisco, Medical Center, San Francisco, California
General Anesthesia and Noncardiac Surgery in Patients with Heart Disease

NADIR M. ALI M.D.

Assistant Professor of Medicine, Baylor College of Medicine, Houston; Interventional Cardiologist, Clear Lake Regional Medical Center, Webster, Texas
Hemostasis, Thrombosis, Fibrinolysis, and Cardiovascular Disease

ELLIOTT M. ANTMAN M.D.

Associate Professor of Medicine, Harvard Medical School; Director, Samuel A. Levine Cardiac Unit, Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts
Acute Myocardial Infarction; Medical Management of the Patient Undergoing Cardiac Surgery

WILLIAM F. ARMSTRONG M.D.

Professor of Internal Medicine and Director, Echocardiography Laboratory, University of Michigan Health System; Associate Clinical Chief, Division of Cardiology, and Associate Chair for Network Development, Department of Internal Medicine, University of Michigan Health System, Ann Arbor, Michigan
Echocardiography

ARTHUR J. BARSKY M.D.

Professor of Psychiatry, Harvard Medical School; Director of Psychosomatic Research, Brigham and Women's Hospital, Boston, Massachusetts
Psychiatric and Behavioral Aspects of Cardiovascular Disease

GEORGE A. BELLER M.D.

Ruth C. Heede Professor of Cardiology and Professor of Internal Medicine, University of Virginia School of Medicine; Chief, Cardiovascular Division, Department of Internal Medicine, University of Virginia Health System, Charlottesville, Virginia
Relative Merits of Cardiovascular Diagnostic Techniques

JOHN BITTL M.D.

Interventional Cardiologist, Ocala Heart Institute, Ocala, Florida
Coronary Angiography and Intravascular Ultrasonography

ROBERT O. BONOW M.D.

Professor of Medicine, Northwestern University Medical School; Chief, Division of Cardiology, Northwestern Memorial Hospital, Chicago, Illinois
Cardiac Catheterization; Chronic Ischemic Heart Disease

HARISIOS BOUDOULAS M.D.

Director, Overstreet Teaching and Research Laboratory, Division of Cardiology, The Ohio State University College of Medicine and Public Health; Staff Cardiologist, The Ohio State University Medical Center, Columbus, Ohio
Renal Disorders and Cardiovascular Disease

EUGENE BRAUNWALD M.D., M.D.(hon), Sc.D. (hon), F.R.C.P.

Vice President for Academic Programs, Partners HealthCare System; Distinguished Hersey Professor of Medicine and Faculty Dean for Academic Programs at Brigham and Women's Hospital and Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts
The History; Physical Examination of the Heart and Circulation;
Pathophysiology of Heart Failure;
Clinical Aspects of Heart Failure: High-Output Heart Failure: Pulmonary Edema;
Acute Myocardial Infarction;
Unstable Angina;
Chronic Coronary Artery Disease;
Valvular Heart Disease;
The Cardiomyopathies and Myocarditides

KENNETH R. BRIDGES M.D.

Associate Professor of Medicine, Harvard Medical School; Director, Joint Center for Sickle Cell and Thalassemic Disorders, Brigham and Women's Hospital, Boston, Massachusetts
Hematological-Oncological Disorders and Cardiovascular Disease

MICHAEL R. BRISTOW M.D., Ph.D.

Professor of Medicine and Head, Division of Cardiology, University of Colorado Health Sciences Center, Denver, Colorado
Treatment of Heart Failure: Pharmacological Methods;
Management of Heart Failure

HUGH CALKINS M.D.

Professor of Medicine, Johns Hopkins University; Director of the Arrhythmia Service and Clinical Electrophysiology Laboratory, Johns Hopkins Hospital, Baltimore, Maryland
Hypotension and Syncope

CHRISTOPHER P. CANNON M.D.

Assistant Professor of Medicine, Harvard Medical School; Cardiovascular Division, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Unstable Angina

AGUSTIN CASTELLANOS M.D.

Professor of Medicine, University of Miami School of Medicine; Director, Clinical Electrophysiology, University of Miami School of Medicine and Jackson Memorial Medical Center, Miami, Florida
Cardiac Arrest and Sudden Cardiac Death

BERNARD R. CHAITMAN M.D.

Professor of Medicine, Cardiology Division, St. Louis University School of Medicine; Chief of Cardiology, St. Louis University Hospital, St. Louis, Missouri
Exercise Stress Testing

MELVIN D. CHEITLIN M.D., M.A.C.C.

Emeritus Professor of Medicine, University of California, San Francisco; Former Chief of Cardiology, San Francisco General Hospital, San Francisco, California
Cardiovascular Disease in the Elderly

STEVEN D. COLAN M.D.

Associate Professor of Pediatrics, Harvard Medical School; Chief, Division of Noninvasive Cardiology, and Senior Associate in Cardiology, Children's Hospital, Boston, Massachusetts
Acquired Heart Disease in Children

WILSON S. COLUCCI M.D.

Professor of Medicine and Physiology, Boston University School of Medicine; Chief, Cardiovascular Medicine, Boston University Medical Center, Boston, Massachusetts
Pathophysiology of Heart Failure; Clinical Aspects of Heart Failure; Primary Tumors of the Heart

MARK A. CREAGER M.D.

Associate Professor of Medicine, Harvard Medical School; Director, Vascular Center, Brigham and Women's Hospital, Boston, Massachusetts
Peripheral Arterial Diseases

ADNAN S. DAJANI M.D.

Professor of Pediatrics, Wayne State University School of Medicine; Director, Division of Infectious Diseases, Children's Hospital of Michigan, Detroit, Michigan
Rheumatic Fever

MICHAEL D. DAKE M.D.

Associate Professor of Radiology and Medicine (Pulmonary), Stanford University; Chief, Cardiovascular and Interventional Radiology, Stanford Medical Center, Stanford, California
Extracardiac Vascular Interventions

CHARLES J. DAVIDSON M.D.

Associate Professor of Medicine, Northwestern University Medical School; Chief, Cardiac Catheterization Laboratories, Northwestern Memorial Hospital, Chicago, Illinois
Cardiac Catheterization

PAMELA S. DOUGLAS M.D.

Dr. Herman and Aileen Tuchman Professor of Cardiovascular Medicine and Head, Section of Cardiovascular Medicine, University of Wisconsin-Madison Medical School, Madison, Wisconsin
Coronary Artery Disease in Women

URI ELKAYAM M.D.

Professor of Medicine and Director, Heart Failure Program, University of Southern California School of Medicine, Los Angeles, California
Pregnancy and Cardiovascular Disease

ANTHONY L. ESTRERA M.D.

Chief Resident, Thoracic Surgery, Baylor College of Medicine, Houston, Texas
Traumatic Heart Disease

JOHN A. FARMER M.D.

Associate Professor, Section of Cardiology and Atherosclerosis, Department of Medicine, Baylor College of Medicine; Chief of Cardiology, Ben Taub General Hospital,

Houston, Texas
Lipid-Lowering Trials

HARVEY FEIGENBAUM M.D.

Distinguished Professor of Medicine and Director, Echocardiography Laboratories, Indiana University School of Medicine and Krannert Institute of Cardiology, Indianapolis, Indiana
Echocardiography

STACY D. FISHER M.D.

Instructor in Medicine/Cardiology, University of Rochester School of Medicine and Dentistry; Attending Physician and Fellow in Adult Congenital Heart Disease, University of Rochester Medical Center and Children's Hospital at Strong, Rochester, New York
Cardiovascular Abnormalities in HIV-Infected Individuals

GERALD F. FLETCHER M.D.

Professor of Medicine, Mayo Medical School; Cardiovascular Disease, Prevention and Rehabilitation, Mayo Clinic, Jacksonville, Florida
Comprehensive Rehabilitation of Patients with Coronary Artery Disease

WILLIAM F. FRIEDMAN M.D.

J. H. Nicholson Professor of Pediatrics (Cardiology) and Senior Dean for Academic Affairs, University of California, Los Angeles (UCLA), School of Medicine, Los Angeles, California
Congenital Heart Disease in Infancy and Childhood

PETER GANZ M.D.

Associate Professor of Medicine, Harvard Medical School; Director of Cardiovascular Research, Cardiac Catheterization Laboratory, Brigham and Women's Hospital, Boston, Massachusetts
Coronary Blood Flow and Myocardial Ischemia

WILLIAM GANZ M.D.

Professor of Medicine, University of California, Los Angeles (UCLA), School of Medicine; Senior Research Scientist, Cedars-Sinai Medical Center, Los Angeles, California
Coronary Blood Flow and Myocardial Ischemia

J. MICHAEL GAZIANO M.D., M.P.H.

Assistant Professor of Medicine, Harvard Medical School; Co-Director, Cardiovascular Epidemiology, Division of Preventive Medicine, Brigham and Women's Hospital; Director, Massachusetts Veterans' Epidemiology and Research Center, Boston VA Healthcare Systems, Boston, Massachusetts
Global Burden of Cardiovascular Disease;
Primary and Secondary Prevention of Coronary Heart Disease

JACQUES GENEST M.D.

Associate Professor of Medicine, McGill University; Director, Division of Cardiology, McGill University Health Center, Montreal, Quebec, Canada
Risk Factors for Atherosclerotic Disease

BERNARD J. GERSH M.D., M.B., Ch.B., D.Phil.

Professor of Medicine, Mayo Medical Center; Consultant in Cardiovascular Diseases, Mayo Clinic, Rochester, Minnesota
Chronic Ischemic Heart Disease

MICHAEL M. GIVERTZ M.D.

Assistant Professor of Medicine, Boston University School of Medicine; Clinical Director, Cardiomyopathy Program, Boston Medical Center, Boston, Massachusetts
Clinical Aspects of Heart Failure

ARY L. GOLDBERGER M.D.

Associate Professor of Medicine, Harvard Medical School; Director, Margret and H.A. Rey Laboratory for Nonlinear Dynamics in Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Electrocardiography

SAMUEL Z. GOLDHABER M.D.

Associate Professor of Medicine, Harvard Medical School; Staff Cardiologist, Director of Cardiac Center's Anticoagulation Service, and Director of Venous Thromboembolism Research Group, Brigham and Women's Hospital, Boston, Massachusetts
Pulmonary Embolism

LEE GOLDMAN M.D., M.P.H.

Julius R. Krevans Distinguished Professor and Chair, Department of Medicine and Associate Dean for Clinical Affairs, School of Medicine, University of California, San Francisco; Attending Physician, University of California Medical Center, San Francisco, California
General Anesthesia and Noncardiac Surgery in Patients with Heart Disease

ANTONIO M. GOTTO JR. M.D., D.Phil.

The Stephen and Suzanne Weiss Dean and Professor of Medicine, Weill Medical College of Cornell University, New York, New York
Lipid-Lowering Trials

WILLIAM J. GROH M.D.

Assistant Professor of Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Neurological Disorders and Cardiovascular Disease

DAVID L. HAYES M.D.

Consultant, Division of Cardiovascular Diseases and Internal Medicine, Mayo Clinic and Mayo Foundation, Mayo Medical School, Rochester, Minnesota

Cardiac Pacemakers and Cardioverter-Defibrillators

CHARLES B. HIGGINS M.D.

Professor of Radiology, University of California, San Francisco, California
Newer Cardiac Imaging Modalities: Magnetic Resonance Imaging and Computed Tomography

MARK A. HLATKY M.D.

Professor of Health Research and Policy and of Medicine (Cardiovascular Medicine), and Chair, Department of Health Research and Policy, Stanford University School of Medicine, Stanford, California
Economics and Cardiovascular Disease

GARY S. HOFFMAN M.D.

Harold C. Schott Chair for Rheumatic and Immunologic Diseases and Professor of Medicine, Cleveland Clinic/Ohio State University; Chairman, Rheumatic and Immunologic Diseases, and Director, Center for Vasculitis Care and Research, Cleveland Clinic, Cleveland, Ohio
Rheumatic Diseases and the Cardiovascular System

ERIC M. ISSELBACHER M.D.

Instructor in Medicine, Harvard Medical School; Medical Director, Thoracic Aortic Center, Massachusetts General Hospital, Boston, Massachusetts
Diseases of the Aorta

NORMAN M. KAPLAN M.D.

Clinical Professor of Medicine, University of Texas Southwestern Medical Center, Dallas, Texas
Systemic Hypertension: Mechanisms and Diagnosis;
Systemic Hypertension: Therapy

ADOLF W. KARCHMER M.D.

Professor of Medicine, Harvard Medical School; Chief, Division of Infectious Diseases, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Infective Endocarditis

RALPH A. KELLY M.D.

Associate Professor of Medicine, Harvard University; Associate Physician, Division of Cardiology, Brigham and Women's Hospital, Boston, Massachusetts
Treatment of Heart Failure: Pharmacological Methods

RICHARD E. KUNTZ M.D.

Associate Professor of Medicine, Harvard Medical School; Brigham and Women's Hospital, Boston, Massachusetts
Percutaneous Coronary and Valvular Intervention

THOMAS H. LEE M.D., S.M.

Associate Professor of Medicine, Harvard Medical School; Medical Director, Partners Community HealthCare, Inc., Boston, Massachusetts
Guidelines: Electrocardiography;
Guidelines: Use of Exercise Tolerance Testing;
Guidelines: Use of Echocardiography;
Guidelines: Management of Heart Failure;
Guidelines: Cardiac Radionuclide Imaging;
Guidelines: Ambulatory Monitoring and Electrophysiological Testing;
Guidelines: Use of Cardiac Pacemakers and Antiarrhythmia Devices; Guidelines:
Diagnosis and Management of Acute Myocardial Infarction;
Guidelines: Management of Unstable Angina/Non-ST Segment Elevation Myocardial Infarction;
Guidelines: Management of Chronic Ischemic Heart Disease;
Guidelines: Management of Valvular Heart Disease;
Guidelines: Prevention, Evaluation, and Treatment of Infective Endocarditis;
Guidelines: Summary of Guidelines for Reducing Cardiac Risk With Noncardiac Surgery;
Guidelines: Management of Valvular Disease in Pregnancy

JEFFREY M. LEIDEN M.D., Ph.D.

Adjunct Professor of Biological Sciences, Harvard School of Public Health; Executive Vice President, Pharmaceuticals, and Chief Scientific Officer, Abbott Laboratories, Abbott Park, Illinois
Principles of Cardiovascular Molecular Biology and Genetics

CARL V. LEIER M.D.

Overstreet Professor of Medicine and Pharmacology, Division of Cardiology, The Ohio State University College of Medicine and Public Health; Staff Cardiologist, The Ohio State University Hospitals, Columbus, Ohio
Renal Disorders and Cardiovascular Disease

GLENN N. LEVINE M.D.

Assistant Professor of Medicine, Baylor College of Medicine; Director, Cardiac Catheterization Laboratory, Houston VA Medical Center, Houston, Texas
Hemostasis, Thrombosis, Fibrinolysis, and Cardiovascular Disease

PETER LIBBY M.D.

Mallinckrodt Professor of Medicine, Harvard Medical School; Chief, Cardiovascular Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Vascular Biology of Atherosclerosis;
Risk Factors for Atherosclerotic Disease;
Peripheral Vascular Disease;
Diabetes Mellitus and Cardiovascular Disease;
Hematological-Oncological Disorders and Cardiovascular Disease

STEVEN E. LIPSHULTZ M.D.

Professor of Pediatrics and Professor of Oncology, University of Rochester School of Medicine and Dentistry; Chief of Pediatric Cardiology, University of Rochester Medical Center and Children's Hospital at Strong, Rochester, New York

Cardiovascular Abnormalities in HIV-Infected Individuals

WILLIAM C. LITTLE M.D.

Chief of Cardiology and Professor of Medicine, Wake Forest University School of Medicine, Bowman Gray Campus; Associate Chief of Professional Services, North Carolina Baptist Hospital, Winston-Salem, North Carolina
Assessment of Normal and Abnormal Cardiac Function

BRIAN F. MANDELL M.D., Ph.D.

Clinical Professor of Medicine, Penn State University School of Medicine, Hershey, Pennsylvania; Associate Professor of Medicine, Ohio State University School of Medicine, Columbus, Ohio; Education Program Director, Rheumatic and Immunologic Diseases, Cleveland Clinic Foundation, Cleveland, Ohio
Rheumatic Diseases and the Cardiovascular System

JOANN E. MANSON M.D., Dr.P.H.

Professor of Medicine, Harvard Medical School; Chief, Division of Preventive Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Primary and Secondary Prevention of Coronary Heart Disease

DANIEL B. MARK M.D., M.P.H.

Professor of Medicine, Duke University Medical Center; Director, Outcomes Research and Assessment Group, Duke Clinical Research Institute, Durham, North Carolina
Economics and Cardiovascular Disease

BARRY J. MARON M.D.

Director, Cardiovascular Research Division, Minneapolis Heart Institute Foundation, Minneapolis, Minnesota
Cardiovascular Disease in Athletes

KENNETH L. MATTOX M.D.

Professor and Vice Chairman, Department of Surgery, Baylor College of Medicine; Chief of Staff and Chief of Surgery, Ben Taub General Hospital, Houston, Texas
Traumatic Heart Disease

VALLERIE V. McLAUGHLIN M.D.

Assistant Professor of Medicine, Rush Medical College; Associate Director, Rush Heart Institute, Center for Pulmonary Heart Disease, Rush-Presbyterian-St. Luke's Medical Center, Chicago, Illinois
Cor Pulmonale

JOHN M. MILLER M.D.

Professor of Medicine, Indiana University School of Medicine; Director, Clinical Cardiac Electrophysiology, Indiana University Medical Center, Indianapolis, Indiana
Management of the Patient with Cardiac Arrhythmias

DOUGLAS N. MINIATI M.D.

Postdoctoral Research Fellow, Department of Cardiothoracic Surgery, Stanford University School of Medicine, Stanford, California
Heart and Heart-Lung Transplantation

DAVID M. MIRVIS M.D.

Professor of Preventive Medicine and Medicine, University of Tennessee; Director, The Center for Health Services Research, Memphis, Tennessee
Electrocardiography

ROBERT J. MYERBURG M.D.

Professor of Medicine and Physiology, University of Miami School of Medicine; Director, Division of Cardiology, University of Miami School of Medicine and Jackson Memorial Medical Center, Miami, Florida
Cardiac Arrest and Sudden Cardiac Death

RICHARD W. NESTO M.D.

Associate Professor of Medicine, Harvard Medical School, Boston; Chairman, Cardiovascular Medicine, Lahey Clinic Medical Center, Burlington, Massachusetts
Diabetes Mellitus and the Cardiovascular System

JANE W. NEWBURGER M.D., M.P.H.

Professor of Pediatrics, Harvard Medical School; Associate Cardiologist-in-Chief, Children's Hospital, Boston, Massachusetts
Acquired Heart Disease in Children

KEITH R. OKEN M.D.

Senior Associate Consultant, Division of Cardiovascular Diseases, Department of Internal Medicine, Mayo Clinic, Jacksonville, Florida
Comprehensive Rehabilitation of Patients with Coronary Artery Disease

JEFFREY E. OLGIN M.D.

Assistant Professor of Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Specific Arrhythmias: Diagnosis and Treatment

LIONEL H. OPIE M.D., D.Phil., D.Sc., F.R.C.P.

Professor of Medicine, University of Cape Town; Director, Cape Heart Centre, University of Cape Town Medical School, Cape Town, South Africa
Mechanisms of Cardiac Contraction and Relaxation

JOSEPH K. PERLOFF M.D.

Streisand/American Heart Association Professor of Medicine and Pediatrics, University of California, Los Angeles, School of Medicine, Division of Cardiology, Departments of Medicine and Pediatrics, UCLA Center for the Health Sciences, Los Angeles, California

Physical Examination of the Heart and Circulation

WILLIAM S. PIERCE M.D.

Evan Pugh Professor of Surgery, The Pennsylvania State University College of Medicine; The Milton S. Hershey Medical Center, Department of Surgery, Section of Artificial Organs, Hershey, Pennsylvania
Treatment of Heart Failure: Assisted Circulation

JEFFREY J. POPMA M.D.

Associate Professor of Medicine, Harvard Medical School; Director, Interventional Cardiology, Brigham and Women's Hospital, Boston, Massachusetts
Coronary Arteriography;
Percutaneous Coronary and Valvular Intervention

J. DAVID PORT Ph.D.

Associate Professor of Medicine/Cardiology and Pharmacology, University of Colorado Health Sciences Center, Denver, Colorado
Treatment of Heart Failure: Pharmacological Methods

REED E. PYERITZ M.D., Ph.D.

Professor of Human Genetics, Medicine, and Pediatrics and Chair, Department of Human Genetics, MCP Hahnemann School of Medicine, Philadelphia, Pennsylvania
Genetics and Cardiovascular Disease

BRUCE A. REITZ M.D.

Professor and Chairman, Department of Cardiothoracic Surgery, Stanford University School of Medicine, Stanford, California
Heart and Heart-Lung Transplantation

STUART RICH M.D.

Professor of Medicine, Rush Medical College; Director, Rush Heart Institute Center for Pulmonary Heart Disease, Rush-Presbyterian-St. Luke's Medical Center, Chicago, Illinois
Pulmonary Hypertension;
Cor Pulmonale

WAYNE E. RICHENBACHER M.D.

Professor of Surgery and Anatomy and Cell Biology and Professor, Division of Cardiothoracic Surgery, The University of Iowa College of Medicine, Iowa City, Iowa
Treatment of Heart Failure: Assisted Circulation

PAUL M RIDKER M.D., M.P.H.

Associate Professor of Medicine, Harvard Medical School; Director of Cardiovascular Research, Division of Preventive Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Risk Factors for Atherosclerotic Disease; Primary and Secondary Prevention of Coronary Heart Disease

ROBERT C. ROBBINS M.D.

Assistant Professor, Department of Cardiothoracic Surgery, Stanford University School of Medicine; Director of Heart and Heart-Lung Transplantation, Stanford University Medical Center, Stanford, California
Heart and Heart-Lung Transplantation

MICHAEL RUBART M.D.

Assistant Scientist, Department of Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Genesis of Cardiac Arrhythmias: Electrophysiological Considerations

ROBERT E. SAFFORD M.D., Ph.D.

Barbara Woodward Lips Professor of Medicine, Mayo Medical School, Rochester, Minnesota; Consultant in Cardiovascular Diseases, Mayo Clinic, Jacksonville, Florida
Comprehensive Rehabilitation of Patients with Coronary Artery Disease

SHAUN L. W. SAMUELS M.D.

Clinical Assistant Professor, Division of Cardiovascular/Interventional Radiology, Stanford University Hospital, Stanford University, Stanford; Staff Physician, Department of Radiology, Palo Alto VA Medical Center, Palo Alto VA Health Care System, Palo Alto, California
Extracardiac Vascular Interventions

ANDREW I. SCHAFER M.D.

The Bob and Vivian Smith Chair in Medicine and Chairman, Department of Medicine, Baylor College of Medicine; Chief, Internal Medicine Service, The Methodist Hospital, Houston, Texas
Hemostasis, Thrombosis, Fibrinolysis, and Cardiovascular Disease

FREDERICK J. SCHOEN M.D., Ph.D.

Professor of Pathology, Harvard Medical School; Vice-Chairman, Department of Pathology, and Director, Cardiac Pathology, Brigham and Women's Hospital, Boston, Massachusetts
Primary Tumors of the Heart

ELLEN W. SEELY M.D.

Assistant Professor of Medicine, Harvard Medical School; Director of Clinical Research, Endocrine-Hypertension Division, Brigham and Women's Hospital, Boston, Massachusetts
The Heart in Endocrine Disorders

NORMAN SILVERMAN M.D., D.Sc. (Med)

Professor of Pediatrics and Radiology (Cardiology) and Director of Pediatric and Fetal Echocardiography, University of California, San Francisco, California
Congenital Heart Disease in Infancy and Childhood

ROBERT SOUFER M.D.

Associate Professor of Medicine, Yale University School of Medicine; Attending Physician and Chief, Cardiology, Yale-New Haven Hospital; VA New England Health Care Systems, West Haven, Connecticut
Nuclear Cardiology

DAVID H. SPODICK M.D.
D.Sc.

Professor of Medicine, University of Massachusetts Medical School; Director of Clinical Cardiology and Cardiovascular Fellowship Training, Worcester Medical Center/St. Vincent's Hospital, Worcester, Massachusetts
Pericardial Diseases

ROBERT M. STEINER M.D.

Professor of Radiology, Weill Medical College of Cornell University; Attending Radiologist, New York Presbyterian Hospital, New York, New York
Radiology of the Heart and Great Vessels

RICHARD M. STONE M.D.

Associate Professor of Medicine, Harvard Medical School; Clinical Director, Adult Leukemia Program, Dana-Farber Cancer Institute and Brigham and Women's Hospital, Boston, Massachusetts
Hematological-Oncological Disorders and Cardiovascular Disease

JUDITH THERRIEN M.D.

Assistant Professor of Medicine, McGill University; Co-Director of Adult Congenital Heart Disease Clinical, Sir Mortimer B. Davis Jewish General Hospital, Montreal, Quebec, Canada
Congenital Heart Disease in Adults

FRANS J. TH. WACKERS M.D.

Professor of Diagnostic Radiology and Medicine and Director, Cardiovascular Nuclear Imaging and Stress Laboratories, Yale University School of Medicine; Attending Physician, Yale-New Haven Hospital, New Haven, Connecticut
Nuclear Cardiology

MATTHEW J. WALL JR. M.D.

Associate Professor of Surgery, Department of Surgery, Baylor College of Medicine, Houston, Texas
Traumatic Heart Disease

GARY D. WEBB M.D.

Professor of Medicine, University of Toronto; Director, University of Toronto Congenital Cardiac Center for Adults, Toronto General Hospital, Toronto, Ontario, Canada
Congenital Heart Disease in Adults

GORDON H. WILLIAMS M.D.

Professor of Medicine, Harvard Medical School; Director, Clinical Research Center, and Chief, Endocrine-Hypertension Division, Brigham and Women's Hospital, Boston, Massachusetts
The Heart in Endocrine Disorders

JOSHUA WYNNE M.D., M.B.A.

Professor of Medicine, Wayne State University; Attending Physician, Detroit Medical Center, Detroit, Michigan
Cardiomyopathies and Myocarditides

BARRY L. ZARET M.D.

Chief, Cardiovascular Medicine, and Associate Chair for Clinical Affairs, Department of Internal Medicine, Yale University School of Medicine; Medical Director, Heart Center, Yale-New Haven Hospital, New Haven, Connecticut
Nuclear Cardiology

DOUGLAS P. ZIPES M.D.

Distinguished Professor of Medicine, Pharmacology, and Toxicology; Director, Krannert Institute of Cardiology; and Director, Division of Cardiology, Indiana University School of Medicine; Attending Physician, University Hospital, Wishard Memorial Hospital, and Roudebush Veterans Affairs Hospital, Indianapolis, Indiana
Genesis of Cardiac Arrhythmias: Electrophysiological Considerations;
Management of the Patient with Cardiac Arrhythmias;
Cardiac Pacemakers and Cardioverter-Defibrillators;
Specific Arrhythmias: Diagnosis and Treatment;
Hypotension and Syncope;
Cardiovascular Disease in the Elderly;
Neurological Disorders and Cardiovascular Disease

Braunwald: Heart Disease: A Textbook of Cardiovascular Medicine, 6th ed., Copyright © 2001 W. B. Saunders Company

Publisher's Note

We are proud to announce that two distinguished cardiologists, Drs. Douglas P. Zipes and Peter Libby, have joined Dr. Braunwald as editors of the sixth edition. Dr. Zipes is a world-renowned arrhythmologist and clinical electrophysiologist, and Dr. Libby is a leading expert in vascular biology and vascular disease. Both new editors head important Divisions of Cardiology with strong academic and clinical programs.

Preface

The accelerating advances in cardiology since the publication of the fifth edition of *Heart Disease* have required the most extensive changes yet made in any revision. This edition, the first in the new millennium, contains 30 chapters that are new (the most for any revision to date), and the remaining 42 have been extensively revised and updated. The editors warmly welcome 56 authors who are new to this edition.

Cardiovascular disease is now, more than ever, a global problem with enormous economic consequences. The various forms of heart disease in different economies and cultures are presented in the new opening chapter by Gaziano, and principles of cost-effective practice are described in a new chapter by Hlatky and Mark. Part II, The Examination of the Patient, begins with the clinical examination and moves progressively from simple to more sophisticated noninvasive and invasive techniques. All of these approaches are described in detail with many new illustrations. The new chapter "Relative Merits of Cardiovascular Diagnostic Techniques," by Beller, provides a rational approach to the selection among several methods available to image the heart.

Heart failure is becoming an increasingly prevalent problem. Bristow has prepared two new chapters on the treatment of this condition, with emphasis on new treatment options based on pathophysiological considerations. There also has been enormous progress in cardiac electrophysiology and arrhythmology. Zipes has enlisted a cadre of talented authors to help update this section, always one of the strongest in *Heart Disease.*

The section on atherosclerosis is entirely new, reflecting greatly expanded information in this field and Libby's expertise in the area. The risk factors for the development of atherosclerosis and methods for its prevention are presented in new chapters. In view of the increasing importance of diabetes as a risk factor for vascular disease, a new chapter on diabetes mellitus and cardiovascular disease has been added. The cardiologist is called upon increasingly to deal with patients with extracardiac vascular disease. In new chapters on this subject, Creager and Libby describe the diagnosis and management of these conditions, and Dake and Samuels describe the extracardiac vascular interventions.

The acute coronary syndromes are, by far, the most common diagnoses for cardiovascular patients admitted to the hospital. In a new chapter on unstable angina, Cannon and Braunwald describe the many new diagnostic techniques and therapeutic measures available to care for these patients, and Antman and Braunwald provide a detailed contemporary description of the clinical manifestations and management of acute myocardial infarction. Interventional cardiology has progressed rapidly since the mid-1990s, and Popma and Kuntz have prepared an excellent new chapter on this important subspecialty of cardiology.

The sixth edition also focuses on the different manifestations in various populations, with new chapters on acquired heart disease in infancy, congenital heart disease in adults, and heart disease in athletes, in diabetics, in the elderly, and in patients with HIV infection and neoplastic disease, and an updated chapter on coronary artery disease in women.

The impact of molecular biology and genetics on cardiovascular disease is growing rapidly. A new chapter, "Principles of Cardiovascular Molecular Biology and Genetics," by Leiden joins the updated chapter "Genetics and Cardiovascular Disease" by Pyeritz in providing clear explanations of this important area. Many cardiovascular diseases result, in part, from coagulation disorders. Schafer and colleagues have prepared an excellent new chapter on hemostasis, thrombosis, and fibrinolysis to equip the cardiologist with the information required to deal effectively with these disorders. Other important new chapters include "Echocardiography," by Armstrong and Feigenbaum, and "Hypotension and Syncope," by Calkins and Zipes.

Practice guidelines are increasingly influencing the diagnosis and therapy of heart disease. Lee provides useful summaries of the most important guidelines developed by authoritative groups and skillfully places them into the perspective of modern patient care.

Considerable revisions were made both in galley proofs and page proofs to include information about the most recent advances in the field. Particular emphasis has been placed on ensuring a comprehensive and up-to-date bibliography of more than 18,000 pertinent references, including hundreds of publications that appeared in 2000. Many of the 1700 figures and 546 tables are new to this edition.

In order to allow the reader to keep pace with the enormous expansion of cardiovascular knowledge, *Heart Disease* is supplemented by a number of companion volumes. These include *Cardiac Imaging, Cardiovascular Therapeutics, Molecular Basis of Heart Disease,* and *Clinical Trials in Cardiovascular Disease.* These books have been well received, and new editions are in preparation. Companion volumes in other important segments of cardiology are planned. In addition, a *Review and Assessment* book will again accompany this edition of *Heart Disease.* It consists of 600 questions based on material discussed in the textbook and provides the answers as well as detailed explanations. The publisher, Harcourt Health Sciences, comprising W.B. Saunders, Mosby, and Churchill Livingstone, is developing a comprehensive website in cardiology: MDConsult-Cardiology. The sixth edition of *Heart Disease* will serve as the "anchor" of this website, which will be updated continuously. This multipronged educational effort--*Heart Disease,* the growing number of companion volumes, and the *Review and Assessment* book, all appearing in print and electronic (CD-ROM) form, as well as the new website--is designed to assist the reader with the awesome task of learning and remaining current in this dynamic field.

We hope that this textbook will prove useful to those who wish to broaden their knowledge of cardiovascular medicine. To the extent that it achieves this goal and thereby aids in the care of patients afflicted with heart disease, credit must be given to the many talented and dedicated persons involved in its preparation. Our deepest appreciation goes to our fellow contributors for their professional expertise, knowledge, and devoted scholarship, which are at the very "heart" of this book. At the W.B. Saunders Company, our editor, Richard Zorab, and the production team, Lynne Gery, Frank Polizzano, and Anne Ostroff, were enormously helpful. Our editorial associates, Kathryn Saxon, Janet Hutcheson, and Karen Williams, rendered invaluable and devoted assistance.

EUGENE BRAUNWALD

PETER LIBBY
2001

Adapted from the Preface to the First Edition

Cardiovascular disease is the greatest scourge affecting the industrialized nations. As with previous scourges--bubonic plague, yellow fever, and smallpox--cardiovascular disease not only strikes down a significant fraction of the population without warning but also causes prolonged suffering and disability in an even larger number. In the United States alone, despite recent encouraging declines, cardiovascular disease is still responsible for almost 1 million fatalities each year and more than half of all deaths; almost 5 million persons afflicted with cardiovascular disease are hospitalized each year. The cost of these diseases in terms of human suffering and of material resources is almost incalculable. Fortunately, research focusing on the causes, diagnosis, treatment, and prevention of heart disease is moving ahead rapidly.

In order to provide a comprehensive, authoritative text in a field that has become as broad and deep as cardiovascular medicine, I chose to enlist the aid of a number of able colleagues. However, I hoped that my personal involvement in the writing of about half of the book would make it possible to minimize the fragmentation, gaps, inconsistencies, organizational difficulties, and impersonal tone that sometimes plague multiauthored texts.

Since the early part of the 20th century, clinical cardiology has had a particularly strong foundation in the basic sciences of physiology and pharmacology. More recently, the disciplines of molecular biology, genetics, developmental biology, biophysics, biochemistry, experimental pathology, and bioengineering have also begun to provide critically important information about cardiac function and malfunction. Although *Heart Disease: A Textbook of Cardiovascular Medicine* is primarily a clinical treatise and not a textbook of fundamental cardiovascular science, an effort has been made to explain, in some detail, the scientific bases of cardiovascular diseases.

EUGENE BRAUNWALD, 1980

NOTICE

Medicine is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the editor assumes any liability for any injury and/or damage to persons or property arising from this publication.

Part I - GENERAL CONSIDERATIONS OF CARDIOVASCULAR DISEASE

Chapter 1 - Global Burden of Cardiovascular Disease

J. MICHAEL GAZIANO

THE EPIDEMIOLOGICAL TRANSITIONS

At the beginning of the 20th century, cardiovascular disease (CVD) accounted for less than 10 percent of all deaths worldwide. At its end, CVD accounted for nearly half of all deaths in the developed world and 25 percent in the developing world.[1] [2] By 2020, CVD will claim 25 million deaths annually and coronary heart disease (CHD) will surpass infectious disease as the world's number one cause of death and disability.

This global rise in CVD is the result of a dramatic shift in the health status of individuals around the world over the course of the 20th century. Equally important, there has been an unprecedented transformation in the dominant disease profile, or the distribution of diseases responsible for the majority of death and debility. Before 1900, infectious diseases and malnutrition were the most common causes of death. These have been gradually supplanted in some (mostly developed) countries by chronic diseases such as CVD and cancer, thanks largely to improved nutrition and public health measures. As this trend spreads to and continues in developing countries, CVD will dominate as the major cause of death by 2020, accounting for at least one in every three deaths.[2]

This shift in the diseases that account for the lion's share of mortality and morbidity is known as the epidemiological transition.[3] [4] The epidemiological transition never occurs in isolation but is tightly intertwined with changes in personal and collective wealth (economic transition), social structure (social transition), and demographics (demographic transition).

Because the epidemiological transition is linked to the evolution of social and economic forces, it takes place at different rates around the world. Although changes in health status have occurred (and are occurring) in every part of the world, at the beginning of the millennium national health and disease profiles vary widely by country and by region. For example, life expectancy in Japan (80 years) is more than twice that in Sierra Leone (37.5 years).[1] In a similar vein, the Group I diseases defined by Murray and Lopez in their comprehensive analysis of the global burden of disease--communicable, infectious, maternal, perinatal, and nutritional diseases--account for just 6 percent of deaths in so-called developed countries compared with 33 percent in India.[2] The vast differences in burden of disease are readily apparent across three broad economic and geographical sectors of the world (Table 1-1) . These include the established market economies (EstME) of Western Europe, North America, Australia, New Zealand, and Japan; the emerging market economies (EmgME) of the former socialist states of Eastern Europe; and the developing economies (DevE), which can further be subdivided into six geographical regions--China, India, other Asia and islands, sub-Saharan Africa, the Middle Eastern Crescent, and Latin America and the Caribbean. Currently, CVD is responsible for 45 percent of all deaths in the EstME, 55 percent of all deaths in EmgME, and only 23 percent of the deaths in DevE.

An excellent model of the epidemiological transition has been developed by Omran.[3] He divides the transition into three basic ages--pestilence and famine, receding pandemics, and degenerative and man-made diseases (Table 1-2) . Olshansky and Ault added a fourth stage, delayed degenerative diseases.[4] Although any specific country or region enters these ages at different times, the progression from one to another tends to proceed in a predictable manner.

TABLE 1-1 -- BURDEN OF DISEASE (1990 ESTIMATES) FOR THE THREE ECONOMIC REGIONS OF THE WORLD

REGION	POPULATION (MILLIONS) (% TOTAL WORLD POPULATION)	% OF DEATHS IN THE REGION DUE TO			
		Cardiovascular Disease	Other Noncommunicable Diseases*	Communicable Diseases	Injuries
Developed					
EstME	798 (15.2)	44.6%	42.8%	6.4%	10.7%
EmgME	346 (6.6)	54.6%	29.5%	5.6%	10.3%
Developing					
DevE§	4124 (78.3)	23.0%	24.3%	46.9%	6.2%
Totals	5267	28.4%	27.4%	34.2%	10.1%

*Includes cancer, diabetes, neuropsychiatric conditions, congenital anomalies, and respiratory, digestive, genitourinary, and musculoskeletal diseases.

EstME: Established market economies--United States, Canada, Western Europe, Japan, Australia, and New Zealand.

EmgME: Emerging market economies--former socialist states of Russian Federation.
§DevE: Developing market economies--China, India, other Asia and islands, sub-Saharan Africa, Middle Eastern Crescent, Latin America and the Caribbean.

The Age of Pestilence and Famine

From the epidemiological standpoint, humans evolved under conditions of pestilence and famine and have lived with them for most of recorded history. This age is characterized by the predominance of malnutrition and infectious disease and by the infrequency of CVD as a cause of death. Infant and child mortality is quite high, necessitating high fertility rates and resulting in a low mean life expectancy, on the order of 30 years or so. In the countries that eventually became today's established market economies, the transition through the age of pestilence and famine was relatively slow, beginning in the late 1700s and developing throughout the 1800s. Competing influences prolonged the transition--improvements in the food supply early in the Industrial Revolution that by themselves would have reduced mortality were offset by increases in communicable disease such as tuberculosis, cholera, dysentery, and influenza that resulted from concentration of the population in urban centers.

Although the transition through the age of pestilence and famine occurred much later in the emerging market economies and the developing economies, it has also taken place more rapidly, driven largely by the transfer of low-cost agricultural products and technologies and well-established, lower-cost public health technologies. Much of the developing world has emerged from the age of pestilence and famine. In sub-Saharan Africa and parts of India, however, malnutrition and infectious disease remain leading causes of death.

TABLE 1-2 -- FOUR TYPICAL STAGES OF THE EPIDEMIOLOGICAL TRANSITION

STAGE	DESCRIPTION	TYPICAL PROPORTION OF DEATHS DUE TO CVD (%)	PREDOMINANT TYPES OF CVD
Pestilence and famine	Predominance of malnutrition and infectious diseases as causes of death; high rates of infant and child mortality; low mean life expectancy	<10	Rheumatic heart disease cardiomyopathies due to infection and malnutrition
Receding pandemics	Improvements in nutrition and public health lead to decrease in rates of deaths due to malnutrition and infection; precipitous decline in infant and child mortality rates	10-35	Rheumatic valvular disease, hypertension, CHD, stroke
Degenerative and man-made diseases	Increased fat and caloric intake and decreased physical activity lead to emergence of hypertension and atherosclerosis; with increased life expectancy, mortality from chronic, noncommunicable diseases exceeds mortality from malnutrition and infectious diseases	35-65	CHD, stroke
Delayed degenerative diseases	Cardiovascular diseases and cancer are the major causes of morbidity and mortality; better treatment and prevention efforts help avoid deaths among those with disease and delay primary events. Age-adjusted CVD mortality declines; CVD affecting older and older individuals	50	CHD, stroke, congestive heart failure

CHD=coronary heart disease; CVD=cardiovascular disease.

Adapted from Omran AR: The epidemiologic transition: A theory of the epidemiology of population change. Milbank Mem Fund Q 49:509-538, 1971; and Olshansky SJ, Ault AB: The fourth stage of the epidemiologic transition: The age of delayed degenerative diseases. Milbank Q 64:355-391, 1986.

The Age of Receding Pandemics

Rising wealth and the resultant increase in the availability of food help usher in the second phase of the epidemiological transition. Better nutrition decreases early deaths due to malnutrition and may also reduce susceptibility to infectious diseases. Increased personal and public wealth is associated with improvements in public health measures that contribute to still further declines in infectious diseases. These advances, in turn, increase the productivity of the average worker, further improving the economic situation. The change most characteristic of this phase is a precipitous decline in infant and child mortality accompanied by a substantial increase in life expectancy. Examples of countries in this phase of the epidemiological transition are the United States early in the 20th century and China today, where approximately 29 percent of deaths are due to CVD and only 16 percent are due to communicable disease.[2] Changes in nutrition and other aspects of life style that cause lower rates of communicable, maternal, perinatal, and nutritional diseases eventually lead to a greater incidence of CVD.

The Age of Degenerative and Man-Made Diseases

Continued improvements in economic circumstances combined with urbanization and radical changes in the nature of work-related activities lead to dramatic life-style changes in diet, activity levels, and behaviors such as smoking. During the age of pestilence and famine, most of the population is deficient in total caloric intake relative to daily caloric expenditure. Easier access to less expensive foods and increased fat content increases total caloric intake, whereas mechanization results in lower daily caloric expenditure. This disparity leads to higher mean body-mass index, plasma lipid level, blood pressure, and blood sugar level. These changes set the stage for the emergence of hypertensive diseases and atherosclerosis. Cancer rates also rise rapidly during the age of degenerative and man-made diseases. As the average life expectancy increases beyond 50 years, mortality from largely chronic noncommunicable diseases--dominated by CVD--exceeds mortality from malnutrition and infectious diseases.[5] [6] Countries currently in this phase of the epidemiological transition are the emerging market economies of the former Soviet socialist states.

The Age of Delayed Degenerative Disease

In the final phase of the epidemiological transition, CVD and cancer remain the major causes of morbidity and mortality. In the industrialized nations, however, major technological advances such as coronary care units, bypass surgery, and thrombolytic therapy are available to manage the acute manifestations of CVD and preventive strategies such as smoking cessation and blood pressure management are widely implemented. As a result of better treatment and widespread primary and secondary prevention efforts, deaths are prevented among those with disease and primary events are delayed. Life expectancy continues to creep upward as age-adjusted CVD mortality tends to decline, with CVD affecting older and older individuals on average.

Changes in CVD through the Epidemiological Transitions

During the transition from the age of pestilence and famine to the age of delayed degenerative disease, both the character of CVD and total rates of CVD change.[6] During the age of pestilence and famine, CVD accounts for only 5 to 10 percent of mortality, with the major forms related to infection and malnutrition--largely rheumatic heart disease and the infectious and nutritional cardiomyopathies. Given the potentially long latent period of these diseases, they are apparent well into the age of receding pandemics, when they persist as major causes of death along with emerging hypertensive heart disease and stroke. During the age of receding pandemics, CVD accounts for 10 to 35 percent of deaths. CHD rates tend to be low relative to stroke rates. In addition, risk factors and risk behaviors that will foreshadow the next phase become more widespread. During the age of degenerative and man-made diseases, increased caloric intake (particularly from saturated animal fats and processed vegetable fats), reduced daily activity, increased smoking rates, and related changes in the prevalence of hypertension, diabetes, and hyperlipidemia result in further increases in hypertensive diseases and rapid increases in CHD and peripheral vascular disease. During this phase, 35 to 65 percent of all deaths are due to CVD. Typically, the rate of CHD deaths greatly exceeds that of stroke by a ratio of 2 to 3:1.

In the final phase of the epidemiological transition, the age of delayed degenerative diseases, age-adjusted death rates from CVD begin to fall, leveling off somewhere below 50 percent of total mortality. The decline in stroke rates tends to precede the decline for CHD; thus, the ratio of CHD to stroke deaths increases, typically to between 2:1 and 5:1 (Fig. 1-1) . The decline in CVD rates is the result of two factors: better access to health technology and adoption of healthier life styles. Improvements in health technology and better access to it decreases the likelihood of death among patients presenting with acute manifestations of atherosclerotic disease, although better survival means more and more individuals living longer with such CVDs as angina pectoris, congestive heart failure, and cardiac arrhythmias.

Reductions in risk behaviors and factors may make even greater contributions to the decline in age-adjusted rates of death. In many cases, these are the result of concerted efforts by public health and health care communities. In other cases, secular trends also play a role. For example, the widespread availability of fresh fruits and vegetables all year long in developed countries, and thus increased consumption, may have contributed to declining mean cholesterol levels before effective drug therapy was widely available. In general, however, even though age-adjusted rates of CVD continue to decline during the final phase of the epidemiological transition,

the prevalence of CVD increases as the population ages.

Economic, Social, and Demographic Transitions

As mentioned earlier, several parallel transformations accompany the epidemiological transition. These include economic, demographic, and social changes that pave the way for major shifts in a population's health and the nature of the diseases that account for most of the mortality and morbidity. The economic transition is characterized by increasing per capita income; the social transition by industrialization and the resulting urbanization, the development of a public health infrastructure, wider access to health care, and increasing application of health technologies; and the demographic transition by declining fertility and age-adjusted mortality rates, leading to increases in life expectancy and an aging population.

ECONOMIC TRANSITION.

This is measured by rising levels of personal wealth, usually measured as per capita gross domestic product (GDP) or gross national product (GNP).

SOCIAL TRANSITION.

Industrialization tends to spark a large number of social changes. It is typically accompanied by urbanization, a major social force that has a significant impact on the epidemiological transition. Urbanization affects living standards and life style and affords the opportunity to develop organized health care systems.

In virtually every region of the world there has been a shift from rural to urban life. For example, in the United States, 60 percent of the population lived in rural settings at the beginning of the 20th century compared with only 20 percent at the beginning of the 21st century. In Asia, the same shift has occurred over the second half of the 20th century (Fig. 1-2) .

Figure 1-1 Increase and decline in heart disease rates through the epidemiological transition in the United States, 1900 to 1996. Rate is per 100,000 population, standardized to the 1940 U.S. population. Diseases are classified according to International Classification of Diseases (ICD) codes in use when the deaths were reported. ICD classification revisions occurred in 1910, 1921, 1930, 1939, 1949, 1958, 1968, and 1979. Death rates before 1933 do not include all states. Comparability ratios were applied to rates for 1970 and 1975. *(From Achievements in public health, 1900-1999: Decline in deaths from heart disease and stroke--United States, 1900-1999. MMWR Morbid Mortal Wkly Rep 48:649-656, 1999.)*

DEMOGRAPHIC TRANSITION.

This refers to the shifting age structure of a population. During the age of pestilence and famine, individuals age 20 and younger may account for 40 to 50 percent of the population. As child and infant mortality are reduced in the age of receding pandemics, rapid gains are seen in life expectancy and the proportion of individuals age 20 and younger decreases. Declines in mortality rates are generally followed by declining fertility rates, further flattening the shape of the population distribution curve. As population growth rates fall, the mean age of the population continues to rise slowly as individuals live longer.

RATE OF CHANGE OF THE EPIDEMIOLOGICAL TRANSITION

Several factors influence how early or how quickly the epidemiological transition occurs in a given country or region. Even within a given country, segments of the population may undergo the transition at varying rates. These factors are related to economic, social, or cultural factors.

CLASS.

Epidemiological transitions occur at different rates across economic groups, generally beginning among those with higher socioeconomic status and eventually spreading to those with lower socioeconomic status. The decline in rates of malnutrition and communicable diseases as well as the rise in coronary risk factors and behaviors occur first in the privileged classes; increases in rates of stroke and CHD soon follow. Later, as the middle class grows, the epidemiological transition spreads to a broad enough sector of the population to have a measurable impact on population rates. As more and more of the burgeoning middle class passes through the second and third phases of the transition, CVD and cancer rates become the population's dominant causes of death and disability. People in the lower socioeconomic strata tend to acquire the risk factors and behaviors last, in part because of their economic situation and in part because they tend to engage in more physical activity at work. Compared with people in the upper and middle socioeconomic strata, those in the lowest stratum are less likely to have access to advanced treatments and to acquire and apply information on modification of risk factors and behaviors. Thus, CVD mortality rates decline later among those with lower socioeconomic status. In Canada, for example, CVD mortality rates are highest among the poorest individuals (Fig. 1-3) .[7]

THE EPIDEMIOLOGICAL TRANSITION IN THE UNITED STATES

Like other established market economies, the United States has proceeded through the first three stages of the epidemiological transition and is currently in the fourth. Given the large amount of economic, social, demographic, and health data available (Table 1-3) , the United States is used as a reference point for later comparisons.

THE AGE OF PESTILENCE AND FAMINE

The United States, like virtually all other countries and regions, was born into pestilence and famine. Infectious diseases killed many of the earliest immigrants to the New World. About half of the Pilgrims arriving in the New World in November of 1620 died of infection and malnutrition by the following spring. In addition, the infectious diseases the immigrants brought with them from Europe had a devastating impact on Native American populations.

At the end of the 1800s, the U.S. economy was still largely agrarian, with more than 60 percent of the population living in rural settings. However, industrialization and urbanization were well under way. Per capita income was increasing, and the food supply was improving. Modest gains in life expectancy were apparent throughout the 19th century. By 1900, life expectancy had increased to 47.8 years for men and 50.7 years for women.[8] Infectious diseases--largely tuberculosis,

Figure 1-2 Number of people living in urban areas, 1970, 1994, and 2025. *(From Population Action International, http://www.populationaction.org/why Epop-graph21.htm)*

Figure 1-3 CVD standardized mortality ratios by neighborhood income for Canadians of European ancestry, ages 35 to 74, in 1986 and 1991. *(From Sheth T, Nair C, Nargundjar M, et al: Cardiovascular and cancer mortality among Canadians of European, south Asian, and Chinese origin from 1979 to 1993: An analysis of 1.2 million deaths. Can Med Assoc J 161:132-138, 1999.)*

pneumonia, and diarrheal diseases--accounted for more deaths than any other cause.[9] CVD accounted for less than 10 percent of all deaths. Tobacco products were out of the economic reach of a large segment of the population.

THE AGE OF RECEDING PANDEMICS

Early in the 20th century, the pace of industrialization accelerated. The shift from a rural, agricultural-based economy to an urban, industrial-based economy had a number of consequences on cardiovascular risk behaviors and factors. Not only had food supplies become abundant, but there was also a dramatic shift in dietary staples. The railway network in place at the turn of the century was capable of moving foodstuffs from the farm to the city. But because the trains were not refrigerated, perishable foodstuffs such as fresh fruits and vegetables could not readily be transported whereas cereal grains and livestock could. Large slaughter houses and

meat-packing plants were established in or near urban areas. As a result, consumption of fresh fruits and vegetables declined and consumption of meat and grains increased, resulting in diets that were higher in fat and processed carbohydrates.[10] In addition, the manufacture of factory-rolled

TABLE 1-3 -- TRENDS IN THE UNITED STATES DURING THE 20TH CENTURY

	1900	1930	1960	1990
Population (millions)	76	123	180	249

cigarettes made them more portable and more affordable for the mass population.[11]

EMERGENCE OF A PUBLIC HEALTH INFRASTRUCTURE.

By 1900, such an infrastructure had emerged--40 states had health departments and many larger towns had major public work efforts to improve water supply and sewage systems.[9] Municipal use of chlorine to disinfect water was becoming widespread, and improvements in food handling such as pasteurization were introduced.[12] The health care system was growing but still largely comprised general practitioners providing care in the office or home; hospitals were largely for the indigent. The Flexner Report of 1910, which took a careful look at the quality of medical education in the United States and Canada, was the first step toward organized quality improvement in health care manpower that, along with other public health changes, was responsible for dramatic declines in infectious disease mortality rates throughout the century (Fig. 1-4) .

URBANIZATION.

The population of urban areas outnumbered that of rural areas for the first time by 1920, and by 1930 56 percent of the population was living in or near urban centers. Infectious disease mortality rates had fallen dramatically, from a crude death rate of approximately 800 per 100,000 population in 1900 to approximately 340 per 100,000 people.[9] Largely as a result of rapidly declining infant, childhood, and adolescent mortality from malnutrition and infectious diseases, life expectancy had increased by 10 years between 1900 and 1930, to 57.8 years for men and 61.1 years for women. At the same time, cigarette smoking was on the rise. Age-adjusted CVD mortality rates, at approximately 390 per 100,000 people, were in the midst of their steady climb up from slightly more than 300 per 100,000 people in 1900. This increase was largely driven by rapidly rising CHD rates.

THE AGE OF DEGENERATIVE AND MAN-MADE DISEASES

By the middle of the 20th century, the United States was predominantly an urban, industrial economy. Only 36 percent of the population lived in rural settings. With continued mechanization and urbanization, activity levels declined considerably. The rise of suburbs meant that more and more people were driving to work or to shopping rather than walking or bicycling. Prevalence of smoking, one of the major contributors to premature mortality and chronic disease, hit its zenith at 55 percent of adult men in 1955 and among women 10 years later, at 34 percent.[13] Annual per capita consumption of cigarettes peaked in 1963 at 4345.[11]

GROWTH OF THE HEALTH CARE INDUSTRY

One of the most remarkable changes in the years after World War II was the growth of the health care industry. Only some of this was stimulated by rises in per capita GDP. In the private sector, the growth of labor unions propelled a major expansion in private health care insurance. In fact, by the late 1950s, more than two thirds of the working U.S. population had some form of private insurance.[14] The federal government also played an important role. Increases in federal funding (the Hill Burton Act of 1948) led to the construction of more hospitals to deal with the acute manifestations of chronic illnesses. These new hospitals drew on the great successes of the military hospitals.[15] In 1966, two key federal insurance programs, Medicare and Medicaid, provided access to medical care for the medically indigent and the elderly. The Health Professions Education Assistance Act of 1966, which provided capitation grants to medical schools, doubled medical school enrollment over the next two decades through expanded class size and establishment of new medical schools. The establishment of the National Institutes of Health, spurred largely by scientific achievements in medicine made during World War II, not only promoted health-related research but also transformed medical education by providing financial support for the establishment of full-time medical school faculty.

By 1965, per capita income had risen to approximately $10,000 (in 1997 adjusted dollars).[16] Deaths from infectious diseases had fallen to under 50 per 100,000 population per year, and life expectancy was up to almost 70 years. However, almost 52 percent of men and 34 percent of women were smokers, and fat consumption represented 41 percent of total calories. Age-adjusted CHD mortality rates were at their peak, at approximately 225 per 100,000 people. Stroke rates were also high, at 75 per 100,000.

The Age of Declining Degenerative Diseases

A decline in age-adjusted CHD mortality rates began in the mid 1960s, and there have been substantial reductions in mortality from both stroke and CHD since then.[17] These reductions have occurred among both whites and blacks, among men and women, and in all age groups. Age-adjusted CHD mortality rates have fallen

approximately 2 percent per year, and stroke rates have fallen 3 percent per year (see Fig. 1-1) . Table 1-4 gives a snapshot of CVD in 1997 , the last year for which complete statistics are available.

DECLINE IN CVD MORTALITY.

Two main factors have been attributed to the decline in CVD mortality rates--therapeutic advances and prevention measures targeted at those with CVD and those potentially at risk for it.[18] [19] Treatments once considered advanced, including the establishment of emergency medical systems, coronary care units, and the widespread use of new diagnostic and therapeutic technologies such as defibrillation, cardiac catheterization, echocardiography, angioplasty, pacemaker implantation, and bypass surgery, are now considered the standard of care. Advances in the pharmaceutical industry have also had a major impact on both primary and secondary prevention. Efforts to improve the acute management of myocardial infarction led to the development of life-saving drugs such as beta blockers, thrombolytics, and angiotensin-converting enzyme inhibitors (see Chap. 35) .[20] The widespread use of an "old" drug, aspirin, has also reduced the risk of dying of acute or secondary coronary events. Low-cost pharmacological treatment for hypertension (see Chap. 29) and the development of highly effective cholesterol-lowering drugs such as statins have also made major contributions

Figure 1-4 Decline in mortality due to infectious diseases in the United States, 1900 to 1996. Rate is per 100,000 population per year. to reducing deaths from CVD in both primary and secondary prevention (see Chaps. 32 and 33) . Such shifts are reflected in the burgeoning cost of medical care. In 1965, Americans spent approximately 5.9 percent of the GDP ($42 billion in unadjusted dollars) on health care.[21] In 1998, the last year for which complete statistics are available, we spent an astounding 13.5 percent of the GDP ($1.1 trillion in unadjusted dollars), or $4094 per capita.[22]

In concert with these advances, public health campaigns have also hammered home the message that certain behaviors increase the risk of CVD and that life-style modifications are particularly effective ways to reduce risk. One such success is with smoking cessation. In 1955, 57 percent of men smoked cigarettes,[13] whereas 40 years later only half that many men smoked. Among women, prevalence of smoking had fallen from a high of 34 percent in 1965 to a low of 22.5 percent in 1993, but there are signs that smoking among women is on the increase. Similar campaigns beginning in the 1970s resulted in dramatic improvements in the detection and treatment of hypertension.[17] This likely had a profound and immediate effect on stroke rates and a more subtle effect on CHD rates. Similar public health messages concerning saturated fat and cholesterol are largely responsible for the decline in overall fat consumption as a percentage of total calories from approximately 45 percent in 1965 to 34 percent in 1995[23] and the decline in population mean cholesterol levels from 220 mg/dl in the early 1960s to 203 mg/dl in the early 1990s.[17]

A main characteristic of the age of declining degenerative diseases is the steadily rising age at which a first CVD event occurs or at which people die of CVD (Fig. 1-5) (Figure Not Available) . Despite declines in age-adjusted mortality, the aging of the

Figure 1-5 (Figure Not Available) Estimated prevalence of cardiovascular disease in Americans aged 20 and older, 1988 to 1994. *(From American Heart Association: 2000 Heart and Stroke Statistical Update. Dallas, TX, American Heart Association, 2000.)*

population will cause CVD to remain the predominant cause of morbidity and mortality. This, in turn, leads to ever-increasing numbers of individuals with CVD as well as ever-increasing health expenditures related to its treatment. In 1997, for example, CVD was the first-listed diagnosis for more than 6.1 million inpatients.[24] Hospital discharges in 1997 included 756,000 for acute myocardial infarction; 635,000 for cardiac dysrhythmias; 957,000 for congestive heart failure; 1,194,000 for cardiac catheterizations; 607,000 for bypass surgery; 447,000 for angioplasty; and 176,000 for insertions or revision of a pacemaker or defibrillator. In addition, there were 1,018,000 hospital discharges for stroke.[24] [25] [26]

At the close of the 20th century, the nation was fully industrialized, with only 2 percent of the population involved in farming. Per capita GDP was approximately $32,400, and life expectancy was 74 years for men and 80 years for women. CVD continued to be the predominant cause of morbidity and mortality, but it afflicted an older population than it did in the middle of the century. Although age-adjusted CVD rates continue to fall, the rate of decline began slowing in the 1990s, with virtually

no change in stroke rates for the last 5-year period for which data are available. The rate of decline of CHD may also be slowing, owing in part to a slowing in the rate of decline in risk factors such as smoking and increases in other risk factors such as obesity.

CURRENT WORLDWIDE VARIATIONS IN THE GLOBAL BURDEN OF CVD

An epidemiological transition much like the one that occurred in the United States is occurring throughout the world. As in the United States, worldwide CVD rates have risen steadily throughout the 1900s. At the close of the 20th century, 28 percent of all deaths worldwide were due to CVD, whereas communicable diseases accounted for 34 percent of the total.[2] With the ongoing global transition--dominated by the transition in the developing world--CVD will be the number one cause of death by 2020, accounting for 36.3 percent of all deaths whereas communicable diseases will account for barely half that, at 15.1 percent.[2]

Looking behind the global transition reveals vast discrepancies in regional rates of change. These wide variations began to appear early in the 20th century. Although most of the world remained in the phase of pestilence and famine, economic circumstances in several relatively confined regions changed rapidly, accelerating the pace of their epidemiological transitions. Thus, the global burden of CVD is best understood by examining the differential rates of change in each economic region. In addition to variability in the rate of the transition, there are unique regional features that have modified aspects of the U.S.-style transition in various parts of the world.

In terms of economic development, the world can be divided into two broad sectors, as described in Table 1-1 : (1) the developed world, which can be further subdivided into the established market economies (EstME) and the emerging market economies (EmgME), and (2) the developing economies (DevE). Given the diversity within the DevE, it is useful to further subdivide it into six distinct economic/geographic regions: China, India, other Asian countries and Pacific islands, sub-Saharan Africa, the Middle Eastern Crescent, and Latin America and the Caribbean. In 2000, four of every five people live in countries with developing economies, and it is these countries that are driving the rates of change in the global burden of CVD.

Like the United States, the rest of the EstME are largely in the fourth phase of the epidemiological transition, with CVD accounting for 45 percent of all deaths in 1990 and communicable diseases accounting for well under 10 percent (see Table 1-1) . The EmgME are in the third phase of the transition, with CVD accounting for 54 percent of deaths. In the DevE overall, 23 percent of deaths are due to CVD, whereas communicable diseases account for 42 percent of deaths. Across the six subgroups of the DevE, however, there remains a high degree of heterogeneity with respect to the phase of the epidemiological transition, as illustrated by the dominant disease rates in each region (Table 1-5) . In sub-Saharan Africa, communicable disease rates still far exceed those of chronic diseases, placing it in the first phase (pestilence and famine). Some regions of India appear to be in the first phase, characterized by high rates of infectious and communicable disease, whereas others are in the second or even the third phase. The Middle East appears to be in the third phase of the epidemiological transition. In this section we briefly describe the difficulties

in assessing and comparing disease rates around the world and discuss the regional rates. We will highlight within-region variations as well.

Established Market Economies

At the beginning of the 21st century, approximately 840 million people (13.6 percent of the world's population) live in the established market economies of the United States, Canada, Australia, New Zealand, Western Europe, and Japan. In these countries, CHD rates tend to be twofold to fivefold higher than stroke rates. Table 1-6 , for example, demonstrates this tendency among selected European countries. There are two notable exceptions. In Portugal, stroke rates for both men and women are higher than CHD rates. The same is true for Japan, where stroke is responsible for far more fatalities than CHD.

Rapid declines in CHD and stroke rates since the early 1970s signal that the EstME countries are in the fourth phase of the epidemiological transition, the age of delayed degenerative disease. In general, stroke rates have fallen faster than CHD rates, increasing the CHD-to-stroke ratio. In the United States, for example, stroke rates over the past three decades have fallen an average of 3 percent per year, whereas CHD rates have fallen approximately 2 percent per year.

The rates of CVD in Western Europe tend to be similar to those in the United States. However, the absolute rates vary by threefold among the countries of Western Europe with a clear north/south gradient, with higher CHD and stroke rates in the north. The highest CVD rates in the European established market economies (two to three times higher than the median rates) are in Finland, Northern Ireland, and Scotland, where CVD-related mortality exceeds 800 deaths per 100,000 for men and 500 deaths per 100,000 for women.[27] The lowest CVD rates are in the Mediterranean countries of Spain and France, where annual CVD rates are under 400 and 200 per 100,000 for men and women, respectively. Although both stroke and CHD rates are higher in northern Europe, the disparity in CHD rates is

much greater. For example, male CHD rates are 362 percent higher in Finland than in Spain, whereas stroke rates are only 49 percent higher.[27] CVD rates in Canada, New Zealand, and Australia are similar to those in the United States.

JAPAN.

This country is unique among the EstME. As its rates of communicable disease fell in the early part of the 20th century, stroke rates increased dramatically; and by the middle of the century they were the highest in the world. CHD rates, however, did not rise as sharply as they did in other industrialized nations and have remained lower than in any other industrialized country. Overall CVD rates have fallen 60 percent since the 1960s, largely due to a decrease in age-adjusted stroke rates. Japanese men and women currently have the highest life expectancies in the world--83 years for women and 77 years for men.[1] The difference between Japan and other industrialized countries may stem from genetic factors, but it is more likely that the average very low-fat diet and resultant low cholesterol levels have played a more important role. As is true for so many countries, Japanese dietary habits are undergoing substantial changes. For example, there has been an estimated 9.3-fold increase in annual per capita consumption of meat between 1955 and 1994, a 5.2-fold increase in egg consumption, a 7.4-fold increase in milk and dairy consumption, and a 5.3-fold increase in consumption of fats and oils.[28] These changes may explain possible recent increases in CHD.

Emerging Market Economies

The EmgME currently have the highest rates of CVD mortality in the world, and they are continuing to increase in several countries. This suggests that the EmgME are largely in the third phase of the epidemiological transition. In the former Soviet and Eastern Bloc countries, CVD predominates as the leading cause of death, accounting for approximately 54 percent of deaths, whereas communicable diseases account for only 6 percent. As expected in this phase of the transition, the average age of people who develop and die of CVD is lower than that in the established market economies.

Overall rates are similar to those seen in the United States in the 1960s, when CVD was at its peak. Although CHD is more common than stroke, the CHD:stroke ratio is relatively low, approximating 1:1 in several countries. Within the EmgME, CVD mortality rates vary widely--the highest CVD mortality rates are in the Ukraine (1,490 for men and 830 for women per 100,000) and Russia (1,343 and 657), and the lowest rates are in Slovenia (692 and 313).[27] CVD rates for women are particularly high compared with rates in EstME countries.

FORMER SOVIET UNION COUNTRIES.

One major difference between the EstME and the EmgME countries is that CVD mortality rates are not falling in many of the latter. On the contrary, since the dissolution of the Soviet Union there has been a surprising increase in CVD rates in some of these countries. In the former socialist countries of the Russian Federation, Belarus, Ukraine, Estonia, Latvia, and Lithuania, there has been a remarkable increase in CVD rates since 1990. In Russia, life expectancy has fallen, from 61.7 years to 57.6 years for men and from 73.0 years to 71.0 years for women.[29] The causes of this decline in life expectancy are not entirely clear. Rapid increases in per capita alcohol consumption may represent one possible cause for the increasing CVD rates that underlie this decline. Inadequate health care infrastructure and lack of institution of preventive public health measures also may contribute to worsening CVD mortality rates.

CVD rates have been stable in Bulgaria, Romania, Hungary, and Poland. The only two emerging market economies in which age-adjusted CVD rates have been declining are

Figure 1-6 Time trends in mortality from CVD in selected European countries, 1970 to 1992, among men and women aged 45 to 74. Fin=Finland; Hun=Hungary; Rus=Russia; Cze=Czechoslovakia; Por=Portugal; Spa=Spain; Gre=Greece; Den=Denmark; E&W=England and Wales. *(From Sans S, Kesteloot H, Kromhout D: The burden of cardiovascular diseases mortality in Europe: Time trends in mortality from CVD in selected European countries. the Czech Republic and Slovenia. Even so, CVD rates remain generally higher than in Western European countries (Fig. 1-6) .

Developing Economies

Approximately 80 percent of the world's inhabitants live in developing economies (DevE). In general, communicable diseases are nearly twice as likely to cause death than CVD in the DevE. Overall, CVD mortality rates are approximately 23 percent, although this represents only 8.2 percent of total lost disability-adjusted life years (DALYs) because CVD tend to affect an older segment of the population than communicable diseases. An infant death due to malnutrition, for example, results in more lost DALYs than a CHD death in the sixth decade of life. There are vast differences within and between the regions and countries that make up the DevE--some are still in the age of pestilence and famine, whereas others are in the second or even third phase of the epidemiological transition (see Table 1-5) . The character of CVD varies greatly by region. In China, stroke rates far exceed CHD rates, whereas in India the reverse is true. Rheumatic heart disease remains a major problem in India, China, and sub-Saharan Africa but is less of a problem in other Asian countries and Latin America (Table 1-7) .

Many factors contribute to the heterogeneity both between and within regions of the DevE. First, the distinct regions are at various stages of the epidemiological transition. Second, vast differences in life style and behavioral risk factors exist. For example, per capita consumption of dairy products (and thus consumption of saturated fat) is much higher in India than it is in China. Third, racial and ethnic differences may lead to altered susceptibilities to various forms of CVD. Finally, social, cultural, political, and economic considerations result in vast disparities in the health care structure in each region.

CHINA.

The People's Republic of China accounts for one fifth of the world's population, with 69 percent residing outside urban centers. Since the 1950s, life expectancy in

China has doubled from 35 years to 70 years. Over the same period, mortality from CVD increased threefold as a percentage of total deaths, from 12 to 36 percent.[30]

As in Japan, stroke is by far the leading cause of cardiovascular death. Hemorrhagic stroke predominates over ischemic stroke, and stroke rates are higher among women than men. These lower rates of CHD and high rates of stroke may be due to genetic factors; however, it has also been hypothesized that overall low serum cholesterol levels may contribute to high rates of hemorrhagic stroke.[31] There appears to be a north/south gradient, with higher CVD rates in northern China compared with southern China. As is the case in most DevE, there is also an urban/rural gradient for CHD, stroke, and hypertension with higher rates in urban centers. Regional differences exist in CVD rates, although they are not as great as those seen in India and sub-Saharan Africa. This is likely due to the system of resource distribution that results in less regional differences in the standard of

TABLE 1-7 -- RHEUMATIC HEART DISEASE, MORTALITY ESTIMATES FOR 2000

REGION	NUMBER OF DEATHS (THOUSAND)	% OF CVD MORTALITY	DALYs (THOUSAND)	% OF CVD DALYs
EstME	21	0.6	15	0.8
EmgME	26	1.0	38	2.3
DevE	338	2.8	5,697	4.8
India	80,000	2.7	1,569	5.5

living compared with Africa or India. In general, China appears to be in the third stage of a Japanese-style epidemiological transition, with CVD rates above 35 percent, although dominated by stroke and not CHD as they are in the EstME and EmgME. Major features of the transition in China are the rapidly rising rates of cigarette smoking and hypertension, much of which remains untreated.

INDIA.

One sixth of the world's population lives in India, with 72 percent of the approximately 1 billion people residing in rural settings. Accurate country-wide data on cause-specific mortality are not available; the most reliable data derive from urban centers. The best estimates suggest that CVD accounts for 24 percent of total deaths.[2] As expected, CVD mortality rates tend to be higher in urban areas than rural areas and CVD is much more prevalent among the upper and middle classes.

In contrast to China and much of the rest of Asia, CHD appears to be the dominant form of CVD. In 1960, CHD represented 4 percent of all CVD deaths, whereas in 1990 the proportion was over 50 percent.[32] CHD death rates are currently about three times higher than stroke rates. This is somewhat unexpected, because stroke tends to be a more dominant factor early in the epidemiological transition. This may reflect inaccuracies in cause-specific mortality estimates. However, it may suggest metabolic differences in response to the Western life style of higher-fat diets and lower levels of activity. It has been suggested that Indians may have an exaggerated insulin insensitivity in response to this life-style pattern that may differentially increase rates of CHD and stroke. Furthermore, the proportion of calories derived from fat, much of which comes from dairy products, is significantly higher in India than in other parts of the developing world.

Although rates of communicable disease remain high, accounting for 51 percent of all deaths and 56 percent of all lost DALYs,[2] the rates are falling rapidly. Thus, India appears to be early in the second phase of the transition with the urban upper classes in the third phase. As in China, rheumatic heart disease continues to be a major cause of morbidity and mortality (see Table 1-7) . Certain remote areas, however, are still in the age of pestilence and famine, with CVD accounting for less than 10 percent of total deaths.[33]

SOUTHEAST ASIA.

The diversity of economic circumstances in the countries of Southeast Asia is reflected in the status and character of the epidemiological transition across the region. In South Korea, for example, 57 percent of the population resides in urban centers and the mean annual per capita GNP is $9,700, whereas in Cambodia only 19 percent of the population lives in urban centers and the per capita GNP is $240. Average life expectancy in Korea is 72 years, compared with 53 years in Cambodia.

The rapid economic expansion occurring in several Southeast Asian countries has been accompanied by the expected shift to urbanization and associated life-style changes. In the most industrialized countries, such as Singapore, CVD rates mirror those in the EstME and EmgME, with CVD predominating as a major cause of death with CHD mortality rates double those of stroke rates. In other less developed parts of Asia, such as Indonesia and Sri Lanka, the character of disease is similar to that of China. In still others, such as Vietnam and Cambodia, pestilence and famine still predominate.

SUB-SAHARAN AFRICA.

In spite of large regional variations, sub-Saharan Africa remains largely in the first phase of the epidemiological transition, with more than 40 percent of all deaths due to infectious and parasitic diseases (see Table 1-5) . Life expectancies, as a result, are the lowest in the world. As is the case in India, accurate county-wide data are not generally available and most data come from urban centers and sampling in rural areas. Overall, CVD in sub-Saharan Africa is responsible for approximately 10 percent of all deaths, with stroke representing the dominant form in keeping with patterns characteristic of the earlier phases of the epidemiological transition. Even in urban centers, CHD was rare in the middle part of the 20th century.[34] As expected, average daily physical activity among urban dwellers is falling and smoking rates are increasing. Hypertension has emerged as a major public health concern, and hypertensive heart disease accounts for the dominance of stroke.[33] Rheumatic heart disease and cardiomyopathies, the latter due mostly to malnutrition, various viral illnesses, and parasitic organisms, are also important causes of CVD mortality and morbidity.

LATIN AMERICA AND THE CARIBBEAN.

As a whole, Latin America appears to be in the third phase of the epidemiological transition. At the turn of the century, approximately 31 percent of all deaths are attributable to CVD, a figure that is expected to increase to 38 percent by 2020.[2] Whereas CHD rates are higher than stroke rates (although not to the degree seen in EstME), the combination of these two accounts for more than 75 percent of CVD in this region. CVD rates are beginning to decline in some countries in Latin America and the Caribbean. However, those with the lowest CVD rates are facing the steepest increases in CVD mortality rates.[35] Rheumatic heart disease appears to be declining in most countries in this region. Chagas' disease remains a major problem in Argentina, Bolivia, Brazil, Chile, Colombia, Costa Rica, Ecuador, El Salvador, Guatemala, Honduras, Mexico, Nicaragua, Paraguay, Peru, Uruguay, and Venezuela, where as much as 30 percent of the population may be infected with the parasite responsible for this disease.

MIDDLE EAST CRESCENT.

In this region, increasing economic wealth has been characteristically accompanied by urbanization but uncharacteristically accompanied by increasing fertility rates as infant and childhood mortality rates declined. This has resulted in rapid population growth and a young mean age of the population (i.e., 44 percent younger than age 15). Mortality from CVD is increasing rapidly, and CVD is now the leading cause of death, ranging from 25 to 45 percent of total deaths. The adoption of a Western diet has occurred at a rapid rate. As in the established market economies, CHD is the predominant cause of CVD, with about three CHD deaths for every stroke death. Rheumatic heart disease remains a major cause of morbidity and mortality, but the number of hospitalizations for rheumatic heart disease is rapidly declining. This

region is entering the third phase of the transition.

GLOBAL TRENDS IN CVD

Estimating global trends in the burden of disease, particularly CVD, is aided by examining regional trends. Because 80 percent or more of the world's population lives in the DevE, global rates of CVD are largely driven by rates in these countries. The acceleration of worldwide CVD rates, for example, is occurring as most DevE countries are entering the second and third phases of the epidemic transition. In this section, we summarize global and regional estimates for 1990 and 2020 provided by Murray and Lopez.[2]

In 1990, the world population stood at 5.3 billion. CVD accounted for more than 14.3 million deaths, or 28.5 percent of the world's 50 million deaths (Table 1-8) . Of these, 6.3 million deaths were due to CHD (44 percent of CVD deaths) and 4.4 million were due to stroke (31 percent of CVD deaths). An estimated 133 million lost DALYs, or 9.7 percent of the total DALYs, were due to CVD.

Expectations for 2020

By 2020, world population is estimated to reach 7.8 billion, with much of the growth occurring in the developing economies (see Table 1-8) . In the EstME, population growth (up 13 percent from 1990 to 905 million people) will be fueled by emigration from the DevE. Even this substantial growth, however, represents a gradually shrinking proportion of the world's population, from 15.1 percent in 1990 to 11.5 percent in 2020. In the EmgME, growth will be more modest (up only 5 percent to 365 million people) and also represents a falling world share, from 6.5 percent in 1990 to 4.6

TABLE 1-8 -- CONTRIBUTION OF VARIOUS CATEGORIES OF DISEASE TO GLOBAL MORTALITY

percent in 2020. Continued rapid growth in the DevE will increase their population by more than 60 percent, from 4.1 billion people in 1990 to 6.6 billion in 2020, or 84 percent of the world's people. By 2020, CVD will be responsible for an estimated 25 million deaths annually (36.3 percent of all deaths), more than double caused by the combination of communicable, maternal, perinatal, and nutritional conditions. As deaths from these conditions fall from 34.2 percent of the total to 15.1 percent, CVD takes on greater significance. In terms of lost DALYs, those due to CVD are expected to double between 1990 and 2020, from under 10 percent to over 20 percent.

In the EstME, the modest decline in CVD death rates begun in the later third of the 20th century will continue, with the proportion of total deaths falling from 44.6 to 42.3 percent. The rate of decline, however, appears to be slowing. The *absolute number* of deaths as well as the prevalence of CVD will continue to increase as the population continues to age. In terms of lost DALYs, the proportion due to CVD will remain stable at about 19 percent.

In the EmgME, there will be little change in the overall proportion of deaths due to CVD (54.6 percent in 1990 and 53.7 percent in 2020). As a reflection of the anticipated decreases in DALYs lost due to communicable, maternal, perinatal, and nutritional diseases, lost DALYs due to CVD will increase as a proportion of the total (23.2 percent in 1990 to 26 percent in 2020). The average age of those afflicted with CVD will increase.

In the DevE, an estimated 9 million persons died of CVD in 1990. By 2020, that figure will more than double to more than 18 million persons annually, accounting for approximately three fourths of all CVD deaths worldwide. What will drive this overall rapid rise in CVD mortality rates in the DevE? One major factor is the projected 60 percent increase in population between 1990 and 2020. Another is that most of the countries that make up the DevE will have entered the third phase of the epidemiological transition by 2020. Substantial declines in communicable disease rates, from 41.2 percent in 1990 to 17.6 percent in 2020, will increase the proportion of DALYs lost due to CVD by more than 50 percent (8.2 percent in 1990 to 13.8 percent in 2020). Because CVD will afflict a younger population in the DevE than in the more developed economies, more than 100 of the 133 million DALYs lost to CVD (75 percent) will occur in the this region.

Only in China and sub-Saharan Africa will stroke rates far exceed CHD rates and remain the predominant form of CVD, accounting for about half of all CVD deaths. In the other Asian countries and Latin America, CHD rates will be only slightly greater than stroke rates, whereas the CHD-to-stroke ratio will exceed 2 in India and the Middle Eastern Crescent.

REGIONAL TRENDS IN RISK FACTORS

As indicated in the previous discussion, the global variation in CVD rates is related to temporal and regional variations in known risk behaviors and factors. Discussions of the strength of the associations of the various factors with CVD are found elsewhere in this text (see Chap. 31) . Recent ecological analyses of major CVD risk factors and mortality demonstrate high correlations between expected and observed mortality rates for the three main risk factors--smoking, serum cholesterol, and hypertension.[36] These analyses suggest that much of the regional variations are based on differences in conventional risk factors. In this section, the focus is on regional differences in these risk factors that help explain regional variations in the rate and character of the epidemiological transition.

Tobacco

Smoking clearly represents an important worldwide avoidable cause of CVD and total death. In 1990, an estimated 6 percent of all deaths were attributable to tobacco. By 2020, the proportion of deaths due to tobacco will more than double as smoking rates rise in the developing economies. [37]

Currently, more than 1 billion of the world's inhabitants smoke.[1] Regionally, the highest per capita cigarette consumption rates are in Europe at 2080 per year (in 1995), followed closely by the countries of the Western Pacific with 1945 per day and the Americas with 1530; they are the lowest in Africa, where annual per capita consumption is 480 cigarettes (Fig. 1-7) . [1]

In the market economies, smoking rates are beginning to decline, with the most substantial changes in the EstME. In the United States, for example, more than 40 percent of adults smoked in 1965, whereas only 23 percent smoked in 1997.[38] Over the same period, per capita consumption declined

Figure 1-7 Tobacco use in the United States, 1900 to 1999. *(From Achievements in Public Health, 1900-1999: Tobacco Use--United States, 1900-1999. MMWR Morbid Mortal Wkly Rep 48:986-993, 1999.)*

from more than 4200 cigarettes per year to approximately 2000 (see Fig. 1-7) .[39] [40] However, although cigarette smoking is declining overall, smoking is on the increase among young men and women in the United States.[41] In the EmgME countries, smoking rates are extremely high--59 percent of men and 26 percent of women smoked in 1995--but are stable or falling.[42]

In the DevE, tobacco represents an important cash crop and source of employment, two things that are often in short supply. On average, about 48 percent of adult men smoke, and smoking rates are increasing about 3.4 percent per year.[1] In some countries included in the DevE, smoking rates among men are staggeringly high, reaching 73 percent in Vietnam[43] and even higher in parts of Nepal.[44] Throughout the developing world, women have traditionally represented only a small proportion of the number of smokers. That is certain to change. In terms of sheer numbers, the number of women living in the DevE will rise from 2.6 billion in 1990 to 3.9 billion by 2020. As women's spending power increases, tobacco companies are targeting them as customers even as woman-specific health education and quitting programs are rare.[45]

A unique feature of the DevE is that there is easy access to relatively low-cost cigarettes during early stages of the epidemiological transition. In the established market economies, cigarette smoking peaked late in the third phase of the transition. In many DevE which are in the first or second stages, however, male smoking rates already exceed peak rates in the EstME, and rates are expected to continue rising among both men and women. The impact of more widespread smoking earlier in the epidemiological transition means a more rapid increase in CVD rates as the DevE enter the third phase of the transition. In China, which is in the early stages of the epidemiological transition, the 1996 National Prevalence Survey determined that 63 percent of men (but only 3.8 percent of women) were current smokers.[46] A massive retrospective study of 1 million deaths estimated that tobacco was responsible for 13 percent (600,000 deaths) of total mortality in China in 1990 and will account for 3 million deaths a year by 2025.[47]

Hypertension

Hypertension is clearly a risk factor for CHD and stroke (see Chap. 28) . Elevated blood pressure is an early hallmark of the epidemiological transition. Rising mean population blood pressure is apparent as countries industrialize--emigration from less-developed to more developed countries, as well as emigration from rural to urban settings, results in increasing blood pressure levels among emigrants. Among urban-dwelling men and women in India, for example, the prevalence of hypertension is 25.5 percent and 29.0 percent, respectively, whereas it is just 14.0 percent and 10.8 percent, respectively, among those living in rural communities.[47A] Whereas the relative increase in mortality associated with a given increase in blood pressure is similar in various regions of the world, the absolute risk at the same blood pressure level varies greatly.[48] In addition, the overall impact of hypertension may vary depending on the proportion of individuals in a country whose hypertension goes untreated.

In the EstME, hypertension remains a major cause of CVD morbidity and mortality despite high rates of detection and treatment. Given the relationship of increasing blood pressure with advancing age, the prevalence of hypertension is increasing in most (aging) established market economies. In most of the EstME, the proportion of the population with untreated hypertension is declining, although in the United States there has been a slight reversal of this trend.[49] In the EmgME, the prevalence of hypertension is at least as high as it is in the EstME, whereas rates of treatment are much lower. This may explain, at least in part, the higher stroke rates in these countries in relation to CHD rates.

Across the DevE countries, hypertension rates are quite variable. One major concern in these countries is the high rate of undetected, and therefore untreated, hypertension.

In northern Asian countries such as China and South Korea, hypertension is rapidly increasing,[50] [51] with higher rates in urban areas than rural areas. The high rates of hypertension throughout Asia likely contribute to the high prevalence of hemorrhagic stroke. In contrast, rates of hypertension remain relatively low in sub-Saharan Africa. However, the attributable risk of hypertension in urban centers is exceedingly high in most countries of this region owing to lack of available treatment. Data on mean blood pressure levels in the population are limited. High rates of hypertension are apparent only in urban centers, where there are a significant number of hospitalizations for hypertension, largely owing to the very low rates of detection and treatment.[33] In Latin America and the Caribbean, as well as in the Middle Eastern Crescent, hypertension rates are also quite variable but follow the general

pattern of being highest in more affluent countries and urban centers.

Fat Consumption

Although dietary habits clearly vary from country to country, intake of dietary fat tends to be low in many DevE and high in many EstME and generally increases with annual per capita income (Fig. 1-8) . For example, fat contributes under 20 percent of calories in rural China and India,[52] under 30 percent in Japan,[53] and well more than 30 percent in the United States. Caloric contributions from fat appear to be falling in the EstME. In the United States, for example, the percent of calories from fat have steadily declined over the past 30 years, from 45 percent of calories in 1965 to 34 percent in 1994, although the total amount of fat in the diet has increased slightly since 1989.[54]

Even in the DevE, which are broadly characterized by low fat intake, fat intake varies greatly, and tends to increase with industrialization and urbanization. Compare, for example, the low levels of fat intake in rural China and India with its contribution of 36 percent of calories in Taiwan.[55]

Lipid Levels

The causal association between plasma cholesterol levels and risk of CVD is indisputable. Low levels of high-density lipoproteins and elevated triglycerides are also clearly associated with excess risk of CVD, and this association holds across racial and ethnic divisions. The lipid profile appears to have a greater impact on CHD than on stroke.

As countries move through the epidemiological transition, mean population plasma cholesterol levels tend to rise. Social and individual changes that accompany urbanization clearly play a role, because plasma cholesterol levels tend be higher among urban residents than among rural residents. This shift is largely driven by greater consumption of dietary fats--primarily from animal products and processed vegetable oils--and decreased physical activity. Cross-cultural differences in mean cholesterol levels reflect this pattern. In rural Nigeria, which is early in the epidemiological transition, mean cholesterol levels are 120 mg/dl (3.1 mmol/liter),[56] whereas in the heavily industrialized United States and northern Europe, which are in the fourth phase, mean cholesterol levels are 200 mg/dl (5.2 mmol/liter) and 240 mg/dl (6.2 mmol/liter),[57] respectively. In the established market economies, mean population cholesterol levels are generally falling. Japan is something of an exception to this pattern, with only relatively recent increases in average serum cholesterol levels.[53] [58] This may help explain why CHD rates did not increase in the third phase of Japan's epidemiological transition. If plasma cholesterol levels continue to rise, however, CHD rates may follow in the coming years. In the emerging market economies, mean population cholesterol levels also tend to be high, but levels are stable or rising.

In the DevE, there is a wide variation in mean population cholesterol levels, although they all tend to be increasing rapidly. In Asia, mean levels range from 110 mg/dl

(2.8 mmol/liter) in rural areas to 220 mg/dl (5.7 mmol/liter) in highly industrialized countries such as Singapore. [52] In many countries in Latin America and the Caribbean, cholesterol levels approach those of northern Europe. A population survey in Bogota, Colombia, for example, found that 46 percent of men had serum cholesterol levels greater than 250 mg/dl (6.5 mmol/L).[59] In sub-Saharan Africa, mean cholesterol levels in rural areas are similar to the low levels seen in China, whereas levels are considerably higher in urban centers.[60] Given the high level of global capacity to produce Western-style food products at low cost, developing countries can now afford to adopt a Western dietary life style earlier in the economic transition than was possible in the past.

As is true for hypertension, rates of hypercholesterolemia are increasing far faster than the resources needed for widespread detection and treatment. Thus, the impact of both of these on atherosclerosis may be far greater than they have been in developed economies.

Physical Inactivity

One byproduct of the increased mechanization that accompanies the economic transition is decreased physical activity. In the market economies, the widespread prevalence of physical inactivity produces a high population attributable risk of cardiovascular consequences. In United States, approximately 25 percent of the population does not participate in any leisure-time physical activity and only 22 percent report engaging in sustained physical activity for at least 30 minutes on 5 or more days a week (the current

Figure 1-8 Association between income and dietary intake, based on country-level sources of energy. *(From Drewnowski A, Popkin BM: The nutrition transition: New trends in the global diet. Nutr Rev 55:31-43, 1997.)*

recommendation). [61] The shift from physically demanding, agricultural-based work to largely sedentary industrial- and office-based work is occurring throughout the developing world. This is also accompanied by a switch from physically demanding transportation to mechanized transportation.

Diabetes Mellitus (See also Chap. 63)

Diabetes and impaired glucose tolerance represent strong risk factors for vascular disease, including CHD, cerebrovascular disorders, and peripheral vascular disease. As a consequence of, or in addition to, increasing body-mass index and decreasing levels of physical activity, worldwide rates of diabetes--predominantly type 2 diabetes, or non-insulin-dependent diabetes mellitus--are on the rise. According to World Health Organization models, the number of persons with diabetes will swell from 135 million people in 1995 to 300 million in 2025, a 35 percent increase in worldwide prevalence (from 4.0 to 5.4 percent).[62] The largest increases in prevalence of diabetes will be in China (up 68 percent between 1995 and 2025) and India (up 59 percent), followed by Latin America and the Caribbean (41 percent), other Asian countries and the Pacific Islands (41 percent), and the Middle Eastern Crescent (30 percent). The market economies will experience increases between 26 percent and 28 percent.

The prevalence of diabetes varies greatly by geographic region, race, and ethnic composition. There appear to be clear genetic susceptibilities of various racial and ethnic groups. For example, Pima Indians living in the southwestern United States are eight times more likely to develop diabetes as the general U.S. population.[63] Hispanic Americans also tend to have higher rates than white Americans.[64] Migration studies suggest that South Asians and Indians also tend to be at higher risk than those of European extraction.

Diabetes mellitus is associated with a number of other CVD risk factors, including high triglyceride levels, low high-density lipoprotein levels, central obesity, and hypertension. In relative terms, the attributable risk of diabetes is higher in women than men.

Obesity

Obesity is clearly associated with increased risk of CHD. However, much of this risk may be mediated by other CVD risk factors, including hypertension, diabetes mellitus, and lipid profile imbalances. While rates of smoking and hypertension tend to increase early in the epidemiological transition, obesity tends to increase later.

In the mid 1980s, the World Health Organization's MONICA Project sampled 48 populations for cardiovascular risk factors. In all but one male population (China), and in most of the female populations, between 50 percent and 75 percent of adults aged 35 to 64 were overweight or obese.[65] A later follow-up study showed that the prevalence of obesity has continued to increase.[66]

In many EstME, mean body-mass index is rising at an alarming rate even as mean plasma cholesterol levels are falling and age-adjusted hypertension levels remain fairly stable during the fourth phase (the age of delayed degenerative diseases). In United States, this is occurring among all sectors of the population; however, rates are increasing faster among minorities and women.[67] Overweight and obesity are not limited to market economies. In many of the DevE countries, obesity appears to coexist with undernutrition and malnutrition. Although the prevalence of obesity in DevE countries is certainly less than among the market economies, it is on the rise there as well. A study in Mauritius, for example, documented rapid increases in obesity between 1987 and 1992,[68] whereas another estimated that 44 percent of African women living in the Cape Peninsula were obese.[69]

Further increases in the prevalence of overweight and obesity are to be expected if data on childhood and adolescent obesity are any indication.[70] Early obesity not only increases the likelihood of adult obesity, but it also increases the prevalence of weight-related disorders, including CVD.

FUTURE CHALLENGES

Although the concept of the epidemiological transition offers tremendous insight into how and why CVD is emerging as the predominant global cause of morbidity and mortality, it does not mandate that this must be so. As has been seen from the experience of established market economies, CVD rates rise in a predictable fashion with increasing rates of risk factors and behaviors. It is equally true that population-based and individual interventions can have an impact on both the rates and consequences of CVD. This raises the possibility of altering the epidemiological transition to blunt the increase in regional CVD rates or to hasten their decline. The transfer of lower cost health and food technologies from the EstME to the DevE have made great gains in the fight against communicable diseases and clearly helped hasten the transition out of the age of pestilence and famine. It is possible that similar interventions could alter the course of later stages.

Given the multifactorial nature of CVD, no single solution will be generally applicable to all geographic and economic regions of the world. In this section are outlined the major challenges facing each economic region and the various strategies to address these problems are discussed. Appropriate regional strategies depend on a number of factors, including a country or region's stage in the epidemiological transition, the rate of change of the epidemiological transition, individual and collective resources, and cultural and political factors.

Three complementary strategies may be used to reduce morbidity and mortality from CVD. First, the overall burden of CVD risk factors in the entire population may be lowered through population-wide public health measures. These include detection and surveillance strategies, public education campaigns, and the institution of low-cost preventive interventions. National campaigns against cigarette smoking are an example of the public health approach. The second approach involves identifying and targeting higher-risk subgroups of the population who stand to benefit the most from moderate, cost-effective prevention interventions. Third, resources can be allocated to acute and chronic higher cost treatments and secondary prevention interventions for those with clinically manifest disease. Typically, resources are allocated simultaneously to all three strategies; however, this three-pronged approach has been implemented mostly in EstME with abundant financial resources for health care. In the following sections are outlined the major challenges and possible solutions for each region.

Established Market Economies

Although CVD mortality rates have fallen in most EstME, several important challenges remain. First, socioeconomic and racial disparities in CVD rates continue to linger. In the United States, for example, whereas rates of CVD mortality have fallen across the population, there are still wide disparities across racial and ethnic boundaries. Thus, a major goal will be to accelerate the widespread application of preventive and therapeutic technologies to all racial, ethnic, and socioeconomic groups.

Second, the rate of declining CVD mortality appears to be stagnating. Over the past 5 years in United States, age-adjusted

stroke mortality rates have not changed and the decline in CHD rates has slowed. These may be the result of troubling trends in a number of coronary risk factors--whereas older men and women continue to stop smoking, young adults and teenagers, particularly young women, are smoking at increasing rates; the rates of those appropriately treated for hypertension has decreased slightly in the past 5 years; obesity and diabetes rates are accelerating at rapid rates. Perhaps most troubling are observations of increasing rates of obesity and physical activity in children. Taken together, these trends may explain the flattening of mortality curves and may also explain why mortality rates have fallen faster than CVD incidence rates.

In the absence of efforts to reverse these trends in risk factors, we may once again see increasing rates of CVD. More public health dollars need to be directed at antismoking efforts that target high-risk groups such as teenage girls and at broader application of guidelines for detecting and managing hypertension and hyperlipidemia. Effective strategies to increase activity and reverse trends in obesity and diabetes must be developed and implemented.

Third, the prevalence of CVD will continue to increase with the increasing mean age of a population even if that population's age-adjusted mortality rates continue to decline. In addition, incremental advances in therapeutic health technology and secondary prevention have led to increasing numbers of people surviving with CVD, which consumes increasing amounts of resources. With the institution of many life-saving strategies among those who present with acute manifestations of atherosclerotic disease, more and more individuals are surviving acute events such as myocardial infarction. For example, approximately one third of those who presented to hospitals with acute myocardial infarction in the 1950s died. Today, mortality is less than half that, despite the fact that sicker and older patients are presenting to the hospital. Furthermore, CHD is being diagnosed in increasing numbers of individuals before cardiovascular events. Thousands of pacemakers and defibrillators are implanted each year. As more and more individuals survive longer with CVD, so does the prevalence of congestive heart failure. Between 1985 and 1995 in the United States, hospitalizations for congestive heart failure increased from 1.7 million to 2.6 million (see Chap. 21) .[71] Over the same time period, mortality from congestive heart failure decreased.[71] [72] Thus, the management of congestive heart failure will consume more and more health care resources.[73] A major challenge for most established market economies will be the increasing financial burden of the management of CVD. More efficient and cost-effective strategies for treating CVD will have to be developed.

Emerging Market Economies

This region is largely in the third phase of the epidemiological transition. However, the resources available are considerably less than those available in the EstME. Annual per capita GNP in the EmgME ranges from about $1000 to $5000, less than the United States spends per capita on health care alone. This mandates making careful choices in terms of allocating health care dollars to each of the strategies outlined earlier.

In the EmgME, the two overarching goals are to manage the increasing number of people with CVD and to hasten the transition from the third to the fourth phase of the epidemiological transition. This will likely enhance overall productivity in the region because during the third phase of the epidemiological transition CVD, and particularly CHD, often afflicts those at the age of highest productivity. In terms of challenges facing the former socialist countries, the region can be divided into two categories: those countries with stable or declining rates and those countries with increasing CVD rates. For countries with stable or declining rates, the three-pronged approach used in the EstME should serve as a model. For those countries experiencing rapid rises in CVD rates, an important first step will be toward more centralized efforts at compiling data on rates of disease and risk factors and then determining the major contributors to the rise. All countries in this economic sector need more careful tracking and assessment of risk factors in terms of population attributable risk. Better tracking of CVD rates risk factors will allow for more careful allocation of scarce preventive resources.

National guidelines that have been developed in the EstME need to be adapted for the EmgME. Governments should initiate major public health initiatives aimed at life-style factors, including lowering rates of smoking and drinking, modifying diet, and increasing physical activity. Major public health priorities should include smoking cessation and the detection and control of hypertension, both of which are highly cost effective. The targeting of higher-risk individuals for higher-cost preventive strategies such as pharmacological cholesterol lowering will initially need to be confined to areas such as urban centers, where the burden is high and the necessary laboratory-based health care infrastructure is available.

Throughout this economic sector, improvements in health care delivery systems will be needed to manage the already high rates of CVD prevalent in these countries. Careful attention must be paid to the transfer of lower-cost health technology, keeping in mind the considerably lower annual health care expenditures in the EmgME countries compared with those in the EstME. Interventions such as the more widespread and appropriate use of aspirin and beta blockers during acute myocardial infarction is an example of an extremely cost-effective life-saving therapy that should be implemented universally before extensive resources are directed at higher-cost interventions such as angioplasty. Manpower issues must also be addressed, given the general shortage of health care professionals in the EmgME.

Developing Economies

The problems facing the DevE may be the most challenging. These countries have rapidly increasing burdens of CVD early in their economic transitions. They often do not have the per capita resources needed to create the three-pronged type of public health and health care infrastructure currently available in the EstME. In many DevE, per capita health care expenditures are less than $50 per year. In addition, there are a number of competing national priorities, including the stimulation of economic growth, social and political change, and the devastation wrought by communicable diseases.

Rising CVD rates will eventually exert a drag on economic growth. Early in the epidemiological transition, CVD deaths occur among younger individuals than they do later in the transition. Thus, the economic impact on both the family and national productivity is greater in developing economies than in established market economies. The loss of the head of a household from CVD (or any other disease) has a devastating impact on the health and well-being of the entire family. In Bangladesh, for example, when there is an adult death, a child who depends on that adult has a 12-fold higher probability of death.[74] At present, the data on the economic consequences of CVD in the DevE are limited. Much more work is needed to refine estimates that would permit more thoughtful allocation of health care resources.

As mentioned earlier, the epidemiological transition has been accelerated at least in part by an efficient translation of risk factors and risk behaviors from the EstME to the DevE early in the economic transition. The rapid spread of cigarette smoking is a prime example of this. A major challenge for developing countries is to attempt to change the natural history of the epidemiological transition. That such

alterations are possible is evidence from the experience of Japan, in which CHD rates were kept relatively low during a fairly rapid economic transition to an industrial-based economy. Although imbedded cultural practice such as diet likely played a large role, the Japanese experience illustrates that the nature of the transition is variable.

As is true for the EmgME, a critical first step in developing a comprehensive plan for many of the DevE is better assessment of cause-specific mortality and morbidity as well as the prevalence of the major preventable risk factors for CVD. This will enable better allocation of resources based on country-wide burdens of disease. Beginning first in the urban centers and then moving out to rural areas, government agencies will need to make careful assessments of, and create longitudinal surveillance of, major CVD risk factors for which low-cost strategies are available. High priorities include smoking and hypertension, for which the population attributable risks are likely to be high and the cost efficacy favorable. The strategy for the detection and management of high cholesterol must be carefully tailored for each region due to higher costs. Public health approaches aimed at educating the general population about diet and exercise may be useful, but precise estimates of cost efficacy are not available on these even for EstME countries. Drug therapy for cholesterol lowering is likely less cost effective than short-term smoking cessation programs or managing hypertension with low-cost medications.

Once these initial assessments have been made, guidelines for their management from a public health standpoint must be developed based on the population attributable risk and the available resources. These guidelines must be implemented with low-cost campaigns. Such prevention-directed efforts could blunt the rise in disease rates already apparent in many developed countries.

Given the extreme limitations in per capita health care resources in many DevE, the allocation of resources to higher-cost strategies for treating CVD may divert resources from the potentially more effective population-wide efforts. Thus, efforts targeted at interventions and high-technology therapeutics may have to be

parsimoniously implemented only in those urban areas where risk is highest.

SUMMARY AND CONCLUSIONS

In the 1999 *World Health Report*, Director General Gro Harlem Brundtland states that we are "halfway through a two century transition" in which CVD will dominate as the major cause of death and disease. Although CVD rates are declining in the EstME, they are increasing in virtually every other region of the world. From a worldwide perspective the rate of change in the global burden of CVD is accelerating, reflecting the change in the developing economies, which represent over 80 percent of the world's population, as they move rapidly through the second and third phases of the epidemiological transition. The consequences of this epidemic will be substantial on many levels--individual mortality and morbidity, family suffering, and staggering economic costs, both the direct costs of diagnosis and treatment and the indirect costs of lost productivity.

Each region of the world faces major challenges presented by the epidemic of CVD. There is no single global solution to the rising burden of CVD given the vast differences in social, cultural, and economic circumstances. The EstME must reverse unfavorable trends in CVD risk factors and behaviors and deal with the increasing prevalence of CVD in an aging population. To hasten the transition from the third to the fourth phase of the epidemiological transition, the EmgME must find ways to efficiently care for increasing numbers of individuals with CVD as well as to deploy lower cost prevention strategies. The most complex challenges are those facing the DevE. They must dedicate often minuscule resources to better assessment of rates of death, disease, and CVD risk factors. The allocation of resources to lower cost preventive strategies will likely be more cost effective than dedicating resources to high-cost management of CVD.

The EstME must continue to bear the burden of research and development into every aspect of prevention and treatment. Through further expansion of the knowledge base, particularly regarding the economic consequences of various treatment and prevention strategies, it is possible that the efficient transfer of low-cost preventive and therapeutic strategies may alter the natural course of the epidemiological transition in every part of the world and thus reduce the excess global burden of preventable CVD.

Chapter 2 - Economics and Cardiovascular Disease

MARK A. HLATKY
DANIEL B. MARK

The United States leads the world in spending on health care, whether measured as a percentage of gross domestic product or as dollars per capita. The decisions made by physicians control the bulk of these expenditures, and society has increasingly called for greater stewardship of the tremendous resources that doctors command. In this chapter some of the key economic principles that underlie clinical and health policy decision-making are discussed and important economic studies evaluating management of cardiovascular disorders are reviewed. Readers interested in more in-depth presentations of health economics can consult several excellent overviews.[1] [2] [3]

KEY ECONOMIC PRINCIPLES

ALTERNATIVE USES.

A key principle of economics is that all resources have alternative uses, so devoting resources to any particular activity makes them unavailable for different, and perhaps better, uses. Society's application of resources to medical care diminishes the resources available for alternative programs, such as public safety, assistance to the elderly or the poor, or environmental protection. This same principle applies to the resources earmarked to health care: the resources devoted to coronary bypass surgery within a health care system might be used to meet alternative health needs, such as treatment of heart failure, prenatal care programs, or provision of vaccinations. Thus, the goal of health economics is to define the most efficient use of the resources available to provide health care to a population of patients.

LAW OF DIMINISHING RETURNS.

An economic principle of special relevance to medicine is the so-called law of diminishing returns, indicated schematically in Figure 2-1 . Because resources are initially applied to a particular end, the returns are large, but with each additional increment of resources applied, the returns become smaller and smaller to the point that there is no further gain, and perhaps even a loss, with application of even more resources. This type of response is familiar to clinicians caring for patients. In the case of acute myocardial infarction (AMI), for example, access to defibrillation and hospital monitoring provides great benefits and the addition of thrombolytic therapy further improves patient outcomes. The provision of yet more care may improve outcomes a bit further, but eventually at some point outcomes cannot be improved further (this point has been called the "flat of the curve" [4]). Beyond this point, providing yet more resources can actually harm patients (e.g., prolonged bed rest, prophylaxis with a type I antiarrhythmic agent). A key economic insight is that society is best served by medical care that operates not on the flat of the curve but at a point on the shoulder of the curve (see Fig. 2-1 , point B) because the resources that would be spent in moving up to the flat of the curve have better alternative uses. A major goal of economic analysis of cardiovascular care is to find the optimal level of resources for a given clinical problem.

SOCIETAL PERSPECTIVE.

Economic analyses most often employ the societal perspective: how will society as a whole benefit from the new clinical program and what will society have to pay for it. In contrast, clinicians are focused on individual patients. Their traditional role is to be the patient's advocate, to do what is possible for the patient before them, regardless of the value provided to society. Thus, economic analysis is really meant as a policy tool, for informing spending decisions about populations, not as a tool for assisting with bedside decision-making. As exemplified in Figure 2-1 , a key economic measure of value is the cost of adding an additional unit of medical benefit, or the slope of the curve.[2] [3] [5] [6] [7] In economic analysis, the costs and effects of an intervention are always compared with an explicitly defined alternative. Thus, cost-effectiveness analysis assesses the marginal (or incremental) costs required to produce one extra unit of outcome. The ratio is defined as:

where $cost_{new}$ is the total cost of the new program, $cost_{old}$ is the total cost of the old program, and $effect_{new}$ and $effect_{old}$ indicate the medical effectiveness of the new and old programs, respectively. The cost of a program includes all relevant costs, including the intervention itself (e.g., streptokinase for an AMI), the cost of complications induced (e.g., bleeding, stroke) and averted (e.g., heart failure) by therapy, and the costs of concomitant treatments (e.g., mechanical coronary revascularization). The effectiveness of a medical intervention should be measured in outcomes of direct relevance to the patient, such as life-years of survival or quality of life. Economic analysis commonly measures effectiveness in "quality-adjusted life years" (QALYs) to assess both of these dimensions of improved clinical outcome on a common outcome scale. Laboratory-based outcome measures (e.g., ejection fraction, serum cholesterol) are intermediate, surrogate measures for ultimate patient benefit and therefore not used in economic analysis.

ECONOMICS OF SCALE.

Another final economic principle of relevance to medical care is that the production of goods and services is often more efficient in larger quantities due to "economies of scale." The high fixed cost of specialized equipment (e.g., an angiography suite) spread over more patients leads to lower costs per patient.[8] Also, large volume facilities can negotiate price discounts from suppliers and achieve more flexible use of personnel with

Figure 2-1 General relationship between application of health care resources (horizontal axis) and health outcomes (vertical axis). At point A, outcomes are improving rapidly with increased resources and treatment is cost effective. At point B, outcomes are still improving with increased resources, but at a rate that is less cost effective. At point C, increased resources are no longer improving outcome (i.e., "flat at the curve"), and at point D increased resources actually lead to worse outcomes, through iatrogenic complications and overtreatment.

their larger staff. In medical care, there is also evidence that higher patient volumes are associated with greater technical proficiency and better clinical outcomes.[9] [10] [11] Of course, beyond a certain scale, the clinical and cost advantages of higher volumes will be diminished and the disadvantages may increase (e.g., poorer

communication, an impersonal approach to patient care). Nevertheless, there is strong empirical evidence of the value of maintaining a minimum level of clinical volume in procedures such as coronary angioplasty and coronary bypass surgery, and in the care of critically ill patients such as those with AMI.

MEDICAL COSTS

Provision of medical care requires resources: the time and energy of physicians, nurses, and other health care professionals; specialized facilities such as intensive care units, angiography suites, and operating rooms; and costly drugs and supplies. Use of these resources has a cost, even if medical care is provided to the patient "for free." In principle, the best measure of this cost is what economists term the *opportunity cost,* or what has been lost by not applying resources to their next best use. As a practical matter, cost is measured by the prices paid in a competitive market. The overall cost of a medical program can then be measured as $\text{Sigma}_i\ P_i\ Q_i$, where P_i is the price for resource "i", Q_i is the quantity of resource "i" that is used, and the summation is over all "i" resources used in care of the patient. Modern hospital cost accounting systems facilitate such "microcosting" of medical care services. When microcosting is not feasible, an alternative measure of the cost of hospital services has been found by multiplying the charge for the service by a correction factor, the ratio of costs to charges,[12] found on the hospital's annual financial reports filed with the Health Care Financing Administration.[13] Because medical care is not provided in a classical competitive market, medical prices or charges are a very distorted (inflated) measure of the medical costs and should generally be avoided.

In medical economic studies, the cost of an intervention includes all relevant costs, regardless of who pays for them. The cost of an angioplasty might be borne in part by the insurance company, in part by the patient (e.g., prescription drugs after discharge), and in part by the hospital (e.g., costs over the contracted insurance payment amount). An expensive new therapy in the angioplasty laboratory may reduce total costs in the year after the procedure, and therefore be quite economically attractive. Nevertheless, hospitals may resist using the new therapy because the costs they pay are increased and they do not share the downstream savings. Even programs that save total medical costs can create economic winners and losers, whose incentives and disincentives can distort optimal resource allocation from a societal perspective. Thus, whereas economic analysis can adopt a number of valid perspectives or points of view, the societal one is preferred because it is the broadest.

Medical costs and benefits are typically spread over long time intervals, which leads to two related issues regarding measurement. Inflation changes the units of cost measurement, such that a dollar in 1995 does not have the same value as a dollar in 2000. To compare costs of alternative strategies within a given study, or those from different studies, it is therefore necessary to adjust all costs to a single standard value, such as 2000 dollars. A separate issue is that even if there were no cost inflation, it is still preferable to be paid today than to be paid in 5 years, and, conversely, it is preferable to repay a debt sometime in the future than to repay it immediately. To adjust for these time preferences, medical economic studies typically discount future costs and medical benefits by 3 percent per year.[6]

ANALYSIS OF SPECIFIC INTERVENTIONS

Economic analysis can be applied to treatment of acute illness (e.g., AMI), procedures (e.g., coronary bypass surgery), treatment of chronic illness (e.g., heart failure), prevention of disease (e.g., reduction of high cholesterol levels), or the use of diagnostic tests (e.g., coronary angiography). In the remainder of this chapter, the principles of economic analysis are illustrated by discussing cardiovascular management strategies drawn from each of these areas. Detailed review of the economics of all cardiovascular therapies is beyond the scope of this chapter and can be found elsewhere.[14]

Application of economic analysis to medical care can be illustrated by the use of thrombolytic therapy for AMI. As discussed in Chapter 35 , AMI most commonly results from the thrombotic occlusion of a major coronary artery at the site of a disrupted atherosclerotic plaque. After plaque rupture, there is a brief initial period of high risk in which appropriate therapy reduces mortality, and after a few weeks the patient's risk and quality of life settle at their chronic, steady state values. Clinical investigations have clearly established that timely reperfusion of the occluded coronary artery improves mortality of the patient with an AMI[15] and that this survival benefit is maintained over long-term follow-up.[16]

The value of streptokinase administration for AMI compared with the alternative of no reperfusion therapy can be analyzed using cost-effectiveness analysis.[17] For the purpose of this example, we assume that streptokinase costs $270 per treatment and that costs of medical care are otherwise equal in treated and untreated AMI patients. We further assume that hospital survival is improved from 88 to 92 percent by streptokinase treatment and that the life expectancy of MI survivors is 15 years, regardless of whether they were treated with streptokinase. Based on these assumptions, the incremental cost-effectiveness of streptokinase for the treatment of AMI can be calculated as:

Thus, the expenditure of $450 on average adds a year to the life of a patient with an AMI. To judge whether streptokinase therapy for AMI represents a good value for the money spent (i.e., is "economically attractive") requires a standard of comparison. Renal dialysis currently costs about $50,000 per patient per year in the United States. Because the cost of dialysis is covered by the federal Medicare program, it represents a good benchmark of how much society is willing to spend to add a life year. Programs that cost up to $50,000 per year of life added provide value that is comparable to that provided by renal dialysis and are generally considered economically attractive. Programs with cost-effectiveness ratios much worse than renal dialysis (i.e., more than $100,000 per year of life added) are generally considered to be economically unattractive. Based on these benchmarks, streptokinase therapy for AMI is a very economically attractive intervention.

Acute Coronary Syndromes

THROMBOLYTIC AGENTS.

Treatment of acute coronary syndromes (AMI [see Chap. 35], unstable angina [see Chap. 36]) has been the subject of intense clinical investigation since the early 1980s. Coronary reperfusion by pharmacological or mechanical methods has been extensively investigated, as have antithrombotic and anticoagulation regimens. Although there are vast differences among these therapies clinically, they share common features from the perspective of economic evaluation. The therapies for acute coronary syndromes are typically short term in duration and expensive, and they provide benefit to patients mainly by reducing the short-term risk of hospital death and/or AMI.

Tissue plasminogen activator (t-PA) has been extensively studied for the treatment of AMI. t-PA is much more expensive than streptokinase, the first thrombolytic agent shown to be effective for AMI. The cost-effectiveness of t-PA was therefore investigated, first by the use of decision analysis[18] and subsequently using empirical data in conjunction with the randomized Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries-1 (GUSTO-1) trial.[19] In GUSTO-1, the resource consumed during the first 6 months were documented in a sample of randomized patients. The cost of therapy was assessed by assigning standardized costs to each resource consumed (e.g., hospital days, cardiac angiography) and summing the costs over all resources used. This evaluation showed that, apart from the cost of the thrombolytic agents themselves, hospital and follow-up costs were quite similar in t-PA- and streptokinase-treated patients. Thus, the high cost of the t-PA ($2200 vs. $270) was not offset by cost savings elsewhere in the patient's care. The 30-day survival rate of t-PA-treated patients was improved by 1 percent in GUSTO-1; and based on long-term post-MI follow-up data collected by the Duke University data base, the life expectancy of survivors was projected to be 15.4 years. Using these data, the costeffectiveness of t-PA relative to streptokinase was calculated to be $27,100 per year of life saved, which was economically attractive by the previously described benchmarks. [19]

The use of streptokinase and t-PA for AMI provides a striking example of the economic principle of diminishing returns. The greatest gain in clinical outcome comes from using the least expensive effective thrombolytic agent (streptokinase) for AMI, which improves survival by 4 percent or more in absolute terms at a net cost of about $270 per patient. t-PA improves survival by a further 1 percent in absolute terms, but at an added cost of over $1900 per patient. Thus, the cost-effectiveness of streptokinase relative to placebo ($450 per life year added) is more favorable than the cost-effectiveness of t-PA relative to streptokinase ($27,100 per life year added). Simple and inexpensive therapies usually provide most of the potential improvement in outcomes for a given clinical condition, with smaller and smaller marginal improvements coming at greater and greater cost. This example also illustrates the comparative nature of economic evaluations--the value of a treatment can only be assessed in light of the therapeutic alternatives. This example also demonstrates that the difference in clinical benefit between two or more active therapies will generally be a fraction of the difference in clinical benefit between the least expensive effective therapy and placebo.

ANGIOPLASTY.

Primary angioplasty for AMI has been compared with thrombolytic therapy in several clinical trials, some of which also included an economic evaluation. A quantitative

overview of trials showed the survival of patients with AMI treated with angioplasty is equal to or better than that of patients treated with thrombolysis.[20] The results of economic analysis have been less consistent, with primary angioplasty being the less expensive strategy in some studies but raising costs in others.[21] [22] [23] This difference is largely due to differences in the rate of subsequent coronary angiography and revascularization in thrombolytic-treated patients. When rates of subsequent angiography are high, the primary angioplasty strategy has only a modest impact on net incremental costs, since many patients treated initially with thrombolysis subsequently undergo angioplasty or coronary artery bypass grafting (CABG) later in the same admission. When rates of subsequent angiography are low, however, primary angioplasty increases costs by adding revascularization procedures that would not otherwise have been done. A formal cost-effectiveness analysis of primary angioplasty relative to thrombolysis showed it to be cost-effective when performed in hospitals with existing cardiac angiography laboratories and minimal delay to therapy.[24] This analysis also suggested it would not be economically justified to build new catheterization laboratories solely to provide primary angioplasty.[24]

ANTICOAGULATION AND ANTIPLATELET REGIMENS.

Anticoagulant and antiplatelet regimens in the treatment of unstable angina and AMI have been investigated intensively in clinical trials. Because the newer agents of these classes tend to be more expensive than the standard alternatives (heparin, aspirin), economic evaluation is important. Economic evaluations are difficult to perform in these settings, however, because some or all of the benefit of these therapies come from reducing nonfatal MI, not hospital mortality. The economic analysis must therefore assess the long-term value of preventing a nonfatal MI, not just the value of improving short-term survival.

In one study, low-molecular-weight heparin (enoxaparin) improved clinical outcomes and lowered overall hospital costs relative to unfractionated heparin, largely because the $75 greater cost of enoxaparin was more than recouped by its greater effectiveness in reducing the need for costly revascularization procedures in patients with recurrent ischemia.[25] The combination of better clinical outcomes and lower cost, termed a *dominant* strategy because no tradeoffs between cost and outcome are involved, is clearly economically attractive. Use of eptifibatide, a glycoprotein IIb/IIIa inhibitor, in patients with acute coronary syndrome improved clinical outcomes, primarily nonfatal MI, at a net cost of $1014 per patient. The cost-effectiveness ratio for this drug appears economically attractive ($16,500 per life year added) based on the assumption that prevention of a

nonfatal MI increases life expectancy by approximately 2 years.[26]

Cardiac Procedures and Devices

CORONARY BYPASS GRAFTING.

In 1997, CABG was performed on 366,000 patients in the United States and 686,000 coronary angioplasty procedures were also performed.[27] With a total cost of roughly 20 billion dollars a year, the use of coronary revascularization procedures has spurred extensive economic evaluation.

CABG is an effective treatment for angina in symptomatic patients and extends life expectancy in patients with extensive coronary disease (see Chap. 37) . An overview of randomized clinical trials of surgery versus medical therapy[28] suggests that patients with left main disease may live more than 0.6 year longer after CABG, patients with three-vessel disease may live more than 0.5 year longer, and patients with one or two-vessel disease may live more than 0.16 year longer (life extension was estimated only over the first 10 years of follow-up). These data suggest that CABG is more economically attractive in patients with more extensive coronary disease who are at higher risk of death, because the absolute improvement in survival is greatest in these patients whereas the cost of the surgery is roughly the same. An early classic study[29] found the cost-effectiveness of CABG versus medical therapy for left main disease was $3800 per year of life added, a highly favorable ratio. More recent analyses[30] confirm that the cost-effectiveness of CABG is most favorable in patients with higher clinical risk (more extensive coronary disease, reduced left ventricular function), and greater degrees of angina.

PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY (PTCA).

Despite the extensive use of PTCA (see Chap. 38) , there have been few randomized trials that compare it with medical therapy. The Randomised Intervention Treatment of Angina-2 (RITA-2) trial[31] found better angina relief but more cardiac events in stable angina patients treated with PTCA compared with medical therapy. The Angioplasty Compared to Medicine (ACME) trial found similar results in patients with single-vessel disease randomized to angioplasty or medical therapy,[32] as did the Atorvastatin Versus Revascularization Trial (AVERT) of aggressive lipid-lowering therapy versus PTCA for stable patients.[33] Economic analyses of these studies have not yet been reported.

PTCA and CABG have been compared directly in several randomized trials conducted in patients with multivessel disease. The clinical results of these studies were quite consistent in showing significantly less angina and a nonsignificant reduction in mortality in surgery patients.[34] [35] Economic analysis in the RITA trial,[36] Emory Angioplasty Versus Surgery Trial (EAST),[37] Argentine Randomized Trial of Percutaneous Transluminal Coronary Angioplasty Versus Coronary Artery Bypass Grafting in Multivessel Disease (ERACI),[38] and Bypass Angioplasty Revascularization Investigation (BARI)[39] all documented significantly lower initial costs with PTCA, roughly one half to two thirds of the cost of CABG. These studies all showed that this initial cost advantage of PTCA was almost completely lost over the subsequent 2 years of follow-up as a result of the frequent need for repeat coronary revascularization procedures among angioplasty-treated patients. At 3 to 5 years of follow-up, the total medical costs averaged 4 to 6 percent lower in PTCA patients than in surgery patients.[37] [39] Economic analysis suggests that CABG is more cost-effective than PTCA in patients with more extensive coronary disease (i.e., three-vessel disease), whereas PTCA has a significant cost advantage in patients with less extensive disease, albeit with somewhat less angina relief.[39]

Coronary stents have now become a standard part of percutaneous revascularization. Stents reduce the need for emergency bypass surgery after initial PTCA and significantly reduce the likelihood of restenosis and frequency of repeat revascularization over the subsequent 4 to 6 months.[40] [41] Use of stents substantially increases the cost of the revascularization procedure, and, in most studies, the higher cost of the stent is only partially offset by the subsequently lower incidence of repeat revascularization.[42] [43] Consequently, the total cost of patients treated with coronary stents remains 7 to 12 percent higher than that of patients treated with balloon PTCA at 1 year of follow-up, with an equivalent incidence of death and nonfatal MI. Formal cost-effectiveness models based on recent randomized trial results have not been reported; an older decision model suggested that stenting would be cost effective if restenosis were reduced by 25 percent or more.[44]

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR (ICD).

Some randomized trials have reported that the ICD (see Chaps. 23 and 26) reduces mortality in patients at risk for sudden death. Because implantation of the defibrillator costs $30,000 or more, several economic evaluations of the device have been performed. In the Multicenter Automatic Defibrillator Implantation Trial (MADIT), ICD implantation reduced mortality by 54 percent.[45] In an economic substudy of the MADIT trial, the hospital costs of ICD-assigned patients were $25,700 higher than the cost of conventionally treated patients.[46] By 4 years of follow-up, the total cost of the ICD patients was still $22,000 higher, indicating that relatively little of the higher initial ICD costs was recouped by reducing the subsequent cost of treating clinical complications. Nevertheless, the cost-effectiveness ratio of the ICD in the MADIT trial was $27,000 per life year added,[46] largely because of the very strong effect of the ICD in reducing mortality in that study. In a decision model that projected lifetime costs and survival for patients with life-threatening ventricular arrhythmias, Owens and coworkers calculated that a 20 percent relative risk reduction by the ICD translates to a cost-effectiveness ratio of $54,000 per year of life added, whereas a 40 percent relative risk reduction translates into a cost-effectiveness ratio of $27,300 per year of life added.[47]

These studies illustrate several general points about the economic evaluation of procedures and devices. The initial cost of procedures and devices is often quite high, but long-term follow-up is needed to assess the total net cost of the procedure relative to alternative therapies. An expensive procedure may have some or all of its incremental costs recouped through prevention of costly adverse events, such as in the case of CABG relative to balloon angioplasty. The higher cost may be only partially offset by later savings (e.g., coronary stents) or barely recovered at all (e.g., implantable defibrillators). zNevertheless, high initial costs of procedures and devices may be justified if survival is sufficiently improved or quality of life is enhanced. These considerations emphasize the importance of a long-term perspective in the economic evaluation of devices and procedures, so that their full costs and benefits can be assessed.

Chronic Disease

Economically efficient management of a chronic disease such as heart failure is very different from that of an acute illness or a surgical procedure. In chronic diseases, the cost of care is spread over many years instead of being concentrated at the outset of treatment. Similarly, the benefits of treatment accrue only over a period of prolonged follow-up. Most medical care for chronic disease is delivered in an ambulatory, outpatient setting, and patient adherence to prescribed regimens has a substantial

impact on the efficacy of therapy. Improvements in clinical and economic outcomes may come either from better therapies or from better ways to deliver established therapies, or both.

HEART FAILURE.

Angiotensin-converting enzyme (ACE) inhibitors have significantly improved survival of patients with heart failure in randomized trials.[48] An economic appraisal of enalapril therapy based on the Studies of Left Ventricular Dysfunction (SOLVD) trial results[49] suggested that over the 48 months of trial, the added cost of enalapril was completely offset by the cost savings from fewer hospitalizations for heart failure in the enalapril arm. Projections of lifetime costs and life expectancy performed using a model suggested that the net lifetime cost per patient was only $25 and that life expectancy was increased by 0.30 year,[49] yielding an extremely favorable cost-effectiveness ratio ($83 per life year added, or $119 per quality-adjusted life year added). An economic analysis based on the Survival and Ventricular Enlargement (SAVE) trial in patients with an ejection fraction less than 40 percent after an acute MI suggested that captopril therapy was economically attractive for this indication, with more favorable cost-effectiveness ratios in older patients than in younger patients.[50] Economic analyses of the Acute Infarction Ramipril Efficacy (AIRE) trial from Germany[51] and Sweden[52] both suggest that trandolapril is also an economically attractive agent in treatment of left ventricular dysfunction after MI.

The data from randomized trials of ACE inhibitors suggest that some of the cost of an intervention for heart failure may be offset by prevention of costly hospital (re)admissions. Epidemiological research has shown that most admissions for heart failure result from lack of patient adherence to drug or dietary regimens.[53] These observations suggest that intervention programs to improve outpatient management of this chronic disease have the potential to improve clinical outcomes and possibly economic outcomes as well. In one study, a nurse-directed multidisciplinary intervention significantly reduced hospital admissions and lowered overall health care costs in patients with heart failure.[54] Similar results have been reported in some,[55] [56] [57] but not all,[58] disease management studies in patients with heart failure.

Disease Prevention

Disease prevention is very important from a clinical perspective. Some preventive measures are very effective and inexpensive, as exemplified by vaccination programs for common infectious diseases that cut risk by over 90 percent at the cost of only a few dollars. Most preventive measures are less effective in reducing the risk of disease and far more costly to implement. Vaccines, in particular, are relatively inexpensive because they are given only two or three times, whereas drugs to lower serum cholesterol or high blood pressure are given daily for decades. Thus, the cost-effectiveness of preventive programs varies considerably according to the intervention, its effectiveness, and its cost.

HYPERCHOLESTEROLEMIA.

Hypercholesterolemia (see Chap. 31) has long been established as a strong, consistent risk factor for coronary atherosclerosis, and recently HMG-CoA-reductase inhibitors ("statins") have been demonstrated to reduce the risk of death and nonfatal cardiovascular events.[59] The cost-effectiveness of this class of drugs has been controversial, largely because of the heterogeneity of patients considered for lipid-lowering therapy. Secondary prevention trials have shown substantial reductions in the absolute rate of cardiac events in patients treated with statins, including simvastatin in the Scandinavian Simvastatin Survival Study (4S) trial[60] and pravastatin in the Cholesterol and Recurrent Events (CARE)[61] and Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID)[62] trials. The efficacy of cholesterol lowering in primary prevention (i.e., subjects at high risk of heart disease but without evidence of clinical disease) has been investigated using pravastatin in the West of Scotland Coronary Prevention Study (WOSCOPS)[63] and lovastatin in the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS).[64]

The cost-effectiveness of HMG-CoA reductase therapy to prevent coronary heart disease varies from extremely favorable values in secondary prevention settings to quite unfavorable in some primary prevention settings.[65] The reason for this wide variation is that higher risk patients have a greater absolute benefit from treatment than lower risk patients. In the 4S trial,[60] for example, the 6-year overall mortality was 8.7 percent in the treated patients and 12.4 percent in the control patients, an absolute mortality difference of 3.7 percent that translates into 27 patients treated over 6 years to save one life. In contrast, the WOSCOPS study found overall mortality rates of 3.2 percent in the pravastatin group and 4.1 percent in the placebo group at 4.9 years,[63] an absolute mortality difference of 0.9 percent, which translates to 111 patients treated to prevent one death. The greater level of clinical efficacy in secondary prevention than primary prevention implies that lipid-lowering therapy is more economically attractive in the secondary prevention setting. Similarly, within the primary prevention setting, treatment of higher-risk patients (i.e., multiple risk factors, higher cholesterol levels) provides greater absolute risk reduction and hence is more cost effective than is the treatment of lower-risk patients. These insights are supported by more formal cost-effectiveness studies. Goldman and coworkers used a decision model and data from randomized trials[65] to show that the economic attractiveness of lipid-lowering therapy varied from saving costs and reducing mortality when used as secondary prevention in men with cholesterol levels above 250 mg/dl to a highly unfavorable cost-effectiveness ratio of over $2 million per year of life added in young women with no other cardiac risk factors. Other analyses have confirmed the basic observations that primary prevention with HMG-CoA reductase therapy in low-risk patients is economically unattractive, whereas treatment of higher-risk patients is quite cost effective. [66] Clinical guidelines stress the importance of tailoring therapy to the patient's risk profile[67] [68] to achieve optimal results.

CIGARETTE SMOKING.

Cigarette smoking (see Chaps. 31 and 39) clearly increases the risk of coronary heart disease events, with evidence of risk reduction after quitting in numerous nonrandomized studies. Although the effectiveness of a physician's advice to stop smoking is low, it does induce some smokers to quit; and because such advice has such a low cost it has a favorable cost-effectiveness ratio of less than $1,000 per year of life added.[69] Use of the nicotine patch as part of a smoking cessation program adds to the number of patients who quit smoking and had a favorable cost-effectiveness rate of less than $10,000 per year of life saved in one study[70] and less than $5,000 in another study.[71] Hospital-based smoking cessation programs have also been shown to be cost effective.[72] Smoking cessation is a particularly attractive preventive measure because the interventions are generally short term and of relatively low cost, and smoking cessation has highly beneficial effects on both cardiac and noncardiac diseases (e.g., various cancers, emphysema) and thus adds considerably to life expectancy.

DIAGNOSTIC TESTING

Proper selection of diagnostic tests to evaluate various clinical problems has become more challenging as a result of the collision between the forces of technological innovation

that develop many new tests to examine different facets of a particular disease and the forces of economic restraint that insist on their cost-effective use. Economic evaluation of diagnostic tests begins from the premise that the test provides information that only has value if physicians use the information to change therapy in a way that actually improves clinical outcomes. Thus, the effectiveness of a test is gauged not solely by its information content but by its ultimate, indirect effects on patient outcomes.

Tests that provide clinical value do so by adding to what is already known about the patient. In practical terms, the test needs to add independent information to what is available from the clinical history, from the physical examination, and from simpler, less expensive tests. The information value of thallium scintigraphy (see Chap. 9) in the diagnosis of coronary artery disease, for example, must be judged by how much unique diagnostic and prognostic information it adds to the clinical examination and the simpler stress electrocardiogram. The evaluation of diagnostic tests by measuring the incremental value of information they provide is analogous to the way that therapies are evaluated by documenting what they add compared with the best available alternative (e.g., how much better is t-PA than streptokinase for AMI). But the additional requirement placed on diagnostic tests is that they add enough information to modify decision-making. A test that is statistically more accurate does not provide value from an economic perspective unless the additional accuracy leads to improved clinical decisions. Demonstrations of a statistical improvement in diagnostic accuracy with new tests is common, but evaluations of the effects of this extra accuracy on clinical management are rare.

The evaluation of chest pain is a critical diagnostic problem that has been carefully analyzed in many studies. Early studies focused on the incremental information provided by noninvasive testing, most commonly the exercise electrocardiogram.[73] [74] These studies, by application of Bayes' rule, showed that the difference between pretest and posttest probability of disease was greatest among patients with an intermediate pretest probability of disease (i.e., between 15 percent and 85 percent). More recent cost-effectiveness analysis extended the earlier studies by considering the health outcomes resulting from detecting (or failing to detect) underlying coronary disease amenable to coronary revascularization.[75] [76] [77] These analyses suggested that immediate coronary angiography was reasonable in patients with very high pretest likelihood of coronary disease, such as an older man with typical exertional angina. In patients with an intermediate probability of coronary disease, noninvasive testing was generally economically attractive in comparison with no testing (cost-effectiveness ratios roughly $30,000 per quality-adjusted life years

added), whereas coronary angiography without prior noninvasive testing was generally not economically attractive (cost-effectiveness ratio more than $65,000 per quality-adjusted life years added, depending on patient characteristics). Alternative noninvasive tests (exercise electrocardiography, exercise single photon emission computed tomographic perfusion imaging, stress echocardiography) are close enough in cost-effectiveness that the determining factors in choosing among them are the likelihood of an indeterminate test result and the degree of local expertise with each alternative. The cost-effectiveness of all diagnostic strategies for chest pain are more favorable when stringent, outcome-based guidelines for coronary revascularization are followed.

The use of routine coronary angiography in survivors of AMI has been controversial, in large part owing to conflicting evidence on the efficacy of routine versus selective angiography practices.[78] [79] [80] [81] Because of the uncertainty of the medical effectiveness of angiography, assessment of its cost-effectiveness is also uncertain at this point. In one recent analysis,[82] coronary angiography was quite economically attractive (cost-effectiveness ratios generally less than $30,000 per quality-adjusted life years added) in patients with postinfarction angina and an ejection fraction below 50 percent. Angiography was projected to be economically unattractive (cost-effectiveness ratios greater than $60,000 per quality-adjusted life years added) in patients without a prior MI unless an exercise test was positive.[82]

DEVELOPMENTS IN ECONOMIC ANALYSIS

Cost-effectiveness analysis has been applied to clinical medicine for just over 20 years.[5] The initial studies were based largely on decision models and related analytical methods and were of more interest to researchers than to clinicians. After considerable experience, consensus on some aspects of the methodology of economic analysis has been reached, although several areas of controversy remain.[3] [6] [7] The most important recent development in cost-effectiveness analysis has been the inclusion of economic endpoints as part of randomized trials, providing rigorous evaluation of the efficacy of therapies. As in all arenas of clinical research, the methods of economic evaluation in clinical trials have become more sophisticated, with application of economic models to extend clinical trial findings.[83] Future developments in cost-effectiveness analysis include wider application of economic evaluations in international settings, improved cost-identification methods, and continued development of statistical methods appropriate to cost and outcome data from clinical trials.[84] [85] [86]

Part II - EXAMINATION OF THE PATIENT

Chapter 3 - The History

EUGENE BRAUNWALD

IMPORTANCE OF THE HISTORY

Specialized examinations of the cardiovascular system, presented in Chapters 5 , 6 , 7 , 8 , 9 , 10 , 11 , 12 , and 13 , provide a large portion of the data base required to establish a specific anatomical diagnosis of cardiac disease and to determine the extent of functional impairment of the heart. The development and application of these methods are a triumph of modern medicine. However, their appropriate use is to *supplement* but not to *supplant* a careful clinical examination. The latter, consisting of the history and physical examination, remains the cornerstone of the assessment of the patient with known or suspected cardiovascular disease. When compared, the initial clinical evaluation is at least as accurate in predicting coronary anatomy and survival as the exercise stress test.[1] There is a temptation in cardiology, as in many other areas of medicine, to carry out expensive, and occasionally uncomfortable or even hazardous, procedures to establish a diagnosis when a detailed and thoughtful history and a thorough physical examination are sufficient. Obviously, it is undesirable to subject patients to the unnecessary risks, discomfort, and expenses inherent in many specialized tests when a diagnosis can be made on the basis of the results of the clinical examination or when management will not be altered significantly as a result of these tests.

Intelligent selection of investigative procedures from the ever-increasing array of tests now available requires far more sophisticated decision-making than was necessary when the choices were limited to electrocardiography and chest roentgenography; some of the principles in such decision-making as they relate to cardiac imaging tests are dealt with in Chapter 13 . The clinical examination provides the critical information necessary for most of these decisions. With the increasing emphasis on the cost of medical care, it is likely that there will be a resurgence of interest in the relatively inexpensive clinical examination. On the other hand, it must be appreciated that there may be little correlation between the intensity of symptoms and the severity of heart disease; asymptomatic persons may have a life-threatening condition, whereas persons with many complaints referable to the cardiovascular system may have no or mild heart disease.

THE ROLE OF THE HISTORY.

The overreliance on laboratory tests has increased as physicians attempt to use their time more efficiently by delegating responsibility for taking the history to an assistant or nurse or even by limiting the history to a questionnaire. I consider this to be an undesirable trend for the patient with known or suspected heart disease. First, it must be appreciated that the history remains the richest source of information concerning the patient's illness[2] [3] and any practice that might diminish the quality or quantity of information provided by the history is likely ultimately to impair the quality of care. Second, the physician's attentive and thoughtful taking of a history establishes a bond with the patient that may be valuable later in securing the patient's compliance in following a complex treatment plan, undergoing hospitalization for an intensive diagnostic work-up or a hazardous operation, and, in some instances, accepting that heart disease is not present at all.

Obtaining the history also permits the physician to evaluate the results of diagnostic tests that have strong subjective components, such as the determination of exercise capacity (see Chap. 6) . Perhaps most importantly, a careful history allows the physician to evaluate the impact of the disease, or the fear of the disease, on the various aspects of the patient's life and to assess the patient's personality, affect, and emotional stability; often it provides a glimpse of the patient's responsibilities, fears, aspirations, and threshold for discomfort as well as the likelihood of compliance with one or another therapeutic regimen. Whenever possible, the physician should question not only the patient but also relatives or close friends to obtain a clearer understanding of the extent of the patient's disability and a broader perspective concerning the impact of the disease on both the patient and the family. For example, the patient's spouse is much more likely than the patient to provide a history of Cheyne-Stokes (periodic) respiration.

The combination of the widespread fear of cardiovascular disorders and the deep-seated emotional, symbolic, and sometimes even religious connotations surrounding the heart may, on the one hand, lower the threshold for the development of symptoms that mimic those of organic heart disease in persons with normal cardiovascular systems. On the other hand, they may cause so much dread that serious symptoms are denied by patients with established heart disease. Patients with established heart disease are often frightened, anxious, and/or depressed; these symptoms may be as troubling as those resulting from the pathophysiology of their disorder. These and other psychological symptoms can be identified only by a careful history.[2]

TECHNIQUE.

Several approaches may be employed successfully in obtaining the medical history. I believe that patients should first be given the opportunity to relate their experiences and complaints in their own way. Although time consuming and likely to include much seemingly irrelevant information, this technique provides considerable insight into the patient's intelligence, emotional make-up, and attitude toward his or her complaints, as well as providing the patient with the satisfaction that he or she has been "heard" by the physician, rather than merely responding to a few questions and then subjected to a battery of laboratory examinations. After the patient has given an account of the illness, the physician should direct the discussion and obtain information concerning the onset and chronology of symptoms; their location, quality, and intensity; the precipitating, aggravating, and alleviating factors; the setting in which the symptoms occur and any associated symptoms; and the response to therapy.

Of course, a detailed general medical history including the personal past history, occupational history, nutritional history, and review of systems must be obtained.[4] Of particular interest is a history of thyroid disease, recent dental extractions or manipulations, catheterization of the bladder, as well as a report of earlier examinations that showed abnormalities of the cardiovascular system as reflected in restriction from physical activity at school and in rejection for life insurance, employment, or military service. Menstrual status in women should be ascertained, as well as changes in body weight, especially during the last 5 years. Personal habits such as exercise, cigarette smoking, alcohol intake, and parenteral use of drugs--illicit and otherwise--should be ascertained. The medications taken and the reasons given to the patient should be obtained. Adults should be routinely questioned about the presence of or history of the major risk factors for coronary artery disease (see Chap.

34) : cigarette smoking, hypertension, hypercholesterolemia, diabetes mellitus, and a family history of premature coronary artery disease. The exact nature of the patient's work, including the physical and emotional stresses, should be assessed. The increasing appreciation of the importance of genetic influences in many forms of heart disease (see Chap. 56) underscores the importance of the family history.

A wide variety of disorders including, but not limited to, the neurological (see Chap. 71) , endocrine (see Chap. 64) , rheumatic (see Chap. 67) , and hematologic/oncologic (see Chap. 69) areas may have important effects on the cardiovascular system; it is vital to ascertain the presence of these and other conditions that are not primarily cardiovascular.

Myocardial and coronary function that may be adequate at rest are often inadequate during exertion; therefore, specific attention should be directed to the influence of activity on the patient's symptoms. Thus, a history of chest discomfort and/or undue shortness of breath that appears only during activity is characteristic of heart disease, whereas the opposite pattern (i.e., the appearance of symptoms at rest and their remission during exertion) is almost never observed in patients with heart disease but is more characteristic of functional disorders. In attempting to assess the severity of functional impairment, both the *extent* of activity and the *rate* at which it is performed before symptoms develop should be determined and related to a detailed consideration of the therapeutic regimen. For example, the development of dyspnea after walking slowly up a flight of stairs in a patient receiving intensive treatment of heart failure denotes far more severe functional disability than does the same symptom occurring in an untreated patient who has run up a flight of stairs.

It is important also to assess the "tempo" of the progression of symptoms. A decline in the threshold for severe anginal discomfort across a 2-week period is much more likely to signify a high risk of an adverse outcome, such as cardiac death or myocardial infarction, than a similar decline occurring over 2 years. Similarly, the history of a "breakthrough" of symptoms despite maintenance of a previously successful regimen should be noted, because it, too, may be a harbinger of a poor outcome and may dictate a change in therapeutic strategy.

As the patient relates the history, important nonverbal clues are often provided. The physician should observe the patient's attitude, reactions, and gestures while being questioned, as well as the choice of words or emphasis. Tumulty has aptly likened obtaining a meaningful clinical history to playing a game of chess[5] : "The patient makes a statement and based upon its content, and mode of expression, the physician asks a counter-question. One answer stimulates yet another question until the clinician is convinced that he understands precisely all of the circumstances of the patient's illness."

CARDINAL SYMPTOMS OF HEART DISEASE

The cardinal symptoms of heart disease include dyspnea, chest pain or discomfort, syncope, collapse, palpitation, edema, cough, hemoptysis, and excess fatigue. Cyanosis is more often a sign than a symptom, but it may be a key feature of the history as well, particularly in patients with congenital heart disease. Without doubt, history-taking is the most valuable technique available for determining whether these symptoms are caused by heart disease. Examples of the manner in which these symptoms may serve as a guide to diagnosis are given in the following pages, and reference is made to other portions of the book that contain more detailed information.

Dyspnea (See also Chap. 17)

Dyspnea is defined as an abnormally uncomfortable awareness of breathing; it is one of the principal symptoms of cardiac and pulmonary disease and ranges from an increased awareness of breathing to intense respiratory distress.[6] Dyspnea occurs after strenuous exertion in normal, healthy, well-conditioned subjects and after only moderate exertion in those who are normal but unaccustomed to exercise (dyspnea of deconditioning). It should therefore be regarded as abnormal only when it occurs at rest or at a level of physical activity not expected to cause this symptom. Dyspnea is associated with a wide variety of diseases of the heart and lungs, chest wall, and respiratory muscles as well as with anxiety[7] [8] [9] [10] ; the history is the most valuable means of establishing the etiology.[11] [12] [13] Among patients with cardiac dyspnea, this symptom is most commonly associated with and caused by pulmonary congestion, as occurs in left ventricular failure or mitral stenosis. The interstitial and alveolar edema stiffens the lungs and stimulates respiration by activating "J" receptors in the lung. Less frequently, cardiac dyspnea occurs secondary to a reduced cardiac output, without pulmonary engorgement, as in tetralogy of Fallot. Table 3-1 provides a list of the various

TABLE 3-1 -- DISORDERS CAUSING DYSPNEA AND LIMITING EXERCISE PERFORMANCE; PATHOPHYSIOLOGY; AND DISCRIMINATING MEASUREMENTS

DISORDERS	PATHOPHYSIOLOGY	MEASUREMENTS THAT DEVIATE FROM NORMAL
Pulmonary		
Air flow limitation	Mechanical limitation to ventilation, mismatching of V_A /Q, hypoxic stimulation to breathing	V_E max/MVV, expiratory flow pattern, V_D , V_T ; V_{O_2} max, V_E /V_{O_2} , V_E response to hyperoxia, (A-a)P_{O_2}
Restrictive	Mismatching V_A /Q, hypoxic stimulation to breathing	
Chest wall	Mechanical limitation to ventilation	V_E max/MVV, P_{ACO_2} , V_{O_2} max
Pulmonary circulation	Rise in physiological dead space as fraction of V_T , exercise hypoxemia	V_D /V_T , work-rate-related hypoxemia, V_{O_2} max, V_E /V_{O_2} , (a-ET)P_{CO_2} , O_2 -pulse
Cardiac		
Coronary	Coronary insufficiency	ECG, V_{O_2} max, anaerobic threshold V_{O_2} , V_E /V_{O_2} , O_2 -pulse, BP (systolic, diastolic, pulse)
Valvular	Cardiac output limitation (decreased effective stroke volume)	
Myocardial	Cardiac output limitation (decreased ejection fraction and stroke volume)	
Anemia	Reduced O_2 -carrying capacity	O_2 -pulse, anaerobic threshold V_{O_2} , V_{O_2} max, V_E /V_{O_2}
Peripheral circulation	Inadequate O_2 flow to metabolically active muscle	Anaerobic threshold V_{O_2} , V_{O_2} max
Obesity	Increased work to move body; if severe, respiratory restriction and pulmonary insufficiency	V_{O_2} -work-rate relationship, P_{AO_2} , P_{ACO_2} V_{O_2} max
Psychogenic	Hyperventilation with precisely regular respiratory rate	Breathing pattern, P_{CO_2}
Malingering	Hyperventilation and hypoventilation with irregular respiratory rate	Breathing pattern, P_{CO_2}
Deconditioning	Inactivity or prolonged bed rest; loss of capability for effective redistribution of systemic blood flow	O_2 -pulse, anaerobic threshold V_{O_2} , V_{O_2} max

$_A$ = alveolar ventilation;
Q = pulmonary blood flow;
$_E$ = minute ventilation; MVV = maximum voluntary ventilation; V_D /V_T = physiological dead space/tidal volume ratio; O_2 = oxygen; V_{O_2} =O_2 consumption; (A-a)P_{O_2} = alveolar-arterial P_{O_2} difference; (a-ET)P_{CO_2} = arterial-end tidal P_{CO_2} difference.

Modified from Wasserman D: Dyspnea on exertion: Is it the heart or the lungs? JAMA 248:2042, 1982. Copyright 1982, the American Medical Association.

syndromes that may cause dyspnea and the primary pathophysiological mechanisms that are responsible, whereas Table 3-2 (Table Not Available) lists the most important causes of acute and chronic dyspnea. Both Borg and Noble[14] and the American Thoracic Society (Table 3-3) (Table Not Available) [15] have developed scales that are useful in quantitating the severity of dyspnea.

TABLE 3-2 -- CAUSES OF ACUTE AND CHRONIC DYSPNEA

(Not Available)

From Fishman AP: Approach to the patient with respiratory symptoms. In Fishman's Pulmonary Diseases and Disorders, 3rd ed. New York, McGraw-Hill, 1998, pp 361-393.

The *sudden* development of dyspnea suggests pulmonary embolism, pneumothorax, acute pulmonary edema, pneumonia, or airway obstruction. In contrast, in most forms of *chronic* heart failure, dyspnea progresses slowly over weeks or months. Such a protracted course may also occur in a variety of unrelated conditions, including obesity, pregnancy, and bilateral pleural effusion. *Inspiratory dyspnea* suggests obstruction of the upper airways, whereas *expiratory dyspnea* characterizes obstruction of the lower airways. Exertional dyspnea suggests the presence of organic diseases, such as left ventricular failure (see Chap. 17) or chronic obstructive lung disease (see Chap. 54) ,

TABLE 3-3 -- AMERICAN THORACIC SOCIETY SCALE OF DYSPNEA

(Not Available)

whereas dyspnea developing at rest may occur in pneumothorax, pulmonary embolism (see Chap. 52) , pulmonary edema (see Chap. 17) , or anxiety neurosis. Dyspnea that occurs only at rest and is absent on exertion is almost always functional. A *functional origin* is also suggested when dyspnea, or simply a heightened awareness of breathing, is accompanied by brief stabbing pain in the region of the cardiac apex or by prolonged (more than 2 hours) dull chest pain. It is often associated with difficulty in getting enough air into the lungs, claustrophobia, and sighing respirations that are *relieved* by exertion, by taking a few deep breaths, or by sedation. Dyspnea in patients with panic attacks is usually accompanied by hyperventilation. A history of relief of dyspnea by bronchodilators and corticosteroids suggests asthma as the etiology, whereas relief of dyspnea by rest, diuretics, and digitalis suggests left ventricular failure. Dyspnea accompanied by wheezing may be secondary to left ventricular failure (*cardiac* asthma) or primary bronchial constriction (*bronchial* asthma).

In patients with *chronic heart failure,* dyspnea is a clinical expression of pulmonary venous and capillary hypertension (see Chap. 17) . It occurs either during exertion or in resting patients in the recumbent position, in whom it is relieved promptly by sitting upright or standing *(orthopnea).* Patients with left ventricular failure soon learn to sleep on two or more pillows to avoid this symptom. In patients with heart failure, dyspnea is often accompanied by edema of the lower extremities, upper abdominal pain (due to congestive hepatomegaly), and nocturia. The *sudden* occurrence of dyspnea in a patient with a history of previously stable mitral valve disease suggests the development of atrial fibrillation, rupture of chordae tendineae (as may occur in infective endocarditis), or pulmonary embolism.

Paroxysmal nocturnal dyspnea is due to interstitial pulmonary edema and sometimes intraalveolar edema and is most commonly secondary to left ventricular failure. This condition, beginning usually 2 to 4 hours after the onset of sleep and often accompanied by cough, wheezing, and sweating, may be quite frightening. Paroxysmal nocturnal dyspnea is often ameliorated by the patient's sitting on the side of the bed or getting out of bed; relief is not instantaneous but usually requires 15 to 30 minutes. Although paroxysmal nocturnal dyspnea secondary to left ventricular failure is usually accompanied by coughing, a careful history often discloses that the dyspnea *precedes* the cough, not vice versa. In contrast, patients with *chronic pulmonary disease* may also awaken at night, but cough and expectoration usually *precede* the dyspnea. These patients also often have a long history of smoking and a chronic cough with sputum production and wheezing and may be able to breathe more easily while leaning forward. Nocturnal dyspnea associated with pulmonary disease is usually relieved after the patient rids himself or herself of secretions rather than specifically by sitting up. Details of the value and limitations of the history of dyspnea in differentiating between primary diseases of the heart and lungs[6] [16] are presented in Chapter 17 .

Patients with *pulmonary embolism* usually experience sudden dyspnea that may be associated with apprehension, palpitation, hemoptysis, or pleuritic chest pain (see Chap. 52) . The development or intensification of dyspnea, sometimes associated with a feeling of faintness, may be the only complaint of the patient with pulmonary emboli. *Pneumothorax* and *mediastinal emphysema* also cause acute dyspnea, accompanied by sharp chest pain. Dyspnea accompanying thoracic pain occurs in *acute myocardial infarction* (see Chap. 35) . Dyspnea is a common "*anginal equivalent*" (see Chap. 37) , that is, a symptom secondary to myocardial ischemia that occurs in place of typical anginal discomfort. This form of dyspnea may or may not be associated with a sensation of tightness in the chest, is present on exertion or emotional stress, is relieved by rest (more often in the sitting than in the recumbent position), is similar to angina in duration (i.e., 2 to 10 minutes), and is usually responsive to or prevented by nitroglycerin. The sudden development of severe dyspnea while sitting rather than lying, or whenever a particular position is assumed, suggests the possibility of a myxoma (see Chap. 49) or ball-valve thrombus in the left atrium. When dyspnea is relieved by squatting, it is caused most commonly by tetralogy of Fallot or a variant thereof (see Chap. 43) .

Patients with exertional dyspnea should be questioned about the duration of the symptom, whether it occurs gradually or abruptly, as well as the conditions that precipitate, intensify, and relieve it. Its severity can be judged in terms of the number of city blocks or flights of stairs that the patient is capable of walking or climbing at a normal pace.

APPROACH TO THE PATIENT.

A combination of the history and physical examination provide the key information required to elucidate the cause of dyspnea. The differentiation between cardiac and pulmonary disease is aided by the approach shown in Figure 3-1 .

Chest Pain or Discomfort (See also Chaps. 35 , 36 , and 37)

Elucidation of the cause of chest pain is one of the key tasks of physicians, and this symptom is responsible for many cardiac consultations. The history remains the most important technique for distinguishing among the many causes of chest discomfort. Although chest pain or discomfort is one of the cardinal manifestations of heart disease, it is important to recognize that such pain may originate not only in the heart but also in (1) a variety of noncardiac intrathoracic structures, such as the aorta, pulmonary artery, bronchopulmonary tree, pleura, mediastinum, esophagus, and diaphragm; (2) the tissues of the neck or thoracic wall, including the skin, thoracic muscles, cervicodorsal spine, costochondral junctions, breasts, sensory nerves, and spinal cord; and (3) subdiaphragmatic organs such as the stomach, duodenum, pancreas, and gallbladder (Table 3-4) . Pain of functional origin or factitious pain may also occur in the chest. Although a wide variety of laboratory tests is available to aid in the differential diagnosis of chest pain, without question the history remains the most valuable mode of examination.

In obtaining the history of a patient with chest pain it is helpful to have a mental checklist and to ask the patient to describe the location, radiation, and character of the discomfort; what causes and relieves it, especially the extent and timing of relief by sublingual nitroglycerin; the duration, frequency, and pattern of recurrence of the discomfort; the setting in which it occurs; and associated symptoms. It is also particularly useful to observe the patient's gestures. Clenching the fist in front of the sternum while describing the sensation (Levine's sign) is a strong indication of an ischemic origin of the pain.

QUALITY OF DISCOMFORT.

Angina pectoris may be defined as a discomfort in the chest and/or adjacent area associated with myocardial ischemia but without myocardial necrosis.[17] [18] [19] [20] It is important to recognize that angina means *tightening,* not pain. Thus, the discomfort of angina often is described not as pain at all but rather as an unpleasant sensation; "pressing," "squeezing," "strangling," "constricting," "bursting," and "burning" are some of the adjectives commonly used to describe this sensation (Table 3-5) . "A band across the chest," "a weight in the center of the chest," and "a vise tightening around the chest" are other frequent descriptors. It is characteristic of angina pectoris that the intensity of effort required to incite it may vary from day to day and throughout the day in the same

Figure 3-1 Algorithm for the evaluation of the patient with dyspnea. The pace and completeness with which one approaches this framework depend on the intensity and acuity of the patient's symptoms. In the patient with severe, acute dyspnea, an arterial blood gas analysis may be one of the first laboratory evaluations, for example, whereas it might not be obtained until much later in the work-up in a patient with chronic breathlessness of unclear cause. A therapeutic trial of a medication, for example, a bronchodilator, may be instituted at any point if one is fairly confident of the diagnosis based on the data available at that time. DVT = deep venous thrombosis; CHF = congestive heart failure; DL_{CO}= diffusing capacity of the lung for carbon monoxide. *(From Schwartzstein RM,*

Thibault GE: Approach to the patient with dyspnea. In Goldman L, Braunwald E [eds]: Primary Cardiology. Philadelphia, WB Saunders, 1998, pp 98-111.)

patient, but often a careful history will uncover explanations for this, such as meals ingested, weather, emotions, and the like. The anginal threshold is lower in the morning than at other times of the day; thus patients note frequently that activities that may cause angina in the morning do not do so later in the day. When the threshold for angina is quite variable, defies any pattern, and is prominent at rest, the possibility that myocardial ischemia is caused by coronary spasm should be considered.[19] [20] A history of prolonged, severe anginal chest discomfort accompanied by profound fatigue often signifies acute myocardial infarction.[21] Thus, a careful history not only may indicate the cause of the pain (i.e., myocardial ischemia) but can also provide a clue to the mechanism.

When dyspnea is an "anginal equivalent," the patient may describe the mid chest as the site of the shortness of breath, whereas true dyspnea is usually not well localized. Other anginal equivalents are discomfort limited to areas that are ordinarily sites of secondary radiation, such as the ulnar aspect of the left arm and forearm, lower jaw, teeth, neck, or shoulders, and the development of gas and belching, nausea, "indigestion," dizziness, and diaphoresis. When angina radiates to the arms it is often described as a "painful heaviness." Anginal equivalents above the mandible or below the umbilicus are quite uncommon. It is useful to determine whether the patient has symptoms or complications caused by atherosclerosis of other vascular beds (e.g., intermittent claudication, transient ischemic attacks,

TABLE 3-4 -- CARDIOVASCULAR CAUSES OF CHEST PAIN

CONDITION	LOCATION	QUALITY	DURATION	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS
Angina	Retrosternal region: radiates to or occasionally isolated to neck, jaw, epigastrium, shoulder, or arms--left common	Pressure, burning, squeezing, heaviness, indigestion	<2-10 min	Precipitated by exercise, cold weather, or emotional stress; relieved by rest or nitroglycerin; atypical (Prinzmetal's) angina may be unrelated to activity, often early morning	S_4 , or murmur of papillary muscle dysfunction during pain
Rest or unstable angina	Same as angina	Same as angina but may be more severe	Usually <20 min	Same as angina, with decreasing tolerance for exertion or at rest	Similar to stable angina, but may be pronounced. Transient cardiac failure can occur
Myocardial infarction	Substernal and may radiate like angina	Heaviness, pressure, burning, constriction	Sudden onset, 30 min or longer but variable	Unrelieved by rest or nitroglycerin	Shortness of breath, sweating, weakness, nausea, vomiting
Pericarditis	Usually begins over sternum or toward cardiac apex and may radiate to neck or left shoulder; often more localized than the pain of myocardial ischemia	Sharp, stabbing, knifelike	Lasts many hours to days; may wax and wane	Aggravated by deep breathing, rotating chest, or supine position; relieved by sitting up and leaning forward	Pericardial friction rub
Aortic dissection	Anterior chest; may radiate to back	Excruciating, tearing, knifelike	Sudden onset, unrelenting	Usually occurs in setting of hypertension or predisposition such as Marfan's syndrome	Murmur of aortic insufficiency, pulse or blood pressure asymmetry; neurological deficit
Pulmonary embolism (chest pain often not present)	Substernal or over region of pulmonary infarction	Pleuritic (with pulmonary infarction) or angina-like	Sudden onset; minutes to <1 hr	May be aggravated by breathing	Dyspnea, tachypnea, tachycardia; hypotension, signs of acute right-sided heart failure, and pulmonary hypertension with large emboli; rales, pleural rub, hemoptysis with pulmonary infarction
Pulmonary hypertension	Substernal	Pressure; oppressive		Aggravated by effort	Pain usually associated with dyspnea; signs of pulmonary hypertension

TABLE 3-5 -- CHARACTERISTICS OF TYPICAL AND ATYPICAL ANGINA PECTORIS

Typical

Substernal

Characterized by a burning, heavy, or squeezing feeling

Precipitated by exertion or emotion

Promptly relieved by rest or nitroglycerin

Atypical

Located in the left chest, abdomen, back, or arm in the absence of mid-chest pain

Sharp or fleeting

Repeated, very prolonged

Unrelated to exercise

Not relieved by rest or nitroglycerin

Relieved by antacids

Characterized by palpitations without chest pain

From Douglas PS, Ginsburg GS: The evaluation of chest pain in women. N Engl J Med 333:1311-1315, 1996.

or stroke). In patients with suspected angina, a history of one of these manifestations of extracardiac atherosclerosis lends weight to the diagnosis of myocardial ischemia.

LOCATION.

Embryologically the heart is a midline viscus; thus, cardiac ischemia produces symptoms that are characteristically felt substernally or across both sides of the chest (Figs. 3-2 and 3-3) (Figure Not Available) . Some patients complain of discomfort only to the left or less commonly only to the right of the midline. If the pain or discomfort can be localized to the skin or superficial structures and can be reproduced by localized pressure, it usually arises from the chest wall and is not caused by myocardial ischemia. If the patient can point directly to the site of discomfort with the tip of a finger, and if that site is quite small (<3 cm in diameter), it is usually not angina pectoris. Like other symptoms arising in deeper structures, angina tends to be diffuse and eludes precise localization. Pain that is localized to the region of or under the left nipple or that radiates to the right lower chest is usually noncardiac in origin and may be functional or due to costochondritis, gaseous distention of the stomach, or the splenic flexure syndrome.[22] Although

Figure 3-2 Pain patterns with myocardial ischemia. The usual distribution is referral to all or part of the sternal region, the left side of the chest, and the neck and down the ulnar side of the left forearm and hand. With severe ischemic pain, the right chest and right arm are often involved as well, although isolated involvement of these areas is rare. Other sites sometimes involved, either alone or together with other sites, are the jaw, epigastrium, and back. *(From Horwitz LD: Chest pain. In Horwitz LD, Groves BM [eds]: Signs and Symptoms in Cardiology. Philadelphia, JB Lippincott, 1985, p 9.)*

Figure 3-3 (Figure Not Available) Differential diagnosis of chest pain according to location where pain starts. Serious intrathoracic or subdiaphragmatic diseases are usually associated with pains that begin in the left anterior chest, left shoulder, or upper arm, the interscapular region, or the epigastrium. The scheme is not all inclusive (e.g., intercostal neuralgia occurs in locations other than the left, lower anterior chest area). *(From Miller AJ: Diagnosis of Chest Pain. New York, Raven Press, 1988, p 175.)*

pain due to myocardial ischemia often radiates to the arm, especially the ulnar aspect of the left arm, wrist, epigastrium, or left shoulder, such radiation may also occur in pericarditis and disorders of the cervical spine. Radiation of pain from the chest to the neck and jaws is typical of myocardial infarction. Dissection of the aorta or enlargement of an aortic aneurysm usually produces pain in the back in addition to the front of the chest.

DURATION.

The duration of the pain is important in determining its etiology. Angina pectoris is relatively brief, usually lasting from 2 to 10 minutes. However, if the pain is very brief (i.e., a momentary, lancinating, sharp pain, or other discomfort that lasts less than 15 seconds), angina can usually be excluded; such a short duration points instead to musculoskeletal pain, pain due to hiatal hernia, or functional pain. Chest pain that is otherwise typical of angina but that lasts for more than 10 minutes or occurs at rest is typical of unstable angina.[18] Chest pain lasting for hours may be seen with acute myocardial infarction, pericarditis, aortic dissection, musculoskeletal disease, herpes zoster, and anxiety.

PRECIPITATING AND AGGRAVATING FACTORS.

Angina pectoris occurs characteristically on exertion, particularly when the patient is hurrying or walking up an incline. Thus, the development of chest discomfort or pain during walking, typically in the cold and up an incline or against a wind, especially after a heavy meal, is typical of angina pectoris. Angina may also be precipitated by strong emotion or fright, by a nightmare, by working with the arms over the head, by hurrying, by cold exposure, or by smoking a cigarette. Prinzmetal's (variant) angina characteristically occurs at rest and may or may not be affected by exertion; however, classical angina, although most often precipitated by effort, may progress to unstable angina, which is characterized by ischemic discomfort at rest (see Chap. 36) .

DIFFERENTIAL DIAGNOSIS.

Chest pain that occurs after protracted vomiting may be due to the Mallory-Weiss syndrome (i.e., a tear in the lower portion of the esophagus). Pain that occurs while the patient is bending over is often radicular and may be associated with osteoarthritis of the cervical or upper thoracic spine. Chest pain occurring on moving the neck may be due to a herniated intervertebral disc.

ESOPHAGEAL AND OTHER GASTROINTESTINAL PAIN.

Substernal and epigastric discomfort after swallowing may be due to *esophageal spasm or esophagitis*, often with acid reflux, with or without a hiatal hernia. These conditions may also be associated with substernal or epigastric burning pain that is brought on by eating or lying down after meals and that may be relieved by antacids. Pain due to esophageal spasm has many of the features of and may be difficult to differentiate from angina pectoris.[22] [23] [24] [25] A history of acid reflux into the mouth (water brash) and/or dysphagia may be a useful diagnostic clue pointing to esophageal disease.[26] [27] The chest discomfort secondary to esophageal reflux is most common after meals and occurs in the supine position or on bending. The difficulty in distinguishing angina from esophageal disease is compounded by the frequent coexistence of these two common conditions, by the observation that esophageal reflux lowers the threshold for the development of angina,[28] and by the observation that esophageal spasm may be precipitated by ergonovine and relieved by nitroglycerin. Esophageal pain radiates to the back more frequently than does angina pectoris.[23]

The term *linked angina* refers to episodes of true angina caused by myocardial ischemia due to gastrointestinal disturbances. Chauhan and colleagues have demonstrated that the installation of hydrochloric acid into the distal esophagus significantly reduced coronary blood flow both in patients with angiographically confirmed coronary artery disease[29] as well as in patients with syndrome X.[30] Such a reduction did not occur in patients who had undergone cardiac transplantation, indicating that it was a reflex response, thus providing an explanation for "linked angina."

The discomfort produced by *peptic ulcer disease* is characteristically located in the mid epigastrium. It may also resemble angina pectoris, but its characteristic relationship to food ingestion and its relief by antacids are important differentiating features. Although the pain of *acute pancreatitis* may mimic acute myocardial infarction, with the former there is usually a history of alcoholism or biliary tract disease. The pain of pancreatitis, like that of acute myocardial infarction, may be predominantly in the epigastrium. However, unlike the pain of myocardial infarction, it is usually transmitted to the back, is position sensitive, and may be relieved in part by leaning forward.[22]

OTHER CAUSES.

The chest discomfort of *pulmonary hypertension* (see Chap. 53) may be identical to that of typical angina[31] [32] ; it is caused by right ventricular ischemia or dilation of the pulmonary arteries. The chest discomfort of *unstable angina* and *acute myocardial infarction* (see Chaps. 35 and 36) is similar in quality to that of angina pectoris in location and character; however, it usually radiates more widely than does angina, is more severe, and therefore is generally referred to by the patient as true *pain* rather than *discomfort.* The development of pain in these conditions is usually unrelated to unusual effort or emotional stress, often with the patient at rest or even sleeping. Characteristically, nitroglycerin does not provide complete or lasting relief.

Acute pericarditis (see Chap. 50) is frequently preceded by a history of a viral upper respiratory infection. The inflammation causes pain that is sharper than anginal discomfort, is more left sided than central, and is often referred to the neck, upper shoulders, and back. The pain of pericarditis lasts for hours and is little affected by effort but is often aggravated by breathing, turning in bed, swallowing, or twisting the body; unlike angina, the pain of acute pericarditis may lessen when the patient sits up and leans forward.

Aortic dissection (see Chap. 40) is suggested by the sudden development of persistent, very severe pain with radiation to the back and into the lumbar region, often in a patient with a history of hypertension. An expanding *thoracic aortic aneurysm* may erode the vertebral bodies and cause localized, severe, boring pain that may be worse at night.

Chest-wall pain due to *costochondritis* or *myositis* is common in patients who present with fear of heart disease. It is associated with both local costochondral and muscle tenderness, which may be aggravated by moving or coughing. Chest-wall pain[33] may also accompany chest injury. In the *Tietze syndrome*, the discomfort is localized in swollen costochondral and costosternal joints, which are painful on palpation. When *herpes zoster* affects the left chest it may mimic myocardial infarction. However, its persistence, its localization to a dermatome, the extreme sensitivity of the skin to touch, and the appearance of the characteristic vesicles allow recognition of this condition. Pain in the chest wall is quite common after cardiac or thoracic surgery and may be confused with myocardial ischemia. Postsurgical pain is usually localized to the incision or the site of insertion of a chest tube.

The *preeruptive stage of herpes zoster* can mimic myocardial ischemia as a tight localized band across the chest.

The pain of *pulmonary embolism* (see Chap. 52) usually commences suddenly and in patients who are at rest. It is seen in patients at high risk for this condition (heart failure, venous disease, the postoperative state) and is accompanied by shortness of breath. It is typically described as tightness in the chest and is accompanied or followed by *pleuritic* chest pain (i.e., sharp pain in the side of the chest that is intensified by respiration or cough). Chest pain associated

with *spontaneous pneumothorax* develops suddenly, is associated with acute dyspnea, and is located in the lateral area of the chest. The chest pain associated with *mediastinal emphysema* also commences suddenly and is accompanied by dyspnea, which is sometimes severe; it is located in the center of the chest.

Functional or *psychogenic chest* pain (see Chap. 70) may be one feature of an anxiety state called Da Costa's syndrome or neurocirculatory asthenia.[34] [35] [36] [37] It is not typical of angina pectoris; it is usually localized to the cardiac apex and consists of a dull, persistent ache that lasts for hours and is often accentuated by or alternates with attacks of sharp, lancinating stabs of inframammary pain of 1 or 2 seconds' duration. The condition may occur with emotional strain and fatigue, bears little relation to exertion, and may be accompanied by precordial tenderness. Attacks may be associated with palpitation, hyperventilation, numbness and tingling in the extremities, sighing, dizziness, dyspnea, generalized weakness, faintness, severe fatigability, and a history of panic attacks and other signs of emotional instability or depression. The pain may not be completely relieved by any medication other than analgesics, but it is often attenuated by many types of interventions, including rest, exertion, tranquilizers, and placebos. Therefore, in contrast to ischemic discomfort, functional pain is more likely to show variable responses to interventions on different occasions. Patients with Da Costa's syndrome are usually young (<40 years), are female, and have high scores on depression and anxiety scales.[38]

Congenital absence of the pericardium (see Chap. 50) produces chest pain that is relieved by changing position in bed, is brought on by lying on the left side, and lasts a few seconds. Pain due to the *scalenus anticus (thoracic outlet) syndrome* may be confused with angina because it is often associated with paresthesias along the ulnar distribution of the arm and forearm. However, in contrast to angina, not only is it typically precipitated by abduction of the arm or lifting a weight but it is also not brought on by walking.

RELIEF OF PAIN.

Rest and sublingual nitroglycerin characteristically relieve the discomfort of angina in 1 to 5 minutes. If more than 10 minutes transpire before relief, the diagnosis of chronic stable angina becomes questionable and instead unstable angina, acute myocardial infarction, or pain not caused by myocardial ischemia at all is the cause. Although nitroglycerin commonly relieves the pain of angina pectoris, the discomfort of esophageal spasm and esophagitis may also be relieved by this drug. Angina pectoris is alleviated by quiet standing or sitting; sometimes resting in the recumbent position does not relieve angina. Chest pain secondary to *acute pericarditis* is characteristically relieved by leaning forward, whereas pain that is relieved by food or antacids may be due to *peptic ulcer disease* or esophagitis. Pain that is alleviated by holding the breath in deep expiration is commonly due to pleuritic inflammation. Some patients with upper gastrointestinal disease or anxiety report relief of symptoms after belching.

CHEST PAIN IN WOMEN (see Chap. 58) .

Chest discomfort that is atypical for angina pectoris is more common in women than in men, perhaps because of the higher prevalence of vasospastic and of microvascular angina and nonischemic causes of chest pain in women[39] (see Table 3-5) . Women with epicardial coronary artery disease more often report chest discomfort at rest, during sleep, or during mental stress than do men.

ACCOMPANYING SYMPTOMS.

The physician should always be concerned about the patient with the combination of chest discomfort and profuse sweating. This combination of symptoms frequently signals a serious disorder, most often acute myocardial infarction but also acute pulmonary embolism or aortic dissection. Severe chest pain accompanied by nausea and vomiting is also often due to myocardial infarction. The latter diagnosis, as well as pneumothorax, pulmonary embolism, or mediastinal emphysema, is suggested by pain associated with shortness of breath. Chest pain accompanied by palpitation may be due to the acute myocardial ischemia precipitated by a tachyarrhythmia-induced increase in myocardial oxygen consumption in the presence of coronary artery disease. Chest pain accompanied by hemoptysis suggests pulmonary embolism with infarction or lung tumor, whereas pain accompanied by fever occurs in pneumonia, pleurisy, and pericarditis. Functional pain is commonly accompanied by frequent sighing, anxiety, or depression.

APPROACH TO THE PATIENT.

This is summarized in the algorithm shown in Figure 3-4 .[40] After administration of emergency treatment, if necessary, a focused history and physical examination should allow determination of a cardiac or possible cardiac cause. The 12-lead electrocardiogram is then helpful in guiding therapy (Fig. 3-5) .[40]

Cyanosis

Cyanosis, both a symptom and a physical sign, is a bluish discoloration of the skin and mucous membranes resulting from an increased quantity of reduced hemoglobin or of abnormal hemoglobin pigments in the blood perfusing these areas.[41] [42] It is more commonly described by a family member and may go unnoticed by the patient. There are two principal forms of cyanosis: (1) central cyanosis, characterized by decreased arterial oxygen saturation due to right-to-left shunting of blood or impaired pulmonary function, and (2) peripheral cyanosis, most commonly secondary to cutaneous vasoconstriction due to low cardiac output or exposure to cold air or water; if peripheral cyanosis is confined to an extremity, localized arterial or venous obstruction should be suspected. A history of cyanosis localized to the hands suggests Raynaud's phenomenon. Patients with central cyanosis due to congenital heart disease or pulmonary disease characteristically report that it worsens during exertion, whereas the resting peripheral cyanosis of congestive heart failure may be accentuated only slightly, if at all, during exertion.

Central cyanosis usually becomes apparent at a mean capillary concentration of 4 gm/dl reduced hemoglobin (or 0.5 gm/dl methemoglobin). In general, a history of cyanosis in light-skinned people is rarely elicited unless arterial saturation is 85 percent or less; in pigmented races, arterial saturation has to drop far lower before cyanosis is perceptible.

Although a history of cyanosis beginning in infancy suggests a congenital cardiac malformation with a right-to-left shunt, hereditary methemoglobinemia is another, albeit rare, cause of congenital cyanosis; the diagnosis of this condition is supported by a family history of cyanosis in the absence of heart disease.

A history of cyanosis limited to the neonatal period suggests the diagnosis of atrial septal defect with transient right-to-left shunting or, more commonly, pulmonary parenchymal disease or central nervous system depression. Cyanosis beginning at age 1 to 3 months may be reported when spontaneous closure of a patent ductus arteriosus causes a reduction of pulmonary blood flow in the presence of right-sided obstructive cardiac anomalies, most commonly tetralogy of Fallot. If cyanosis appears at age 6 months or later in childhood, it may be due to the development or progression of obstruction to right ventricular outflow in patients with ventricular septal defect. A history of the development of cyanosis in a patient with congenital heart disease between 5 and 20 years of age suggests an Eisenmenger reaction with right-to-left shunting as a consequence of a progressive increase in pulmonary vascular resistance (see Chaps. 43 and 44) . Cyanosis secondary to a pulmonary arteriovenous fistula also usually appears first in childhood.

Figure 3-4 Diagnostic approach to the patient with new, acute, often ongoing chest pain. *(From Goldman L: Chest discomfort and palpitation. In Fauci A, Braunwald E, et al [eds]: Harrison's Principles of Internal Medicine, 14th ed. New York, McGraw-Hill, 1998, p 61.)*

Figure 3-5 Diagnostic approach to the patient with new, acute, often ongoing pain of potential cardiac cause or of uncertain cause. *(From Goldman L: Approach to the patient with chest pain. In Goldman L, Braunwald E [eds]: Primary Cardiology. Philadelphia, WB Saunders, 1998, pp 84-97.)*

Syncope (See Chap. 27)

A loss of consciousness results most commonly from reduced perfusion of the brain. The history is extremely valuable in the differential diagnosis of syncope (Table 3-6) . Several daily attacks of loss of consciousness suggest (1) Stokes-Adams attacks (i.e., transient asystole or ventricular fibrillation in the presence of atrioventricular block); (2) other cardiac arrhythmias; or (3) a seizure disorder (i.e., petit mal epilepsy). These diagnoses are suggested when the loss of consciousness is abrupt and occurs over 1 or 2 seconds; a more gradual onset suggests vasodepressor syncope (i.e., the common faint) or syncope due to hyperventilation or, much less commonly, hypoglycemia.

CARDIAC SYNCOPE.

This condition is usually of rapid onset without aura and is usually not associated with convulsive movements, urinary incontinence, or a postictal confusional state. Syncope in aortic stenosis[43] [44] [45] is usually precipitated by effort. Patients with syncope secondary to a convulsive disorder often have a prodromal aura preceding the seizure. Injury from falling is common, as are urinary incontinence and a postictal confusional state, associated with headache and drowsiness. Unconsciousness developing gradually and lasting for a few seconds suggests vasodepressor syncope or syncope secondary to postural hypotension (see Chap. 27) , whereas a longer period suggests aortic stenosis or hyperventilation. Hysterical fainting is usually not accompanied by any untoward display of anxiety or change in pulse, blood pressure, or skin color, and there may be a question whether any true loss of consciousness occurred. It is often associated with paresthesias of the hands or face, hyperventilation, dyspnea, chest pain, and feelings of acute anxiety.

REGAINING CONSCIOUSNESS.

Consciousness is usually regained quite promptly in syncope of cardiovascular origin but more slowly in patients with convulsive disorders. When consciousness is regained after vasodepressor syncope, the patient is often pale and diaphoretic with a slow heart rate, whereas after a Stokes-Adams attack the face is often flushed and there may be cardiac acceleration. Patients who report an injury when falling during a fainting spell usually have a convulsive disorder or occasionally syncope of cardiac origin, but patients who have unconsciousness related to emotional disturbance rarely sustain physical trauma.

DIFFERENTIAL DIAGNOSIS.

A family history of syncope or near-syncope can often be elicited in patients with hypertrophic cardiomyopathy (see Chap. 48) or ventricular tachyarrhythmias associated with QT prolongation (see Chap. 25) . A history of syncope during childhood suggests the possibility of obstruction to left ventricular outflow--valvular, supravalvular, or subvalvular aortic stenosis. In patients with hypertrophic cardiomyopathy, syncope may be posttussive and occurs characteristically in the erect position, when arising suddenly, after standing erect for long periods, and during or immediately after cessation of exertion.

Patients with syncope secondary to orthostatic hypotension may have a history of drug therapy for hypertension or of abnormalities of autonomic function, such as impotence, disturbances of sphincter function, peripheral neuropathy, and anhidrosis.[46] [47] [48]

Calkins and coworkers demonstrated the value of the clinical history in the differentiation between serious arrhythmias (ventricular tachycardia or atrioventricular block) and neurocardiogenic syncope. Features predictive of the former were male gender, age older than 54 years, two or fewer episodes of syncope, and duration of warning of 5 seconds or less. On the other hand, features of syncope not due to arrhythmia included palpitations, blurred vision, nausea, diaphoresis, or lightheadedness before syncope, and nausea, warmth, diaphoresis, or fatigue after syncope.[49]

Palpitation (See Chap. 22)

This common symptom is defined as an unpleasant awareness of the forceful or rapid beating of the heart. Patients may describe it as pounding, jumping, racing, or irregularity of the heart beat, a "flip flopping" or "rapid fluttering" in the chest, or pounding in the neck.[50] [51] It may be brought about by a variety of disorders involving changes in cardiac rhythm or rate, including all forms of tachycardia, ectopic beats, compensatory pauses, augmented stroke volume due to valvular regurgitation, hyperkinetic (high cardiac output) states, and the sudden onset of bradycardia. In the case of premature contractions the patient is more

TABLE 3-6 -- CLUES FROM THE HISTORY IN ELUCIDATING THE CAUSE OF SYNCOPE

Preceding Events	**Mechanisms of Syncope**
Drugs:	Orthostatic hypotension (antihypertensives), hypoglycemia (insulin)
Severe pain, emotional stress:	Vasovagal syncope, hyperventilation
Movement of head and neck:	Carotid sinus hypersensitivity
Exertion:	Any form of obstruction to left ventricular outflow, Takayasu's arteritis
Upper extremity exertion:	Subclavian "steal"
Type of Onset	
Sudden:	Neurological (seizure disorder); arrhythmia (ventricular tachycardia or fibrillation, Stokes-Adams)
Rapid with premonition:	Vasovagal, neurological (aura)
Gradual:	Hyperventilation, hypoglycemia
Position at Onset	
Arising:	Orthostatic hypotension
Prolonged standing:	Vasovagal
Any position:	Arrhythmias, neurological, hypoglycemia, hyperventilation
Postsyncopal Clearing of Sensorium	
Slow:	Neurological
Rapid:	All others
Associated Events	
Incontinence, tongue biting, injury:	Neurological

Modified from Lindenfeld JA: Syncope. In Horwitz LD, Groves BM (eds): Signs and Symptoms in Cardiology. Philadelphia, JB Lippincott, 1985.

commonly aware of the postextrasystolic beat than of the premature beat itself, and it appears that it is the increased motion of the heart within the chest that is perceived. This explains why palpitation is not a characteristic feature of aortic or pulmonic stenosis or of severe systemic or pulmonary hypertension, conditions characterized by an increased force of cardiac contraction.

When episodes of palpitation last for an instant, they are described as "skipped beats" or a "flopping sensation" in the chest and most commonly are due to extrasystoles. On the other hand, the sensation that the heart has "stopped beating" often correlates with the compensatory pause after a premature contraction. When palpitation secondary to premature contraction increases during exercise, the prognosis is more ominous than when they disappear during exercise.

DIFFERENTIAL DIAGNOSIS.

Palpitation characterized by a slow heart rate may be due to atrioventricular block or sinus node disease. When palpitation begins and ends abruptly, it is often due to a paroxysmal tachycardia such as paroxysmal atrial or junctional tachycardia, atrial flutter, or atrial fibrillation, whereas a gradual onset and cessation of the attack suggest sinus tachycardia and/or an anxiety state. A history of chaotic, rapid heart action suggests the diagnosis of atrial fibrillation; fleeting and repetitive palpitation suggests multiple ectopic beats. A history of multiple paroxysms of tachycardia followed by palpitation that occurs only with effort or excitement suggests paroxysmal atrial fibrillation that has become permanent, with the palpitation being experienced only when the ventricular rate rises. A history of dizziness, presyncope, or syncope

with palpitations may be due to ventricular tachycardia and may be an ominous prognostic sign.

Some patients have taken their pulse during palpitation or have asked a companion to do so. A regular rate between 100 and 140 beats/min suggests sinus tachycardia, a regular rate of approximately 150 beats/min suggests atrial flutter, and a regular rate exceeding 160 beats/min suggests paroxysmal supraventricular tachycardia. As an adjunct to the history, it may be possible to ascertain the rhythm responsible for the palpitation by tapping the finger on the patient's chest in a variety of rhythms and asking the patient to identify the pattern that most closely resembles the abnormal feeling. Alternatively, patients can be asked to reproduce the arrhythmia by tapping their fingers on a tabletop at the rate and rhythm they perceived during palpitation. These maneuvers may provide important clues to the etiology of the responsible arrhythmia.

A history of palpitation during strenuous physical activity is normal, whereas palpitation during mild exertion suggests the presence of heart failure, atrial fibrillation, anemia, or thyrotoxicosis or that the individual is severely deconditioned. When palpitation can be relieved suddenly by stooping, breath-holding, or induced gagging or vomiting (i.e., by vagal maneuvers), the diagnosis of paroxysmal supraventricular tachycardia is suggested. A history of syncope *after* an episode of palpitation suggests either asystole or severe bradycardia following the termination of a tachyarrhythmia. Palpitation followed by angina suggests that myocardial ischemia has been precipitated by increased oxygen demands induced by the rapid heart rate. Palpitations are frequently accompanied by, and are often caused by, anxiety, panic reactions, or emotionally startling experiences. [50]

A directed history is useful in elucidating the cause of palpitation (Table 3-7) . Is there a history of cocaine or amphetamine abuse? Thyrotoxicosis? Anemia? Do the palpitations occur after heavy cigarette smoking or caffeine ingestion? Is there a family history of syncope, arrhythmia, or sudden death?

DIAGNOSTIC APPROACH TO THE PATIENT.

The diagnostic approach is shown in Figure 3-6 (Figure Not Available) . The key decision points are the determination of whether structural heart disease is present and whether the patient complains of severe symptoms, including syncope and presyncope.

Edema

LOCALIZATION.

This is helpful in elucidating the etiology of edema.[52] [53] [53A] Unilateral leg edema is most commonly due to deep venous thrombosis or cellulitis. Thus a history of edema of the legs that is most pronounced in the evening is characteristic of heart failure or bilateral chronic venous insufficiency. Inability to fit the feet into shoes is a common early complaint. In most patients, any visible edema of both lower extremities is preceded by a weight gain of at least 3 to 5 kg. Cardiac edema is generally symmetrical. As it progresses, it usually ascends to involve the legs, thighs, genitalia, and abdominal wall. In patients with heart failure who are confined largely to bed, the edematous fluid localizes in the sacral area. Edema may be generalized (anasarca) in the nephrotic syndrome, severe heart failure, and hepatic cirrhosis. These three conditions can be distinguished by consideration of the history, physical examination, and simple laboratory tests (Table 3-8) . A variety of drugs interfere with sodium excretion and may cause edema as well (Table 3-9) . A careful history regarding their recent use is indicated in patients with generalized edema.

A history of edema around the eyes and face is characteristic of the nephrotic syndrome, acute glomerulonephritis, angioneurotic edema, hypoproteinemia, and myxedema. A history of edema limited to the face, neck, and upper arms may be associated with obstruction of the superior vena cava, most commonly by carcinoma of the lung, lymphoma, or aneurysm of the aortic arch. A history of edema restricted to one extremity is usually due to venous thrombosis or lymphatic blockage of that extremity.

ACCOMPANYING SYMPTOMS.

A history of dyspnea associated with edema is most frequently due to heart failure, but it may also be observed in patients with large bilateral pleural effusions, elevation of the diaphragms due to ascites, angioneurotic edema with laryngeal involvement, and pulmonary embolism. When dyspnea precedes edema, the underlying disorder is usually left ventricular dysfunction, mitral stenosis, or chronic lung disease with cor pulmonale. A history of jaundice suggests that edema may be of hepatic origin, whereas edema associated with a history of ulceration and pigmentation of the skin of the legs is most

TABLE 3-7 -- ITEMS TO BE COVERED IN HISTORY OF PATIENT WITH PALPITATION

DOES THE PALPITATION OCCUR:	IF SO, SUSPECT:
As isolated "jumps" or "skips"?	Extrasystoles
In attacks, known to be of abrupt beginning, with a heart rate of 120 beats/min or over, with regular or irregular rhythm?	Paroxysmal rapid heart action
Independent of exercise or excitement adequate to account for the symptom?	Atrial fibrillation, atrial flutter, thyrotoxicosis, anemia, febrile states, hypoglycemia, anxiety state
In attacks developing rapidly though not absolutely abruptly, unrelated to exertion or excitement?	Hemorrhage, hypoglycemia, tumor of the adrenal medulla
In conjunction with the taking of drugs?	Tobacco, coffee, tea, alcohol, epinephrine, ephedrine, aminophylline, atropine, thyroid extract, monoamine oxidase inhibitors
On standing?	Postural hypotension
In middle-aged women, in conjunction with flushes and sweats?	Menopausal syndrome
When the rate is known to be normal and the rhythm regular?	Anxiety state

From Goldman L, Braunwald E: Chest discomfort and palpitation. In Isselbacher KJ, Braunwald E, et al (eds): Harrison's Principles of Internal Medicine, 13th ed. New York, McGraw-Hill, 1994.

Figure 3-6 (Figure Not Available) Diagnostic approach to the patient with palpitations. *(From Hlatky MA: Approach to the patient with palpitations. In Goldman L, Braunwald E [eds]: Primary Cardiology. Philadelphia, WB Saunders, 1998, pp 122-128.)*

commonly due to chronic venous insufficiency or postphlebitic syndrome. When cardiac edema is not associated with orthopnea, it may be due to tricuspid valve disease or constrictive pericarditis. A history of leg edema after prolonged sitting (particularly in the elderly) may be due to simple venous stasis and not be associated with disease at all.

A history of ascites *before* edema suggests cirrhosis, whereas a history of ascites *after* edema suggests cardiac or renal disease. Idiopathic cyclic edema is associated with the menstrual cycle. A history of edema on prolonged standing is observed in patients with chronic venous insufficiency.

TABLE 3-8 -- PRINCIPAL CAUSES OF GENERALIZED EDEMA: HISTORY, PHYSICAL EXAMINATION, AND LABORATORY FINDINGS

ORGAN SYSTEM	HISTORY	PHYSICAL EXAMINATION	LABORATORY FINDINGS
Cardiac	Dyspnea with exertion prominent--often associated with orthopnea--or paroxysmal nocturnal dyspnea	Elevated jugular venous pressure, ventricular (S_3) gallop; occasionally with displaced or dyskinetic apical pulse; peripheral cyanosis, cool extremities, small pulse pressure when severe	Elevated urea nitrogen-to-creatinine ratio common; elevated uric acid; serum sodium often diminished; liver enzymes occasionally elevated with hepatic congestion

Hepatic	Dyspnea infrequent, except if associated with significant degree of ascites; most often a history of ethanol abuse	Frequently associated with ascites; jugular venous pressure usually normal or low; blood pressure typically lower than in renal or cardiac disease; one or more additional signs of chronic liver disease (jaundice, palmar erythema, Dupuytren contracture, spider angiomata, male gynecomastia or testicular atrophy, caput medusa); asterixis and other signs of encephalopathy may be present	If severe, reductions in serum albumin, cholesterol, other hepatic proteins (transferrin, fibrinogen); liver enzymes may or may not be elevated, depending on the cause and acuity of liver injury; tendency toward hypokalemia, respiratory alkalosis; magnesium and phosphorus often markedly reduced if associated with ongoing ethanol intake; uric acid typically low; macrocytosis from folate deficiency
Renal	Usually chronic; associated with uremic signs and symptoms, including decreased appetite, altered (metallic or fishy) taste, altered sleep pattern, difficulty concentrating, restless legs or myoclonus; dyspnea can be present, but generally less prominent than in heart failure	Blood pressure often high; hypertensive or diabetic retinopathy in selected cases; nitrogenous fetor; periorbital edema may predominate; pericardial friction rub in advanced cases with uremia	Elevation of serum creatinine and urea nitrogen most prominent; also frequent hyperkalemia, metabolic acidosis, hyperphosphatemia, hypocalcemia, anemia (usually normocytic)

COUGH

Cough, one of the most frequent of all cardiorespiratory symptoms, may be defined as an explosive expiration that provides a means of clearing the tracheobronchial tree of secretions and foreign bodies.[54] [55] [56] It can be caused by a variety of infectious, neoplastic, or allergic disorders of the lungs and tracheobronchial tree. Cardiovascular disorders most frequently responsible for cough include those that lead to pulmonary venous hypertension, interstitial and alveolar pulmonary edema, pulmonary infarction, and compression of the tracheobronchial tree (aortic aneurysm).

Cough due to pulmonary venous hypertension secondary to left ventricular failure or mitral stenosis tends to be dry, irritating, spasmodic, and nocturnal. When cough accompanies exertional dyspnea, it suggests either chronic obstructive lung disease or heart failure, whereas in a patient with a history of allergy and/or wheezing, cough is often a concomitant of bronchial asthma. A history of a combination of cough with hoarseness without upper respiratory disease may be due to pressure of a greatly enlarged left atrium on an enlarged pulmonary artery compressing the recurrent laryngeal nerve. A history of cough associated with expectoration for months or years occurs in chronic obstructive lung disease and/or chronic bronchitis.

The character of the sputum may be helpful in the differential diagnosis. Thus, a cough producing frothy, pink-tinged sputum occurs in pulmonary edema, whereas blood-streaked sputum suggests tuberculosis, bronchiectasis, carcinoma of the lung, or pulmonary infarction.

HEMOPTYSIS

The expectoration of blood or of sputum, either streaked or grossly contaminated with blood, may be due to (1) escape of red cells into the alveoli from congested vessels in the lungs (acute pulmonary edema); (2) rupture of dilated endobronchial vessels that form collateral channels between the pulmonary and bronchial venous systems (mitral stenosis); (3) necrosis and hemorrhage into the alveoli (pulmonary infarction); (4) ulceration of the bronchial mucosa or the slough of a caseous lesion (tuberculosis); (5) minor damage to the tracheobronchial mucosa, produced by excessive coughing of any cause, which can result in mild hemoptysis; (6) vascular invasion (carcinoma of the lung); or (6) necrosis of the mucosa with rupture of pulmonary-bronchial venous connections (bronchiectasis).

The history is often decisive in pinpointing the etiology of hemoptysis.[56] Recurrent episodes of minor bleeding are observed in patients with chronic bronchitis, bronchiectasis, tuberculosis, and mitral stenosis. Rarely, these conditions result in the expectoration of large quantities of blood (i.e., more than one-half cup). Massive hemoptysis may also be due to rupture of a pulmonary arteriovenous fistula; exsanguinating hemoptysis may occur with rupture of an aortic aneurysm into the bronchopulmonary tree.[55] [57] [58]

Hemoptysis associated with shortness of breath suggests mitral stenosis; in this condition the hemoptysis is often precipitated by sudden elevations in left atrial pressure during effort or pregnancy and is attributable to rupture of small pulmonary or bronchopulmonary anastomosing veins. Blood-tinged sputum in patients with mitral stenosis may also be due to transient pulmonary edema; in these circumstances it is usually associated with severe dyspnea. A history of hemoptysis associated with acute pleuritic chest pain suggests pulmonary embolism with infarction. Recurrent hemoptysis in a young, otherwise asymptomatic woman favors the diagnosis of bronchial adenoma. Hemoptysis associated with congenital heart disease and cyanosis suggests Eisenmenger's syndrome.

OTHER SYMPTOMS

Cardiovascular disorders can cause symptoms emanating from every organ system. Several of these are mentioned here primarily to point out how detailed the history

should be in providing a comprehensive evaluation of a patient suspected of having cardiovascular disease; fuller discussions are found elsewhere in this text.

FATIGUE.

This is among the most common symptoms in patients with impaired cardiovascular function. However, it is also one of the most nonspecific of all symptoms. In patients with impaired systemic circulation as a consequence of a depressed cardiac output, fatigue may be associated with muscular weakness. In other patients with heart disease, fatigue may be caused by drugs, such as beta-adrenoceptor blocking agents. It may be the result of excessive blood pressure reduction in patients treated too vigorously for hypertension or heart failure. In patients with heart failure, fatigue may also be caused by excessive diuresis and by diuretic-induced hypokalemia. Extreme fatigue sometimes precedes or accompanies acute myocardial infarction.

OTHER SYMPTOMS.

Nocturia is a common early complaint in patients with congestive heart failure. *Anorexia,* abdominal fullness, right upper quadrant discomfort, weight loss, and cachexia are symptoms of advanced heart failure (see Chap. 17) . Anorexia, *nausea, vomiting,* and *visual changes* are important signs of digitalis intoxication (see Chap. 18) . Nausea and vomiting occur frequently in patients with acute myocardial infarction. Hoarseness may be caused by compression of the recurrent laryngeal nerve by an aortic aneurysm, a dilated pulmonary artery, or a greatly enlarged left atrium. A history of *fever* and *chills* is common in patients with infective endocarditis (see Chap. 47) .

THE HISTORY IN SPECIFIC FORMS OF HEART DISEASE

Just as the history is of central importance in determining whether or not a specific symptom is caused by heart disease, it is equally valuable in elucidating its etiology. A few examples are given below, whereas considerably greater detail is provided in chapters that deal with each specific disease entity.

Heart Disease in Infancy and Childhood (See Chaps. 43 and 45)

The history is particularly helpful in establishing the diagnosis of congenital heart disease. In view of the familial incidence of certain congenital malformations (see Chaps. 43 and 56) , a history of congenital heart disease, cyanosis, or heart murmur in the family should be ascertained. Rubella in the first 2 months of pregnancy is associated with a number of congenital cardiac malformations (patent ductus arteriosus, atrial and ventricular septal defect, tetralogy of Fallot, and supravalvular aortic stenosis). A maternal viral illness in the last trimester of pregnancy may be responsible for neonatal myocarditis. Exertional syncope in a child with congenital heart disease suggests a lesion in which the cardiac output is fixed, such as aortic or pulmonic stenosis. Exertional angina in a child suggests severe aortic stenosis, pulmonary stenosis, primary pulmonary hypertension, or anomalous origin of the left coronary artery. A history of syncope or faintness with straining and associated with cyanosis suggests tetralogy of Fallot.

In infants or children with cardiac murmurs, it is important to ascertain by history as precisely as possible when the murmur was first detected. Murmurs due to either aortic or pulmonic stenosis are usually audible within the first 48 hours of life, whereas those produced by a ventricular septal defect are usually apparent a few days or weeks later. On the other hand, the murmur produced by an atrial septal defect often is not heard until age 2 to 3 months.

Frequent episodes of pneumonia early in infancy suggest a large left-to-right shunt, and a history of excessive diaphoresis

occurs in left ventricular failure, most commonly due to ventricular septal defect in this age group. A history of squatting is most frequently associated with tetralogy of Fallot or tricuspid atresia. Dysphagia in early infancy suggests the presence of an aortic arch anomaly such as double aortic arch or an anomalous origin of the right subclavian artery passing behind the esophagus. A history of headaches, weakness of the legs, and intermittent claudication is compatible with the diagnosis of coarctation of the aorta. Weakness or lack of coordination in a child with heart disease suggests cardiomyopathy associated with Friedreich's ataxia or muscular dystrophy (see Chap. 71) . Recurrent bleeding from the nose, lips, or mouth, associated with dizziness and visual disturbances, and a family history of bleeding in a cyanotic child suggest hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) with pulmonary arteriovenous fistula(s). A cerebrovascular accident in a cyanotic patient may be due to cerebral thrombosis or abscess or paradoxical embolization.

MYOCARDITIS AND CARDIOMYOPATHY

Rheumatic fever (see Chap. 66) is suggested by a history of sore throat followed by rash and chorea (St. Vitus' dance). The latter is characterized by twitching or clumsiness for a few months in childhood, as well as by frequent episodes of epistaxis and growing pains (i.e., nocturnal pains in the legs). In patients suspected of having myocarditis or cardiomyopathy, a history of Raynaud's phenomenon, dysphagia, or tight skin suggests *scleroderma* (see Chap. 67) . A history of dyspnea following an influenza-like illness with myalgia suggests *acute myocarditis*. Pain in the hip or lower back that awakens the patient in the morning and is followed by morning back stiffness suggests *rheumatoid spondylitis*, which is often associated with aortic valve disease (see Chap. 67) . *Carcinoid heart disease* (see Chap. 48) is associated with a history of diarrhea, bronchospasm, and flushing of the upper chest and head. A history of diabetes, particularly if resistant to insulin and associated with bronzing of the skin, suggests *hemochromatosis* (see Chap. 69) , which may be associated with heart failure due to cardiac infiltration. *Amyloid heart disease* (see Chap. 48) is often associated with a history of postural hypotension and peripheral neuropathy. *Hypertrophic cardiomyopathy* (see Chap. 48) is often associated with a family history of this condition and sometimes with a family history of sudden death. The characteristic symptoms are angina, dyspnea, and syncope, which are often intensified paradoxically by digitalis and which occur during or immediately after exercise.

HIGH-OUTPUT HEART FAILURE

Patients with symptoms of heart failure (breathlessness and excess fluid accumulation) with warm extremities often have *high-output heart failure* (see Chap. 17) . They should be questioned about a history of anemia and of its common causes and accompaniments, such as menorrhagia, melena, peptic ulcer, hemorrhoids, sickle cell disease, and the neurological manifestations of vitamin B_{12} deficiency. Also, in such patients an attempt should be made to elicit a history of thyrotoxicosis (weight loss, polyphagia, diarrhea, diaphoresis, heat intolerance, nervousness, breathlessness, muscle weakness, and goiter [see Chap. 64]). Patients with beriberi heart disease responsible for high-output heart failure often have a history characteristic of peripheral neuritis, alcoholism, poor eating habits, fad diets, or upper gastrointestinal surgery.

COR PULMONALE.

Patients with chronic cor pulmonale (see Chap. 54) frequently present with a history of smoking, chronic cough and sputum production, dyspnea, and wheezing relieved by bronchodilators. Alternatively, they may have a history of pulmonary emboli, phlebitis, and the sudden development of dyspnea at rest with palpitations, pleuritic chest pain, and, in the case of massive infarction, syncope.

PERICARDITIS.

In patients in whom *pericarditis* or *cardiac tamponade* is suspected (see Chap. 50) , an attempt should be made to elicit a history of chest trauma, a recent viral infection, recent cardiac surgery, neoplastic disease of the chest with or without radiation therapy, myxedema, scleroderma, tuberculosis, or contact with tuberculous patients. The sequence of development of abdominal swelling, ankle edema, and dyspnea should be determined, since in patients with chronic constrictive pericarditis, ascites often precedes edema, which in turn usually precedes exertional dyspnea. A history of joint symptoms with a face rash suggests the possibility of systemic lupus erythematosus, an important cause of pericarditis, and it should be recalled that procainamide, hydralazine, and isoniazid can produce a syndrome resembling systemic lupus.

INFECTIVE ENDOCARDITIS.

The diagnosis of this condition is suggested by a history of fever, severe night sweats, anorexia, and weight loss and embolic phenomena expressed as hematuria, back pain, petechiae, tender finger pads, and a cerebrovascular accident (see Chap. 47) .

Drug-Induced Heart Disease

Because a wide variety of cardiac abnormalities can be induced by drugs,[59] a meticulous history of drug intake is of great importance. Table 3-10 summarizes the major drugs responsible for various cardiovascular manifestations.

TABLE 3-10 -- CARDIOVASCULAR MANIFESTATIONS OF ADVERSE REACTIONS TO DRUGS

Acute chest pain (nonischemic)
Bleomycin
Angina exacerbation
Alpha blockers
Beta-blocker withdrawal
Ergotamine
Excessive thyroxine
Hydralazine
Methysergide
Minoxidil
Nifedipine
Oxytocin
Sumatriptan
Vasopressin
Arrhythmias
Adriamycin
Antiarrhythmic drugs
Astemizole
Atropine
Anticholinesterases
Beta blockers
Cisapride
Daunorubicin
Digitalis
Emetine
Erythromycin
Guanethidine
Arrhythmias (*cont.*)
Ketanserin
Lithium
Papaverine
Pentamidine
Phenothiazines, particularly thioridazine
Probucol
Sympathomimetics
Terfenadine
Theophylline
Thyroid hormone
Tricyclic antidepressants
Verapamil
Atrioventricular block
Beta blockers
Clonidine
Methyldopa
Verapamil
Cardiomyopathy
Daunorubicin
Doxorubicin
Emetine
Lithium
Phenothiazines
Sulfonamides
Sympathomimetics
Fluid retention/congestive heart failure/edema
Beta blockers
Calcium blockers
Carbenoxolone
Diazoxide
Estrogens
Indomethacin
Mannitol
Minoxidil
Phenylbutazone

- Steroids
- Verapamil

Hypotension (see also arrhythmias)
- Amiodarone (perioperative)
- Calcium channel blockers (e.g., nifedipine)
- Citrated blood
- Diuretics
- Interleukin-2
- Levodopa
- Morphine
- Nitroglycerin
- Phenothiazines
- Protamine
- Quinidine

Hypertension
- Clonidine withdrawal
- Corticotropin
- Cyclosporine
- Glucocorticoids
- Monoamine oxidase inhibitors with sympathomimetics
- NSAIDs (some)
- Oral contraceptives
- Sympathomimetics
- Tricyclic antidepressants with sympathomimetics

Pericarditis
- Emetine
- Hydralazine
- Methysergide
- Procainamide

Pericardial effusion
- Minoxidil

Thromboembolism
- Oral contraceptives

NSAIDs = nonsteroidal antiinflammatory drugs.

From Wood A: Adverse reactions to drugs. In Fauci A, Braunwald E, et al (eds): Harrison's Principles of Internal Medicine, 14th ed. New York, McGraw-Hill, 1998.

Catecholamines, whether administered exogenously or secreted by a pheochromocytoma (see Chap. 64) , may produce myocarditis and arrhythmias. *Digitalis glycosides* can be responsible for a variety of tachyarrhythmias and bradyarrhythmias as well as gastrointestinal, visual, and central nervous system disturbances (see Chap. 18) . Paradoxically, the administration of antiarrhythmic drugs is one of the major causes of serious cardiac arrhythmias (see Chap. 23) . For example, *quinidine* may cause QT prolongation, ventricular tachycardia of the torsades de pointes variety, syncope, and sudden death, presumably due to ventricular fibrillation.

Disopyramide, *beta-adrenoceptor blockers*, and the calcium channel antagonists *diltiazem* and *verapamil* may depress ventricular performance, and in patients with ventricular dysfunction these drugs may intensify heart failure. *Alcohol* is also a potent myocardial depressant and may be responsible for the development of cardiomyopathy (see Chap. 48) , arrhythmias, and sudden death. *Tricyclic antidepressants* may cause orthostatic hypotension and arrhythmias. *Lithium,* also used in the treatment of psychiatric disorders, can aggravate preexisting cardiac arrhythmias, particularly in patients with heart failure in whom the renal clearance of this ion is impaired. *Cocaine* can cause coronary spasm with resultant myocardial ischemia, myocardial infarction, and sudden death.[60] [61]

The *anthracycline compounds* doxorubicin (Adriamycin) and daunorubicin, which are widely used because of their broad spectrum of activity against various tumors, may cause or intensify left ventricular failure, arrhythmias, myocarditis, and pericarditis (see Chap. 69) . *Cyclophosphamide,* an antineoplastic alkylating agent, may also cause left ventricular dysfunction, whereas 5-fluorouracil and its derivatives may be responsible for angina secondary to coronary spasm. Radiation therapy to the chest may cause acute and chronic pericarditis (see Chap. 50) , pancarditis, or coronary artery disease; furthermore, it may enhance the aforementioned cardiotoxic effects of the anthracyclines.

ASSESSING CARDIOVASCULAR DISABILITY (Table 3-11)

One of the greatest values of the history is in categorizing the degree of cardiovascular disability, so that a patient's status can be followed over time, the effects of a therapeutic intervention assessed, and patients compared with one another. The Criteria Committee of the New York Heart Association has provided a widely used classification that relates functional activity to the ability to carry out "ordinary" activity.[62] The term *ordinary,* of course, is subject to widely varying interpretation, as are terms such as *undue fatigue* that are used in this classification, and this has limited its accuracy and reproducibility. More recently, the New York Heart Association changed its evaluation from functional activity to a broader one, called cardiac status, which takes account of symptoms and other data gathered from the patient.[62] Cardiac status is classified as (1) uncompromised,

TABLE 3-11 -- A COMPARISON OF THREE METHODS OF ASSESSING CARDIOVASCULAR DISABILITY

CLASS	NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION	CANADIAN CARDIOVASCULAR SOCIETY FUNCTIONAL CLASSIFICATION	SPECIFIC ACTIVITY SCALE
I	Patients with cardiac disease but without resulting limitations of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina with strenuous or rapid or prolonged exertion at work or recreation.	Patients can perform to completion any activity requiring 7 metabolic equivalents (e.g., can carry 24 lb up eight steps; carry objects that weigh 80 lb; do outdoor work [shovel snow, spade soil]; do recreational activities [skiing, basketball, squash, handball, jog/walk 5 mph]).

II	Patients with cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.	Slight limitation of ordinary activity. Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal conditions.	Patients can perform to completion any activity requiring 5 metabolic equivalents (e.g., have sexual intercourse without stopping, garden, rake, weed, roller skate, dance fox trot, walk at 4 mph on level ground) but cannot and do not perform to completion activities requiring 7 metabolic equivalents.
III	Patients with cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.	Marked limitation of ordinary physical activity. Walking one to two blocks on the level and climbing more than one flight in normal conditions.	Patients can perform to completion any activity requiring 2 metabolic equivalents (e.g., shower without stopping, strip and make bed, clean windows, walk 2.5 mph, bowl, play golf, dress without stopping) but cannot and do not perform to completion any activities requiring 5 metabolic equivalents.
IV	Patient with cardiac disease resulting in inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	Inability to carry on any physical activity without discomfort--anginal syndrome *may be* present at rest.	Patients cannot or do not perform to completion activities requiring 2 metabolic equivalents. *Cannot* carry out activities listed above (Specific Activity Scale, Class III).

Reproduced with permission from Goldman L, Hashimoto B, Cook EF, Loscalzo A: Comparative reproducibility and validity of systems for assessing cardiovascular functional class: Advantages of a new specific activity scale. Circulation 64:1227, 1981. Copyright 1981, American Heart Association.

(2) slightly compromised, (3) moderately compromised, and (4) severely compromised.

Somewhat more detailed and specific criteria were provided by the Canadian Cardiovascular Society,[63] but this classification is limited to patients with angina pectoris. Goldman and coworkers[64] developed a specific activity scale in which classification is based on the estimated metabolic cost of various activities. This scale appears to be more reproducible and to be a better predictor of exercise tolerance than either the New York Heart Association classification or the Canadian Cardiovascular Society criteria.

A key element of the history is to determine whether the patient's disability is stable or progressive. A useful way to accomplish this is to inquire whether a specific task that now causes symptoms (e.g., dyspnea after climbing two flights of stairs) did so 3, 6, and 12 months previously. Precise questioning on this point is important because a gradual reduction of ordinary activity as heart disease progresses may lead to an underestimation of the apparent degree of disability.[65]

Chapter 4 - Physical Examination of the Heart and Circulation

EUGENE BRAUNWALD
JOSEPH K. PERLOFF

A common pitfall in cardiovascular medicine is the failure by the cardiologist to recognize that a patient's heart disease is part of a systemic illness. Equally important is the failure by the noncardiologist to recognize the presence of a cardiac disorder that is a component of a systemic illness whose major effect may be on other organ systems. To avoid these two pitfalls, patients known to have or suspected of having heart disease require not only a detailed examination of the cardiovascular system but also a careful general physical examination. For example, the presence of coronary artery disease should prompt a careful search for frequent noncardiac concomitants such as atherosclerosis of the carotid arteries and of the arteries of the lower extremities and aorta. Conversely, the very high incidence (approximately 50 percent) of coronary artery disease in patients with cerebrovascular disorders must be considered in dealing with patients with these conditions.

As well stated by Mangione and coworkers,[1] "There are still many reasons to promote the teaching of bedside diagnostic skills such as cardiac auscultation. Among these are cost-effectiveness, the possibility of making inexpensive serial observations, the early detection of critical findings, the intelligent and well-guided selection of costly diagnostic technology, and the therapeutic value of the physical contact between physician and patient."

Shaver has pointed out that in this era of cost containment in the practice of medicine, and the great expense of many "high tech" diagnostic procedures, the physical examination remains a relatively inexpensive, useful "test."[2] An additional benefit is that the actual physical contact, that is, the "laying on of hands" by the physician creates a valued closer bond with the patient at a time when the patient's encounter with the medical care system is often so impersonal.

The General Physical Examination

GENERAL APPEARANCE

An assessment of the patient's general appearance is usually begun with a detailed inspection at the time when the history is being obtained.[3] [4] [5] [6] [7] The general build and appearance of the patient, the skin color, and the presence of pallor or cyanosis should be noted, as well as the presence of shortness of breath, orthopnea, periodic (Cheyne-Stokes) respiration (see Chap. 17) , and distention of the neck veins. If the patient is in pain, is he or she sitting quietly (typical of angina pectoris); moving about, trying to find a more comfortable position (characteristic of acute myocardial infarction); or most comfortable sitting upright (heart failure) or leaning forward (pericarditis)? Simple inspection also reveals whether the patient's whole body shakes with each heartbeat and whether Corrigan pulses (bounding arterial pulsations, as occur with the large stroke volume of severe aortic regurgitation, arteriovenous fistula, or complete atrioventricular [AV] block) are present in the head, neck, and upper extremities. Malnutrition, and cachexia, which occur in severe chronic heart failure (see Chap. 17) , may also be readily evident. The cold, sweaty palms and frequent sighing respirations typical of *neurocirculatory asthenia* may be detected, as well as the marked obesity, somnolence, and cyanosis reflecting the *Pickwickian syndrome* (see Chap. 53) . Obesity, which is predominant in the abdomen (diameter of waist/diameter of hips >0.85; normal=0.7) is often associated with adult-onset diabetes and is a high risk factor for coronary artery disease and should also be looked for.

The distinctive general appearance of the *Marfan syndrome* (see Chap. 56) is often apparent: long extremities with an arm span that exceeds the height; a longer lower segment (pubis to foot) than upper segment (head to pubis); and arachnodactyly (spider fingers). In *Cushing syndrome,* a cause of treatable secondary hypertension (see Chap. 64) , there is truncal obesity and rounding of the face with disproportionately thin extremities.

HEAD AND FACE

Examination of the face often aids in the recognition of many disorders that can affect the cardiovascular system. For example, *myxedema* (see Chap. 64) is characterized by a dull, expressionless face; periorbital puffiness; loss of the lateral eyebrows; a large tongue; and dry, sparse hair. An *earlobe crease* occurs more frequently in patients with coronary artery disease than in those without this condition.[8] [9]

Bobbing of the head coincident with each heartbeat (de Musset sign) is characteristic of severe aortic regurgitation. Facial edema may be present in patients with *tricuspid valve disease* or *constrictive pericarditis.*

The *muscular dystrophies,* the cardiac manifestations of which are described in Chapter 71 , also affect facial appearance profoundly. Patients with *myotonic dystrophy* exhibit a dull, expressionless face, with ptosis due to weakness of the levator muscles.

EYES

External ophthalmoplegia and ptosis due to muscular dystrophy of the extraocular muscles occur in the *Kearns-Sayre syndrome,* which may be associated with complete heart block.

Exophthalmos and stare occur in hyperthyroidism, an important cause of high-output cardiac failure (see Chap. 17) . Severe tricuspid regurgitation can also cause pulsation of the eyeballs[10] (pulsatile exophthalmos), as well as of the earlobes.[11]

Blue sclerae may be seen in patients with osteogenesis imperfecta,[12] a disorder that may be associated with aortic dilatation, regurgitation, and dissection and with prolapse of the mitral valve (see Chap. 56) .

FUNDI.

Examination of the fundi allows classification of arteriolar disease in patients with hypertension (Fig. 4-1 *A*) and may also be helpful in the recognition of arteriosclerosis. Beading of the retinal artery may be present in patients with hypercholesterolemia (see Fig. 4-1 *B*). Hemorrhages near the discs with white spots in the center (Roth spots) occur in infective endocarditis (see Fig. 47-7). Embolic retinal occlusions may occur in patients with rheumatic heart disease, left atrial myxoma, and

atherosclerosis of the aorta or arch vessels. Papilledema may be present not only in patients with malignant hypertension (see Chap. 28) but also in those with cor pulmonale with severe hypoxia (see Chap. 54) .

SKIN AND MUCOUS MEMBRANES

Central cyanosis (due to intracardiac or intrapulmonary right-to-left shunting) involves the entire body, including warm, well-perfused sites such as the conjunctivae and the mucous membranes of the oral cavity. Peripheral cyanosis (due to reduction of peripheral blood flow, such as occurs in heart failure and peripheral vascular disease) is characteristically most prominent in cool, exposed areas that may not be well perfused, such as the extremities, particularly the nail beds and nose. Polycythemia can often be suspected from inspection of the conjunctivae, lips, and tongue, which are darkly congested in polycythemia and pale in anemia.

Bronze pigmentation of the skin and loss of axillary and pubic hair occur in *hemochromatosis* (which may result in cardiomyopathy owing to iron deposits in the heart [see Chap. 69]). Jaundice may be observed in patients after pulmonary infarction as well as in patients with congestive hepatomegaly or cardiac cirrhosis. *Lentigines,* which are small brown macular lesions on the neck and trunk that begin at about age 6 and do not increase in number with sunlight, are observed in patients with pulmonic stenosis and hypertrophic cardiomyopathy.[13]

Figure 4-1 *A,* Severe hypertensive retinopathy. The patient was a 43-year-old man with the symptoms of malignant hypertension. He subsequently died of massive cerebral hemorrhage. *B,* Beading of the retinal artery in a patient with hypercholesterolemia. The patient was a 37-year-old man with a serum cholesterol level of 400 mg/dl. *C,* Proliferative retinopathy of Takayasu-Ohnishi disease. The patient was a 27-year-old Asian woman with postural amaurosis and hemiplegia. Brachial pulses were unobtainable. *D,* Roth spots (hemorrhage with white center) in a patient with subacute bacterial endocarditis. *(From Cogan DG: Ophthalmic Manifestations of Systemic Vascular Disease. Philadelphia, WB Saunders, 1974, p 52.)*

Figure 4-2 Tendinous xanthomas of the knees in a patient with familial hypercholesterolemia. The patient was a 10-year-old girl with a serum cholesterol level of 665 mg/dl. Several other members of her family had a similar syndrome. *(From Cogan DG: Ophthalmic Manifestations of Systemic Vascular Disease. Philadelphia, WB Saunders, 1974, pp 14 and 15.)*

Several types of *xanthomas* (i.e., cholesterol-filled nodules) are found either subcutaneously or over tendons in patients with hyperlipoproteinemia (see Chap. 31) . Premature atherosclerosis frequently develops in these individuals. *Tuberoeruptive xanthomas,* present subcutaneously or on the extensor surfaces of the extremities, and *xanthoma striatum palmare,* which produce yellowish, orange, or pink discoloration of the palmar and digital creases, occur most commonly in patients with type III hyperlipoproteinemia. Patients with *xanthoma tendinosum* (Fig. 4-2) (i.e., nodular swellings of the tendons, especially of the elbows, extensor surfaces of the hands, and Achilles tendons) usually have type II hyperlipoproteinemia. *Eruptive xanthomas* are tiny yellowish nodules, 1 to 2 mm in diameter on an erythematous base, that may occur anywhere on the body and are associated with hyperchylomicronemia and are therefore often found in patients with type I and type V hyperlipoproteinemia.

Hereditary telangiectases are multiple capillary hemangiomas occurring in the skin, lips (Fig. 4-3) , nasal mucosa, and upper respiratory and gastrointestinal tracts and resemble the spider nevi seen in patients with liver disease. When present in the lung, they are associated with pulmonary arteriovenous fistulas and cause central cyanosis.

EXTREMITIES

A variety of congenital and acquired cardiac malformations are associated with characteristic changes in the extremities. Among the congenital lesions, short stature, cubitus valgus, and medial deviation of the extended forearm are characteristic of *Turner syndrome* (see Chap. 43) . Patients with the *Holt-Oram syndrome*[14] (i.e., atrial septal defect with skeletal deformities) often have a thumb with an extra

Figure 4-3 Hemorrhagic telangiectasia on the lips of a 25-year-old woman with pulmonary arteriovenous fistulas. *(From Perloff JK: The Clinical Recognition of Congenital Heart Disease. 4th ed. Philadelphia, WB Saunders, 1994, p 719.)*

Figure 4-4 *A,* Normal finger. *B,* Advanced clubbing in a young cyanotic adult. *(From Perloff JK: The Clinical Recognition of Congenital Heart Disease. 4th ed. Philadelphia, WB Saunders, 1994, p 7.)*

phalanx, a so-called fingerized thumb, which lies in the same plane as the fingers, making it difficult to appose the thumb and fingers. In addition, they may exhibit deformities of the radius and ulna, causing difficulty in supination and pronation.

Arachnodactyly is characteristic of Marfan syndrome (see Chap. 56) . Normally, when a fist is made over a clenched thumb the latter does not extend beyond the ulnar side of the hand, but it usually does so in Marfan syndrome.

Systolic flushing of the nail beds, which can be readily detected by pressing a flashlight against the terminal digits (Quincke sign), is a sign of aortic regurgitation and of other conditions characterized by a greatly widened pulse pressure. *Differential cyanosis,* in which the hands and fingers (especially on the right side) are pink and the feet and toes are cyanotic, is indicative of patent ductus arteriosus with reversed shunt due to pulmonary hypertension (see Chap. 53) ; this finding can often be brought out by exercise. On the other hand, *reversed differential cyanosis,* in which cyanosis of the fingers exceeds that of the toes, suggests Taussig-Bing anomaly with pulmonary vascular disease and reversed flow through a patent ductus arteriosus. Alternatively, it may occur with transposition of the great arteries, pulmonary hypertension, preductal narrowing of the aorta, and reversed flow through a patent ductus arteriosus.[15]

CLUBBING OF THE FINGERS AND TOES.

Clubbing of the digits is characteristic of central cyanosis (cyanotic congenital heart disease or pulmonary disease with hypoxia) (Fig. 4-4) .[16] It may also appear within a few weeks of the development of infective endocarditis. The earliest forms of clubbing are characterized by increased glossiness and cyanosis of the skin at the root of the nail.[17] After obliteration of the normal angle between the base of the nail and the skin, the soft tissue of the pulp becomes hypertrophied, the nail root floats freely, and its loose proximal end can be palpated. In the more severe forms of clubbing, bony changes occur (i.e., *hypertrophic osteoarthropathy*); these changes involve the terminal digits and in rare instances even the wrists, ankles, elbows, and knees. *Unilateral clubbing* of the fingers is rare but can occur when an aortic aneurysm interferes with the arterial supply to one arm.

Osler nodes are small, tender, purplish erythematous skin lesions due to infected microemboli and occurring most frequently in the pads of the fingers or toes and in the palms of the hands or soles of the feet,[18] whereas *Janeway lesions* are slightly raised, nontender hemorrhagic lesions in the palms of hands and soles of the feet; both of these lesions as well as petechiae occur in infective endocarditis (see Chap. 47) . When the latter occur under the nail beds, they are termed *splinter hemorrhages.*

EDEMA.

The presence of edema of the lower extremities is a common finding in congestive heart failure (see Chap. 3) [19] ; however, if it is present in only one leg, it is more likely due to obstructive venous or lymphatic disease than to heart failure. Firm pressure on the pretibial region for 10 to 20 seconds may be necessary for the detection of edema. In patients confined to bed, edema appears first in the sacral region. Edema may involve the face in children with heart failure of any etiology and in adults with heart failure associated with marked elevation of systemic venous pressure (e.g., constrictive pericarditis and tricuspid valve disease).

CHEST AND ABDOMEN

Examination of the thorax should begin with observations of the rate, effort, and regularity of respiration. The shape of the chest is important as well; thus, a barrel-shaped chest with low diaphragm suggests emphysema, bronchitis, and cor pulmonale.

Inspection of the chest is an integral part of the cardiac examination (see p. 54). It may reveal a bulging to the right of the upper sternum caused by an aortic aneurysm. The latter can also produce a venous collateral pattern caused by obstruction of the superior vena cava. *Kyphoscoliosis* of any etiology can cause cor pulmonale; this skeletal abnormality, as well as pectus excavatum (funnel chest)[20] [21] [22] and pectus carinatum (pigeon breast), is often present in Marfan syndrome.

Left ventricular failure and other causes of elevation of pulmonary venous pressure may cause pulmonary rales; wheezing is sometimes audible in pulmonary edema (cardiac asthma).

Painful enlargement of the liver may be due to venous congestion; the tenderness disappears in long-standing heart failure. Hepatic systolic expansile pulsations occur in patients with severe tricuspid regurgitation, and presystolic pulsations can be felt in patients with tricuspid stenosis and sinus rhythm. Patients with constrictive pericarditis also often have pulsatile hepatomegaly, the contour of the pulsations resembling those of the jugular venous pulse in this condition.[23] When firm pressure over the abdomen causes cervical venous distention, that is, when there is *abdominojugular reflux,* right-sided heart failure[24] [25] (see later) or tricuspid valve disease is usually present. *Ascites* is also characteristic of heart failure, but it is especially characteristic of tricuspid valve disease and chronic constrictive pericarditis.

Splenomegaly may occur in the presence of severe congestive hepatomegaly, most frequently in patients with constrictive pericarditis or tricuspid valve disease. The spleen may be enlarged and painful in infective endocarditis, as well as after splenic embolization. Splenic infarction is frequently accompanied by an audible friction rub.

Both *kidneys* may be palpably enlarged in patients with hypertension secondary to polycystic disease. Auscultation of the abdomen should be carried out in all patients with hypertension; a systolic bruit secondary to renal artery stenosis may be audible near the umbilicus or in the flank.

Atherosclerotic aneurysms of the abdominal aorta are usually readily detected on palpation of the abdomen below the umbilicus (see Chap. 40) , except in markedly obese patients. In patients with *coarctation of the aorta,* no abdominal pulsations are palpable despite the presence of prominent arterial pulses in the neck and upper extremities; arterial pulses in the lower extremities are reduced or absent.

JUGULAR VENOUS PULSE

Important information concerning the dynamics of the right side of the heart can be obtained by observation of the jugular venous pulse.[6] [26] [27] [28] [29] The *internal* jugular vein is ordinarily examined; the venous pulse can usually be analyzed more readily on the right than on the left side of the neck, because the right innominate and jugular veins extend in an almost straight line cephalad to the superior vena cava, thus favoring transmission of hemodynamic changes from the right atrium, while the left innominate vein is not in a straight line and may be kinked or compressed by a variety of normal structures, by a dilated aorta, or by an aneurysm.

During the examination the patient should be lying comfortably. Although the head should rest on a pillow, it must not be at a sharp angle from the trunk. The jugular venous pulse may be examined effectively by shining a light tangentially across the neck. Most patients with heart disease are examined most effectively in the 45-degree position, but in patients in whom venous pressure is high, a greater inclination (60 or even 90 degrees) is required to obtain visible pulsations, whereas in those in whom jugular venous pressure is low, a lesser inclination (30 degrees) is desirable.

The internal jugular vein is located deep within the neck, where it is covered by the sternocleidomastoid muscle and is therefore not usually visible as a discrete structure except in the presence of venous hypertension. However, its pulsations are transmitted to the skin of the neck, where they are usually easily visible. Sometimes difficulty may be experienced in differentiating between the carotid and jugular venous pulses in the neck, particularly when the latter exhibits prominent v waves, as occurs in patients with tricuspid regurgitation, in whom the valves in the internal jugular veins may be incompetent. However, there are several helpful clues:

1. The arterial pulse is a sharply localized rapid movement that may not be readily visible but that strikes the palpating fingers with considerable force; in contrast, the venous pulse, whereas more readily visible, often disappears when the palpating finger is placed lightly on or below the pulsating area.
2. The arterial pulse usually exhibits a single upstroke, whereas (in patients in sinus rhythm) the venous pulse has two peaks and two troughs per cardiac cycle.
3. The arterial pulsations do not change when the patient is in the upright position or during respiration, whereas venous pulsations usually disappear or diminish greatly in the upright position and during inspiration, unless the venous pressure is greatly elevated.
4. Compression of the root of the neck does not affect the arterial pulse but usually abolishes venous pulsations, except in the presence of extreme venous hypertension.

Two principal observations can usually be made from examination of the neck veins: the level of venous pressure and the type of venous wave pattern. To estimate jugular venous pressure, the height of the oscillating top of the distended proximal portion of the internal jugular vein, which reflects right atrial pressure, should be determined. The upper limit of normal is 4 cm above the sternal angle, which corresponds to a central venous pressure of approximately 9 cm H_2O, since the right atrium is approximately 5 cm below the sternal angle. When the veins in the neck collapse in a subject breathing normally in the horizontal position, it is likely that the central venous pressure is subnormal. When obstruction of veins in the lower extremities is responsible for edema, pressure in the neck veins is not elevated and the abdominal-jugular reflux is negative.

ABDOMINAL-JUGULAR REFLUX.

This can be tested by applying firm pressure to the periumbilical region for 10 to 30 seconds with the patient breathing quietly while the jugular veins are observed[24] [25] [30] ; increased respiratory excursions or straining should be avoided. In normal subjects, jugular venous pressure rises less than 3 cm H_2O and only transiently while abdominal pressure is continued, whereas in right or left ventricular failure and/or tricuspid regurgitation the jugular venous pressure remains elevated. In the absence of these conditions, a positive abdominal-jugular reflux suggests an elevated pulmonary artery wedge[26] or central venous pressure.[25]

PATTERN OF THE VENOUS PULSE.

The events of the cardiac cycle, shown in Figure 14-22 , provide an explanation for the details of the jugular venous waveform (Fig. 4-5) . The a wave in the venous pulse results from venous distention due to right atrial systole, whereas the *x* descent is due to atrial relaxation and descent of the floor of the right atrium during right ventricular systole. The c wave, which occurs simultaneously with the carotid arterial pulse, is an inconstant wave in the jugular venous pulse and/or interruption of the *x* descent after the peak of the a wave. The continuation of the *x* descent after the c wave is referred to as the *x* descent. The v wave results from the rise in right atrial pressure when blood flows into this chamber during ventricular systole when the tricuspid valve is shut, and the *y* descent (i.e., the downslope of the v wave) is related to the decline in right atrial pressure when the tricuspid valve reopens. After the bottom of the *y*

Figure 4-5 *Top,* Normal jugular venous pulse: the jugular v wave is built up during systole, and its height reflects the rate of filling and the elasticity of the right atrium. Between the bottom of the y descent (y trough) and beginning of the a wave is the period of relatively slow filling of the "atrioventricle" or diastasis period. The wave built up during diastasis is the H wave. The H wave height also reflects the stiffness of the right atrium. S_1 and S_2 refer to the first and second heart sounds, respectively. *Center,* As the degree of tricuspid regurgitation (TR) increases, the x descent is increasingly encroached upon. With severe TR, no x descent is seen, and the jugular pulse wave is said to be "ventricularized." *Bottom,* Black broken line=normal jugular venous pulse and sinus rhythm; red continuous line=after development of atrial fibrillation. The dominant descent in atrial fibrillation is almost always the y descent; that is, it has the superficial appearance of the pulse wave of TR. *(From Constant J: Bedside Cardiology. 4th ed. Boston, Little, Brown & Co, 1994, pp 81 and 89.)*

descent (the *y* trough) and beginning of the a wave is a period of relatively slow filling of the atrium or ventricle, the diastasis period, a wave termed the H wave.

Although all or most of these events can usually be recorded, they may not be readily distinguishable on inspection. The descents or downward collapsing movements of the jugular veins are more rapid, produce larger excursions, and are therefore more prominent to the eye than are the ascents (see Fig. 4-5) . The normal dominant

jugular venous descent, the *x* descent, occurs between the first (S_1) and second (S_2) heart sounds, whereas the *y* descent ends well after S_2. With an increase in central venous pressure, the v wave becomes higher and the *y* collapse becomes more prominent. The a wave occurs just before the first sound or carotid pulse and has a sharp rise and fall. The v wave occurs just after the arterial pulse and has a slower, undulating pattern.

ALTERATIONS IN DISEASE.

Elevation of jugular venous pressure reflects an increase in right atrial pressure and occurs in heart failure, reduced compliance of the right ventricle, pericardial disease, hypervolemia, obstruction of the tricuspid orifice, and obstruction of the superior vena cava. During inspiration, the jugular venous pressure normally declines but the *amplitude* of the pulsations increases. *Kussmaul sign* is a paradoxical rise in the height of the jugular venous pressure during inspiration, which typically occurs in patients with chronic constrictive pericarditis and sometimes in patients with congestive heart failure and tricuspid stenosis.

The a wave is particularly prominent in conditions in which the resistance to right atrial contraction is increased, such as right ventricular hypertrophy, pulmonary hypertension, and tricuspid stenosis (Fig. 4-6 *A*). The a wave may also be tall in left ventricular hypertrophy when the thickened ventricular septum interferes with right ventricular filling. Tall a waves are present in patients with sinus rhythm and tricuspid stenosis or atresia, right atrial myxoma, or reduced compliance and/or marked hypertrophy of the right ventricle. Cannon (amplified) a waves are noted in patients with AV dissociation when the right atrium contracts against a closed tricuspid valve. In atrial fibrillation, the a wave and *x* descent disappear and the v wave and *y* descent (see Fig. 4-5 , *bottom*) become more prominent. In right ventricular failure and sinus rhythm, there may be increases in prominence of both the a and v waves. A steeply rising H wave (see Fig. 4-5) is observed (or recorded) in restrictive cardiomyopathy, constrictive pericarditis, and right ventricular infarction. The *x* descent may be prominent in patients with large a waves, as well as in patients with right ventricular volume overload (atrial septal defect).

Constrictive pericarditis (see Fig. 4-6 *B*) is characterized by a rapid and deep *y* descent followed by a rapid rise to a diastolic plateau (H wave) without a prominent a wave; occasionally, the *x* descent is prominent in this condition as well, causing a "W"-shaped jugular venous pulse. However, it is in *cardiac tamponade* that the *x* descent is most prominent. A prominent v wave or a c-v wave (i.e., fusion of the c and v waves in the absence or attenuation of an *x* descent) occurs in tricuspid regurgitation, sometimes causing a systolic movement of the earlobe[29] (see Fig. 4-5 , *center*) and a right-to-left head movement with each ventricular systole. Equal a and v waves are seen in atrial septal defect; the *y* descent is gradual when right atrial emptying is impeded, as in tricuspid stenosis, and rapid when it is unimpeded, as in tricuspid regurgitation. A steep *y* descent is seen in any condition in which there is myocardial dysfunction, ventricular dilatation, and an elevated central venous pressure.

SPHYGMOMANOMETRIC MEASUREMENT OF ARTERIAL PRESSURE

Systolic arterial pressure can be *estimated* without a sphygmomanometer by gradually compressing the brachial artery while palpating the radial artery; the force required to obliterate

Figure 4-6 *A,* Jugular venous pressure (JVP) in mitral stenosis with pulmonary hypertension. The JVP is dominated by a very large a wave resulting from diminished compliance of the right ventricle associated with pulmonary hypertension. The peaked a wave represents a brief period of retrograde flow from right atrium to great veins. *B,* JVP in constrictive pericarditis. In this severe and long-standing case, the x descent has become very shallow and the y descent is the principal feature, indicating that antegrade flow from the venous system to the right side of the heart is now limited to early diastole. A pericardial knock (K) is seen at approximately the nadir of the y descent. *(From Craige E, Smith P: Heart sounds. In Braunwald E [ed]: Heart Disease: A Textbook of Cardiovascular Medicine. 3rd ed. Philadelphia, WB Saunders, 1988, pp 61 and 62.)*

the radial pulse represents the systolic blood pressure, and, with practice, one can often estimate this level within 20 mm Hg. Ordinarily, however, a sphygmomanometer is used to obtain an indirect measurement of blood pressure.[31] [32] The cuff should fit snugly around the arm, with its lower edge at least 1 inch above the antecubital space, and the diaphragm of the stethoscope should be placed close to or under the edge of the sphygmomanometer cuff. The width of the cuff selected should be at least 40 percent of the circumference of the limb to be used.

The standard size, with a 5-inch-wide cuff, is designed for adults with an arm of average size. When this cuff is applied to a large upper arm or a normal adult thigh, arterial pressure is overestimated, leading to spurious hypertension in the obese (arm circumference >35 cm)[33] [34] ; when it is applied to a small arm, the pressure is underestimated. The cuff width should be approximately 1.5 inches in infants and small children, 3 inches in young children (2 to 5 years), and 8 inches in obese adults. The rubber bag should be long enough to extend at least halfway around the limb (10 inches in adults). In patients with rigid, sclerotic arteries the systolic pressure may also be overestimated, by as much as 30 mm Hg. Mercury manometers are, in general, more accurate and reliable than the aneroid type; the latter should be calibrated at least once yearly.

BLOOD PRESSURE IN THE UPPER EXTREMITIES.

To measure arterial pressure in an upper extremity,[35] [36] [37] the patient should be seated or lying comfortably and relaxed, the arm should be slightly flexed and at heart level, and the arm muscles should be relaxed. The cuff should be inflated rapidly to approximately 30 mm Hg above the anticipated systolic pressure. These maneuvers, which diminish the volume of blood in the venous bed, decrease the tissue pressure distal to the cuff and thereby increase the flow into the occluded brachial artery. The cuff is then deflated slowly, no faster than 3 mm Hg/sec; the pressure at which the brachial pulse can be palpated is close to the systolic pressure.

The cuff should be deflated rapidly after the diastolic pressure is noted and a full minute allowed to elapse before pressure is remeasured in the same limb. Although excessive pressure on the stethoscope head does not affect systolic pressure, it does erroneously lower diastolic readings. In one study, the anxiety associated with blood pressure measurement was shown to elevate arterial pressure by an average of 27/17 mm Hg[38] ("white coat hypertension," see Chap. 28) .

BLOOD PRESSURE IN THE LOWER EXTREMITIES.

To measure pressure in the legs, the patient should lie on the abdomen, an 8-inch-wide cuff should be applied with the compression bag over the posterior aspect of the mid thigh and should be rolled diagonally around the thigh to keep the edges snug against the skin, and auscultation should be carried out in the popliteal fossa. To measure pressure in the lower leg, an arm cuff is placed over the calf and auscultation is carried out over the posterior tibial artery. Regardless of where the cuff is applied, care must be taken to avoid letting the rubber part of the balloon of the cuff extend beyond its covering and to avoid placing the cuff on so loosely that central ballooning occurs.

KOROTKOFF SOUNDS.

There are five phases of Korotkoff sounds (i.e., sounds produced by the flow of blood as the constricting blood pressure cuff is gradually released). The first appearance of clear, tapping sound (phase I) represents the systolic pressure. These sounds are replaced by soft murmurs during phase II and by louder murmurs during phase III, as the volume of blood flowing through the constricted artery increases. The sounds suddenly become muffled in phase IV, when constriction of the brachial artery diminishes as arterial diastolic pressure is approached. Korotkoff sounds disappear in phase V, which is usually within 10 mm Hg of phase IV.

Diastolic pressure measured directly through an intraarterial needle and external manometer corresponds closely to phase V. In severe aortic regurgitation, however, when the disappearance point is extremely low, sometimes 0 mm Hg, the sound of muffling (phase IV) is much closer to the intraarterial diastolic pressure than is the disappearance point (phase V). When the difference between phases IV and V of the Korotkoff sounds exceeds 10 mm Hg, both pressures should be recorded (e.g., 142/54/10 mm Hg).

Korotkoff sounds may be difficult to hear and arterial pressure difficult to measure when arterial pressure rises at a slow rate (as in severe aortic stenosis), when the arteries are markedly constricted (as in shock), and when the stroke volume is reduced (as in severe heart failure). Very soft or inaudible Korotkoff sounds can often be accentuated by dilating the blood vessels simply by opening and closing the fist repeatedly. Sometimes in states of shock, the indirect method of measuring blood pressure is unreliable and arterial pressure should be measured through an intraarterial needle.

The Auscultatory Gap.

This is a silence that sometimes separates the first appearance of the Korotkoff sounds from their second appearance at a lower pressure. The phenomenon tends to occur when there is venous distention or reduced velocity of arterial flow into the arm. If the first muffling of sounds is considered to be the diastolic pressure, it will be overestimated. If the second appearance is taken as the systolic pressure, it will be underestimated. On the other hand, sounds transmitted through the arterial tree from prosthetic aortic valves may be responsible for falsely high readings.

BLOOD PRESSURE IN THE BASAL CONDITION.

To determine arterial pressure in the basal condition, the patient should have rested in a quiet room for 15 minutes. It is desirable to record the arterial pressure in both arms at the time of the initial examination; differences in systolic pressure between the two arms that exceed 10 mm Hg when measurements are made simultaneously or in rapid sequence[37] suggest obstructive lesions involving the aorta or the origin of the innominate and subclavian arteries or supravalvular aortic stenosis (in which pressure in the right arm exceeds that in the left). In patients with vertebral-basal artery insufficiency, a difference in pressure between the arms may signify that a subclavian "steal" is responsible for the cerebrovascular symptoms.

To be certain from physical examination that the systolic pressure is different in the two arms or in the upper and lower extremities, two examiners should measure the pressures simultaneously and then switch extremities and measure the pressures again.

ORTHOSTATIC HYPOTENSION.

To determine whether orthostatic hypotension is present, arterial pressure should be determined with the patient in both the supine and the erect positions. However, regardless of the patient's posture, the brachial artery should be at the level of the heart to avoid superimposition of the effects of gravity on the recorded pressure.

Normally, the systolic pressure in the legs is up to 20 mm Hg higher than in the arms but the diastolic pressures are usually virtually identical. The recording of a higher diastolic pressure in the legs than in the arms suggests that the thigh cuff is too small. When systolic pressure in the popliteal artery exceeds that in the brachial artery by more than 20 mm Hg (Hill sign), aortic regurgitation is usually present.[39] Blood pressure should be measured in the lower extremities in patients with hypertension to detect coarctation of the aorta or when obstructive disease of the aorta or its immediate branches is suspected.

ARTERIAL PULSE

The volume and contour of the arterial pulse are determined by a combination of factors, including the left ventricular stroke volume, the ejection velocity, the relative compliance and capacity of the arterial system, and the pressure waves that result from the antegrade flow of blood and reflections of the arterial pressure pulse returning from the peripheral circulation.[39] Bilateral palpation of the carotid, radial, brachial, femoral, popliteal, dorsalis pedis, and posterior tibial pulses should be part of the examination of all cardiac patients (Fig. 4-7) . Caution should be exercised in bilateral carotid palpation, especially in the elderly. The frequency, regularity, and shape of the pulse wave and the character of the arterial wall should be determined.[40]

The carotid pulse (see Fig. 4-7 A) provides the most accurate representation of the central aortic pulse.[41] The

Figure 4-7 *A,* Technique for evaluating the carotid artery pulsations. *B,* Technique for timing the femoral and radial arteries. *C,* Technique for palpation of the dorsalis pedis arteries. *D,* Technique for palpation of the posterior tibial arteries. *(From Swartz MH [ed]: Textbook of Physical Diagnosis: History and Examination. 3rd ed. Philadelphia, WB Saunders, 1998, pp 300, 329, and 330.)*

brachial artery is the vessel ordinarily most suitable for appreciating the rate of rise of the pulse and the contour, volume, and consistency of the peripheral vessels. This artery is located at the medial aspect of the elbow, and it may be helpful to flex the arm to improve palpation; palpation of the artery should be carried out with the thumb exerting pressure on the artery until its maximal movement is detected. A normal rate of rise of the arterial pulse suggests that there is no obstruction to left ventricular outflow, whereas a pulse wave of small amplitude with normal configuration suggests a reduced stroke volume.

THE NORMAL PULSE.

The pulse in the ascending aorta normally rises rapidly to a rounded dome (Fig. 4-8) ; this initial rise reflects the peak velocity of blood ejected from the left ventricle. A slight anacrotic notch or pause is frequently recorded, but only occasionally felt, on the ascending limb of the pulse. The descending limb of the central aortic pulse is less steep than is the ascending limb, and it is interrupted by the incisura, a sharp downward deflection related to closure of the aortic valve. Immediately thereafter, the pulse wave rises slightly and then declines gradually throughout diastole. As the pulse wave is transmitted to the periphery, its upstroke becomes steeper, the systolic peak becomes higher, the anacrotic shoulder disappears, and the sharp incisura is replaced by a smoother, later dicrotic notch followed by a dicrotic wave.[42] [43] [44] Normally, the height of this dicrotic wave diminishes with age, hypertension, and arteriosclerosis. In the central arterial pulse (central aorta and innominate and carotid arteries), the rapidly transmitted impact of left ventricular ejection results in a peak in early systole, referred to as the *percussion wave;* a second, smaller peak, the *tidal wave,* presumed to represent a reflected wave from the periphery, can often be recorded but is not normally palpable. However, in older subjects, particularly those with increased peripheral resistance, as well as in patients with arteriosclerosis and diabetes, the tidal wave may be somewhat higher than the percussion wave; that is, the pulse reaches a peak in late systole. In peripheral arteries, the pulse wave normally has a single sharp peak.

ABNORMAL PULSES.

When peripheral vascular resistance and arterial stiffness are increased, as in hypertension or with the increased arterial stiffness that accompanies normal aging, there is an elevation in pulse wave velocity and the pulse contour has a more rapid upstroke and greater amplitude. Reduced or unequal carotid arterial pulsations occur in patients with carotid atherosclerosis and with diseases of the aortic arch, including aortic dissection, aneurysm, and Takayasu disease (see Chap. 40) . In *supravalvular aortic stenosis,* there is a selective streaming of the jet toward the innominate artery, the carotid and brachial arterial pulses are stronger and rise more rapidly on the right than on the left side, and pressures may be higher in the right than in the left arm (see Chap. 43) . The pulses of the upper extremities may be reduced or unequal in a variety of other conditions, including arterial embolus or thrombosis, anomalous origin or aberrant path of the major vessels, and cervical rib or scalenus anticus syndrome. Asymmetry of right and left popliteal pulses is characteristic of iliofemoral obstruction. Weakness or absence of radial, posterior tibial, or dorsalis pedis pulses on one side suggests arterial insufficiency (see Fig. 4-7 *C* and *D*). In *coarctation of the aorta* the carotid and brachial pulses are bounding, rise rapidly, and have large volumes, whereas in the lower extremities, the systolic and pulse pressures are reduced, their rate of rise is slow, and there is a late peak. This delay in the femoral arterial pulses can usually be readily detected by simultaneous palpation of the femoral and brachial arterial pulses (see Fig. 4-7B) .

In patients with fixed obstruction to left ventricular outflow (valvular aortic stenosis and congenital fibrous subaortic stenosis), the carotid pulse rises slowly *(pulsus tardus)* (see Fig. 4-8 *B*); the upstroke is frequently characterized by a thrill (the *carotid shudder*); and the peak is reduced, occurs late in systole, and is sustained. There is a notch on the upstroke of the carotid pulse (anacrotic notch) that is so distinct that two separate waves can be palpated in what is termed an *anacrotic pulse. Pulsus parvus* is a pulse of small amplitude, usually because of a reduction of stroke volume. *Pulsus parvus et tardus* refers to a small pulse with a delayed systolic peak, which is characteristic of severe aortic stenosis. This type of pulse is more readily appreciated by palpating the carotid rather than a more peripheral artery. Patients with severe aortic stenosis and heart failure usually exhibit simply a reduced pulse amplitude (i.e., *pulsus parvus*), and the delay in the upstroke is not readily apparent. However, this delay is readily recorded. In elderly patients with inelastic peripheral arteries, the pulse may rise normally despite the presence of aortic stenosis.

The carotid arterial pulse may be prominent or exaggerated in any condition in which pulse pressure is increased, including anxiety, the hyperkinetic heart syndrome, anemia, fever, pregnancy, or other high cardiac output states (see Chap. 17) , as well as in bradycardia and

Figure 4-8 Schematic diagrams of the configurational changes in the carotid pulse and their differential diagnosis. Heart sounds are also illustrated. *A,* Normal. *B,* Anacrotic pulse with slow initial upstroke. The peak is close to the second heart sound. These features suggest fixed left ventricular outflow obstruction. *C,* Pulsus bisferiens with both percussion and tidal waves occurring during systole. This type of carotid pulse contour is most frequently observed in patients with hemodynamically significant aortic regurgitation or combined aortic stenosis and regurgitation with dominant regurgitation. It is rarely observed in mitral valve prolapse or in normal individuals. *D,* Pulsus bisferiens in hypertrophic obstructive cardiomyopathy. It is rarely appreciated at the bedside by palpation. *E,* Dicrotic pulse results from an accentuated dicrotic wave and tends to occur in sepsis, severe heart failure, hypovolemic shock, and cardiac tamponade and after aortic valve replacement. S_4 =fourth heart sound; S_1 =first heart sound; A_2 =aortic component of the second heart sound; P_2 =pulmonic component of the second heart sound. *(From Chatterjee K: Bedside evaluation of the heart: The physical examination. In Chatterjee K, et al [eds]: Cardiology: An Illustrated Text/Reference. Philadelphia, JB Lippincott, 1991, pp 3.11-3.51.)*

peripheral arteriosclerosis with reduction in arterial distensibility. In patients with *mitral regurgitation* or *ventricular septal defect,* the forward stroke volume (from the left ventricle into the aorta) is usually normal but the fraction ejected during early systole is greater than normal; hence, the arterial pulse is of normal volume (the pulse pressure is normal) but the pulse may rise abnormally rapidly.[45] Exaggerated or bounding arterial pulses may be observed in patients with an elevated stroke volume, with sympathetic hyperactivity, and in patients with a rigid, sclerotic aorta. In *aortic regurgitation,* there is a very brisk rate of rise with an increased pulse pressure.

The *Corrigan* or *water-hammer pulse* of aortic regurgitation consists of an abrupt upstroke (percussion wave) followed by rapid collapse later in systole but no dicrotic notch. Corrigan pulse reflects a low resistance in the reservoir into which the left ventricle rapidly discharges an abnormally elevated stroke volume, and it can be exaggerated by raising the patient's arm. In *acute* aortic regurgitation, the left ventricle may not be significantly dilated and premature closure of the mitral valve may occur and limit the volume of aortic reflux; therefore, the aortic diastolic pressure may *not* be very low, the arterial pulse *not* bounding, and the pulse pressure *not* widened despite a serious abnormality of valve function (see Chap. 46) .

Signs characteristic of severe chronic aortic regurgitation include "pistol shot" sounds heard over the femoral artery when the stethoscope is placed on it (*Traube sign*); a systolic murmur heard over the femoral artery when the artery is gradually compressed proximally; a diastolic murmur when the artery is compressed distally (*Duroziez sign*[39]) and Quincke sign (phasic blanching of the nail bed). Of these, Duroziez sign is the most predictive of severe aortic regurgitation. Bounding arterial pulses are also present in patients with patent ductus arteriosus or large arteriovenous fistulas; in hyperkinetic states such as thyrotoxicosis, pregnancy, fever, and anemia; in severe bradycardia; and in arteries proximal to coarctation of the aorta. In *Hill sign* of aortic regurgitation (or any condition leading to an increased stroke volume or the hyperkinetic circulatory state) the indirectly recorded systolic pressures in the lower extremities exceed that in the arms by more than 20 mm Hg. Other signs of increased pulse pressure include *Becker sign* (visible pulsations of the retinal arterioles) and *Mueller sign* (pulsating uvula).

In the presence of AV dissociation, when atrial activity is irregularly transmitted to the ventricles, the strength of the peripheral arterial pulse depends on the time interval between atrial and ventricular contractions. In a patient with rapid heart action, the presence of such variations suggests ventricular tachycardia; with an equally rapid rate, an absence of variation of pulse strength suggests a supraventricular mechanism.

BISFERIENS PULSE.

A bisferiens pulse (see Fig. 4-8 *C*) is characterized by *two systolic peaks,* the percussion and tidal waves, separated by a distinct midsystolic dip; the peaks may be equal, or either may be larger. This type of pulse is detected most readily by palpation of the carotid and, less commonly, of the brachial arteries. It occurs in conditions in which a large stroke volume is ejected rapidly[46] and is observed most commonly in patients with pure aortic regurgitation or with a combination of aortic regurgitation and stenosis; it may disappear as heart failure supervenes.

A bisferiens pulse also occurs in patients with *hypertrophic obstructive cardiomyopathy,*[46] but the bifid nature may only be recorded, not palpated; on palpation there may merely be a rapid upstroke. In these patients the initial prominent percussion wave is associated with rapid ejection of blood into the aorta during early systole, followed by a rapid decline as obstruction becomes manifest in midsystole and by a tidal (reflected) wave. In some patients with hypertrophic cardiomyopathy with no or little obstruction to left ventricular outflow, the arterial pulse is normal or simply hyperkinetic in the basal state, but obstruction and a bisferiens pulse can be elicited by means of the Valsalva maneuver or inhalation of amyl nitrite. Occasionally, a bisferiens pulse is observed in hyperkinetic circulatory states, and very rarely it occurs in normal individuals.

DICROTIC PULSE.

Not to be confused with a bisferiens pulse, in which both peaks occur in systole, is a dicrotic pulse, in which the second peak is in diastole immediately after S_2 (see Fig. 4-8 *E*).[40] [41] [43] [44] The normally small wave that follows aortic valve closure (i.e., the dicrotic notch) is exaggerated and measures more than 50 percent of the pulse pressure on direct pressure recordings and in which the dicrotic notch is low (i.e., near the diastolic pressure). A dicrotic wave may be present in normal hypotensive subjects with reduced peripheral resistance, as occurs in fever, and it may be elicited or exaggerated by inhalation alone or the inhalation of amyl nitrite. Rarely, a dicrotic pulse is noted in healthy adolescents or young adults, but it usually occurs in conditions such as cardiac tamponade, severe heart failure, and hypovolemic shock, in which a low stroke volume is ejected into a soft elastic aorta. In these conditions the dicrotic pulse is due to a reduction of the systolic wave with preservation of the incisura. A dicrotic pulse is rarely present when systolic pressure exceeds 130 mm Hg.

PULSUS ALTERNANS (Alternating Strong and Weak Pulses).

Mechanical alternans is a sign of depression of left ventricular function (see Chap. 17) .[47] [48] Although more readily recognized on sphygmomanometry, when the systolic pressure alternates by more than 20 mm Hg, pulsus alternans can be detected by palpation of a peripheral (femoral or brachial) pulse more frequently than by a more central pulse. Palpation should be carried out with light pressure and with the patient's breath held in mid expiration to avoid the superimposition of respiratory variation on the amplitude of the pulse. Pulsus alternans is generally accompanied by alternation in the intensity of the Korotkoff sounds and occasionally by alternation in intensity of the heart sounds. Rarely, pulsus alternans is so marked that the weak beat is not perceived at all.[49] Aortic regurgitation, systemic hypertension, and reducing venous return by administration of nitroglycerin or by tilting the patient into the upright position all exaggerate pulsus alternans and assist in its detection. Pulsus alternans, which is frequently precipitated by a premature ventricular contraction, is characterized by a regular rhythm and must be distinguished from pulsus bigeminus (see later), which is usually irregular.

PULSUS BIGEMINUS.

A bigeminal rhythm is caused by the occurrence of premature contractions, usually ventricular, after every other beat and results in alternation of the strength of the pulse, which can be confused with pulsus alternans. However, in contrast to the latter, in which the rhythm is regular, in pulsus bigeminus the weak beat always follows the shorter interval. In normal persons or in patients with fixed obstruction to left ventricular outflow, the compensatory pause after a premature beat is followed by a stronger-than-normal pulse. However, in patients with hypertrophic obstructive cardiomyopathy, the postpremature ventricular contraction beat is weaker than normal because of increased obstruction to left ventricular outflow[50] (see Chap. 48) .

PULSUS PARADOXUS.

This is an exaggerated reduction in the strength of the arterial pulse during normal inspiration due to an exaggerated inspiratory fall in systolic pressure (more than 10 mm Hg during quiet breathing) (see Chap. 50) . When marked (i.e., an inspiratory reduction of pressure greater than 20 mm Hg), the paradoxical pulse can be detected by simple palpation of the brachial arterial pulse[51] ; in severe cases there is inspiratory disappearance of the pulse. Milder degrees of a paradoxical pulse can be readily detected on sphygmomanometry: the cuff is inflated to suprasystolic levels and is deflated slowly at a rate of about 2 mm Hg per heartbeat; the peak systolic pressure during exhalation is noted. The cuff is then deflated even more slowly, and the pressure is again noted when Korotkoff sounds become audible throughout the respiratory cycle. Normally, the difference between the two pressures should not exceed 10 mm Hg during quiet respiration. (Pulsus alternans can also be detected by this maneuver by noting whether peak systolic pressure or the intensity of the Korotkoff sounds alternates when the breath is held.)

Pulsus paradoxus represents an exaggeration of the normal decline in systolic arterial pressure with inspiration. It results from the reduced left ventricular stroke volume and

the transmission of negative intrathoracic pressure to the aorta. It is a frequent, indeed characteristic, finding in patients with cardiac tamponade, occurs less frequently (in about half) in patients with chronic constrictive pericarditis, and is also observed in patients with emphysema and bronchial asthma (who have wide respiratory

swings of intrapleural pressure),[52] as well as in hypovolemic shock, pulmonary embolus, pregnancy, and extreme obesity. Aortic regurgitation tends to prevent the development of pulsus paradoxus despite the presence of cardiac tamponade. *Reversed* pulsus paradoxus (an inspiratory rise in arterial pressure) may occur in hypertrophic obstructive cardiomyopathy.[53]

THE ARTERIAL PULSE IN VASCULAR DISEASE.

(See also Chap. 41.) Examination of the arterial pulses is of critical importance in the diagnosis of extracardiac obstructive arterial disease. Systematic bilateral palpation of the common carotid, brachial, radial, femoral, popliteal, dorsalis pedis, and posterior tibial vessels (see Fig. 4-7 *C* and *D*), as well as palpation of the abdominal aorta (both above and below the umbilicus), should be part of every examination in patients suspected of having ischemic heart disease. A normal aorta is often palpable above the umbilicus, but a palpable aorta below the umbilicus suggests the presence of an aneurysm of the abdominal aorta. To diminish cold-induced vasoconstriction, peripheral pulses should be palpated after the patient has been in a warm room for at least 20 minutes.[54] Absent or weak peripheral pulses usually signify obstruction. However, the dorsalis pedis and posterior tibial arteries may be absent in approximately 2 percent of normal persons because they pursue an aberrant course.

Arterial bruits should be sought at specific anatomical sites. When the lumen diameter is reduced by approximately 50 percent, a soft short systolic bruit is heard; as the obstruction becomes more severe, the bruit becomes high pitched, louder, and longer. With approximately 80 percent diameter reduction the murmur spills into early diastole, but it disappears with more severe stenosis or complete occlusion. Arterial bruits are augmented by elevation of the cardiac output (e.g., as occurs in anemia), by poor development of collaterals, and by increased arterial outflow (as occurs in regional exercise).

Auscultation over the spine in the interscapular region in patients with coarctation of the aorta may reveal a systolic or continuous murmur, and a systolic murmur may be heard over the lower abdomen in patients with aortic or iliofemoral obstructions.

The Cardiac Examination

INSPECTION

The cardiac examination proper should commence with inspection of the chest, which can usually best be accomplished with the examiner standing at the side or foot of the bed or examining table. Respirations--their frequency, regularity, and depth--as well as the relative effort required during inspiration and exhalation, should be noted. Simultaneously, one should search for cutaneous abnormalities, such as spider nevi (seen in hepatic cirrhosis and Osler-Weber-Rendu disease). Dilation of veins on the anterior chest wall with caudal flow suggests obstruction of the superior vena cava, whereas cranial flow occurs in patients with obstruction of the inferior vena cava. Precordial prominence is most striking if cardiac enlargement developed before puberty, but it may also be present, although to a lesser extent, in patients in whom cardiomegaly developed in adult life, after the period of thoracic growth.[55] [56]

A heavy muscular thorax, contrasting to less developed lower extremities, may occur in coarctation of the aorta, in which collateral arteries may be visible in the axillae and along the lateral chest wall. The upper portion of the thorax exhibits symmetrical bulging in children with stiff lungs in whom the inspiratory effort is increased. A "shield chest" is a broad chest in which the angle between the manubrium and the body of the sternum is greater than normal and is associated with widely separated nipples; shield chest is frequently observed in Turner and Noonan syndromes (see Chap. 43) . Careful note should be made of other deformities of the thoracic cage, such as *kyphoscoliosis,* which may be responsible for cor pulmonale (see Chap. 54) ; *ankylosing spondylitis,* sometimes associated with aortic regurgitation (see Chap. 67) ; and *pectus carinatum* (pigeon chest), which may be associated with Marfan syndrome but does not directly affect cardiovascular function.

Pectus excavatum,[20] [21] [22] a condition in which the sternum is displaced posteriorly, is commonly observed in Marfan syndrome, homocystinuria, Ehlers-Danlos syndrome, Hunter-Hurler syndrome, and a small fraction of patients with mitral valve prolapse. This thoracic deformity rarely compresses the heart or elevates the systemic and pulmonary venous pressures, and the signs of heart disease are more often apparent rather than real.[57] Displacement of the heart into the left thorax, prominence of the pulmonary artery, and a parasternal midsystolic murmur, all key features of this deformity, may falsely suggest the presence of organic heart disease. Pectus excavatum may be associated with palpitations, tachycardia, fatigue, mild dyspnea, and some impairment of cardiac function.[57] Lack of normal thoracic kyphosis (i.e., the *straight back* syndrome) is often associated with expiratory splitting of S_2 , a parasternal midsystolic murmur, and prominence of the pulmonary artery on radiography.

CARDIOVASCULAR PULSATIONS

Cardiovascular pulsations should be looked for on the entire chest but specifically in the regions of the cardiac apex, the left parasternal region, and the third left and second right intercostal spaces. Prominent pulsations in these areas suggest enlargement of the left ventricle, right ventricle, pulmonary artery, and aorta, respectively. A thrusting apex exceeding 2 cm in diameter suggests left ventricular enlargement; systolic retraction of the apex may be visible in constrictive pericarditis. Normally, cardiac pulsations are not visible lateral to the midclavicular line; when present there, they signify cardiac enlargement unless there is thoracic deformity or congenital absence of the pericardium. Shaking of the entire precordium with each heartbeat may occur in patients with severe valvular regurgitation, large left-to-right shunts, especially patent ductus arteriosus, complete AV block, hypertrophic obstructive cardiomyopathy, and various hyperkinetic states (see Chap. 17) . Aortic aneurysms may produce visible pulsations of one of the sternoclavicular joints of the right anterior thoracic wall.

PALPATION

Pulsations of the heart and great arteries that are transmitted to the chest wall are best appreciated when the examiner is positioned on the right side of a supine patient. To palpate the movements of the heart and great arteries, the examiner should use the fingertips or the area just proximal thereto. Precordial movements should be timed with the simultaneously palpated carotid pulse or auscultated heart sounds.[58] [59] The examination should be carried out with the chest completely exposed and elevated to 30 degrees, both with the patient supine and in the partial left lateral decubitus positions (Fig. 4-9) . [2] Rotating the patient into the left lateral decubitus position with the left arm elevated over the head causes the heart to move laterally and increases the palpability of both normal and pathological thrusts of the left ventricle. The subxiphoid region, which allows palpation of the right ventricle, should be examined with the tip of the index finger during held inspiration. Obese, muscular, emphysematous, and elderly persons may have weak or undetectable cardiac pulsations in the absence of cardiac abnormality, and thoracic deformities (e.g.,

Figure 4-9 *A,* Palpation of the anterior wall of the right ventricle by applying the tips of three fingers in the third, fourth, and fifth interspaces, left sternal edge (arrows), during full held exhalation. Patient is supine with the trunk elevated 30 degrees. *B,* Subxiphoid palpation of the inferior wall of the right ventricle (RV) with the relative position of the abdominal aorta (Ao) shown by the arrow. *C,* The bell of the stethoscope is applied to the cardiac apex while the patient lies in a partial left lateral decubitus position. The thumb of the examiner's free left hand is used to palpate the carotid artery for timing purposes. *D,* The soft, high-frequency early diastolic murmur of aortic regurgitation or pulmonary hypertensive regurgitation is best elicited by applying the stethoscopic diaphragm very firmly to the mid-left sternal edge. The patient leans forward with breath held in full exhalation. *E,* Palpation of the left ventricular impulse with a fingertip (arrow). The patient's trunk is 30 degrees above the horizontal. The examiner's right thumb palpates the carotid pulse for timing purposes. *F,* Palpation of the liver. The patient is supine with knees flexed to relax the abdomen. The flat of the examiner's right hand is placed on the right upper quadrant just below the expected inferior margin of the liver; the left hand is applied diametrically opposite. *(From Perloff JK: Physical Examination of the Heart and Circulation. 2nd ed. Philadelphia, WB Saunders, 1990.)*

kyphoscoliosis, pectus excavatum) can alter the pulsations transmitted to the chest wall. In the course of cardiac palpation, precordial tenderness may be detected; this finding may result from costochondritis (Tietze syndrome) and may be an important indication that chest pain is not due to myocardial ischemia.

THE LEFT VENTRICLE.

The *left ventricular impulse*, also referred to as the cardiac impulse, the *apex beat,* and the apical thrust, is normally produced by left ventricular contraction and is the lowest and most lateral point on the chest at which the cardiac impulse can be appreciated and is normally above the anatomical apex. Although the left ventricular impulse may also be the point of maximal impulse, this is not necessarily the case, because the pulsations produced by other structures (e.g., an enlarged right ventricle, a dilated pulmonary artery, or an aneurysm of the aorta) may be more powerful than the apex beat. Normally, the left ventricular impulse is medial and superior to the intersection of the left midclavicular line and the fifth intercostal space and is palpable as a single, brief outward motion. Although it may not be palpable in the supine position in as many as half of all normal subjects more than 50 years of age, the left ventricular impulse can usually be felt in the left lateral decubitus position. Displacement of the apex beat lateral to the midclavicular line or more than 10 cm lateral to the midsternal line is a sensitive but not specific indicator of left ventricular enlargement. However, when the patient is in the left lateral decubitus position a palpable apical impulse that has a diameter of more than 3 cm is an accurate sign of left ventricular enlargement.[60] Thoracic deformities--particularly scoliosis, straight back, and pectus excavatum--can result in the lateral displacement

of a normal-sized heart.

APEX CARDIOGRAM.

This recording reflects the movement of the chest wall and represents the pulsation of the entire left ventricle. Its contour differs from what is perceived on palpation of the apex or what is recorded by the kinetocardiogram, a device in which the motion of specific points on the chest wall is recorded relative to a fixed point in space[61] and which therefore presents a more faithful graphic registration of the movements of the palpating finger on the chest wall.

SYSTOLIC MOTION

During isovolumetric contraction, the heart normally rotates counterclockwise (as one faces the patient), and the lower anterior portion of the left ventricle strikes the anterior chest wall, causing a brief outward motion followed by medial retraction of the adjacent chest wall during ejection. The peak outward motion of the left ventricular impulse occurs simultaneously with, or just after, aortic valve opening; then the left ventricular apex moves inward. In asthenic persons, in patients with mild left ventricular enlargement, and in subjects with a normal left ventricle but an augmented stroke volume, as occurs in anxiety and other hyperkinetic states, and in mitral or aortic regurgitation, the cardiac impulse may be overactive but with a normal contour; that is, the outward thrust during systole is exaggerated in amplitude but it is not sustained during ejection.

HYPERTROPHY AND DILATATION.

With moderate or severe left ventricular concentric hypertrophy, the outward systolic thrust persists throughout ejection, often lasting up to the second heart sound,[62] and this motion is accompanied by retraction of the left parasternal region. This rocking motion can often be appreciated by placing the index finger of one hand on the apex beat and that of the other hand in the parasternal region and by palpating the simultaneous outward motion of the former while observing retraction of the latter. The left ventricular heave or lift, which is more prominent in concentric hypertrophy than in left ventricular dilatation without volume overload, is characterized by a sustained outward movement of an area that is larger than the normal apex; that is, it is more than 2 to 3 cm in diameter. In patients with left ventricular enlargement the systolic impulse is displaced laterally and downward into the sixth or seventh interspaces. In patients with ischemic heart disease a sustained apex beat is usually associated with a reduced ejection fraction.[63]

In patients with volume overload and/or sympathetic stimulation, the left ventricular impulse is *hyperkinetic,* that is, it is brisker and larger than normal. It is hypokinetic in patients with reduced stroke volume, especially in acute myocardial infarction or dilated cardiomyopathy.

OTHER CONDITIONS.

Left ventricular aneurysm produces a larger-than-normal area of pulsation of the left ventricular apex. Alternatively, it may produce a sustained systolic bulge several centimeters superior to the left ventricular impulse, sometimes termed an *ectopic impulse*.

A double systolic outward thrust of the left ventricle is characteristic of patients with hypertrophic obstructive cardiomyopathy, who may also often exhibit a typical presystolic cardiac expansion, thus resulting in three separate outward movements of the chest wall during each cardiac cycle.[64]

Constrictive pericarditis is characterized by systolic retraction of the chest, particularly of the ribs in the left axilla (Broadbent sign). This inward movement results from interference with the descent of the base of the heart and the compensatory exaggerated motion of the free wall of the left ventricle during ventricular ejection.[64]

DIASTOLIC MOTION.

The outward motion of the apex characteristic of rapid left ventricular diastolic filling is most readily palpated with the patient in the left lateral decubitus position and in full exhalation. The outward motion is accentuated when the inflow of blood into the left ventricle is accelerated. This occurs in mitral regurgitation, when the volume of the left ventricle is increased or its function is impaired.[56] This motion is the mechanical equivalent of and occurs simultaneously with a third heart sound (S_3). Prominent early diastolic left ventricular filling in constrictive pericarditis may be palpable.

PRESYSTOLIC EXPANSION.

When the atrial contribution to ventricular filling is augmented, as occurs in patients with reduced left ventricular compliance associated with concentric left ventricular hypertrophy, myocardial ischemia, and myocardial fibrosis, a presystolic pulsation (usually accompanying a fourth heart sound [S_4]) is palpable, resulting in a double outward movement of the left ventricular impulse. This presystolic expansion is most readily discernible during exhalation, when the patient is in the left lateral decubitus position, and it can be confirmed by detecting the motion of the stethoscope placed over the left ventricular impulse or by observing the motion of an X mark over the left ventricular impulse. Presystolic expansion of the left ventricle can be enhanced by sustained handgrip and is usually associated with marked elevation of left ventricular end-diastolic (rather than early diastolic) pressure. In patients with ischemic heart disease, presystolic pulsation is usually associated with a reduction in left ventricular compliance.[63] Presystolic expansion of the right ventricle occurs in right ventricular hypertrophy and pulmonary hypertension and may be appreciated by subxiphoid palpation of the right ventricle during inspiration.

RIGHT VENTRICLE

Except in the first few months of life, neither this chamber, nor its motion, is palpable. A palpable anterior systolic movement (replacing systolic retraction) in the left parasternal region, best felt by the proximal palm or fingertips, and with the patient supine, usually represents *right ventricular enlargement* or hypertrophy. [65] In the absence of associated left ventricular enlargement, the right ventricular impulse is accompanied by reciprocal systolic retraction of the apex. In patients with pulmonary emphysema, even an enlarged right ventricle is not readily palpable at the left sternal edge but is better appreciated in the subxiphoid region. Exaggerated motion of the entire parasternal area (i.e., a hyperdynamic impulse with normal contour) usually reflects increased right ventricular contractility due to augmented stroke volume, as occurs in patients with atrial septal defect or tricuspid regurgitation. A sustained left parasternal outward thrust reflects right ventricular hypertrophy due to pressure overload, as occurs in pulmonary hypertension or pulmonic stenosis. With marked right ventricular enlargement, this chamber occupies the apex because the left ventricle is displaced posteriorly.

PULMONARY ARTERY

Pulmonary hypertension and/or increased pulmonary blood flow frequently produce a prominent systolic pulsation of the pulmonary trunk in the second intercostal space just to the left of the sternum. This pulsation is often associated with a prominent left parasternal impulse, reflecting right ventricular enlargement, or with hypertrophy and a palpable shock synchronous with the second heart sound, reflecting forceful closure of the pulmonic valve.

LEFT ATRIUM.

An enlarged left atrium or a large posterior left ventricular aneurysm can make right ventricular pulsations more prominent by displacing the right ventricle anteriorly against the left parasternal area; and in severe mitral regurgitation an expanding left atrium may be responsible for marked left parasternal movement, even in the absence of right ventricular hypertrophy. The systolic bulging of the left atrium, which is transmitted through the right ventricle, commences and terminates *after* the left ventricular thrust. Movement imparted by the systolic expansion of the left atrium can be appreciated by placing the index finger of one hand at the left ventricular apex and the index finger of the other in the left parasternal region in the third intercostal space; the movement of the latter finger begins and ends slightly later than that of the former.

AORTA.

Enlargement or aneurysm of the ascending aorta or aortic arch may cause visible or palpable systolic pulsations of the right or left sternoclavicular joint and may also cause a systolic impulse in the suprasternal notch or the first or second right intercostal space.[1]

THRILLS

The flat of the hand or the fingertips usually best appreciate thrills, which are vibratory sensations that are palpable manifestations of loud, harsh murmurs *having low- to medium-frequency components.*[66] Because the vibrations must be quite intense before they are felt, far more information can be obtained from the auscultatory than from the palpatory features of heart murmurs. High-pitched murmurs such as those produced by valvular regurgitation, even when loud, are not usually associated with thrills.

PERCUSSION

Palpation is far more helpful than is percussion in determining cardiac size. However, in the absence of an apical beat, as in patients with pericardial effusion, or in some patients with dilated cardiomyopathy, heart failure, and marked displacement of a hypokinetic apical beat, the left border of the heart can be approximately outlined by means of percussion. Also, percussion of dullness in the right lower parasternal area may, in some instances, aid in the detection of a greatly enlarged right atrium. Percussion aids materially in determining visceral situs, that is, in ascertaining the side on which the heart, stomach, and liver are located. When the heart is in the right side of the chest but the abdominal viscera are located normally, congenital heart disease is usually present. When both the heart and abdominal viscera are in the opposite side of the chest (situs inversus), congenital heart disease is uncommon.

CARDIAC AUSCULTATION

Principles and Technique

The modern binaural stethoscope is a well-crafted, airtight instrument with earpieces selected for comfort, with metal tubing joined to single flexible 12-inch-long, thick-walled rubber tubing (internal diameter of 1/8 inch), and with dual chest pieces--diaphragm for high frequencies, bell for low or lower frequencies--designed so that the examiner can readily switch from one chest piece to the other.[67] [68] [69] [70] [71] When the bell is applied with just enough pressure to form a skin seal, low frequencies are accentuated; when the bell is pressed firmly, the stretched skin becomes a diaphragm, damping low frequencies. Variable pressure with the bell provides a range of frequencies from low to medium.

Cardiac auscultation is best accomplished in a quiet room with the patient comfortable and the chest fully exposed. Palpation and percussion should precede auscultation to establish visceral and cardiac situs, so that auscultation can be carried out with confidence in the topographical anatomy of the heart. Terms such as "mitral area," "tricuspid area," "pulmonary area," and "aortic area" should be avoided because they assume situs solitus without ventricular inversion and with normally related great arteries. The topographical areas for auscultation (Fig. 4-10) , irrespective of cardiac situs, are best designated by descriptive terms--cardiac apex, left and right sternal borders interspace by interspace, and subxiphoid. For patients in situs solitus with a left-sided thoracic heart, auscultation should begin at the cardiac apex (best identified in the left lateral decubitus) and contiguous lower left sternal edge (inflow), proceeding interspace by interspace up the left sternal border to the left base and then to the right base (outflow). In addition, the stethoscope should be applied regularly to the axillae, the back, the anterior chest on the opposite side, and above the clavicles. In patients with increased anteroposterior chest dimensions (emphysema), auscultation is often best achieved by applying the stethoscope in the epigastrium (subxiphoid).

In auscultation, benefits are derived not only from knowledge of the cardiac situs but also from identification of palpable and visible movements of the ventricles. During auscultation, the examiner is generally on the patient's right; three positions are routinely employed: left lateral decubitus (assuming left thoracic heart), supine, and sitting. Auscultation should begin by applying the stethoscope to the cardiac apex with the patient in the left lateral decubitus position (Fig. 4-11) . If tachycardia makes identification

Figure 4-10 Maximal intensity and radiation of six isolated systolic murmurs. HCM=hypertrophic cardiomyopathy; MR=mitral regurgitation; Pulm=pulmonary; VSD=ventricular septal defect. *(From Barlow JB: Perspectives on the Mitral Valve. Philadelphia, FA Davis, 1987, p 140.)*

of S_1 difficult, timing can be established, with few exceptions, by simultaneous palpation of the carotid artery with the thumb of the free left hand. Once the S_1 is identified, analysis then proceeds by systematic, methodical, sequential attention to early, mid, and late systole, S_2 , then early, mid, and late diastole (presystole), and returning to S_1 . When auscultation at the apex has been completed, the patient is turned into the supine position. Each topographical area--lower to upper left sternal edge interspace by interspace and then the right base--is interrogated using the same systematic sequence of analysis (Fig. 4-12) .

Assessment of pitch or frequency ranging from low to moderately high can be achieved by variable pressure of the stethoscopic bell, whereas for high frequencies the diaphragm should be employed. It is practical to begin by using the stethoscopic bell with varying pressure at the apex and lower left sternal edge, changing to the diaphragm when the base is reached. Low frequencies are best heard by applying the bell just lightly enough to achieve a skin seal. High-frequency events are best elicited with firm pressure of the diaphragm, often with the patient sitting, leaning forward in full held exhalation.

Figure 4-11 The bell of the stethoscope is applied to the cardiac apex while the patient lies in a left lateral decubitus position. The thumb of the examiner's free left hand palpates the carotid artery (arrow) for timing purposes.

Figure 4-12 The soft, high-frequency early diastolic murmur of aortic regurgitation or pulmonary hypertensive regurgitation is best elicited by applying the diaphragm of the stethoscope very firmly to the mid-left sternal edge (arrow) as the patient sits and leans forward with breath held in full exhalation.

The Heart Sounds

Heart sounds are relatively brief, discrete auditory vibrations that can be characterized by intensity (loudness), frequency (pitch), and quality (timbre). S_1 identifies the onset of ventricular systole, and S_2 identifies the onset of diastole. These two auscultatory events establish a framework within which other heart sounds and murmurs can be placed and timed.[1] [4]

The basic heart sounds are the S_1 , S_2 , S_3 , and S_4 (Fig. 4-13 *A*). Each of these events can be normal or abnormal. Other heart sounds are, with few exceptions, abnormal, either intrinsically so or iatrogenic (e.g., prosthetic valve sounds, pacemaker sounds). A heart sound should first be characterized by a simple descriptive term that identifies where in the cardiac cycle the sound occurs. Accordingly, heart sounds within the framework established by S_1 and S_2 are designated as "early systolic, midsystolic, late systolic," and "early diastolic, mid-diastolic, late diastolic (presystolic)" (see Fig. 4-13) . [2] The next step is to draw conclusions based on what a sound so identified represents.

For example, an *early systolic* sound might be an ejection sound (aortic or pulmonary) or an aortic prosthetic sound. Mid- and late systolic sounds are typified by the click(s) of mitral valve prolapse but occasionally are "remnants" of pericardial rubs. *Early diastolic* sounds are represented by opening snaps (usually mitral), an early S_3 (constrictive pericarditis, less commonly mitral regurgitation), the opening of a mechanical inflow prosthesis, or the abrupt seating of a pedunculated mobile atrial myxoma ("tumor plop"). *Mid-diastolic* sounds are generally S_3 or summation sounds (synchronous occurrence of S_3 and S_4). *Late diastolic* or *presystolic* sounds are almost always S_4 sounds, rarely pacemaker sounds.

First Heart Sound

S_1 consists of two components (see Fig. 4-13 *C*). The initial component is most prominent at the cardiac apex when the apex is occupied by the left ventricle.[72] The

second component, if present, is normally confined to the lower left sternal edge, is less commonly heard at the apex, and is seldom heard at the base. The first major component is associated with closure of the mitral valve and coincides with abrupt arrest of leaflet motion when the cusps--especially the larger and more mobile anterior mitral cusp--reach their fully closed positions. The origin of the second component of S_1 has been debated but is generally assigned to closure of the tricuspid valve based on an analogous line of reasoning.[73] Opening of the semilunar valves with ejection of blood into the aortic root or pulmonary trunk usually produces no audible sound in the normal heart, although phonocardiograms sometimes record a low-amplitude sound following the mitral and tricuspid components and coinciding with the maximal opening excursion of the aortic cusps.[1] In complete right bundle branch block, S_1 is widely split as a result of delay of the tricuspid component.[74] In complete left bundle branch block, S_1 is single as a result of delay of the mitral component.[75]

When S_1 is split, its first component is normally louder. The softer second component is confined to the lower left sternal edge but may also be heard at the apex. Only the louder first component is heard at the base. The intensity of the S_1 , particularly its first major audible component, depends chiefly on the position of the bellies of the mitral leaflets, especially the anterior leaflet, at the time the left ventricle begins to contract and less on the rate of left ventricular contraction.[76] S_1 is therefore loudest when the onset of left ventricular systole finds the mitral leaflets maximally recessed into the left ventricular cavity, as in the presence of a rapid heart rate, a short PR interval[77] (Fig. 4-14) , short cycle lengths in atrial fibrillation, or mitral stenosis with a mobile anterior leaflet. When this mobility is lost the intensity of S_1 decreases.

Figure 4-13 *A,* The basic heart sounds consist of the first heart sound (S_1), the second heart sound (S_2), the third heart sound (S_3), and the fourth heart sound (S_4). *B,* Heart sounds within the auscultatory framework established by S_1 and S_2 . The additional heart sounds are designated descriptively as early systolic (ES), midsystolic (MS), late systolic (LS), early diastolic (ED), mid-diastolic (MD), and late diastolic (LD) or presystolic. *C,* Upper tracing illustrates a low-frequency S_4 , and the lower tracing illustrates a split S_1 , the two components of which are of the same quality.

Figure 4-14 *Top,* Phonocardiogram and electrocardiogram (lead 2) from a 12-year-old girl with congenital complete heart block. The first heart sound (S_1) varies from soft (long PR interval) to loud (short PR interval). There is a grade 2/6 vibratory midsystolic murmur (SM). A soft fourth heart sound (arrow) follows the second P wave. *Bottom,* Phonocardiogram and electrocardiogram from a 15-year-old boy with congenital complete heart block. Arrows point to independent P waves. The S_1 varies from loud to soft depending on the PR interval. The short diastolic murmurs (DM) are especially prominent when atrial contraction (P wave) coincides with and reinforces the rapid filling phase (shortly after the T wave).

Early Systolic Sounds

Aortic or pulmonary ejection sounds are the most common early systolic sounds.[78] [79] "Ejection sound" is preferred to the term ejection "click," with the latter designation best reserved for the mid- to late systolic clicks of mitral valve prolapse (see Chap. 46) . Ejection sounds coincide with the fully opened position of the relevant semilunar valve, as in congenital aortic valve stenosis (Fig. 4-15 *A*), bicuspid aortic valve in the left side of the heart, or pulmonary valve stenosis in the right side of the heart.[75] [77] Ejection sounds are relatively high frequency events and, depending on intensity, have a pitch similar to that of S_1 . An ejection sound originating in the aortic valve (congenital aortic stenosis or bicuspid aortic valve) or in the pulmonary valve (congenital pulmonary valve stenosis) indicates that the valve is mobile because the ejection sound is caused by abrupt cephalad doming (see Fig. 4-15 *B*).[80] Less certain is the origin of an ejection sound within a dilated arterial trunk distal to a normal semilunar valve (Fig. 4-16 *A*). Origin of the sound is assigned either to opening movement of the leaflets that resonate in the arterial trunk or to the wall of the dilated great artery. Aortic ejection sounds do not vary with respiration.

Pulmonary ejection sounds often selectively and distinctively decrease in intensity during normal inspiration (Fig. 4-17) . Early systolic sounds accompany mechanical prostheses in the aortic location, especially the Starr-Edwards ball-in-cage valve, less so with a tilting disc valve such as the Bjork-Shiley. Early systolic sounds do not occur with bioprosthetic valves (tissue valves) in either the aortic or pulmonary location.

Figure 4-15 *A,* Phonocardiogram over the left ventricular impulse in a patient with mild congenital bicuspid aortic valve stenosis. The aortic ejection sound (E) is louder than the first heart sound (S_1). A_2 =aortic component of the second heart sound. *B,* Left ventriculogram (LV) in another patient with congenital aortic valve stenosis. The cephalad systolic doming of the stenotic valve (arrows) produces the ejection sound.

Figure 4-16 *A,* Tracings from a 32-year-old woman with an ostium secundum atrial septal defect, pulmonary hypertension, and a small right-to-left shunt. In the second left intercostal space (2LICS), the first heart sound is followed by a prominent pulmonary ejection sound (E). The second sound remains split. The pulmonic component (P_2) is very loud and is transmitted to the apex. CAR=carotid pulse. *B,* Phonocardiogram recorded in the left lateral decubitus position over the left ventricular impulse in a patient with pure rheumatic mitral stenosis. The first heart sound (S_1) is loud. The second heart sound (S_2) is followed by an opening snap (OS). There is a mid-diastolic murmur (MDM). The prominent presystolic murmur (PM) goes up to the subsequent loud S_1 .

Figure 4-17 Phonocardiogram from an 11-year-old girl with tetralogy of Fallot and pulmonary atresia. The upper tracing from the second right intercostal space (2RICS) shows an aortic ejection sound (E) that is prominent during exhalation (EXP) but absent during inspiration (INSP). S_1 =first heart sound.

Mid- to Late Systolic Sounds

The most common mid- to late systolic sound(s) are associated with mitral valve prolapse[4] [81] (see Chap. 46) . The term "click" is appropriate because these mid- to late systolic sounds are of relatively high frequency. Mid- to late systolic clicks of mitral valve prolapse coincide with maximal systolic excursion of a prolapsed anterior leaflet (or scallop of the posterior leaflet) into the left atrium and are ascribed to sudden tensing of the redundant leaflet(s) and elongated chordae tendineae. Physical or pharmacological interventions that *reduce* left ventricular volume, such as the Valsalva maneuver, or a change in position from squatting to standing (Fig. 4-18) causes the click(s) to occur earlier in systole.[81] [82] Conversely, physical or pharmacological interventions that *increase* left ventricular volume, such as squatting or sustained hand grip, delay the click(s). Multiple clicks are thought to arise from asynchronous tensing of different portions of redundant mitral leaflets, especially the triscalloped posterior leaflet.

The Second Heart Sound (Table 4-1)

S_2 , like S_1 , has two components. The first component of the second heart sound is designated "aortic" (A_2) and the second "pulmonic" (P_2) (Fig. 4-19) .[83] [84] Each component coincides with the incisura of its great arterial pressure pulse.

Figure 4-18 A midsystolic nonejection sound (C) occurs in mitral valve prolapse and is followed by a late systolic murmur that crescendos to the second heart sound (S_2). Standing decreases venous return; the heart becomes smaller; C moves closer to the first heart sound (S_1) and the mitral regurgitant murmur has an earlier onset. With prompt squatting, venous return increases; the heart becomes larger; C moves toward S_2 and the duration of the murmur shortens. *(From Shaver JA, Leonard JJ, Leon DF: Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 13. Copyright 1990, American Heart Association.)*

TABLE 4-1 -- CAUSES OF SPLITTING OF THE SECOND HEART SOUND

NORMAL SPLITTING

Delayed Pulmonic Closure
Delayed electrical activation of the right ventricle
Complete right bundle branch block (proximal type)
Left ventricular paced beats
Left ventricular ectopic beats
Prolonged right ventricular mechanical systole
Acute massive pulmonary embolus
Pulmonary hypertension with right-sided heart failure
Pulmonic stenosis with intact septum (moderate to severe)
Decreased impedance of the pulmonary vascular bed (increased hangout)
Normotensive atrial septal defect
Idiopathic dilatation of the pulmonary artery
Pulmonic stenosis (mild)
Atrial septal defect, postoperative (70%)
Early Aortic Closure
Shortened left ventricular mechanical systole (LVET)
Mitral regurgitation
Ventricular septal defect
REVERSED SPLITTING
Delayed Aortic Closure
Delayed electrical activation of the left ventricle
Complete left bundle branch block (proximal type)
Right ventricular paced beats
Right ventricular ectopic beats
Prolonged left ventricular mechanical systole
Complete left bundle branch block (peripheral type)
Left ventricular outflow tract obstruction
Hypertensive cardiovascular disease
Arteriosclerotic heart disease
Chronic ischemic heart disease
Angina pectoris
Decreased impedance of the systemic vascular bed (increased hangout)
Poststenotic dilatation of the aorta secondary to aortic stenosis or insufficiency
Patent ductus arteriosus
Early Pulmonic Closure
Early electrical activation of the right ventricle
Wolff-Parkinson-White syndrome, type B
LVET=left ventricular ejection time.
Modified from Shaver JA, O'Toole JD: The second heart sound: Newer concepts. Parts 1 and 2. Mod Concepts Cardiovasc Dis 46:7 and 13, 1977.

Inspiratory splitting of S_2 is due chiefly to a delay in P_2 , less to earlier timing of A_2 .[85] During inspiration, the pulmonary arterial incisura moves away from the descending limb of the right ventricular pressure pulse because of an inspiratory increase in capacitance of the pulmonary vascular bed, delaying P_2 .[86] Exhalation has the opposite effect. The earlier inspiratory timing of A_2 is attributed to a transient reduction in left ventricular volume coupled with unchanged impedance (capacitance) in the systemic vascular bed. Normal respiratory variations in the timing of S_2 are therefore ascribed principally to the variations in impedance characteristics (capacitance) of the pulmonary vascular bed and secondarily to an inspiratory increase in right ventricular volume as originally proposed.[69] [72] When an increase in capacitance of the pulmonary bed is lost because of a rise in pulmonary vascular resistance, inspiratory splitting of S_2 narrows and, if present at all, reflects an increase in right ventricular ejection time and/or earlier timing of A_2 .[4]

The frequency compositions of the aortic and pulmonary components of S_2 are similar, but their normal amplitudes differ appreciably, the aortic component being the louder,

Figure 4-19 *Top,* Normal physiological splitting. During expiration, the aortic (A_2) and pulmonic (P_2) components of the second heart sound are separated by less than 30 milliseconds and are appreciated as a single sound. During inspiration, the splitting interval widens, and A_2 and P_2 are clearly separated into two distinct sounds. *Bottom,* Audible expiratory splitting. In contrast to normal physiological splitting, two distinct sounds are easily heard during expiration. Wide physiological splitting is caused by a delay in P_2 . Reversed splitting is caused by a delay in A_2 , resulting in paradoxical movement; that is, with inspiration P_2 moves toward A_2 , and the splitting interval narrows. Narrow physiological splitting occurs in pulmonary hypertension, and both A_2 and P_2 are heard during expiration at a narrow splitting interval because of the increased intensity and high-frequency composition of P_2 . *(From Shaver JA, Leonard JJ, Leon DF: Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 17. Copyright 1990, American Heart Association.)*

reflecting the differences in systemic (aortic) and pulmonary arterial closing pressures. Splitting of S_2 is most readily identified in the second left intercostal space, because the softer P_2 is normally confined to that site, whereas the louder A_2 is heard at the base, sternal edge, and apex.[4] [83]

ABNORMAL SPLITTING OF THE SECOND HEART SOUND.

Three general categories of abnormal splitting are recognized: (1) persistently single, (2) persistently split (fixed or nonfixed), and (3) paradoxically split (reversed). When S_2 remains single throughout the respiratory cycle, one component is absent or the two components are persistently synchronous. The most common cause of a single S_2 is inaudibility of the P_2 in older adults with increased anteroposterior chest dimensions. In the setting of congenital heart disease, a single S_2 due to absence of the pulmonary component is a feature of pulmonary atresia, severe pulmonary valve stenosis, dysplastic pulmonary valve, or complete transposition of the great arteries (pulmonary component inaudible because of the posterior position of the pulmonary trunk). Conversely, a single S_2 due to inaudibility of the A_2 occurs when the aortic valve is immobile (severe calcific aortic stenosis) or atretic (aortic atresia). A single S_2 due to persistent synchrony of its two components is a feature of Eisenmenger syndrome with nonrestrictive ventricular septal defect, in which the aortic and pulmonary arterial incisurae are virtually identical in timing.[78]

Both components of the S_2 are sometimes inaudible at *all* precordial sites. This is likely to be so in older adults in whom fibrocalcific changes limit mobility of the aortic valve, whereas the pulmonary component is inaudible because of a large anteroposterior chest dimension (see earlier).

A single semilunar valve, as in truncus arteriosus, does not necessarily generate what is judged on auscultation to be a single S_2 . Instead, the S_2 may be perceived as "split" because of asynchronous closure of the unequal cusps of a quadricuspid valve.[78] In systemic or pulmonary hypertension, the duration of a single loud S_2 may be sufficiently prolonged and slurred (reduplicated) to encourage the mistaken impression of splitting.

Persistent Splitting of S_2 .

This term applies when the two components remain audible (or recordable) during both inspiration and exhalation (see Fig. 4-19) . Persistent splitting may be due to a delay in P_2 , as in simple complete right bundle branch block,[72] or to early timing of the A_2 , as occasionally occurs in mitral regurgitation. [87] Normal directional changes in the interval of the split (greater with inspiration, lesser with exhalation) in the presence of persistent audibility of both components defines the split as *persistent* but not *fixed.*

Fixed Splitting of the S_2 .

This term applies when the interval between the A_2 and P_2 is not only wide and persistent but also remains unchanged during the respiratory cycle.[72] Fixed splitting is an auscultatory hallmark of uncomplicated ostium secundum atrial septal defect (Fig. 4-20 (Figure Not Available) ; see Chaps. 43 and 44) . A_2 and P_2 are widely separated during exhalation and exhibit little or no change in the degree of splitting during inspiration or with the Valsalva maneuver. The *wide* splitting is caused by a delay in the P_2 because a marked increase in pulmonary vascular capacitance prolongs the interval between the descending limbs of the pulmonary arterial and right ventricular pressure pulses ("hangout"), and therefore delays the pulmonary incisura and the P_2 . The capacitance (impedance) of the pulmonary bed is appreciably increased, and the right ventricular stroke volume is not influenced by respiration, so there is little or no additional increase during inspiration and little or no inspiratory delay in the P_2 . Phasic changes in systemic venous return during respiration in atrial septal defect are associated with reciprocal changes in the volume of the left-to-right shunt, minimizing respiratory variations in right ventricular filling. The net effect is the characteristic wide, fixed splitting of the two components of the S_2 .[78]

Paradoxical (Reversed) Splitting of S_2 .

This term refers to a reversed sequence of semilunar valve closure, the P_2 preceding the A_2 .[72] Common causes of paradoxical splitting

---

Figure 4-20 (Figure Not Available) Simultaneous base and apex phonocardiograms recorded with the carotid pulse during quiet respiration in a young woman with a large atrial septal defect. Wide fixed splitting of the second heart sound (S_2) is present, and the pulmonic component (P_2) is easily recorded at the apex. A prominent systolic ejection murmur (SEM) is recorded at the base and is attributable to the large stroke volume across the RV outflow tract. The tricuspid component of S_1 is prominent at the apex. EKG=electrocardiogram. *(From Shaver JA: Innocent murmurs. Hosp Med 14:8-35, 1978. Copyright 1999, QUADRANT HEALTHCOM, INC.)*

are complete left bundle branch block[88] or a right ventricular pacemaker, both of which are associated with initial activation of the right side of the ventricular septum, and delayed activation of the left ventricle owing to transseptal (right-to-left) depolarization.[89] When the S_2 splits paradoxically, its two components separate during *exhalation* and become single (synchronous) during *inspiration* (see Fig. 4-19) . Inspiratory synchrony is achieved as the two components fuse because of a delay in the P_2 , less to earlier timing of the aortic component.

ABNORMAL LOUDNESS (INTENSITY) OF THE TWO COMPONENTS OF S_2 .

Assessment of intensity requires that both components be compared when heard simultaneously at the same site. The relative softness of the normal P_2 is responsible for its localization in the second left intercostal space, whereas the relative loudness of the normal A_2 accounts for its audibility at all precordial sites (see earlier). An increase in intensity of the A_2 occurs with systemic hypertension. The intensity of the A_2 also increases when the aorta is closer to the anterior chest wall, owing to root dilatation or transposition of the great arteries or when an anterior pulmonary trunk is small or absent, as in pulmonary atresia.[78]

A loud P_2 is a feature of pulmonary hypertension, and the loudness is enhanced by dilatation of a hypertensive pulmonary trunk. An accentuated P_2 can be transmitted to the mid or lower left sternal edge and, when very loud, throughout the precordium to the apex and right base. A loud P_2 in the second left interspace may obscure a closely preceding A_2 . In this eventuality, auscultation at other precordial sites often identifies the transmitted but attenuated P_2 and allows detection of splitting. A moderate increase in loudness of the P_2 sometimes occurs in the absence of pulmonary hypertension when the pulmonary trunk is dilated, as in ostium secundum atrial septal defect or when there is a decrease in anteroposterior chest dimensions (loss of thoracic kyphosis) that places the pulmonary trunk closer to the chest wall.[90] [91]

Early Diastolic Sounds

The opening snap of rheumatic mitral stenosis is the best known early diastolic sound (see Fig. 4-16 *B*). The diagnostic value derived from the pitch, loudness, and timing of the opening snap in the assessment of rheumatic mitral stenosis was established by Wood in his classic monograph, *An Appreciation of Mitral Stenosis.*[92] An audible opening snap indicates that the mitral valve is mobile, at least its longer anterior leaflet.[93] The snap is generated when superior systolic bowing of the anterior mitral leaflet is rapidly reversed toward the left ventricle in early diastole in response to high left atrial pressure. The mechanism of the opening snap is therefore a corollary to the loud S_1 (see Fig. 4-16 *B*), which is generated by abrupt superior systolic displacement of a mobile anterior mitral leaflet that was recessed into the left ventricle during diastole by high left atrial pressure until the onset of left ventricular isovolumetric contraction (see earlier). The designation "snap" is appropriate because of the relatively high frequency of the sound.

The timing of the opening snap relative to the A_2 has important physiological meaning.[4] A short A_2 /opening snap interval generally reflects the high left atrial pressure of *severe* mitral stenosis. However, in older subjects with systolic hypertension, mitral stenosis of appreciable severity can occur without a short A_2 /opening snap interval because the elevated left ventricular systolic pressure takes longer to fall below the left atrial pressure. In the presence of atrial fibrillation, the A_2 /opening snap interval varies inversely with cycle length, because (all else being equal) the higher the left atrial pressure (short cycle length), the earlier the stenotic valve opens and vice versa.

Early diastolic sounds are not confined to the opening snap of rheumatic mitral stenosis but include the pericardial "knock" of chronic constrictive pericarditis.[94] [95] The term "knock" has also been applied to an early diastolic sound in pure severe mitral regurgitation with reduced left ventricular compliance. Both the "pericardial knock" and the "knock" of mitral regurgitation are rapid filling sounds that are early and loud because a high-pressure atrium rapidly decompresses across an unobstructed mitral valve into a recipient ventricle whose compliance is impaired.

Early diastolic sounds are sometimes caused by atrial myxomas[96] (see Chap. 49) . The generation of such a sound, called a tumor "plop," requires a mobile myxoma attached to the atrial septum by a long stalk. The "plop" is believed to result from abrupt diastolic seating of the tumor within the right or left AV orifice.[96]

An early diastolic sound can also be generated by the opening movement of a mechanical prosthesis in the mitral position. This opening sound is especially prominent with a ball-in-cage prosthesis (Starr-Edwards) and less prominent with a tilting disc prosthesis (Bjork-Shiley).

Mid-Diastolic and Late Diastolic (Presystolic) Sounds

Mid-diastolic sounds are, for all practical purposes, either normal or abnormal S_3 sounds, and most, if not all, late diastolic or presystolic sounds are S_4 sounds (Fig. 4-21) . Each sound coincides with its relevant diastolic filling phase.[97] In sinus rhythm, the ventricles receive blood during two filling phases. The first phase occurs

when ventricular pressure drops sufficiently to allow the AV valve to open; blood then flows from atrium into ventricle. This flow coincides with the *y* descent of the atrial pressure pulse and is designated the "rapid filling phase," accounting for about 80 percent of normal ventricular filling. The rapid filling phase is not a passive event in which the recipient ventricle merely expands in response to augmented inflow volume. Rather, ventricular relaxation is an active, complex, energy-dependent process (see Chaps. 14 and 15) .

Figure 4-21 Atrial pressure pulse showing the a wave and *x* descent and the v wave and *y* descent. The fourth heart sound (S_4) coincides with the phase of ventricular filling after atrial contraction. The third heart sound (S_3) coincides with the *y* descent (the phase of rapid ventricular filling). S_1 =first heart sound; S_2 =second heart sound.

S_3 is generated during the rapid filling phase (see Fig. 4-21) .[98] The second filling phase--diastasis--is variable in duration, usually accounting for less than 5 percent of ventricular filling. The third phase of diastolic filling is in response to atrial contraction, which accounts for about 15 percent of normal ventricular filling. S_4 is generated during the atrial filling phase (see Fig. 4-21) . Both S_3 and S_4 occur *within* the recipient ventricle as that chamber receives blood. The addition of either an S_3 or an S_4 to the cardiac cycle produces a *triple* rhythm. If both S_3 and S_4 are present, a *quadruple* rhythm is produced. When diastole is short or the PR interval is long, S_3 and S_4 occur simultaneously to form a summation sound. [4]

Children and young adults often have a normal (physiological) S_3 but do not have a normal S_4 .[99] A normal S_3 sometimes persists beyond age 40 years, especially in women.[100] After that age, however, especially in men, S_3 is likely to be abnormal.[101] An S_4 is sometimes heard in healthy older adults without clinical evidence of heart disease, particularly after exercise.[102] Such observations have led to the conclusion, still debated, that such an S_4 may be normal in the elderly.

Because an S_4 requires active atrial contribution to ventricular filling, the sound disappears when coordinated atrial contraction ceases, as in atrial fibrillation. When the atria and ventricles contract independently as in complete heart block (see Fig. 4-14) , an S_4 or summation sound occurs randomly in diastole because the relationship between the P wave and the QRS of the electrocardiogram is random. S3 and S4 are events caused by rapid ventricular filling, so obstruction of an AV valve, by impeding ventricular inflow, removes one of the prime preconditions for the generation of these filling sounds. Accordingly, the presence of an S3 or S4 implies an unobstructed (or relatively unobstructed) AV orifice on the side of the heart in which the sound originates. An S3 or S4 originating from the right ventricle often responds selectively and distinctively to respiration, becoming more prominent during inspiration.[4] The inspiratory increase in right atrial flow is converted into an inspiratory augmentation of both mid-diastolic and presystolic filling.

S_3 and S_4 , either normal or abnormal, are relatively low-frequency events that vary considerably in intensity (loudness), that originate in either the left or right ventricle, and that are best elicited when the bell of the stethoscope is applied with just enough pressure to provide a skin seal. An S_3 or S_4 originating from the left ventricle should be sought over the left ventricular impulse identified with the patient in the left lateral decubitus position. An S_3 or S_4 originating from the right ventricle should be sought over the right ventricular impulse (lower left sternal edge, occasionally subxiphoid) with the patient supine. An understanding of these simple principles sets the stage for bedside detection. The same principles can be used with advantage to distinguish an S_4 preceding a single S_1 from splitting of the two components of the S_1 (see Fig. 4-13 *C*). The two components of S_1 are similar in frequency (pitch) although not in intensity (loudness) but differ in pitch from a preceding S_4 . Selective pressure with the bell of the stethoscope enhances these distinctions.

Audibility of S_3 is improved by isotonic exercise that augments venous return and mid-diastolic AV flow. A few sit-ups usually suffice to produce the desired increase in venous return and acceleration in heart rate that increase the rate and volume of AV flow. Venous return can be increased by simple passive raising of both legs with the patient supine. The heart rate is also transiently increased by vigorous coughing. Left ventricular S_4 , especially in patients with ischemic heart disease, can be induced or augmented when resistance to left ventricular discharge is increased by sustained hand-grip (isometric exercise, see later).

In the presence of sinus tachycardia, atrial contraction may coincide with the rapid filling phase, making it impossible to determine whether a given filling sound is an S_3 , an S_4 , or a summation sound. Carotid sinus massage transiently slows the heart rate, so the diastolic sound or sounds can be assigned their proper timing in the cardiac cycle.[4]

CAUSES OF S_3 AND S_4 .

The normal S_3 is believed to be caused by sudden limitation of longitudinal expansion of the left ventricular wall during brisk early diastolic filling.[103] [104] [105] [106] [107] The majority of *abnormal* S_3 sounds are generated by altered physical properties of the recipient ventricle and/or an increase in the rate and volume of AV flow during the rapid filling phase of the ventricle.[108] An abnormal S_4 occurs when augmented atrial contraction generates presystolic ventricular distention (an increase in end-diastolic segment length) so that the recipient chamber can contract with greater force.[109] [110] [111] [112] Typical substrates are the left ventricular hypertrophy of aortic stenosis or systemic hypertension[113] or the right ventricular hypertrophy of pulmonary stenosis or pulmonary hypertension in the right side of the heart.[109] S_4 sounds are also common in ischemic heart disease and are almost universal during angina pectoris or acute myocardial infarction because the atrial "booster pump" is needed to assist the relatively stiff ischemic ventricle.[114]

A variation on the theme is the presystolic pacemaker sound. A pacemaker electrode in the apex of the right ventricle may produce a presystolic sound that is relatively high pitched and clicking and therefore different in pitch from an S_4 . The presystolic pacemaker sound is believed to be extracardiac, resulting from contraction of chest wall muscle after spread of the electrical impulse from the pacemaker site.[115] [116]

HEART MURMURS

A cardiovascular murmur is a series of auditory vibrations that are more prolonged than a sound and are characterized according to timing in the cardiac cycle, intensity (loudness), frequency (pitch), configuration (shape), quality, duration, and direction of radiation. When these features are established, the stage is set for diagnostic conclusions.[2] [117] The principal causes of heart murmurs are listed in Table 4-2 .

Intensity or loudness is graded from 1 to 6, based on the original recommendations of Samuel A. Levine in 1933.[118] A grade 1 murmur is so faint that it is heard only with special effort. A grade 2 murmur is soft but readily detected; a grade 3 murmur is prominent but not loud; a grade 4 murmur is loud (and usually accompanied by a thrill); a grade 5 murmur is very loud. A grade 6 murmur is loud enough to be heard with the stethoscope just removed from contact with the chest wall. Frequency or pitch varies from high to low. The configuration or shape of a murmur is best characterized as crescendo, decrescendo, crescendo-decrescendo (diamond-shaped), plateau (even), or variable

TABLE 4-2 -- PRINCIPAL CAUSES OF HEART MURMURS

A. Organic Systolic Murmurs
1. Midsystolic (ejection)
a. Aortic
(1) Obstructive
(a) Supravalvular--supraaortic stenosis, coarctation of the aorta
(b) Valvular--aortic stenosis and sclerosis
(c) Infravalvular--HOCM

(2) Increased flow, hyperkinetic states, aortic regurgitation, complete heart block
(3) Dilatation of ascending aorta, atheroma, aortitis, aneurysm of aorta
b. Pulmonary
(1) Obstructive
(a) Supravalvular--pulmonary arterial stenosis
(b) Valvular--pulmonic valve stenosis
(c) Infravalvular--infundibular stenosis
(2) Increased flow, hyperkinetic states, left-to-right shunt (e.g., ASD, VSD)
(3) Dilatation of pulmonary artery
2. Pansystolic (regurgitant)
a. Atrioventricular valve regurgitation (MR, TR)
b. Left-to-right shunt to ventricular level
B. Early Diastolic Murmurs
1. Aortic regurgitation
a. Valvular: rheumatic deformity; perforation postendocarditis, posttraumatic, postvalvulotomy
b. Dilatation of valve ring: aorta dissection, annuloectasia, cystic medial necrosis, hypertension
c. Widening of commissures: syphilis
d. Congenital: biscuspid valve, with VSD
2. Pulmonic regurgitation
a. Valvular: postvalvulotomy, endocarditis, rheumatic fever, carcinoid
b. Dilatation of valve ring: pulmonary hypertension; Marfan syndrome
c. Congenital: isolated or associated with tetralogy of Fallot, VSD, pulmonic stenosis
C. Mid-Diastolic Murmurs
1. Mitral stenosis
2. Carey-Coombs murmur (mid-diastolic apical murmur in acute rheumatic fever)
3. Increased flow across nonstenotic mitral valve (e.g., MR, VSD, PDA, high-output states, and complete heart block)
4. Tricuspid stenosis
5. Increased flow across nonstenotic tricuspid valve (e.g., TR, ASD, and anomalous pulmonary venous return)
6. Left and right atrial tumors
D. Continuous Murmurs
1. PDA
2. Coronary arteriovenous fistula
3. Ruptured aneurysm of sinus of Valsalva
4. Aortic septal defect
5. Cervical venous hum
6. Anomalous left coronary artery
7. Proximal coronary artery stenosis
8. Mammary souffle
9. Pulmonary artery branch stenosis
10. Bronchial collateral circulation
11. Small (restrictive) ASD with mitral stenosis
12. Intercostal arteriovenous fistula

(uneven). The duration of a murmur varies from short to long, with all gradations in between. A loud murmur radiates from its site of maximal intensity, and the direction of radiation is sometimes diagnostically useful.

There are three broad categories of murmurs--systolic, diastolic, and continuous. A *systolic* murmur begins with or after S_1 and ends at or before S_2 on its side of origin. A *diastolic* murmur begins with or after S_2 and ends before the subsequent S_1 . A *continuous* murmur begins in systole and continues without interruption through the S_2 into all or part of diastole. The following classification of murmurs is based on their timing relative to S_1 and S_2 .

Systolic Murmurs

Systolic murmurs are classified according to their time of onset and termination as midsystolic, holosystolic, early systolic, or late systolic (Fig. 4-22) [119] [120] A midsystolic murmur begins after S_1 and ends perceptibly before S_2 . The termination of a systolic murmur must be related to the relevant component of S_2 . Accordingly, midsystolic murmurs originating in the *left* side of the heart end before A_2 ; midsystolic murmurs originating in the *right* side of the heart end before P_2 . A *holosystolic* murmur begins with S_1 , occupies all of systole, and ends with the S_2 on its side of origin. Holosystolic murmurs originating in the *left* side of the heart end with A_2 , and holosystolic murmurs originating in the *right* side of the heart end with P_2 .

The term "regurgitant systolic murmur," originally applied to murmurs that occupied all of systole,[72] has fallen out of use because "regurgitation" can be accompanied by holosystolic, midsystolic, early systolic, or late systolic murmurs.[2] Similarly, the term "ejection systolic murmur," originally applied to midsystolic murmurs, should be discarded, because midsystolic murmurs are not necessarily due to "ejection."[4]

Figure 4-22 Systolic murmurs as illustrated here are descriptively classified according to their time of onset and termination as midsystolic, holosystolic, early systolic, and late systolic. The termination of the murmur must be related to the component of the second heart sound on its side of origin, that is, the aortic component (A_2) for systolic murmurs originating in the left side of the heart and the pulmonic component (P_2) for systolic murmurs originating in the right side of the heart.

MIDSYSTOLIC MURMURS.

Midsystolic murmurs occur in five settings: (1) obstruction to ventricular outflow, (2) dilatation of the aortic root or pulmonary trunk, (3) accelerated systolic flow into the aorta or pulmonary trunk, (4) innocent (normal) midsystolic murmurs, and (5) some forms of mitral regurgitation. The physiological mechanism of *outflow* midsystolic murmurs reflects the pattern of phasic flow across the left or right ventricular outflow tract as originally described by Leatham (Fig. 4-23) .[72] Isovolumetric contraction generates S_1 . Ventricular pressure rises, the semilunar valve opens, flow commences, and the murmur begins. As flow proceeds, the murmur increases in crescendo; as flow decreases, the murmur decreases in decrescendo. The murmur ends before ventricular pressure drops below the pressure in the central great artery, at which time the aortic and pulmonary valves close, generating A_2 and P_2 .

Aortic valve stenosis (see Chap. 46) is associated with a midsystolic murmur, which may have an early systolic peak and a short duration, a relatively late peak and a prolonged duration, or all gradations in between. Whether long or short, however, the murmur retains a symmetrical diamond shape beginning after S_1 (or with an aortic ejection sound), rising in crescendo to a systolic peak, and declining in decrescendo to end before A_2 . The high-velocity jet within the aortic root results in radiation of the murmur upward, to the right (second right intercostal space), and into the neck. An important variation occurs in older adults with previously normal trileaflet aortic valves rendered sclerotic or stenotic by fibrocalcific changes. The accompanying murmur in the second right intercostal space is harsh, noisy, and impure, whereas the murmur over the left ventricular impulse is pure and often musical (Fig. 4-24) . These two distinctive midsystolic murmurs--the noisy right basal and the musical apical--were described in 1925 by Gallavardin,[121] and the designation "Gallavardin dissociation" is still used. The impure right basal component of the murmur originates within the aortic root because of turbulence caused by the high-velocity jet. The pure musical component of the murmur heard over the left ventricular impulse originates from periodic high-frequency vibrations of the fibrocalcific aortic cusps. The musical apical midsystolic murmur is sometimes dramatically loud.

The high-frequency apical midsystolic murmur of aortic sclerosis or stenosis should be distinguished from the high-frequency apical murmur of mitral regurgitation, a distinction that may be difficult or impossible, especially if A_2 is

Figure 4-23 Illustration of the physiological mechanism of a midsystolic murmur generated by phasic flow into aortic root or pulmonary trunk. Ventricular (V) and great arterial (GA) pressure pulses are shown with phonocardiogram. The midsystolic murmur begins after the first heart sound (S_1), rises in crescendo to a peak as flow proceeds, then declines in decrescendo as flow diminishes, ending just before the second heart sound (S_2) as ventricular pressure falls below the pressure in the great artery.

soft or absent. However, when premature ventricular contractions are followed by pauses longer than the dominant cycle length, the apical midsystolic murmur of aortic stenosis or sclerosis increases in intensity in the beat after the premature contraction, whereas the intensity of the murmur of mitral regurgitation (whether midsystolic or holosystolic) remains relatively unchanged.[115] The same patterns hold after longer cycle lengths in atrial fibrillation.

The murmur of *pulmonary valve stenosis* (see Chaps. 43 and 44) is prototypical of a midsystolic murmur originating in the *right* side of the heart. [78] The murmur begins after S_1 or with a pulmonary ejection sound, rises in crescendo to a peak, then decreases in a slower decrescendo to end before a delayed or soft P_2 . The length and configuration of the murmur are useful signs of the severity of obstruction.[78] When the ventricular septum is intact (Fig. 4-25 , *left*), as obstruction becomes more severe, the murmur lengthens and envelops A_2 , and P_2 becomes softer. When obstruction to right ventricular outflow is accompanied by a ventricular

Figure 4-24 *A,* Illustration of "Gallavardin dissociation" of the basal and apical murmurs associated with a fibrocalcific trileaflet aortic valve in older adults. The impure, noisy midsystolic murmur at the right base originates within the aortic root because of turbulence caused by the high-velocity jet. The pure, musical midsystolic murmur at the apex results from high-frequency vibrations originating in the fibrocalcific but mobile aortic cusps and radiates selectively into the left ventricular cavity (LV). *B,* Left ventricular intracardiac phonocardiogram of an older adult with calcific aortic stenosis on a previously normal trileaflet valve. The pure, musical midsystolic murmur (SM) is recorded over the apex of the left ventricle (LV). A prominent fourth heart sound (S_4) coincides with presystolic distention of the left ventricle (lower vertical arrow). Upper vertical arrow identifies inaudible low-frequency vibrations preceding S_4 . S_1 =first heart sound; S_2 =second heart sound.

Figure 4-25 *Left,* In valvular pulmonic stenosis with intact ventricular septum, right ventricular systolic ejection becomes progressively longer, with increasing obstruction to flow. As a result, the murmur becomes louder and longer, enveloping the aortic component of the second heart sound (A_2). The pulmonic component (P_2) occurs later, and splitting becomes wider but more difficult to hear because A_2 is lost in the murmur and P_2 becomes progressively fainter and lower pitched. As pulmonic diastolic pressure progressively decreases, isometric contraction shortens until the pulmonary valvular ejection sound fuses with the first heart sound (S_1). In severe pulmonic stenosis with concentric hypertrophy and decreasing right ventricular compliance, a fourth heart sound appears. *Right,* In tetralogy of Fallot with increasing obstruction at pulmonic infundibular area, an increasing amount of right ventricular blood is shunted across the silent ventricular septal defect and flow across the obstructed outflow tract decreases. Therefore, with increasing obstruction the murmur becomes shorter, earlier, and fainter. P_2 is absent in severe tetralogy of Fallot. A large aortic root receives almost all cardiac output from both ventricular chambers, and the aorta dilates and is accompanied by a root ejection sound that does not vary with respiration. *(From Shaver JA, Leonard JJ, Leon DF: Examination of the Heart, Part 4, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 45. Copyright 1990, American Heart Association.)*

septal defect (tetralogy of Fallot), the midsystolic murmur becomes shorter with increased severity of obstruction (see Fig. 4-25 , *right*).

Short, soft midsystolic murmurs originate within a dilated aortic root or dilated pulmonary trunk. Midsystolic murmurs are also generated by rapid ejection into a *normal* aortic root or pulmonary trunk, as during pregnancy, fever, thyrotoxicosis, or anemia. The pulmonary midsystolic murmur of ostium secundum atrial septal defect results from *rapid* ejection into a *dilated* pulmonary trunk (see Fig. 4-22) . *Normal* (innocent) systolic murmurs are, except for the systolic mammary souffle, all midsystolic.[78]

The normal vibratory midsystolic murmur (Still murmur) is short, buzzing, pure, and medium in frequency (Fig. 4-26) and is believed to be generated by low-frequency periodic vibrations of normal pulmonary leaflets at their attachments or periodic vibrations of a left ventricular false tendon.[122] [123] A second type of innocent midsystolic murmur occurs in children, adolescents, and young adults and represents an exaggeration of normal ejection vibrations within the pulmonary trunk. This normal pulmonary midsystolic murmur is relatively impure and is best heard in the second left intercostal space, in contrast to the vibratory

Figure 4-26 Four vibratory midsystolic murmurs (SM) from healthy children. These murmurs, designated "Still murmur," are pure, medium frequency, relatively brief in duration, and maximal along the lower left sternal border (LSB). The last of the four murmurs was from a 5-year-old girl who was febrile. After defervescence, the murmur decreased in loudness and duration.

midsystolic murmur of Still, which is typically heard between the lower left sternal edge and apex. Normal pulmonary midsystolic murmurs are also heard in patients with diminished anteroposterior chest dimensions (e.g., loss of thoracic kyphosis).[90]

The most common form of "innocent" midsystolic murmur in older adults has been designated the "aortic sclerotic" murmur (see earlier). The cause of this functionally benign murmur is fibrous or fibrocalcific thickening of the bases of otherwise normal aortic cusps as they insert into the sinuses of Valsalva.[78] As long as the fibrous or fibrocalcific thickening is confined to the *base* of the leaflets, the free edges remain mobile. No commissural fusion and no obstruction occur. The Gallavardin dissociation phenomenon associated with such an aortic valve was described earlier.

It is not uncommon for *mitral regurgitation* to generate a midsystolic murmur.[87] [124] The clinical setting is usually ischemic heart disease associated with left ventricular regional wall motion abnormalities. The physiological mechanism responsible for the midsystolic murmur of mitral regurgitation in this setting reflects impaired integrity of the muscular component of the mitral apparatus, with early systolic competence of the valve, and midsystolic incompetence, followed by a late systolic decline in regurgitant flow. These midsystolic murmurs are unrelated to "ejection."

HOLOSYSTOLIC MURMURS.

Just as the term "midsystolic" is preferable to "ejection" systolic, the term "holosystolic" is preferable to "regurgitant" because holosystolic murmurs are not necessarily due to regurgitant flow. A holosystolic murmur begins with S_1 and occupies all of systole up to the S_2 on its side of origin (see Fig. 4-22) . [72] Such murmurs are generated by flow from a vascular bed whose pressure or resistance throughout systole is higher than the pressure or resistance in the vascular bed receiving the flow. Holosystolic murmurs occur in the left side of the heart with mitral regurgitation, in the right side of the

Figure 4-27 Illustration of great arterial (GA), ventricular (VENT), and atrial pressure pulses with phonocardiogram showing the physiological mechanism of a holosystolic murmur in some forms of mitral regurgitation and in high-pressure tricuspid regurgitation. Ventricular pressure exceeds atrial pressure at the very onset of systole, so regurgitant flow and murmur commence with the first heart sound (S_1). The murmur persists up to or slightly beyond the second heart sound (S_2) because regurgitation persists to the end of systole (ventricular pressure still exceeds atrial pressure). V=atrial v wave.

heart with high-pressure tricuspid regurgitation, between the ventricles through a restrictive ventricular septal defect, and between the great arteries through aortopulmonary connections.

The timing of holosystolic murmurs reflects the physiological and anatomical mechanisms responsible for their genesis. Figure 4-27 illustrates the mechanism of the holosystolic murmur of mitral regurgitation or high-pressure tricuspid regurgitation. Ventricular pressure exceeds atrial pressure at the very onset of systole (isovolumetric contraction), so regurgitant flow begins with the S_1 . The murmur persists up to or slightly beyond the relevant component of the S_2 , provided that ventricular pressure at end systole exceeds atrial pressure and provided that the AV valve remains incompetent.

Direction of radiation of the intraatrial jet of mitral regurgitation determines the chest wall distribution of the murmur.[87] [125] When the direction of the intraatrial jet is forward and medial against the atrial septum near the origin of the aorta, the murmur radiates to the left sternal edge, to the base, and even into the neck (Fig. 4-28) . When the flow generating the murmur of mitral regurgitation is directed posterolaterally within the left atrial cavity, the murmur radiates to the axilla, to the angle of the left scapula, and occasionally to the vertebral column, with bone conduction from the cervical to the lumbar spine.

The *murmur of tricuspid regurgitation* is holosystolic when there is a substantial elevation of right ventricular systolic pressure, as schematically illustrated in Figure 4-27 . A distinctive and diagnostically important feature of the tricuspid murmur is its selective inspiratory increase in loudness--Carvallo sign.[126] The tricuspid murmur is occasionally audible only during inspiration. The increase in intensity occurs because the inspiratory augmentation in right ventricular volume is converted into an increase in stroke volume and in the velocity of regurgitant flow.[127] When the right ventricle fails, this capacity is lost; thus, Carvallo sign vanishes.

The murmur of an uncomplicated restrictive *ventricular septal defect* (see Chap. 43) is holosystolic because left ventricular systolic pressure and systemic resistance exceed right ventricular systolic pressure and pulmonary resistance from the onset to the end of systole. Holosystolic murmurs are perceived as such in patients with large aortopulmonary connections (aortopulmonary window, patent ductus arteriosus) when a rise in pulmonary vascular resistance abolishes the diastolic portion of the continuous murmur, leaving a murmur that is holosystolic or nearly so.[78]

EARLY SYSTOLIC MURMURS.

Murmurs confined to early systole begin with S_1 , diminish in decrescendo, and end well before S_2 , generally at or before midsystole (see Fig. 4-22) . Certain types of mitral regurgitation, tricuspid regurgitation, or ventricular septal defects are the substrates.

Acute severe mitral regurgitation is accompanied by an early systolic murmur or a holosystolic murmur that is decrescendo, diminishing if not ending before S_2 (Fig. 4-29 *A*).[128] [129] The physiological mechanism responsible for this early systolic decrescendo murmur is acute severe regurgitation into a relatively normal-sized left atrium with limited distensibility. A steep rise in left atrial v wave approaches the left ventricular pressure at end systole; a late systolic decline in left ventricular pressure favors this tendency (see Fig. 4-29 *B*). The stage is set for regurgitant flow that is maximal in early systole and minimal in late systole.

Figure 4-28 Phonocardiograms illustrating wide radiation of the murmur of mitral regurgitation. *A,* The holosystolic murmur (SM) radiates from the apex to the second left intercostal space (2LICS) to the second right intercostal space (2RICS) and into the neck. S_1 =first heart sound; A_2 =aortic component of the second sound; P_2 =pulmonic component of the second sound; S_3 =third heart sound; MDM=mid-diastolic murmur; CAR=carotid pulse; DN=dicrotic notch. *B,* The murmur of mitral regurgitation radiates to the cervical spine, down the thoracic spine (T4-T5, T10) to the lumbar spine.

Figure 4-29 *A,* Phonocardiogram recorded from the cardiac apex of a patient with acute severe mitral regurgitation due to ruptured chordae tendineae. There is an early systolic decrescendo murmur (SM) diminishing if not ending before the aortic component (A_2) of the second heart sound. P_2 =pulmonic component of the second heart sound; S_1 =first heart sound; S_3 =third heart sound. *B,* Left ventricular (LV) and left atrial (LA) pressure pulses with schematic illustration of the phonocardiogram showing the relationship between the decrescendo configuration of the early systolic murmur and late systolic approximation of the tall left atrial v wave and left ventricular end-systolic pressure. Regurgitant flow diminishes or ceases. The murmur therefore is early systolic and decrescendo, paralleling the hemodynamic pattern of regurgitation.

The systolic murmur parallels this pattern, declining or vanishing before S_2 .

An early systolic murmur is a feature of tricuspid regurgitation with *normal* right ventricular systolic pressure.[130] An example is tricuspid regurgitation caused by infective endocarditis in drug abusers. The mechanisms responsible for the timing and configuration of the early systolic murmur of low-pressure tricuspid regurgitation are analogous to those just described for mitral regurgitation. The crest of the right atrial v wave reaches the level of normal right ventricular pressure in latter systole; the regurgitation and murmur are therefore chiefly, if not exclusively, *early* systolic. These murmurs are of medium frequency because normal right ventricular systolic pressure generates comparatively low-velocity regurgitant flow in contrast to elevated right ventricular systolic pressure that generates a high-frequency holosystolic murmur (see earlier).

Early systolic murmurs also occur through ventricular septal defects, but under two widely divergent anatomical and physiological circumstances. A soft, pure, high-frequency, early systolic murmur localized to the mid- or lower left sternal edge is typical of a very small ventricular septal defect in which the shunt is confined to early systole.[78] A murmur of similar timing and configuration occurs through a nonrestrictive ventricular septal defect when an elevation in pulmonary vascular resistance decreases or abolishes late systolic shunting.

LATE SYSTOLIC MURMURS.

The term "late systolic" applies when a murmur begins in mid- to late systole and proceeds up to the S_2 (see Fig. 4-22) . The late systolic murmur of *mitral valve prolapse* is prototypical (see Figs. 4-18 and 4-30) .[131] [131A] One or more mid- to late systolic clicks often introduce the murmur. The responses of the late systolic murmur and clicks to postural maneuvers (see earlier discussion) are illustrated in Figure 4-18 . In response to a *diminution* in left ventricular volume, best achieved by prompt standing after squatting but also achieved by the Valsalva maneuver, the late systolic murmur becomes longer although softer.[82] In response to an *increase* in left ventricular volume associated with squatting or with sustained handgrip, the late systolic murmur becomes shorter but louder.[82] Pharmacological interventions that variably alter left ventricular volume, especially amyl nitrite (see Fig. 4-30) , produce analogous effects but are less practical at the bedside.

The late systolic murmur of mitral valve prolapse is occasionally replaced by an intermittent, striking, and sometimes disconcerting systolic whoop or honk, either spontaneously or in response to physical maneuvers. The whoop is of high frequency, musical, widely transmitted, and occasionally loud enough to be disturbing to the patient.[132] The musical whoop is thought to arise from mitral leaflets and chordae tendineae set into high-frequency periodic vibration.

SYSTOLIC ARTERIAL MURMURS.

Systolic murmurs can originate in anatomically normal arteries in the presence of normal or increased flow or in abnormal arteries because of tortuosity or luminal narrowing. Detection of systolic arterial murmurs requires auscultation at nonprecordial sites. Timing with S_1 and S_2 is imprecise because the murmurs begin at variable distances from the heart. Nevertheless, the arterial murmurs dealt with here are essentially systolic and tend to have a crescendo-decrescendo configuration that reflects the rise and fall of pulsatile arterial flow.[4]

The "supraclavicular systolic murmur," often heard in children and adolescents, is believed to originate at the aortic origins of normal major brachiocephalic arteries. The configuration of these murmurs is crescendo-decrescendo, the onset is abrupt, the duration is brief, and the intensity at times is surprisingly loud with radiation below the clavicles. Normal supraclavicular systolic murmurs decrease or vanish in response to hyperextension of the shoulders, which is achieved by bringing the elbows back until the shoulder girdle muscles are drawn taut.

In older adults, the most common cause of a systolic arterial murmur is atherosclerotic narrowing of a carotid, subclavian, or iliofemoral artery. A variation on this theme is the "compression artifact" that can be induced in the femoral artery in the presence of free aortic regurgitation. When the femoral artery is moderately compressed by the examiner's stethoscopic bell, a systolic arterial murmur is generated. Further compression causes the systolic murmur to continue into diastole, a sign described in 1861 by Duroziez.[78] The eponym is still in use.

A systolic "mammary souffle" is sometimes heard over the breasts because of increased flow through normal arteries during late pregnancy or more especially in the postpartum period in lactating women.[78] [133] The murmur begins well after S_1 because of the interval between left ventricular ejection and arrival of flow at the artery of origin.

A systolic arterial murmur is present in the interscapular region over the site of coarctation of the aortic isthmus.[78] Transient systolic arterial murmurs originating in the pulmonary artery and its branches are occasionally heard in normal neonates because the angulation and disparity in size between the pulmonary trunk and its branches set the stage for turbulent systolic flow. These normal or innocent pulmonary arterial systolic murmurs disappear with maturation of the pulmonary bed, generally within the first few weeks or months of life.[78] [134] Similar if not identical pulmonary arterial systolic murmurs

Figure 4-30 Phonocardiograms illustrating the response of the systolic clicks (C) and late systolic murmur (SM) of mitral valve prolapse to amyl nitrite inhalation. At 20 to 30 seconds, the clicks become earlier and the systolic murmur becomes longer but softer. At 50 seconds, the murmur is holosystolic and louder. M_1 =mitral component of the first heart sound; T_1 =tricuspid component of the first heart sound; A_2 =aortic component of the second heart sound; P_2 =pulmonary component of the second sound.

are generated at sites of congenital stenosis of the pulmonary artery and its branches. Rarely, a pulmonary arterial systolic murmur is caused by luminal narrowing after a pulmonary embolus.[109]

Diastolic Murmurs

Diastolic murmurs are classified according to their time of *onset* as early diastolic, mid-diastolic, or late diastolic (presystolic) (Fig. 4-31) . An *early* diastolic murmur begins with A_2 or P_2 , depending on its side of origin. A mid-diastolic murmur begins at a clear interval *after* S_2 . A late diastolic or presystolic murmur begins immediately before S_1 .

EARLY DIASTOLIC MURMURS.

An early diastolic murmur originating in the left side of the heart occurs in *aortic regurgitation* (see Chap. 46) . This murmur is heard best with the diaphragm of the stethoscope, with the patient leaning forward and during a held, deep, exhalation (see Fig. 4-12) . The murmur begins with the aortic component of S_2 (Fig. 4-32 *A*), that is, as soon as left ventricular pressure falls below the aortic incisura. The configuration of the murmur tends to reflect the volume and rate of regurgitant flow. In chronic aortic regurgitation of moderate severity, the aortic diastolic pressure consistently and appreciably exceeds left ventricular diastolic pressure, so the decrescendo is subtle and the murmur is well heard throughout diastole. In chronic *severe* aortic regurgitation, the decrescendo is more obvious, paralleling the dramatic decline in aortic root diastolic pressure. Selective radiation of the murmur of aortic regurgitation to the *right* sternal edge implies aortic root dilatation, as in Marfan syndrome. When an inverted cusp is set into high-frequency periodic vibration by aortic regurgitation, the accompanying murmur is musical, early diastolic, and decrescendo (see Fig. 4-32 *B*).

The diastolic murmur of *acute severe* aortic regurgitation differs importantly from the murmur of chronic severe aortic regurgitation as just described[135] (Fig. 4-33) . When regurgitant flow is both sudden *and* severe (as may occur in

Figure 4-31 Diastolic murmurs are descriptively classified according to their time of onset as early diastolic, mid-diastolic, or late diastolic (presystolic). Diastolic murmurs originate in either the left or the right side of the heart.

infective endocarditis or aortic dissection), the diastolic murmur is relatively short because the aortic diastolic pressure rapidly equilibrates with the steeply rising diastolic pressure in the unprepared, nondilated left ventricle. The pitch of the murmur is likely to be medium rather than high because the velocity of regurgitant flow is less rapid than in chronic severe aortic regurgitation. This short, medium-frequency diastolic murmur of sudden severe aortic regurgitation may be quite soft (grade 2). These auscultatory features are in contrast to the long, pure, high-frequency,

Figure 4-32 *A,* Phonocardiogram recorded from the mid-left sternal edge of a patient with chronic pure severe aortic regurgitation. An early diastolic murmur (EDM) proceeds immediately from the aortic component (A_2) of the second heart sound. The murmur has an early crescendo followed by a late long decrescendo. There is a prominent midsystolic flow murmur (SM) across an unobstructed aortic valve. *B,* Phonocardiogram in the third left intercostal space (3LICS) records a high-frequency, musical, early diastolic decrescendo murmur (EDM) caused by eversion of an aortic cusp. S_1 =first heart sound; SM=midsystolic murmur; A_2 =aortic component of the second sound.

Figure 4-33 Contrast between the auscultatory findings in chronic and acute aortic regurgitation. In chronic aortic regurgitation, a prominent systolic ejection murmur resulting from the large forward stroke volume is heard at the base and the apex and ends well before the second heart sound (S_2). The aortic diastolic regurgitant murmur begins with S_2 and continues in a decrescendo fashion, terminating before the first heart sound (S_1). At the apex, the early diastolic component of Austin Flint murmur (AF) is introduced by a prominent third heart sound (S_3). A presystolic component of the AF is also heard. In acute aortic regurgitation there is a significant decrease in the intensity of the systolic ejection murmur compared with that of chronic aortic regurgitation because of the decreased forward stroke volume. The S_1 is markedly decreased in intensity because of preclosure of the mitral valve, and at the apex the presystolic component of the AF murmur is absent. The early diastolic murmur at the base ends well before S_1 because of equilibration of the left ventricle and aortic end-diastolic pressures. Significant tachycardia is usually present. *(From Shaver JA: Diastolic murmurs. Heart Dis Stroke 2:100, 1994.)*

blowing and often loud (grade 4) early diastolic murmur of chronic severe aortic regurgitation (see Figs. 4-32 and 4-33) .

The *Graham Steell* murmur of pulmonary hypertensive pulmonary regurgitation begins with a loud P_2 because the elevated pressure exerted on the incompetent pulmonary valve begins at the moment that right ventricular pressure drops below the pulmonary arterial incisura. The high diastolic pressure generates high-velocity

regurgitant flow and results in a high-frequency blowing murmur that may last throughout diastole. Because of the persistent and appreciable difference between pulmonary arterial and right ventricular diastolic pressures, the amplitude of the murmur is usually relatively uniform throughout most, if not all, of diastole.

MID-DIASTOLIC MURMURS.

A mid-diastolic murmur begins at a clear interval after S_2 (see Figs. 4-31 and 4-34) . The majority of mid-diastolic murmurs originate across mitral or tricuspid valves during the rapid filling phase of the cardiac cycle (AV valve obstruction or abnormal patterns of AV flow) or across an incompetent pulmonary valve in the absence of pulmonary hypertension.

The mid-diastolic murmur of rheumatic mitral stenosis is a prime example.[136] [137] The murmur characteristically follows the mitral opening snap (see Fig. 4-16 *B*). Because the murmur originates within the left ventricular cavity, transmission to the chest wall is maximal over the left ventricular impulse. Care must be taken to place the bell of the stethoscope lightly against the skin precisely over the left ventricular impulse with the patient turned into the left lateral decubitus position (see Fig. 4-11) . Soft mid-diastolic murmurs are reinforced when the heart rate and mitral valve flow are transiently increased by vigorous voluntary coughs or a few sit-ups. In atrial fibrillation, the *duration* of the mid-diastolic murmur is a useful sign of the degree of obstruction at the mitral orifice. A murmur that lasts up to S_1 even after long cycle lengths indicates that the stenosis is severe enough to generate a persistent gradient even at the end of long diastoles.

The mid-diastolic murmur of *tricuspid* stenosis occurs in the presence of atrial fibrillation. The tricuspid mid-diastolic murmur differs from the *mitral* mid-diastolic murmur in two important respects: (1) the loudness of the tricuspid murmur increases with inspiration, and (2) the tricuspid murmur is confined to a relatively localized area along the left lower sternal edge. The inspiratory increase in loudness occurs because inspiration is accompanied by an augmentation in right ventricular volume, by a fall in right ventricular

Figure 4-34 Diastolic filling murmur (rumble) in mitral stenosis. In mild mitral stenosis, the diastolic gradient across the valve is limited to the two phases of rapid ventricular filling in early diastole and presystole. The rumble may occur during either period or both periods. As the stenotic process becomes severe, a large pressure gradient exists across the valve during the entire diastolic filling period, and the rumble persists throughout diastole. As the left atrial pressure becomes greater, the interval between A_2 and the opening snap shortens. In severe mitral stenosis, secondary pulmonary hypertension develops and results in a loud P_2 and the splitting interval usually narrows. ECG=electrocardiogram. *(From Shaver JA, Leonard* ***JJ, Leon DF:*** *Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 55. Copyright 1990, American Heart Association.)*

Figure 4-35 Phonocardiogram recorded over the left ventricular impulse of a patient with pure mitral regurgitation. When regurgitant flow is augmented in response to a pressor amine, the holosystolic crescendo murmur (SM) becomes more prominent and a mid-diastolic flow murmur (MDM) appears.

diastolic pressure, and by an increase in gradient and flow rate across the stenotic tricuspid valve.[138] The murmur is localized to the lower left sternal edge because it originates within the inflow portion of the right ventricle and is transmitted to the overlying chest wall.

Mid-diastolic murmurs across *unobstructed* AV valves occur in the presence of augmented volume and velocity of flow. Examples in the left side of the heart are the mid-diastolic flow murmur of pure mitral regurgitation (Fig. 4-35) and the mid-diastolic mitral flow murmur that accompanies a large left-to-right shunt through a ventricular septal defect (Fig. 4-36 *A*). Mid-diastolic murmurs due to augmented flow across unobstructed *tricuspid* valves are generated by severe tricuspid regurgitation or by a large left-to-right shunt through an atrial septal defect (see Fig. 4-36 *B*). These mid-diastolic murmurs indicate appreciable AV valve incompetence or large left-to-right shunts and are often preceded by an S_3 , especially in the presence of mitral or tricuspid regurgitation.

Short, mid-diastolic AV flow murmurs occur intermittently in complete heart block when atrial contraction coincides with the phase of rapid diastolic filling (see Fig. 4-14) . These murmurs are believed to result from antegrade flow across AV valves that are closing rapidly during filling of the recipient ventricle.[136] A similar mechanism is believed to be responsible for the Austin Flint murmur (see Fig. 4-33) . [139] [140] [141]

A mid-diastolic murmur is a feature of pulmonary valve regurgitation, provided that the pulmonary arterial pressure is not elevated (Fig. 4-37 *A*). The diastolic murmur typically begins at a perceptible interval after P_2 is crescendo-decrescendo, ending well before the subsequent S_1 . [78] The physiological mechanism responsible for the timing of this

Figure 4-36 *A,* Phonocardiogram recorded at the apex of a patient with a moderately restrictive ventricular septal defect and increased pulmonary arterial blood flow. The mid-diastolic murmur (DM) results from augmented flow across the mitral valve. SM=holosystolic murmur; S_1 =first heart sound; S_2 =second heart sound. *B,* Phonocardiogram at the lower left sternal edge of a patient with an ostium secundum atrial septal defect and increased pulmonary arterial blood flow. A mid-diastolic murmur (DM) resulted from augmented flow across the tricuspid valve. SM=midsystolic murmur; A_2 and P_2 =aortic and pulmonic components of a conspicuously split S_2 .

murmur is shown in Figure 4-37 *B*. The diastolic pressure exerted on the incompetent pulmonary valve is negligible at the inception of P_2 , so regurgitant flow is minimal. Regurgitation accelerates as right ventricular pressure dips below the diastolic pressure in the pulmonary trunk; at that point the murmur reaches its maximum intensity. Late diastolic equilibration of pulmonary arterial and right ventricular pressures eliminates regurgitant flow and abolishes the murmur before the next S_1 .

LATE DIASTOLIC OR PRESYSTOLIC MURMURS.

A late diastolic murmur occurs immediately before S_1 , that is, in *presystole* (see Fig. 4-31) . With few exceptions, the late diastolic timing of the murmur coincides with the phase of ventricular filling that follows atrial systole and implies the presence of sinus rhythm and coordinated atrial contraction. Late diastolic or presystolic murmurs usually originate at the mitral or tricuspid orifice because of obstruction, but occasionally because of abnormal patterns of presystolic AV flow.

The best known presystolic murmur accompanies rheumatic mitral stenosis in sinus rhythm as AV flow is augmented in response to an increase in the force of left atrial contraction (see Figs. 4-16 *B* and 4-38*A*). [92] Presystolic accentuation of a mid-diastolic murmur is occasionally heard

Figure 4-37 *A,* Phonocardiogram illustrating the mid-diastolic murmur (DM) of low-pressure pulmonary regurgitation in a heroin addict who had pulmonary valve infective endocarditis. The murmur begins well after the second heart sound (S_2) and is of medium frequency and mid-diastolic, ending well before the subsequent first heart sound (S_1). *B,* Pressure pulses and phonocardiogram illustrate the physiological mechanism of the mid-diastolic murmur of low-pressure pulmonary regurgitation. Because the pressure exerted against the incompetent pulmonary valve is low, the murmur does not begin until well after the right ventricular (RV) and pulmonary arterial (PA) pressure pulses diverge. The murmur is maximal when the diastolic gradient (cross-hatched area) is greatest. After an early diastolic dip in the RV pressure pulse, there is equilibration of the PA and RV pressures in later diastole, so the regurgitant gradient is abolished and the murmur disappears.

Figure 4-38 *A,* Phonocardiogram from the cardiac apex of a patient with pure rheumatic mitral stenosis. A presystolic murmur (PM) rises in a crescendo that is interrupted by a loud first heart sound (S_1). S_2 =second heart sound; OS=mitral opening snap. *B,* Phonocardiogram from the lower left sternal edge of a patient with rheumatic tricuspid stenosis. The first cycle is during inspiration and is accompanied by a prominent presystolic murmur (PM) that is crescendo-decrescendo, decreasing before the S_1 . During exhalation (second cycle), the presystolic murmur all but vanishes.

in mitral stenosis with atrial fibrillation, especially during short cycle lengths[142] [143] ; but the timing is actually early systolic, and the mechanism differs from the true presystolic murmur as described earlier and as shown in Figure 4-38 *A*.

In *tricuspid* stenosis with sinus rhythm, a late diastolic or presystolic murmur typically occurs in the absence of a perceptible mid-diastolic murmur (see Fig. 4-38 *B*). This is so because the timing of tricuspid diastolic murmurs reflects the maximal acceleration of flow and gradient, which is usually negligible until powerful right atrial contraction.[138] The presystolic murmur of tricuspid stenosis is crescendo-decrescendo and relatively discrete, fading before S_1 (see Fig. 4-38 *B*). This is in contrast to the presystolic murmur of mitral stenosis, which tends to rise in a crescendo up to S_1 (see Fig. 4-38 *A*). The most valuable auscultatory sign of tricuspid stenosis in sinus rhythm is the effect of respiration on the intensity of the presystolic murmur (see Figs. 4-38 and 4-39) . Inspiration increases right atrial

Figure 4-39 Pressure pulses and phonocardiogram illustrating the physiological mechanism of the respiratory variation in the presystolic murmur of tricuspid stenosis. During inhalation, a fall in intrathoracic pressure and an increase in systemic venous return result in an increase in the right atrial (RA) A wave and a decline in right ventricular (RV) end-diastolic pressure, so the presystolic murmur (PSM) increases in loudness. During exhalation, the right atrial A wave declines, the RV diastolic pressure increases, the tricuspid gradient is at its minimum, and the PSM all but vanishes.

contractile force that coincides with a fall in right ventricular end-diastolic pressure. The result is an increase in the tricuspid gradient, in the velocity of tricuspid flow, and in the intensity of the tricuspid stenotic presystolic murmur (see Fig. 4-39) .[138]

Short, crescendo-decrescendo presystolic murmurs are occasionally heard in *complete heart block* when atrial contraction falls in late diastole. However, the murmur is usually mid-diastolic, as already described, occurring when atrial contraction coincides with and reinforces the rapid filling phase of the cardiac cycle (see Fig. 4-16) .

In 1862, Austin Flint described a presystolic murmur in patients with aortic regurgitation and proposed a mechanism that was astonishingly perceptive.[139] [140] [141] [144] [145] "Now in cases of considerable aortic insufficiency, the left ventricle is rapidly filled with blood flowing back from the aorta as well as from the auricle, before the auricular contraction takes place. The distention of the ventricle is such that the mitral curtains are brought into coaptation; and when the auricular contraction takes place, the mitral direct current passing between the curtains throws them into vibration and gives rise to the characteristic blubbering murmur."[139]

Continuous Murmurs

The term "continuous" appropriately applies to murmurs that begin in systole and *continue* without interruption through S_2 into all or part of diastole (Fig. 4-40) . The presence of murmurs throughout both phases of the cardiac cycle (holosystolic followed by holodiastolic) is *not* the criterion for the designation "continuous." Conversely, a murmur that fades completely before the subsequent S_1 *may be* continuous, provided that the systolic portion of the murmur proceeds without interruption through S_2 .

Continuous murmurs are generated by uninterrupted flow from a vascular bed of higher pressure or resistance into a vascular bed of lower pressure or resistance without phasic interruption between systole and diastole. Such murmurs are due chiefly to (1) aortopulmonary connections, (2) arteriovenous connections, (3) disturbances of flow patterns in arteries, and (4) disturbances of flow patterns in veins (Table 4-3) .

The best known continuous murmur is associated with the aortopulmonary connection of *patent ductus arteriosus* (Fig. 4-41) (see Chaps. 43 and 44) . The murmur characteristically peaks just before and after S_2 , which it envelops, decreases in late diastole (often appreciably), and may be soft or even absent before the subsequent first heart sound.[78] George Gibson's description in 1900 was even more precise.[146] "It persists through S_2 and dies away gradually during the long pause. The murmur is rough and thrilling. It begins softly and increases in intensity so as to reach its acme just about, or immediately after, the incidence of the second sound, and from that point gradually wanes until its termination" (see Fig. 4-41) .

Figure 4-40 Comparison of the continuous murmur and the to-fro murmur. During abnormal communication between high-pressure and low-pressure systems, a large pressure gradient exists through the cardiac cycle, producing a continuous murmur. A classic example is patent ductus arteriosus. At times this type of murmur is confused with a to-fro murmur, which is a combination of systolic ejection murmur and a murmur of semilunar valve incompetence. A classic example of a to-fro murmur is aortic stenosis and regurgitation. A continuous murmur crescendos to around the second heart sound (S_2), whereas a to-fro murmur has two components. The midsystolic ejection component decrescendos and disappears as it approaches S_2 . *(From Shaver JA, Leonard JJ, Leon DF: Examination of the Heart, Part IV, Auscultation of the Heart. Dallas, American Heart Association, 1990, p 55. Copyright 1990, American Heart Association.*

ARTERIOVENOUS CONTINUOUS MURMURS.

These can be congenital or acquired and are represented in part by arteriovenous fistulas, coronary arterial fistulas, anomalous origin of the left coronary artery from the pulmonary trunk, and sinus of Valsalva-to-right side of heart communications.[78] The configuration, location, and intensity of arteriovenous continuous murmurs vary considerably among these different lesions. *Acquired* systemic arteriovenous fistulas are created surgically by forearm shunts for hemodialysis. *Congenital* arteriovenous continuous murmurs occur when a coronary arterial fistula enters the pulmonary trunk, right atrium, or right ventricle. At the latter site, the continuous murmur can be either softer or louder in systole, depending on the degree of compression exerted on the fistulous coronary artery by right ventricular contraction.[78] Rupture of a congenital aortic sinus aneurysm into the right side of the heart results in a continuous murmur that tends to be louder in either systole or diastole, sometimes creating a to-and-fro impression.[78]

ARTERIAL CONTINUOUS MURMURS.

These originate in either *constricted* or *nonconstricted* arteries. A common example of a continuous murmur arising in a constricted artery is carotid or femoral arterial atherosclerotic obstruction. Not surprisingly, these murmurs are characteristically louder in systole and more often than not are purely systolic.

Disturbances of flow patterns in *normal, nonconstricted* arteries sometimes produce continuous murmurs. The "mammary souffle" described earlier,[133] an innocent murmur heard during late pregnancy and the puerperium, is an arterial murmur that, when continuous, is typically louder in systole and maximal over either lactating breast. A distinct gap separates the S_1 from the onset of the mammary souffle because of the relatively long interval that elapses before blood ejected from the left ventricle arrives at the artery of origin.[78] Light pressure with the stethoscope tends to augment the murmur and bring out its continuous features, whereas firm pressure with the stethoscope or by digital compression adjacent to the site of auscultation often abolishes the murmur.

Continuous murmurs in nonconstricted arteries originate in the large systemic-to-pulmonary arterial collaterals in certain types of cyanotic congenital heart disease, typically tetralogy of Fallot with pulmonary atresia. These continuous murmurs are randomly located throughout the thorax because of the random location of the aortopulmonary collaterals.[78]

CONTINUOUS VENOUS MURMURS.

These are well represented by the innocent cervical venous hum (Fig. 4-42) . The hum is by far the most common type of normal continuous murmur, universal in healthy children, and frequently present in healthy young adults, especially during pregnancy. Thyrotoxicosis and anemia, by augmenting cervical venous flow, initiate or reinforce the venous hum. The term "hum" does not necessarily characterize the quality of these cervical venous murmurs, which may be rough and noisy and are occasionally accompanied by a high-pitched whine.[78] The hum is truly continuous, although typically louder in diastole, as is generally the case with venous continuous murmurs. The mechanism of the venous hum is unsettled. Silent laminar flow in the internal jugular vein may be disturbed by deformation of the vessel at the level of the transverse process of the atlas during head rotation designed to elicit the hum.[147]

Approach to the Patient with a Heart Murmur

Although a careful physical examination with emphasis on detailed auscultation is useful in establishing a cardiac diagnosis, or excluding serious cardiac disease, echocardiography is decisive in confirming the diagnosis and determining the severity of the condition (Fig. 4-43) . As delineated by O'Rourke,[148] the approach to the patient with a heart murmur depends on its intensity, timing, location, response to maneuvers, and the presence of other cardiac and noncardiac symptoms and signs.

Patients with diastolic murmurs, or continuous murmurs that are not cervical venous

TABLE 4-3 -- DIFFERENTIAL DIAGNOSIS OF CONTINUOUS THORACIC MURMURS (IN ORDER OF FREQUENCY)

DIAGNOSIS	KEY FINDINGS
Cervical venous hum	Disappears on compression of the jugular vein
Hepatic venous hum	Often disappears with epigastric pressure
Mammary souffle	Disappears on pressing hard with stethoscope
Patent ductus arteriosus	Loudest at second left intercostal space
Coronary arteriovenous fistula	Loudest at lower sternal borders
Ruptured aneurysm of sinus of Valsalva	Loudest at upper right sternal border, sudden onset
Bronchial collaterals	Associated signs of congenital heart disease
	High-grade coarctation
	Brachial pedal arterial pressure gradient
Anomalous left coronary artery arising from pulmonary artery	Electrocardiographic changes of myocardial infarction
Truncus arteriosus	
Pulmonary artery branch stenosis	Heard outside the area of cardiac dullness
Pulmonary arteriovenous fistula	Same as above
Atrial septal defect with mitral stenosis or atresia	Altered by the Valsalva maneuver
Aortic-atrial fistulas	

Adapted from Sapira JD: The Art and Science of Bedside Diagnosis. Baltimore, Urban & Schwartzenberg, 1990.

Figure 4-41 The classic continuous murmur of patent ductus arteriosus recorded from within the main pulmonary artery (upper tracing) and simultaneously on the chest wall at the second left intercostal space (2LICS). The murmur "begins softly and increases in intensity so as to reach its acme just about, or immediately after, the incidence of the second sound, and from that point gradually wanes until its termination," as originally described by Gibson in 1900.[146]

hums, or mammary souffles of pregnancy, should ordinarily go to two-dimensional and Doppler echocardiography, and subsequent work-up, including cardiac consultation, is guided by the echocardiographic findings. In general, echocardiography is also advised for patients with systolic murmurs having the following characteristics: (1) loud murmur (i.e.,
grade 3); (2) holosystolic or late systolic murmur, especially at the left sternal edge or apex; (3) systolic murmurs that become louder or longer during the strain of the Valsalva maneuver (suggesting the diagnosis of hypertrophic obstructive cardiomyopathy or mitral valve prolapse respectively; see p. 76); (4) other systolic murmurs in patients with clinical findings suggesting infective endocarditis (see Chap. 47) , thromboembolism, or syncope; (5) a systolic murmur accompanied by an abnormal electrocardiogram.

According to this schema, a large majority of patients with heart murmurs (i.e., patients with grade 1 or grade 2 midsystolic murmurs) without any other clinical manifestations

Figure 4-42 The phonocardiogram shows the continuous murmur of a normal venous hum. The diastolic component is louder (paired arrows). Digital pressure over the right internal jugular vein (vertical arrow) abolishes the murmur. The photographs show maneuvers used to elicit or abolish the venous hum. *Left,* The bell of the stethoscope is applied to the medial aspect of the right supraclavicular fossa as the examiner's left hand grasps the patient's chin from behind and pulls it tautly to the left and upward, stretching the neck. *Right,* The patient's head has returned to a more neutral position, and digital compression of the right internal jugular vein (arrow) abolishes the hum.

of cardiac disease ordinarily do not require extensive work-up.

Pericardial Rubs (see Chap. 50)

In sinus rhythm, the typical pericardial rub is triple phased, that is, midsystolic, mid-diastolic, and presystolic. Recognition is simplest when all three phases are present and when the characteristic superficial scratchy, leathery quality is evident. Pericardial rubs may be more readily detected when the patient is on elbows and knees (Fig. 4-44) , a physical maneuver designed to increase the contact

Figure 4-43 An approach to the evaluation of a heart murmur that also uses the results of the electrocardiogram (ECG), chest radiograph, and echocardiogram in asymptomatic patients with soft midsystolic murmurs and no other physical findings. This algorithm is useful in patients older than age 40 years in whom the prevalence of coronary artery disease and aortic stenosis increases as the cause of systolic murmurs. *(From O'Rourke RA: Approach to the patient with a heart murmur. In Goldman L, Braunwald E [eds]: Primary Cardiology. Philadelphia, WB Saunders, 1998, pp 155-173.)*

Figure 4-44 A technique for eliciting a pericardial rub. The diaphragm of the stethoscope is firmly applied to the precordium (arrow) while the patient rests on elbows and knees.

of visceral and parietal pericardium (see earlier). The term "rub" is appropriate because the auscultatory sign is generated by abnormal visceral and parietal pericardial surfaces "rubbing" against each other. In the supine position, firm pressure with the stethoscopic diaphragm during full held exhalation reinforces visceral and parietal pericardial contact and accentuates the rub. Apposition of visceral and parietal pericardium can be even better achieved by examination while the patient rests on elbows and knees.

Of the three phases of the pericardial rub, the systolic phase is the most consistent, followed by the presystolic phase. In atrial fibrillation, the presystolic component necessarily disappears. The diagnosis of a pericardial rub is least secure when only one phase remains, which is typically the midsystolic. The most common clinical setting in which pericardial rubs are heard is immediately after open heart surgery. However, auscultation often detects instead a "crunch" synchronous with the heartbeat, especially in the left lateral decubitus position. This is not a pericardial rub but is Hamman sign caused by air in the mediastinum.[149] Pericardial rubs are frequently audible in acute pericarditis. They may become softer or even disappear in the presence of a large pericardial effusion.

Dynamic Auscultation

Dynamic auscultation refers to the technique of altering circulatory dynamics by a variety of physiological and pharmacological maneuvers and determining the effects of these maneuvers on heart sounds and murmurs.[150] [151] [152] [153] The conditions and interventions most commonly employed in dynamic auscultation include respiration, postural changes, the Valsalva maneuver, premature ventricular contractions, isometric exercise, and one of the vasoactive agents--amyl nitrite, methoxamine, or phenylephrine. The clinical applications of dynamic auscultation are summarized in Table 4-4 .

RESPIRATION

SECOND HEART SOUND.

The splitting of S_2 is most audible along the left sternal border and can usually be appreciated when A_2 and P_2 are separated by more than 0.02 second. The effects of respiration on the splitting of the second heart sound are discussed on p. 60.

DIASTOLIC SOUNDS AND EJECTION SOUNDS.

When S_3 and S_4 originate from the right ventricle, they are characteristically augmented during inspiration and diminished during exhalation, whereas they exhibit the opposite response when they originate from the left side of the heart. Like other left-sided events, the opening snap of the mitral valve may become softer during inspiration and louder during exhalation owing to respiratory alterations in venous return, whereas the opening snap of the tricuspid valve behaves in the opposite fashion. Inspiration also diminishes the intensity of ejection sounds in pulmonary valve stenosis because the elevation of right ventricular diastolic pressure causes partial presystolic opening of the pulmonary valve and therefore less upward motion of the valve during systole. On the other hand, respiration does not affect the intensity of aortic ejection sounds, except in tetralogy of Fallot with pulmonary atresia.

MURMURS.

Respiration exerts more pronounced and consistent alterations on murmurs originating from the right than from the left side of the heart. During inspiration, the diastolic murmurs of tricuspid stenosis (see Fig. 4-39) and low pressure pulmonary regurgitation, the systolic murmurs of tricuspid regurgitation[154] (Carvallo sign), and the presystolic murmur of Ebstein anomaly may all be accentuated. The inspiratory reduction in left ventricular size in patients with mitral valve prolapse increases the redundancy of the mitral valve and therefore the degree of valvular prolapse; consequently, the midsystolic click and the systolic murmurs occur earlier during systole and may become accentuated.[155]

THE VALSALVA MANEUVER.

This maneuver consists of a relatively deep inspiration followed by forced exhalation against a closed glottis for 10 to 20 seconds. The patient should first be instructed on how to perform the maneuver. Simulation by the examiner is a simple means of doing so. The examiner then places the flat of the hand on the abdomen to provide the patient with a force against which to strain and to permit assessment of the degree and duration of the straining effort.[156] [157] [158] The normal response to the Valsalva maneuver consists of four phases. *Phase I* is associated with a transient rise in systemic arterial pressure as straining commences. *Phase II* is accompanied by a perceptible decrease in systemic venous return, systolic pressure, and pulse pressure (small pulse) and by reflex tachycardia. *Phase III* begins promptly with cessation of straining and is associated with an abrupt, transient decrease in arterial pressure. *Phase IV* is characterized by an overshoot of systemic arterial pressure and reflex bradycardia. During phase II, S_3 and S_4 are attenuated and the A_2 -P_2 interval narrows or is abolished (Fig. 4-45) . As stroke volume and systemic arterial pressure fall, the systolic murmurs of aortic and pulmonary stenosis and of mitral and tricuspid regurgitation diminish and the diastolic murmurs of aortic and pulmonary regurgitation and of tricuspid and mitral stenosis soften. As left ventricular volume is reduced, the systolic murmur of hypertrophic obstructive cardiomyopathy amplifies and the click and late systolic murmur of mitral valve prolapse begin earlier. In phase III, the sudden increase in systemic venous return is accompanied by wide splitting of the S_2 and by augmentation of murmurs and filling sounds in the right side of the heart. Murmurs and filling sounds in the left side of the heart return to control levels and may transiently increase during the overshoot of phase IV.

In patients with atrial septal defect, mitral stenosis, or heart failure, the Valsalva maneuver provokes a "square

TABLE 4-4 -- RESPONSE OF MURMURS AND HEART SOUNDS TO PHYSIOLOGICAL AND PHARMACOLOGICAL INTERVENTIONS

CLINICAL DISORDER	INTERVENTION AND RESPONSE
Systolic Murmurs	
Aortic outflow obstruction	
Valvular aortic stenosis	Louder with passive leg-raising, with sudden squatting, with Valsalva release (after five to six beats), following a pause induced by a premature beat, or after amyl nitrite; fades during Valsalva strain and with isometric handgrip
Hypertrophic obstructive cardiomyopathy	Louder with standing, during Valsalva strain, or with amyl nitrite; fades with sudden squatting, recumbency, or isometric handgrip
Pulmonic stenosis	Midsystolic murmur increases with amyl nitrite except with marked right ventricular hypertrophy; also increases during first few beats after Valsalva release
Mitral regurgitation	
Rheumatic	Murmur louder with sudden squatting, isometric handgrip, or phenylephrine; softens with amyl nitrite
Mitral valve prolapse	Midsystolic click moves toward S_1 and late systolic murmur starts earlier with standing, Valsalva strain, and amyl nitrite; click may occur earlier on inspiration; murmur starts later and click moves toward S_2 during squatting, with recumbency, and often after pause induced by a premature beat
Papillary muscle dysfunction	Late systolic murmur generally softer after a pause induced by a premature beat; response to amyl nitrite variable, depending on acute or chronic nature of this disorder
Tricuspid regurgitation	Murmur increases during inspiration, with passive leg-raising, and with amyl nitrite
Ventricular septal defect	

Small defect with pulmonary hypertension	Fades with amyl nitrite; increases with isometric handgrip or phenylephrine
Large defect with hyperkinetic pulmonary hypertension	Louder with amyl nitrite; fades with phenylephrine
Large defect with severe pulmonary vascular disease	Little change with any of above interventions
Tetralogy of Fallot	Murmur softens with amyl nitrite
Supraclavicular bruit	Altered by compression of subclavian artery; may be eliminated by extension of ipsilateral shoulder
Diastolic Murmurs	
Aortic regurgitation	Increases with sudden squatting, isometric handgrip, or phenylephrine
Blowing diastolic murmur	
Austin Flint murmur	Fades with amyl nitrite
Pulmonary regurgitation	Early or mid-diastolic rumble increases on inspiration and with amyl nitrite
Congenital	High-frequency blowing murmur not altered by above interventions
Pulmonary hypertension	
Mitral stenosis	Mid-diastolic and presystolic murmurs louder with exercise, left lateral position, coughing, isometric handgrip, or amyl nitrite; phenylephrine widens A_2 /OS interval; inspiration produces sequence of A_2 /P_2 /OS
Tricuspid stenosis	Mid-diastolic and presystolic murmurs increase during inspiration, with passive leg-raising, and with amyl nitrite
Continuous Murmurs	
Patent ductus arteriosus	Diastolic phase amplified with isometric handgrip or phenylephrine; diastolic phase fades with amyl nitrite
Cervical venous hum	Obliterated by direct compression of jugular veins or by Valsalva strain
Added Heart Sounds	
Gallop rhythm	
Ventricular gallop (S_3) and atrial gallop (S_4)	Accentuated by lying flat with passive leg-raising; decreased by standing or during Valsalva; right-sided gallop sounds usually increase during inspiration; left-sided during expiration
Summation gallop	Separates into ventricular gallop (S_3) and atrial gallop (S_4) sounds when heart rate slowed by carotid sinus massage
Ejection sounds	Ejection sound in pulmonary stenosis fades and occurs closer to the first sound during inspiration

OS=opening snap of mitral valve.

From Criscitiello MG: Physiologic and pharmacologic aids in cardiac auscultation. In Fowler NO (ed): Cardiac Diagnosis and Treatment. Hagerstown, MD, Harper & Row, 1980.

wave" response, negating the four phases and their auscultatory equivalents. The Valsalva maneuver should not be performed in patients with ischemic heart disease because of the accompanying fall in coronary blood flow.

THE MULLER MANEUVER.

This maneuver is the converse of the Valsalva maneuver but is less frequently employed because it is not as useful.[81] In this maneuver the patient forcibly *inspires* while the nose is held closed and the mouth is firmly sealed for about 10 seconds. The Muller maneuver exaggerates the inspiratory effort, widens the split S_2 , and augments murmurs and filling sounds originating in the right side of the heart.

Figure 4-45 Changes in four left-sided systolic murmurs during the strain phase of the Valsalva maneuver. *(From Grewe K, Crawford MH, O'Rourke RA: Differentiation of cardiac murmurs by auscultation. Curr Probl Cardiol 13:669, 1988.)*

POSTURAL CHANGES AND EXERCISE (See Fig. 4-46.)

Sudden assumption of the lying from the standing or sitting position or sudden passive elevation of both legs results in an increase in venous return, which augments first right ventricular and, several cardiac cycles later, left ventricular stroke volume. The principal auscultatory changes include widening of the splitting of S_2 in all phases of respiration and augmentations of right-sided S_3 and S_4 and, several cardiac cycles later, left-sided S_3 and S_4 . The systolic murmurs of pulmonic valve stenosis and aortic stenosis, the systolic murmurs of mitral and tricuspid regurgitation and ventricular septal defect, and most functional systolic murmurs are augmented. On the other hand, because left ventricular end-diastolic volume is increased, the systolic murmur of hypertrophic obstructive cardiomyopathy is diminished and the midsystolic click and late systolic murmur associated with mitral valve prolapse are delayed and sometimes attenuated (see Fig. 4-18 and p. 68).

Rapid standing or sitting up from a lying position or rapid standing from a squatting posture has the opposite effect; in patients in whom there is relatively wide splitting of S_2 during exhalation--a finding that may be confused with fixed splitting--the width of the splitting is reduced, so that a normal pattern emerges during the respiratory cycle. No change in splitting occurs in patients with true fixed splitting. The decrease in venous return reduces stroke volume and innocent pulmonary flow murmurs as well as the murmurs of semilunar valve stenosis and of AV valve regurgitation. The auscultatory changes in hypertrophic cardiomyopathy and mitral valve prolapse are opposite to those on assumption of the lying posture just described.

SQUATTING.

A sudden change from standing to squatting increases venous return and systemic resistance simultaneously. Stroke volume and arterial pressure rise, and the latter may induce a transient reflex bradycardia. The auscultatory features include augmentation of S_3 and S_4 (from both ventricles) and as a consequence of an increase in stroke volume, the systolic murmurs of pulmonary and aortic stenosis and the diastolic murmurs of tricuspid and mitral stenosis become louder, with right-sided events preceding left-sided events. Squatting may make audible a previously inaudible murmur of aortic regurgitation.

The elevation of arterial pressure increases blood flow through the right ventricular outflow tract of patients with tetralogy of Fallot and increases the volume of mitral regurgitation and of the left-to-right shunt through a ventricular septal defect, thereby increasing the intensity of the systolic murmur in these conditions. Also, the diastolic murmur of aortic regurgitation is augmented consequent to an increase in aortic reflux. The combination of elevated arterial pressure and increased venous return increases left ventricular size, which reduces the obstruction to outflow and thus the intensity of the systolic murmur of hypertrophic obstructive cardiomyopathy, the midsystolic click and the late systolic murmur of mitral valve prolapse are delayed.

OTHER POSITIONAL CHANGES.

Assumption of the left lateral recumbent position accentuates the intensity of S_1 , S_3 , and S_4 originating from the left side of the heart; the opening snap and the murmurs associated with mitral stenosis and regurgitation; the midsystolic click and late systolic murmur of mitral valve prolapse; and the Austin Flint murmur associated with aortic regurgitation. *Sitting up and leaning forward* (see Fig. 4-12) make the diastolic murmurs of aortic and pulmonary regurgitation more readily audible.

Hyperextension of the shoulders is an important positional maneuver that assists in assessing supraclavicular systolic murmurs. The mechanism responsible for diminution in the intensity of normal supraclavicular systolic murmurs with hyperextension of the shoulders is apparently related to the effect of the maneuver on the site of origin of the murmurs in the proximal brachiocephalic arteries as they leave the aortic arch. *Stretching the neck* to elicit a venous hum is illustrated in Figure 4-42 . *Passive elevation of the legs* with the patient supine transiently increases venous return and augments S_3 .

ISOMETRIC EXERCISE.

This can be carried out simply and reproducibly using a calibrated handgrip device or hand ball. (It is useful to carry out isometric exercise bilaterally simultaneously.) Isometric exercise should be avoided in patients with ventricular arrhythmias and myocardial ischemia, both of which can be intensified by this activity. Handgrip should be sustained for 20 to 30 seconds, but a Valsalva maneuver during the handgrip must be avoided. Isometric exercise results in transient but significant increases in systemic vascular resistance, arterial pressure, heart rate, cardiac output, left ventricular filling pressure, and heart size. As a consequence, (1) S_3 and S_4 originating from the left side of the heart become accentuated, (2) the systolic murmur of aortic stenosis is diminished as a result of reduction of the pressure gradient across the aortic valve,[158] [159] (3) the diastolic murmur of aortic regurgitation and the systolic murmurs of rheumatic mitral regurgitation and ventricular septal defect increase in intensity, (4) the diastolic murmur of mitral stenosis becomes louder consequent to the increase in cardiac output, and (5) the systolic murmur of hypertrophic obstructive cardiomyopathy diminishes and the systolic click and late systolic murmur of mitral valve prolapse are delayed because of the increased left ventricular volume.

Figure 4-46 Diagrammatic representation of the character of the systolic murmur and of the second heart sound in five conditions. The effects of posture, amyl nitrite inhalation, and phenylephrine injection on the intensity of the murmur are shown. *(Modified from Barlow JB: Perspectives on the Mitral Valve. Philadelphia, FA Davis, 1987, p 138.)*

PHARMACOLOGICAL AGENTS (See Fig. 4-46.)

Inhalation of *amyl nitrite* is carried out by placing an ampule in gauze near the supine patient's nose and then crushing the ampule. The patient is asked to take three or four deep breaths over 10 to 15 seconds, after which the amyl nitrite is removed. The drug produces marked vasodilatation, resulting in the first 30 seconds in a reduction of systemic arterial pressure and 30 to 60 seconds later in a reflex tachycardia, followed in turn by a reflex *increase* in cardiac output, velocity of blood flow, and heart rate.[4] [150] [151] [152] [153] [160] The major auscultatory changes occur in the first 30 seconds after inhalation. S_1 is augmented, and A_2 is diminished. The opening snaps of the mitral and tricuspid valves become louder, and as arterial pressure falls, the A_2 /opening snap interval shortens. An S_3 originating in either ventricle is augmented, owing to greater rapidity of ventricular filling; but because mitral regurgitation is reduced, the S_3 associated with this lesion is diminished. The systolic murmurs of aortic valve stenosis, pulmonary stenosis, hypertrophic obstructive cardiomyopathy, tricuspid regurgitation, and functional systolic murmurs are all accentuated.

In patients with tetralogy of Fallot, the reduction of arterial pressure increases the right-to-left shunt and decreases the blood flow from the right ventricle to the pulmonary artery and diminishes the midsystolic murmur. The increase in cardiac output augments the diastolic murmurs of mitral and tricuspid stenosis and of pulmonary regurgitation and the systolic murmur of tricuspid regurgitation. However, as a result of the fall in systemic arterial pressure, the systolic murmurs of mitral regurgitation and ventricular septal defect, the diastolic murmurs of aortic regurgitation, and the Austin Flint murmur as well as the continuous murmurs of patent ductus arteriosus and of systemic arteriovenous fistula are all diminished.[158] The reduction of cardiac size results in an earlier appearance of the midsystolic click and late systolic murmur of mitral valve prolapse; the intensity of the systolic murmur exhibits a variable response.

The response to amyl nitrite is useful in distinguishing (1) the systolic murmur of aortic stenosis (which is augmented) from that of mitral regurgitation (which is diminished),[160] (2) the systolic murmur of tricuspid regurgitation (augmented) from that of mitral regurgitation (diminished), (3) the systolic murmur of isolated pulmonary stenosis (augmented) from that of tetralogy of Fallot (diminished), (4) the diastolic rumbling murmur of mitral stenosis (augmented) from the Austin Flint murmur of aortic regurgitation (diminished), and (5) the early blowing diastolic murmur of pulmonary regurgitation (augmented) from that of aortic regurgitation (diminished).

Methoxamine and *phenylephrine* increase systemic arterial pressure and exert an effect opposite to that of amyl nitrite. In general, methoxamine, 3 to 5 mg intravenously, elevates arterial pressure by 20 to 40 mm Hg for 10 to 20 minutes, but phenylephrine is preferred because of its shorter duration of action; 0.3 to 0.5 mg of phenylephrine administered intravenously elevates systolic pressure by approximately 30 mm Hg for only 3 to 5 minutes. Both drugs cause reflex bradycardia and decreased contractility and cardiac output. They should not be used in the presence of congestive heart failure and systemic hypertension.

After administration, the intensity of S_1 is usually reduced, and the A_2 /mitral opening snap interval becomes prolonged. The responses of S_3 and S_4 are variable. As a

result of the increased arterial pressure, the diastolic murmur of aortic regurgitation, the systolic murmurs of mitral regurgitation (see Fig. 4-35) , ventricular septal defect, and tetralogy of Fallot, and the continuous murmurs of patent ductus arteriosus and systemic arteriovenous fistula all become louder. On the other hand, as a consequence of the increase in left ventricular size, the systolic murmur of hypertrophic obstructive cardiomyopathy becomes softer and the click and late systolic murmur of mitral valve prolapse are delayed. The reduction in cardiac output diminishes the systolic murmur of aortic valve stenosis, functional systolic murmurs, and the diastolic murmur of mitral stenosis. The rumbling diastolic murmurs of mitral regurgitation and the Austin Flint murmur also diminish.

Chapter 5 - Electrocardiography

DAVID M. MIRVIS
ARY L. GOLDBERGER

The electrocardiogram (ECG), as used today, is the product of a series of technological and physiological advances pioneered over the past two centuries.[1] Early demonstrations of the heart's electrical activity reported during the last half of the 19th century, for example, by Marchand and others, were closely followed by direct recordings of cardiac potentials by Waller in 1887. Invention of the string galvanometer by Willem Einthoven in 1901 provided a reliable and direct method for registering electrical activity of the heart. By 1910, use of the string galvanometer had emerged from the research laboratory into the clinic. Subsequent achievements built on the limited, but very solid foundation supplied by the early electrocardiographers. The result has become a widely used and invaluable clinical tool for the detection and diagnosis of a broad range of cardiac conditions, as well as a technique that has contributed to the understanding and treatment of virtually every type of heart disease. Furthermore, the ECG is essential in the management of major metabolic abnormalities such as hyperkalemia and certain other electrolyte disorders, as well as assessing drug effects and toxicities such as caused by digitalis, antiarrhythmic agents, and tricyclic antidepressants. Moreover, it has remained the most direct method for assessing abnormalities of cardiac rhythm.

FUNDAMENTAL PRINCIPLES

Use of the ECG for any of these clinically important purposes is the final outcome of a complex series of physiological and technological processes. This sequence is depicted in Figure 5-1 . First, an extracellular cardiac electrical field is generated by ion fluxes across cell membranes and between adjacent cells. These ion currents are synchronized by cardiac activation and recovery sequences to generate a cardiac electrical field in and around the heart that varies with time during the cardiac cycle.

This electrical field passes through numerous other structures, including the lungs, blood, and skeletal muscle, before reaching the body surface. These structures--known as *transmission factors*--differ in their electrical properties and perturb the cardiac electrical field as it passes through them. The potentials reaching the skin are then detected by electrodes placed in specific locations on the extremities and torso and configured to produce *leads*. The outputs of these leads are amplified, filtered, and displayed by a variety of electronic devices to construct an ECG recording. Finally, diagnostic criteria are applied to these recordings to produce an interpretation. The criteria have statistical characteristics that determine the clinical utility of the findings. Each of these steps influences the final product--the clinical ECG--and will be considered in detail in this chapter to provide a foundation for considering the common abnormalities found in clinical practice and as a basis for further learning.

GENESIS OF THE CARDIAC ELECTRICAL FIELD

CARDIAC ELECTRICAL FIELD GENERATION DURING ACTIVATION.

Transmembrane ionic currents are ultimately responsible for the cardiac potentials that are recorded as an ECG. Current may be analyzed as though carried by positively charged or negatively charged ions. Through a purely arbitrary choice, electrophysiological currents are considered to be the movement of positive charge. A positive current moving in one direction is equivalent to a negative current of equal strength moving in the opposite direction.

The process of generating the cardiac electrical field during activation can be illustrated by considering the events in a single cardiac fiber that is activated by a stimulus applied to its left-most margin[2] (Fig. 5-2 , left, panel *A*). Transmembrane potentials (V_m) are recorded as the difference between intracellular and extracellular potentials (k_i and k_e , respectively). Figure 5-2 , left, panel *B* plots V_m along the length of the fiber at the instant during the propagation (t_o) at which activation has reached the point designated as X_0 . As each site is activated, the polarity of the transmembrane potential is converted from negative to positive. Thus, sites to the left of the point X_0 , which have already undergone excitation, have positive transmembrane potentials (that is, the inside of the cell is positive relative to the outside of the cell), whereas those to the right of X_0 (which remain in a resting state) have negative transmembrane potentials. Near the site undergoing activation (site X_0), the potentials reverse polarity over a short distance.

Figure 5-2 , left, panel C displays the direction and magnitude of transmembrane currents (I_m) along the fiber at the instant (t_o) at which excitation has reached site X_0 . Current flow is inwardly directed in fiber regions that have undergone activation (that is, to the left of point X_0) and outwardly directed in neighboring zones still at rest (that is, to the right of X_0). Sites of outward current flow are *current sources* and those with inward current flow are *current sinks*. As depicted in this panel, current flow is most intense in each direction near the site of activation X_0 . Because the border between inwardly and outwardly directed currents is relatively sharp, we can visualize these currents as though they were limited to the sites of maximal current flow, as depicted in panel D, and separated by distance d that is usually 1.0 mm or less. As activation proceeds along the fiber, the source-sink pair moves to the right at the speed of propagation for the particular type of fiber.

Two point sources of equal strength but of opposite polarity located very near each other, such as the current source and the current sink depicted in Figure 5-2 , left, panel *D*, may be represented as a current dipole (arrow in panel *D*). Thus, activation of a fiber can be modeled as a current dipole that moves in the direction of propagation of activation. Such a dipole is fully characterized by three parameters--strength or *dipole moment*, location, and orientation. In this case, the location of the dipole is the site undergoing activation (point X_0), and its orientation is in the direction of activation (that is, from left to right along the fiber). Dipole moment is proportional to the rate of change of intracellular potential with respect to distance along the fiber, that is, action potential shape.

A current dipole produces a characteristic potential field with positive potentials projected ahead of and negative potentials projected behind the moving dipole. The actual potential recorded at any site within this field is directly proportional to the dipole moment, inversely proportional to the square of the distance from the dipole to the recording site, and directly proportional to the cosine of the angle between the axis of the dipole and a line drawn from the dipole to the recording site (Fig. 5-2 , right).

Figure 5-1 Schematic representation of the factors resulting in recording the electrocardiogram (ECG). The major paths leading to the ECG are marked by solid arrows, while factors influencing or perturbing this path are shown with dotted arrows.

This example from one cardiac fiber can be generalized to the more realistic case in which multiple adjacent fibers are activated in synchrony to produce an *activation front*. Activation of each fiber creates a dipole oriented in the direction of activation. The net effect of all the dipoles in this wave front is a single dipole equal to the (vector) sum of the effects of all the simultaneously active component dipoles. Thus, an activation front propagating through the heart can be represented by a single dipole that projects positive potentials ahead of it and negative potentials behind it.

This relationship between activation direction, orientation of the current dipole, and polarity of potentials is a critical one in electrocardiography. It describes a fundamental relationship between the polarity of potentials sensed by an electrode and the direction of movement of an activation front--*an electrode senses positive potentials when an activation front is moving toward it and negative potentials when the activation front is moving away from it.*

The dipole model, while useful in describing cardiac fields and understanding clinical electrocardiography, has significant theoretical limitations. These limits derive primarily from the inability of a single dipole to accurately represent more than one wave front that is propagating through the heart at any one instant. As will be discussed, during much of the time of ventricular excitation, more than one wave front is present.

One important and commonly used method of estimating the potentials projected to some point away from an activation front is an application of the *solid angle theorem*.[3] A *solid angle* is a geometric measure of the size of a region when viewed from a distant site. It equals the area on the surface of a sphere of unit radius constructed around an electrode that is cut by lines drawn from the recording electrode to all points around the boundary of the region of interest. This region may be a wave front, a zone of infarction, or any other region in the heart.

The solid angle theorem states that the potential recorded by a remote electrode (Phi) is defined by Phi=(
/4pi)(V_{m2} - V_{m1})K where
is the solid angle, V_{m2} - V_{m1} is the potential difference across the boundary under study, and K is a constant reflecting differences in intracellular conductivity. This equation indicates that the recorded potential equals the product of two factors. First, the solid angle reflects *spatial parameters*, such as the size of the boundary of the region under study and the distance from the electrode to that boundary. The potential will rise as the boundary size increases and as the distance to the electrode shrinks. A second set of parameters includes *nonspatial factors*, such as the potential difference across the surface and intracellular and extracellular conductivity. Nonspatial effects include, as one example, myocardial ischemia, which changes transmembrane action potential shapes and alters conductivity.

CARDIAC ELECTRICAL FIELD GENERATION DURING VENTRICULAR RECOVERY.

The cardiac electrical field during recovery (phases 1 through 3 of the action potential) differs in fundamental ways from that described for activation. First, intercellular potential differences and, hence, the directions of current flow during recovery are the opposite of those described for activation. As a cell undergoes recovery, its intracellular potential becomes progressively more negative. Hence, for two adjacent cells, the intracellular potential of the cell whose recovery has progressed further is more negative than that of an adjacent, less recovered cell. Intracellular currents then flow from the less toward the more recovered cell. An equivalent dipole can then be constructed for recovery, just as for activation. Its orientation, however, points from less to more recovered cells. Thus, the recovery dipole is oriented away from the activation front, that is, in the direction opposite that of the activation dipole.

The moment or strength of the recovery dipole also differs from that of the activation dipole. As described previously, the strength of the activation dipole is proportional to the rate of change in transmembrane potential. Rates of change in potential during the recovery phases of the action potential are considerably slower than during activation, so dipole moment at any one instant during recovery is less than that during activation.

A third difference between activation and recovery is the rate of movement of the activation and recovery dipoles. Activation, because it is rapid (as fast as 1 millisecond in duration), occurs over only a small distance along the fiber. Recovery, in contrast, lasts 100 milliseconds or longer and occurs simultaneously over extensive portions of the fiber.

These features result in characteristic ECG differences between activation and recovery patterns. All other factors being equal (an assumption that is often not true, as described below), ECG waveforms generated during recovery of a linear fiber with uniform recovery properties may be expected to be of opposite polarity, lower amplitude, and longer duration than those due to activation. As will be described, these features are explicitly demonstrated in the clinical ECG.

THE ROLE OF TRANSMISSION FACTORS.

These activation and recovery forces exist within a complex three-dimensional physical environment (the *volume conductor*). The structures within the volume conductor modify the cardiac electrical field in significant ways.[4] They may be called *transmission factors* to emphasize their effects on transmission of the cardiac electrical field throughout the body and may be grouped into four broad categories--*cellular factors*, *cardiac factors*, *extracardiac factors*, and *physical factors*.

Cellular factors determine the intensity of current fluxes that result from local transmembrane potential gradients and include intracellular and extracellular resistance and the concentration of relevant ions, especially the sodium ion. Lower ion concentrations reduce the intensity of current flow by reducing the equivalent dipole moment and lowering extracellular potentials.

Cardiac factors affect the relationship of one cardiac cell to another. Two major factors are (1) *anisotropy*, that is, the property of cardiac tissue that results in greater current flow and more rapid propagation along the length of a fiber than transversely, and (2) the presence of connective tissue between cardiac fibers that disrupts effective electrical coupling between adjacent fibers. These factors alter the paths of extracellular currents and produce changes in the amplitude and configuration of recorded electrograms. Recording electrodes oriented along the long axis of a cardiac fiber register larger potentials than do electrodes oriented perpendicular to the long axis, and waveforms recorded from fibers with little or no intervening connective tissue are narrow in width and smooth in contour, whereas those recorded from tissues with abnormal fibrosis are prolonged and heavily fractionated.[5]

Extracardiac factors encompass all the tissues and structures that lie between the activation region and the body surface, including the ventricular walls, intracardiac and intrathoracic blood volume, the pericardium, and the lungs, as well as skeletal muscle, subcutaneous fat, and skin. These tissues alter the cardiac field because of differences in the electrical resistivity of adjacent tissues, that is, the presence of *electrical inhomogeneities* within the torso. For example, intracardiac blood has much lower resistivity (162
-cm) than do the lungs (2150
-cm). When the cardiac field encounters the boundary between two tissues with differing resistivity, the field is altered.

Other transmission factors reflect basic laws of physics. First, changes in the distance between the heart and the recording electrode reduce potential magnitudes in accord with the *inverse square law*, that is, amplitude decreases in proportion to the square of the distance. A related factor is the effect of *eccentricity*. The heart is located eccentrically within the chest in that it lies closer to the anterior than to the posterior of the torso, so the right ventricle and the anteroseptal aspect of the left ventricle are located closer to the anterior of the chest than are other parts of the left ventricle and the atria. Therefore, ECG potentials will be higher anteriorly than posteriorly, and waveforms projected from the anterior of the left ventricle will be greater than those generated by posterior ventricular regions.

As a result of all of these factors, body surface potentials have an amplitude of only 1 percent of the amplitude of transmembrane potentials and are smoothed in detail so that surface potentials have only a general spatial relationship to the underlying cardiac events.

Figure 5-2 Example of potentials and currents generated by the activation of a single (e.g., ventricular) cardiac fiber. *Left, Panel A,* Intracellular (Phi_i) and extracellular (Phi_e) potentials are recorded with a voltmeter (V_m) from a fiber 20 mm in length. The fiber is stimulated at site X=0, and propagation proceeds from left to right. *B,* Plot of transmembrane potential (V_m) at the instant in time at which activation reaches point X_0 as a function of the length of the fiber. Positive potentials are recorded from activated tissue to the left of site X_0 , and negative ones are registered from not yet excited areas to the right of site X_0 . *C,* Membrane current (I_m) flows along the length of the fiber at time t_o . The outward current is the depolarizing current that propagates ahead of activation site X_0 , while an inward one flows behind site X_0 . *D,* Representation of the sites of peak inward and outward current flow as two point sources, a sink (at the site of peak inward current flow) and a source (at the site of peak outward current flow) separated by distance d. The dipole produced by the source-sink pair is represented by the arrow. *(Modified from Barr RC: Genesis of the electrocardiogram. In MacFarlane PW, Lawrie TDV [eds]: Comprehensive Electrocardiography. New York, Pergamon, 1989.) Right, Formula for computing the electrical potential (phi) recorded by an electrode in terms of the distance*

from an extracellular dipole generated during activation of a linear cardiac fiber to the electrode (r=radius), the angle between the radius to the electrode and the dipole (O), the dipole moment (M) and extracellular conductivity (sigma). The direction of activation of the fiber is indicated.

The modifying effect of these physical structures is a biophysical one dependent on the physical properties of the structures and the related laws of physics, in contrast to the biological cardiac generators, whose output is dependent on cellular structure and physiological and biochemical processes. Thus, ECG potentials on the body surface are dependent on both biological and biophysical properties.[6]

RECORDING ELECTRODES AND LEADS

Potentials generated by the cardiac electrical generator and modified by transmission factors are processed by a series of electrical and electronic devices to yield a clinical ECG (Fig. 5-3) . They are first sensed by electrodes placed on the torso that are configured to form various types of *leads*.

ELECTRODE CHARACTERISTICS.

Electrodes used to sense the cardiac electrical field are not passive devices that merely detect the field. Rather, they are intricate systems that are affected by the properties of the dermal and epidermal layers of the skin, the electrolytic paste applied to the skin, the electrode itself, and the mechanical contact between the electrode and skin. The net effect is a complex electrical circuit that includes the resistance, capacitance, and voltage produced by these different components and the interfaces between them. Each of these factors modifies the cardiac potentials that reach the electrodes themselves before they are displayed as an ECG.[7]

BIPOLAR AND UNIPOLAR LEAD CONFIGURATIONS.

ECG leads may be subdivided into two general types--*bipolar leads* and *unipolar leads*. A bipolar lead consists of two electrodes placed at two different sites. These leads register the difference in potential between these two sites. The actual potential at either electrode is not known, and only the difference between them is recorded. One electrode is designated as the positive input; the potential at the other, or negative, electrode is subtracted from the potential at the positive electrode to yield the bipolar potential.

Unipolar leads, in contrast, measure the absolute electrical potential at one site. To do so requires a *reference site*, that is, a site at which the potential is deemed to be zero. The reference site may be a location far away from the active electrode (as in an experimental

Figure 5-3 Components used in the recording and processing of an electrocardiogram.*(From Mirvis DM: Electrocardiography: A Physiologic Approach. St Louis, Mosby-Year Book, 1993.)*

preparation) or, as in clinical electrocardiography, a specially designed electrode configuration such as described below. The unipolar recording is then the potential sensed by a single electrode at one site--the *recording* or *active* or *exploring electrode*--in relation to the designated zero or reference potential.

Clinical Electrocardiographic Lead Systems

The standard clinical ECG includes recordings from 12 leads. These 12 leads include three *bipolar limb leads* (leads I, II, and III), six *unipolar precordial leads* (leads V_1 through V_6), and three modified unipolar limb leads (the *augmented limb leads* aV_r , aV_l , and aV_f). Definitions of the positive and negative inputs for each lead are listed in Table 5-1 .

BIPOLAR LIMB LEADS.

Bipolar limb leads record the potential differences between two limbs, as detailed in Table 5-1 and illustrated in Figure 5-4 , top. As bipolar leads, the output is the potential difference between the limbs serving as positive and negative inputs. Lead I represents the potential difference between the left arm (positive electrode) and the right arm (negative electrode), lead II displays the potential difference between the left foot (positive electrode) and the right arm (negative electrode), and lead III represents the potential difference between the left foot (positive electrode) and the left arm (negative electrode). The electrode on the right foot that is not included in these leads serves as a ground connection.

The electrical connections for these leads are such that the potential in lead II equals the sum of potentials sensed in leads I and III. That is,
I+III=II.
This relationship is known as *Einthoven's law*.

UNIPOLAR PRECORDIAL LEADS AND THE WILSON CENTRAL TERMINAL.

The unipolar precordial leads register the potential at each of the six designated torso sites (Fig. 5-4 , bottom left panel) in relation to a theoretical zero reference potential. To do so, an exploring electrode is placed on each precordial site and connected to the positive input of the recording system (Fig. 5-4 , bottom right panel).

The negative or reference input is composed of a *compound electrode* (that is, a configuration of more than one electrode connected electrically) known as the *Wilson central terminal*. This terminal is formed by combining the output of the left arm, right arm, and left leg electrodes through 5000-
resistances (Fig. 5-4 , bottom right panel). The result is that each precordial lead registers the potential at a precordial site with reference to the average potential on three limbs. The potential recorded by the Wilson central terminal remains relatively constant during the cardiac cycle, so the output of a precordial lead is determined

TABLE 5-1 -- LOCATION OF ELECTRODES AND LEAD CONNECTIONS FOR THE STANDARD 12-LEAD ELECTROCARDIOGRAM AND ADDITIONAL LEADS

LEAD TYPE, LEAD	POSITIVE INPUT	NEGATIVE INPUT
Bipolar Limb Leads		
Lead I	Left arm	Right arm
Lead II	Left leg	Right arm
Lead III	Left leg	Left arm
Augmented Unipolar Limb Leads		
aV_r	Right arm	Left arm + left leg
aV_l	Left arm	Right arm + left leg
aV_f	Left leg	Left arm + left arm
Precordial Leads*		
V_1	Right sternal margin,4th intercostal space	Wilson central terminal
V_2	Left sternal margin,4th intercostal space	Wilson central terminal
V_3	Midway between V_2 and V_4	Wilson central terminal
V_4	Left midclavicular line,5th intercostal space	Wilson central terminal
V_5	Left anterior axillary line	Wilson central terminal

V_6	Left midaxillary line	Wilson central terminal
V_7	Posterior axillary line	Wilson central terminal
V_8	Posterior scapular line	Wilson central terminal
V_9	Left border of spine	Wilson central terminal

*The right-sided precordial leads V_3 R to V_6 R are taken in mirror image positions on the right side of the chest: V_1 R ¬ V_2 ; V_2 R ¬ V_1 .

Leads V_5 to V_9 are taken in the same horizontal plane as V_4 .QT interval (corrected) DURATION (msec)

Figure 5-4 *Top,* Electrode connections for recording the three bipolar limb leads I, II, and III. R, L, and F indicate locations of electrodes on the right arm, the left arm, and the left foot, respectively. *Bottom,* Electrode locations and electrical connections for recording a unipolar precordial lead. *Left,* The positions of the exploring electrode (V) for the six precordial leads. *Right,* Connections to form the Wilson central terminal for recording a precordial (V) lead. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)*

predominantly by changes in the potential at the precordial site.

AUGMENTED UNIPOLAR LIMB LEADS.

The three augmented limb leads aV_r , aV_l , and aV_f are modified or *augmented unipolar leads*. The exploring electrode (Fig. 5-5) is the right arm electrode for lead aV_r , the left arm electrode for lead aV_l , and the left foot electrode for aV_f . It is the reference electrode that is modified. Instead of consisting of a full Wilson central terminal composed of the output from three limb electrodes, the reference potential is

Figure 5-5 Electrode locations and electrical connections for recording the three augmented unipolar leads aV_r , aV_l , and aV_f . Dotted lines indicate connections to generate the reference electrode potential.

Figure 5-6 Lead vectors for the three bipolar limb leads, the three augmented unipolar limb leads *(left),* and the six unipolar precordial leads *(right).*

the mean of the potentials sensed by only two of the three limb electrodes; the electrode used for the exploring electrode is excluded from the reference electrode. For lead aV_l , for example, the exploring electrode is on the left arm and the reference electrode is the mean output of the electrodes on the right arm and the left foot. Similarly, for lead aV_f , the reference potential is the mean of the output of the two arm electrodes.

This modified reference system was designed to increase the amplitude of the output. The output of the limb leads without augmentation tended to be small, in part because the same electrode potential was included in both the exploring and reference potential input. Eliminating this duplication results in a theoretical increase in amplitude of 50 percent.

OTHER LEAD SYSTEMS.

Other lead systems may be used for specific purposes. For example, additional unipolar right precordial leads may be used to assess right ventricular lesions, and locations posterior to V_6 may be used to detect posterior infarctions[8] [8A] [8B] (see Table 5-1) . Such posterior locations include lead V_7 with the exploring electrode at the left posterior axillary line at the level of V_6 , lead V_8 with the exploring electrode on the left midscapular line, lead V_4 R with the exploring electrode on the right midclavicular line in the 4th intercostal space, and so forth. A vertical parasternal bipolar pair may facilitate detection of P waves for diagnosing arrhythmias.[9] Precordial and anterior-posterior thoracic electrode arrays of up to 150 (or more) electrodes may be used to display the spatial distribution of body surface potentials as *body surface isopotential maps*.[10] Modified lead systems are also used in ambulatory ECG recording and exercise stress testing, as described elsewhere, and for bedside cardiac monitoring.[11]

Other lead systems that have had clinical utility include those designed to record a *vectorcardiogram* (VCG). The VCG depicts the orientation and strength of a single cardiac dipole or vector at each instant during the cardiac cycle. Lead systems for recording the VCG are referred to as *orthogonal systems* because they record the three orthogonal or mutually perpendicular components of the dipole moment--the horizontal (x axis), frontal (y axis) and sagittal or anteroposterior (z axis) axes. Clinical use of the VCG has waned in recent years. However, the VCG may be useful in certain situations,[12] and as described below, vectorial principles remain essential to understanding the physiology and pathology of ECG waveform genesis.

LEAD VECTORS AND HEART VECTORS

A lead can be represented as a vector (the *lead vector).* For simple bipolar leads, such as leads I, II, and III, the lead vectors are directed from the negative electrode toward the positive one (see Fig. 5-6 , left). For unipolar leads such as the augmented limb and precordial leads, the origin of the lead vectors lies on the axis connecting the electrodes that make up the compound electrode. That is, for lead aV_l , the vector points from the midpoint of the axis connecting the right arm and left leg electrodes toward the left arm (see Fig. 5-6 , left). For the precordial leads, the lead vector points from the center of the torso to the precordial electrode site (Fig. 5-6 , right).

Instantaneous cardiac activity may also be approximated as a single dipole representing the vector sum of the various active wave fronts (the *heart vector).* Its location, orientation, and intensity vary from instant to instant because of the changing pattern of cardiac activation.

The amplitude and polarity of the potentials sensed in a lead equal the length of the projection of the heart vector on the lead vector multiplied by the length of the lead vector:
V_L =(H)(cos O) (L)
where L and H are the length of the lead and heart vectors, respectively, and O is the angle between the two vectors, as illustrated in Figure 5-7 .

If the projection of the heart vector on the lead vector points toward the positive pole of the lead axis, the lead will record a positive potential. If the projection is directed away from the positive pole of the lead axis, the potential will be negative.

The lead axes of the six frontal plane leads can be overlaid to produce the *hexaxial reference system*. As depicted in Figure 5-8, the six lead axes divide the frontal plane into 12 segments subtending 30 degrees.

Figure 5-7 The heart vector H and its projections on the lead axes of leads I and III. Voltages recorded in lead I will be positive whereas potentials in lead III will be negative.

Figure 5-8 The hexaxial reference system composed of the lead axes of the six frontal plane leads. The lead axes of the six frontal plane leads have been rearranged so that their centers overlay one another. These axes divide the plane into 12 segments, each subtending 30 degrees. Positive ends of each axis are labeled with the name of the lead.

The Electrical Axis

The concepts of the heart vector and the lead vector allow calculation of the *mean electrical axis* of the heart. The process for computing the axis of the mean force during activation (the *mean electrical axis*) is illustrated in Figure 5-9 and is the reverse of that used to compute potential magnitudes in the leads from the orientation and moment of the heart vector. The mean force during activation is represented by the area under the QRS waveform measured as millivolt-milliseconds. Areas above the baseline are assigned a positive polarity and those below the baseline have a negative polarity; the overall area equals the sum of the positive and the negative areas.

The area in each lead (typically two are chosen) is represented as a vector oriented along the appropriate lead axis in the hexaxial reference system (see Fig. 5-8) , and the

Figure 5-9 Calculation of the mean electrical axis during the QRS complex from the areas under the QRS complex in leads I and III. Magnitudes of the areas of the two leads are plotted as vectors on the appropriate lead axes, and the mean QRS axis is the sum of these two vectors.*(From Mirvis DM: Electrocardiography: A Physiologic Approach. St Louis, Mosby-Year Book, 1993.)*

mean electrical axis equals the resultant or the sum of the two vectors. An axis directed toward the positive end of the lead axis of lead I, that is, oriented horizontally away from the right arm and toward the left arm, is designated as an axis of zero degrees. Axes oriented in a clockwise direction from this zero level are assigned positive values and those oriented in a counterclockwise direction are assigned negative values.

The mean electrical axis in the horizontal plane can be computed in an analogous manner by using the areas and the lead axes of the six precordial leads (see Fig. 5-6 , right). A horizontal plane axis located along the lead axis of lead V_6 is assigned a value of zero degrees, and those directed more anteriorly have positive values.

This process can be applied to compute the mean electrical axis for other phases of cardiac activity. Thus, the mean force during atrial activation will be represented by the areas under the P wave, and the mean force during ventricular recovery will represented by the areas under the ST-T wave. In addition, the instantaneous electrical axis can be computed at each instant during ventricular activation by using voltages or amplitudes at a specific point in time rather than using areas to calculate the axis.

The orientation of the mean electrical axis represents the direction of the activation front (or recovery direction) in an "average" cardiac fiber. The direction of the front, in turn, is determined by the interaction of three factors--the anatomical position of the heart in the chest, the properties of the cardiac conduction system, and the activation and recovery properties of the myocardium. Differences in the anatomical position of the heart within the chest would be expected to change the relationship between cardiac regions and the lead axes and would thus change recorded voltages. Similarly, changes in conduction patterns, even of minor degree, can significantly alter relationships between activation (or recovery) of various cardiac areas and, hence, the direction of instantaneous as well as mean electrical force. In practice, differences in anatomy contribute relatively little to shifts in axis[13] ; the major influences on the mean electrical axis are the properties of the conduction system and cardiac muscle.

ELECTROCARDIOGRAPHIC DISPLAY SYSTEMS

Another group of factors that determines ECG waveforms includes the characteristics of the electronic systems used to amplify, filter, and digitize the sensed signals. ECG amplifiers are *differential amplifiers*, that is, they amplify the difference between two inputs. For bipolar leads, the differential output is the difference between the two active leads; for unipolar leads, the difference is between the exploring electrode and the reference electrode. This differential configuration significantly reduces the electrical noise that is sensed by both inputs and hence is canceled. The standard amplifier gain for routine electrocardiography is 1000 but may vary from 500 (*half-standard*) to 2000 (*double standard*).

Amplifiers respond differently to the range of signal frequencies included in an electrophysiological signal. The *bandwidth* of an amplifier defines the frequency range over which the amplifier accurately amplifies the input signals. Waveform components with frequencies above or below the bandwidth may be artifactually reduced or increased in amplitude. In addition, recording devices include high- and low-pass filters that intentionally reduce the amplitude of specific frequency ranges of the signal. Such reduction in amplitude may be done, for example, to reduce the effect of body motion or line voltage frequencies, that is, 60-Hz interference. For routine electrocardiography, the standards of the American Heart Association require a bandwidth of 0.05 to 100 Hz.

Amplifiers for routine electrocardiography include a capacitor stage between the input and the output terminals; that is, they are *capacitor coupled*. This configuration blocks direct-current (DC) voltage while permitting flow of alternating-current (AC) signals. Because the ECG waveform may be viewed as an AC signal (which accounts for the waveform shape) that is superimposed on a DC baseline (which determines the actual voltage levels of the recording), this coupling has significant effects on the recording process. First, unwanted DC potentials, such as those produced by the electrode interfaces, are eliminated. Second, elimination of the DC potential from the final product means that ECG potentials are not calibrated against an external reference level. ECG potentials must be measured in relation to an internal standard. Thus, amplitudes of waves are measured in millivolts or microvolts relative to another portion of the waveform. The TP segment, which begins at the end of the T wave of one cardiac cycle and ends with onset of the P wave of the next cycle, is usually the most appropriate internal ECG baseline.

An additional issue is the *digitizing* or *sampling rate* for computerized systems. Too low a sampling rate will miss brief signals such as

notches in QRS complexes or brief bipolar spikes and reduce the precision and accuracy of waveform morphologies. Too fast a sampling rate may introduce artifacts, including high-frequency noise, and requires excessive digital storage capacity.[14] In general, the sampling rate should be at least twice the frequency of the highest frequencies of interest in the signal being recorded. Standard electrocardiography is most commonly performed with a sampling rate of 500 Hz, with each sample representing a 2-millisecond period.

Cardiac potentials may be processed for display in numerous formats. The most common of these formats is the classic *scalar ECG*. Scalar recordings depict the potentials recorded from one lead as a function of time. For standard electrocardiography, amplitude is displayed on a scale of 1 mV to 10-mm vertical displacement and time as 200 msec/cm on the horizontal scale. Other display formats are used for ambulatory electrocardiography, as described in Chapter 23 , and for bedside ECG monitoring.[11]

THE NORMAL ELECTROCARDIOGRAM

The heart is activated with each cardiac cycle in a very characteristic manner determined by the anatomy and physiology of working cardiac muscle and the specialized cardiac conduction systems. The waveforms and intervals that make up the standard ECG are displayed in the diagram in Figure 5-10 , and a normal 12-lead ECG is shown in Figure 5-11 . The *P wave* is generated by activation of the atria, the *PR segment* represents the duration of atrioventricular (AV) conduction, the *QRS complex* is produced by activation of both ventricles, and the *ST-T wave* reflects ventricular recovery. Table 5-2 includes normal values for the various intervals and waveforms of the ECG.

Atrial Activation and the P Wave

Atrial activation[15] begins with impulse generation in the atrial pacemaker complex in or near the sinoatrial (SA) node. The rate of discharge of the SA node and, hence,

the heart rate is dependent on parasympathetic and sympathetic tone, as well as the intrinsic properties of the SA node, extrinsic factors such as mechanical stretch,[16] and various pharmacological effects (see Chap. 22) .

Increasing attention is being directed at the beat-to-beat changes in heart rate, termed *heart rate variability,* to gain insight into neuroautonomic control mechanisms and their perturbations with aging, disease, and drug effects.[17] [18] [19] [172A] [178A] [187A] [187B] For example, high-frequency (0.15-0.5 Hz) fluctuations mediated by the vagus nerve occur phasically, with heart

Figure 5-10 The waves and intervals of a normal electrocardiogram.*(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)*

rate increasing during inspiration and decreasing during expiration. Attenuation of this respiratory sinus arrhythmia is a consistent marker of physiological aging and also occurs with diabetes mellitus, congestive heart failure, and a wide range of other cardiac and noncardiac conditions that alter autonomic tone.[18] [19] [20] [187A] [187B] Lower-frequency (0.05-0.15 Hz) physiological oscillations in heart rate are associated

TABLE 5-2 -- NORMAL VALUES FOR DURATIONS OF ELECTROCARDIOGRAPHIC WAVES AND INTERVALS IN ADULTS

WAVE/INTERVAL	DURATION (msec)
P wave duration	<120
PR interval	<120-200*
QRS duration	<120*
QT interval (corrected)	440-460*

*See the text for further discussion.

Figure 5-11 Normal electrocardiogram recorded from a 48-year-old woman. The vertical lines on the grid on which the scalar electrocardiogram is recorded represent time, with lines spaced at 40-millisecond intervals. Horizontal lines represent voltage amplitude, with lines spaced at 100-muV intervals. Every fifth line in each direction is typically darkened. The heart rate is about 72 beats/min; the PR interval, QRS, and QT_c durations measure about 140, 84, and 400 milliseconds, respectively; and the mean QRS axis is approximately +35 degrees.

with baroreflex activation and appear to be jointly regulated by sympathetic and parasympathetic interactions. A variety of complementary signal processing techniques are being developed to analyze heart rate variability, including the very low-frequency (<0.05 Hz) components and circadian rhythms. These methods include time-domain statistics, frequency domain techniques based on spectral (Fourier) methods, and tools derived from nonlinear dynamics, including chaos (complexity) theory and statistical physics.[21] For further discussion, see Chapter 22 .

Once the impulse leaves this pacemaker site, atrial activation spreads in several directions. First, propagation is rapid along the crista terminalis and moves anteriorly toward the lower portion of the right atrium. It also spreads across the anterior and posterior surfaces of the atria toward the left atrium. The last area to be activated is over the inferolateral aspect of the left atrium, which is activated by convergence of these anterior and posterior wave fronts moving from right to left. Although right atrial activation begins before activation of the left atrium, activation occurs simultaneously in both atria during much of the overall atrial activation time. At the same time, activation spreads through the interatrial septum, beginning high on the right side and moving around the fossa ovalis to the reach the top of the interventricular septum.

The pattern of atrial activation noted above produces the normal P wave. Activation beginning high in the right atrium and proceeding simultaneously leftward toward the left atrium and inferiorly toward the AV node corresponds to a mean frontal plane P wave axis of approximately 60 degrees. Based on this orientation of the heart vector, normal atrial activation projects positive or upright P waves in leads I, II, aV_l , and aV_f . The pattern in lead III may be either upright or downward, depending on the exact orientation of the mean axis, that is, upright if the mean axis is more positive than +30 degrees and negative otherwise.

P wave patterns in the precordial leads correspond to the direction of atrial activation wave fronts in the horizontal plane. Atrial activation early in the P wave is oriented primarily anteriorly over the right atrium and later posteriorly over the left atrium. Thus, the P wave in the right precordial leads (V_1 and, occasionally, V_2) is commonly biphasic, with an initial positive deflection followed by a later negative one. In the more lateral leads, the P wave is upright and reflects right-to-left spread of the activation fronts.

P wave duration is normally under 120 milliseconds. The amplitude in the limb leads is normally under 250 muV, and the terminal negative deflection in the right precordial leads is normally under 100 muV in depth.

Atrial depolarization is followed by atrial repolarization. The potentials generated by atrial repolarization are not usually seen on the surface ECG because of their low amplitude (usually under 100 muV) and because they are superimposed on the much higher amplitude QRS complex.[22] They may be observed as a low-amplitude wave with a polarity opposite that of the P wave (the T_a *wave*) during heart block and may have special significance in influencing ECG patterns during exercise testing.[23] Deviation of the PR segment (corresponding to the atrial ST segment) is, as described below, also an important marker of acute pericarditis and, more rarely, atrial infarction.

AV Node Conduction and the PR Segment

The *PR segment* is the isoelectric region beginning with the end of the P wave and ending with onset of the QRS complex. It forms part of the *PR interval*, which extends from onset of the P wave to onset of the QRS complex. The normal PR interval measures 120 to 200 milliseconds in duration.

The PR segment is the temporal bridge between atrial activation and ventricular activation. It is during this period that activation of the AV node, the bundle of His, the bundle branches, and the intraventricular specialized conduction system occurs. As noted above, atrial repolarization also occurs during this period. Most of the conduction delay during this segment is due to slow conduction within the AV node.[24]

Upon exiting the AV node, the impulse traverses the bundle of His to enter the bundle branches and then travels through the specialized intraventricular conduction paths to finally activate ventricular myocardium. The PR segment appears isoelectric because the potentials generated by these structures are too small to produce detectable voltage on the body surface at the normal amplifier gains used in clinical electrocardiography. The standard ECG detects only activation and recovery of working myocardium, not the specialized conduction system. Signals from elements of the conduction system can be recorded from the body surface by using very high gains (over 25,000) and signal-averaging techniques[25] or from intracardiac recording electrodes placed against the base of the interventricular septum near the bundle of His, as described in Chapter 25 .

Ventricular Activation and the QRS Complex

Ventricular excitation is the product of two temporally overlapping functions--*endocardial activation* and *transmural activation*.[26] Endocardial activation is guided by the anatomical distribution and physiology of the His-Purkinje system. The broadly dispersed ramifications of this treelike or fractal system[27] and the rapid conduction within it result in depolarization of most of the endocardial surfaces of both ventricles within several milliseconds and the simultaneous activation of multiple endocardial sites.

The sequence of ventricular endocardial activation is depicted in Figure 5-12. Earliest activity begins in three sites: (1) the anterior paraseptal wall of the left ventricle, (2) the posterior paraseptal wall of the left ventricle, and (3) the center of the left side of the septum. These loci generally correspond to the sites of insertion of the three branches of the left bundle branch. Wave fronts spread from these sites in anterior and superior directions to activate the anterior and lateral walls of the left

ventricle. The posterobasal areas of the left ventricle are the last to be activated. Septal activation begins in the middle third of the left side and spreads across the septum from left to right and from apex to base.

Excitation of the right ventricle begins near the insertion point of the right bundle branch close to the base of the anterior papillary muscle and spreads to the free wall. The final areas to be involved are the pulmonary conus and posterobasal areas. Thus, in both ventricles, the overall endocardial excitation pattern begins on septal surfaces and

Figure 5-12 Activation sequence of the normal right and left ventricles. A portion of the left and right ventricles has been removed to visualize the endocardial surfaces of the ventricles and the interventricular septum. Isochrone lines connect sites that are activated at equal instants after the earliest evidence of ventricular activation.*(From Durrer D: Electrical aspects of human cardiac activity: A clinical-physiological approach to excitation and stimulation. Cardiovasc Res 2:1, 1968.)*

sweeps down and around the anterior free walls to the posterior and basal regions in an apex-to-base direction.

The activation fronts then move from endocardium to epicardium. Excitation of the endocardium begins at sites of Purkinje-ventricular muscle junctions and proceeds by muscle cell-to-muscle cell conduction in an oblique direction toward the epicardium.

This sequence of endocardial and transmural activation results in the characteristic waveforms of the QRS complex. QRS patterns are described by the sequence of waves constituting the complex. An initial negative deflection is called the *Q wave*, the first positive wave is the *R wave,* and the first negative wave after a positive wave is the *S wave*. A second upright wave following an S wave is an *R wave*. Tall waves are denoted by capital letters and smaller ones by lowercase letters. A monophasic negative complex is referred to as a *QS complex*. Thus, for example, the overall QRS complex may be described as qRS if it consists of an initial small negative wave (the q wave) followed by a tall upright one (the R wave) and a deep negative one (an S wave). In an RSr complex, initial R and S waves are followed by a small positive wave (the r wave).

The complex pattern of activation described above can be simplified into two vectors representing septal and left ventricular free wall activation (Fig. 5-13) . Initial activation of the interventricular septum corresponds to a vector oriented from left to right in the frontal plane and anteriorly in the horizontal plane, as determined by the anatomical position of the septum within the chest. This arrangement produces an initial positive wave in leads with axes directed to the right (lead aV_r) or anteriorly (lead V_1). Leads with axes directed to the left (leads I, aV_l , V_5 , and V_6) will register initial negative waves (*septal q waves*). These initial forces are normally of low amplitude and are brief (less than 40 milliseconds). Absence of these septal q waves is associated with septal infarction or fibrosis and commonly correlates with other ECG evidence of myocardial infarction[28] and left ventricular mechanical dysfunction.[29]

Subsequent parts of the QRS complex reflect activation of the free walls of the left and right ventricles. Because right ventricular muscle mass is considerably smaller than that of the left ventricle, it contributes little to QRS complexes recorded in the standard ECG. Thus, the second phase of the normal QRS can be considered to represent only left ventricular activity with relatively little oversimplification.

Once free wall activation begins, leads with leftward axes (leads I, aV_l , V_5 , and V_6) show positive deflections following the initial septal q waves. Leads with axes oriented to the right (including lead aV_r) record negative potentials. As activation proceeds, the height of the R waves and the depth of the S waves progressively increase. Thus, leads I, aV_l , V_5 , and V_6 typically show qR patterns and lead aV_r registers rS waveforms.

The forms of the QRS complex frontal plane leads are variable and reflect differences in the mean QRS electrical axis. The normal mean QRS axis in adults lies between -30 degrees and +90 degrees. Mean QRS axes more positive than +90 degrees represent *right axis deviation,* and those more negative than -30 degrees represent *left axis deviation*. Mean axes lying between -90 and -180 degrees (or equivalently between +180 and +270 degrees) are referred to as *extreme axis deviations*. The designation *indeterminate axis* is applied when all six extremity leads show biphasic (QR or RS) patterns; this finding can occur as a normal variant or may be seen in a variety of pathological conditions.[30]

The wide span of the normal axis results in a range of QRS patterns, especially in the inferior leads. This characteristic can be understood by referring to the hexaxial reference system in Figure 5-8 . If the mean axis is near 90 degrees, the QRS complex in leads II, III, and aV_f will be predominantly upright with qR complexes; lead I will record an isoelectric qRS pattern because the heart vector lies perpendicular to the lead axis. This configuration is commonly referred to as a *vertical heart* position, although it probably has little to do with the anatomical position of the heart within the chest.[13] If the mean axis is nearer 0 degrees, the patterns will be reversed; lead I (and aV_l) will register a predominantly upright qR pattern, and leads II, III, and aV_f will show rS or RS patterns, a configuration often referred to as a *horizontal heart* pattern.

PRECORDIAL LEADS.

In the precordial leads V_1 and V_2 , free wall activation generates S waves following the initial r waves. These S waves are produced by the spread of activation in the free wall to the left and posteriorly, with generation of a heart vector directed away from the axes of these leads. Thus, these leads are characterized by rS patterns.

Patterns in the midprecordial leads V_3 and V_4 are more variable. Potentials sensed in these leads reflect, as in the case of the right precordial leads, the activation front in the ventricular free wall approaching the exploring electrode, followed by it moving leftward and posterior to more remote regions of the left ventricle. This front generates an R or r wave and later an S wave to produce rS or RS complexes in these leads. As the exploring electrode moves laterally to the left, however, the R wave becomes more dominant and the S wave becomes smaller because of the greater time period during which the activation front moves toward the positive end of the electrode.

Thus, in the precordial leads, the QRS complex is usually characterized by consistent progression from an rS complex in the right precordial leads to a qR pattern in the left precordial leads. The point during this transition at which the pattern changes from an rS to an Rs configuration,

Figure 5-13 Schematic representation of ventricular depolarization as two sequential vectors representing septal *(left)* and left ventricular free wall *(right)* activation. QRS waveforms generated by each stage of activation in leads V_1 and V_6 are shown.

that is, the lead in which an isoelectric RS pattern is present, is known as the *transition zone* and normally occurs in leads V_3 or V_4 . An example of a normal precordial QRS pattern is shown in Figure 5-11 . Transition zones shifted to the right, i.e., to lead V_2 , are referred to as *early transitions,* and those shifted leftward to V_5 or V_6 are *delayed transitions*. These variations in the horizontal plane axis are sometimes described as *counterclockwise* and *clockwise rotations*, respectively, although these descriptors do not necessarily correlate with cardiac anatomical findings.

QRS DURATION.

The upper normal value for QRS duration is traditionally given as <120 milliseconds. In a survey of 1224 men with normal QRS morphology and frontal plane axis, the 98 percent upper bound of QRS duration was 116 milliseconds.[31] Women, on average, have somewhat smaller (about 5 to 8 milliseconds) QRS durations than men do.[32]

An additional feature of the QRS complex is the *intrinsicoid deflection*. An electrode overlying the ventricular free wall will record a rising R wave as transmural

activation of the underlying ventricular free wall proceeds. Once the activation front reaches the epicardium, the full thickness of the wall under the electrode will be in an active state with no propagating electrical activity. At that moment, the electrode will register negative potentials from remote cardiac areas still undergoing activation. The sudden reversal of potential with a sharp downslope is the intrinsicoid deflection and marks the timing of activation of the epicardium under the electrode.

Ventricular Recovery and the ST-T Wave

The normal ST-T wave begins as a low-amplitude, slowly changing wave (the *ST segment*) that gradually leads to a larger wave, the *T wave*. Onset of the ST-T wave is the *junction* or *J point* and is normally at or near the isoelectric baseline of the ECG (see Fig. 5-10) .

The polarity of the ST-T wave is generally the same as the net polarity of the preceding QRS complex. Thus, T waves are upright in leads I, II, aV_l , aV_f , and the lateral precordial leads. They are negative in leads aV_r and variable in leads III and V_1 through V_3 .

Like activation, recovery in the ventricles occurs in a characteristic geometrical pattern. Differences in recovery timing occur both across the ventricular wall and between regions of the left ventricle. Transmural differences in recovery times are the net result of two effects--differences in action potential duration across the ventricular wall and the relatively slow spread of activation across the wall.[33] As activation moves from endocardium to epicardium, sites further away from the endocardium are activated later and later in sequence. However, action potential durations are longest near the endocardium and shortest near the epicardium, which produces a transmural gradient in recovery periods. Differences in action potential duration are greater than differences in activation times, so recovery is completed near the epicardium before it is completed near the endocardium. For example, one endocardial site may be excited 10 milliseconds earlier than the overlying epicardium (that is, transmural activation may require 10 milliseconds), and the action potential duration at the endocardium may be 22 milliseconds longer than on the epicardium. As a result, recovery will be completed 12 milliseconds earlier in the epicardium than in the endocardium.

The resulting recovery dipole will then be directed from sites of less recovery (that is, the endocardium) toward sites of greater recovery (that is, near the epicardium). The orientation of this dipole is in the same direction as transmural activation dipoles and is contrary to the expected direction as described earlier in this chapter; this difference is due to the presence of nonuniform recovery properties across the wall. If recovery times were uniform across the wall (or if differences in recovery times were less than differences in transmural activation times), the recovery dipole would have been directed toward the endocardium, that is, in the direction opposite the activation dipole. The result is, in normal persons, *concordant* QRS and ST-T wave patterns.

Regional differences in recovery properties likewise exist. Under normal conditions, it is the transmural gradients that predominantly determine ST patterns. However, as will be described, these regional differences account for the discordant ST-T patterns observed with intraventricular conduction defects.

THE QRST ANGLE.

This concordance between orientation of the QRS complex and ST-T wave can also be expressed vectorially. An angle can be visualized between the vector representing the mean QRS force and that representing the mean ST-T force--the *QRST angle*. This angle in the frontal plane is normally less than 60 degrees and usually under 30 degrees. Abnormalities of the QRST angle reflect abnormal relationships between the properties of activation and recovery.

THE VENTRICULAR GRADIENT.

If the two vectors representing mean activation and mean recovery forces are added, a third vector known as the *ventricular gradient* is created. The concept of the ventricular gradient was developed to assess differences in the properties of ventricular activation and recovery. According to this concept, the more variability that exists in regional repolarization properties, the greater the difference from zero of the sum of the QRS and ST-T areas will be. In other words, the net QRST area, as measured by the ventricular gradient, correlates with the magnitude of regional differences in recovery properties. In addition, because changes in activation patterns produced by, for example, bundle branch block also cause corresponding changes in recovery patterns (see below), the ventricular gradient should allow a measure of regional recovery properties that is independent of the activation pattern. This measurement has possible relevance to the genesis of reentrant arrhythmias that are due, in part, to regional variations in refractory periods.

The U Wave

The T wave may be followed by an additional low-amplitude wave known as the *U wave*. It is usually under 100 muV in amplitude, normally has the same polarity as the preceding T wave, and is largest in the midprecordial leads and at slow heart rates. Its basis in cardiac electrophysiology is uncertain, but it may be caused by repolarization of the Purkinje fibers or by delayed repolarization in areas of the ventricle that undergo late mechanical relaxation.[34]

The QT Interval

A final interval of the ECG waveform is the *QT interval*, which is measured from the beginning of the QRS complex to the end of the T wave. It includes the total duration of ventricular activation and recovery and, in a general sense, corresponds to the duration of the ventricular action potential.

The normal QT interval is defined by its duration, measured in milliseconds. Like the ventricular action potential duration, the duration of the QT interval decreases as heart rate increases. Thus, the normal range for the QT interval is rate dependent. One formula for relating QT interval duration to heart rate was developed by Bazett in 1920. The result is computation of a *corrected QT interval,* or QT_c , by using the equation $QT_c = QT/(R - R)^{½}$ where the QT and RR intervals are measured in seconds. The normal QT_c is generally accepted to be less than or equal to 440 milliseconds. Some studies suggest that it may be 20 milliseconds longer, and it is slightly longer, on average, in women (see Chapter 25) . Because the end of the T wave can overlap with the beginning of a U wave, the QT interval is sometimes referred to as the *QT(U) interval*; this designation is particularly appropriate when considering the ECG effects of certain metabolic abnormalities that alter the duration of repolarization and the amplitude of the U wave (see below).

The Bazett formula, while widely used to adjust the QT interval duration for the effects of heart rate, has limited accuracy in predicting the effects of heart rate on the QT interval. Many other formulas and methods for correcting the QT interval for the effects of heart rate, including logarithmic, hyperbolic, and exponential functions, have been developed and tested, but they also have limitations.[35] [36] These limitations result from both physiological and computational problems. On one hand, the Bazett formula predicts an ever-increasing increment in the QT interval as the heart rate slows and an ever-decreasing increment as the rate rises, both of which are physiologically improbable. In addition, all these formulas do not account for the effects of autonomic tone on the QT interval independent of the effects on rate. They also do not account for the relatively slow adaptation of repolarization to changes in rate; for example, several minutes

may be required for the QT interval to reach a new steady state after an abrupt change in heart rate.

A second property of the QT interval is that its duration is lead dependent, that is, the duration of the QT interval varies from lead to lead. In normal persons, the QT interval varies between leads by up to 50 milliseconds and is longest in the midprecordial leads V_2 and V_3 . This range of intervals, referred to as *QT interval dispersion*,[37] [38] may be related to electrical instability and the risk of ventricular arrhythmogenesis.[38A]

Normal Variants

These descriptions of the waveforms of the normal ECG represent patterns most often observed in normal adults. It is important to understand the limitations of assigning and interpreting normal ranges to ECG measurement. Values for many of the intervals and amplitudes to be described vary widely within the population as a function of age, race, gender, and body habitus and within individuals as a function of autonomic tone and activity level. Thus, what is normal in one condition may be abnormal in another. Tables of values for these and other measures for different population subgroups have been published.[39] Some variations have been described above, including, for example, variations in rate, QRS axis, and QT intervals.

Other common variations occur in patterns of the ST segment and T wave. These variations are important to recognize because they may be mistaken for significant abnormalities. First, ST-T patterns are affected by maneuvers that change autonomic tone. For example, changing body position, hyperventilating, drinking cold water,

and performing the Valsalva maneuver can produce modest ST segment depression and T wave inversion in as many as one-third of subjects.[40]

T waves can be inverted in the right precordial leads (Fig. 5-14). In adults, this inversion reflects the uncommon, but not necessarily abnormal persistence of patterns commonly seen in infants and children. T waves can be inverted in all precordial leads at birth and usually become more limited to the right side of the chest as time passes; by the age of 10 years, T wave inversion is generally limited to leads V_1 and V_2 . A *persistent juvenile pattern* is more common in women than in men and among the black population than among other racial or ethnic groups.[41]

Figure 5-14 Normal tracing with a juvenile T wave inversion pattern in leads V_1 , V_2 , and V_3 , as well as early repolarization pattern manifested by ST segment elevation in leads I, II, aV_f , V_4 , V_5 , and V_6 . *(Courtesy of C. Fisch, M.D.)*

Second, the ST segment can be significantly elevated, especially in the midprecordial leads (Fig. 5-15). The elevation begins from an elevated J point, is usually concave in form, is commonly associated with notching of the downstroke of the QRS complex, and can reach 500 muV in amplitude.[42] This pattern is more common at slow than at rapid heart rates and in men than in women and is most often seen among black men.[41] [42A] Although this physiological ST segment elevation pattern is commonly referred to as *early repolarization*, clinical studies have failed to demonstrate an earlier than normal onset of ventricular recovery.[43]

THE ABNORMAL ELECTROCARDIOGRAM

Atrial Abnormalities

Various pathological and physiological events alter the normal sequence of atrial activation and produce abnormal P wave patterns in the ECG. Three general categories of P

Figure 5-15 Normal variant pattern with functional ST elevations ("early repolarization" variant). These benign ST segment elevations are usually most marked in the midprecordial leads (V_4 here). Note the absence of reciprocal ST depression (except in lead aV_r), as well as the absence of PR segment deviation, which may be helpful in the differential diagnosis of ischemia and pericarditis, respectively. Note also that lead II has a baseline recording shift. *(From Goldberger AL: Myocardial Infarction: Electrocardiographic Differential Diagnosis. 4th ed. St Louis, Mosby-Year Book, 1991.)*

wave changes will be described, including those reflecting abnormal sites or patterns of activation, those caused by left atrial abnormalities, and those resulting from right atrial abnormalities.

ABNORMAL SITES OF ATRIAL ACTIVATION.

Shifts in the site of initial activation away from the SA node to other, ectopic sites can lead to major changes in the pattern of atrial activation and, hence, in the morphology of P waves.[44] These shifts can occur either as escape rhythms if the normal SA nodal pacemaker fails or as accelerated ectopic rhythms if the automaticity of an ectopic site is enhanced (see AV dissociation, Chap. 25) . The resulting ECG abnormalities most commonly include recording negative P waves in the leads in which P waves are normally upright (leads I, II, aV_f , and V_4 through V_6), with or without shortening of the PR interval.

P wave patterns may suggest the site of impulse formation based on simple vectorial principles.[44A] For example, a negative P wave in lead I predicts a left atrial rhythm. Inverted P waves in the inferior leads normally correspond to a posterior atrial site. Because of the uncertainties with this localization, these ECG patterns can as a group be referred to as *ectopic atrial rhythms*.

Left Atrial Abnormality

ECG ABNORMALITIES.

Anatomical or functional abnormalities of the left atrium alter the morphology, duration, and amplitude of the P waves in the clinical ECG. Specific abnormalities include increases in the amplitude and duration of the P wave in the limb leads, as well as an increase in the amplitude of the terminal negative portion of the P wave in lead V_1 . These features are illustrated in Figures 5-16 and 5-17 .

DIAGNOSTIC CRITERIA.

Commonly used criteria for diagnosing left atrial abnormality are listed in Table 5-3 .

MECHANISMS FOR ECG ABNORMALITIES.

These ECG patterns may reflect increases in left atrial mass or chamber size or reflect conduction delays within the atria. Increasing mass causes increased P wave amplitudes. Because the left atrium is activated (in general) late during the P wave, the increased electrical force accounts for the prolonged P wave duration and the augmented P terminal force in the right precordial leads.

Clinical conditions associated with these patterns also correlate with delays in interatrial conduction. For example, the interval between the onset of the P wave marking the onset of right atrial activation and the onset of left atrial activation is commonly prolonged. This delay prolongs P wave duration and shortens the PR segment. It also reduces the overlap between right and left atrial activation so that the ECG patterns generated by each atrium are separated as two notches in lead II (*P mitrale*).

DIAGNOSTIC ACCURACY.

The diagnostic accuracy of these criteria is limited. Comparison of the various ECG abnormalities to echocardiographic criteria for left atrial enlargement demonstrates limited sensitivity but high specificity for the ECG criteria. For example, recent studies have demonstrated that the presence of classic P mitrale patterns has a sensitivity of only 20 percent but a specificity of 98 percent for detecting echocardiographically enlarged left atria[45] and that P wave duration has limited correlation with left atrial pressure and dimension.[46] Others have reported better correlations of these ECG abnormalities with ventricular dysfunction (e.g., with reduced ventricular compliance) than with atrial morphology.[47] Because of the correlation of these ECG features with high atrial pressure, intraatrial conduction defects, and ventricular dysfunction, as well as increased atrial size, these ECG abnormalities are preferably referred to as criteria for *left atrial abnormality* rather than left atrial enlargement.

CLINICAL SIGNIFICANCE.

ECG findings of left atrial abnormality are associated with more severe left ventricular dysfunction in patients with ischemic heart disease and with more severe valve damage in patients with mitral or

Figure 5-16 Schematic representation of atrial depolarization *(diagram)* and P wave patterns associated with normal atrial activation (left panel) and with right *(middle panel)* and left *(right panel)* atrial abnormalities. *(Modified from Park MK, Guntheroth WG: How to Read Pediatric ECGs. 3rd ed. St Louis, Mosby-Year Book, 1993.)*

Figure 5-17 Biatrial abnormality, with tall P waves in lead II (right atrial abnormality) and an abnormally large terminal negative component of the P wave in lead V_1 (left atrial abnormality). The P wave is also notched in lead V_5 .

aortic valve disease.[48] Patients with left atrial changes may have paroxysmal atrial tachyarrhythmias.

Right Atrial Abnormality

ECG ABNORMALITIES.

ECG features of *right atrial abnormality* are illustrated in Figures 5-16 and 5-17 . They include abnormally high P wave amplitudes in the limb and right precordial leads. As in the case of left atrial abnormality, the term *right atrial abnormality* is preferred over others such as right atrial enlargement.

DIAGNOSTIC CRITERIA.

Criteria commonly used to diagnose right atrial abnormality are listed in Table 5-3 .

MECHANISMS FOR ECG ABNORMALITIES.

Greater right atrial mass generates greater electrical force early during overall atrial activation, with production of taller P waves and augmentation of the initial P wave deflection in lead V_1 . In patients with chronic lung disease, the abnormal P pattern may reflect a more vertical heart position within the chest caused by pulmonary hyperinflation rather than true cardiac damage. The QRS changes commonly associated with right atrial abnormalities correspond to the underlying pathology that is producing the right atrial hemodynamic changes--right ventricular hypertrophy (RVH), which produces tall R waves in the right precordial leads, and a shift of the position of the heart within the chest by obstructive lung disease, which produces initial Q waves.

DIAGNOSTIC ACCURACY.

As in the case of ECG criteria for left atrial abnormality, the finding of right atrial abnormality has limited sensitivity but high specificity. Echocardiographic correlations have shown, for example, that P pulmonale has very low sensitivity but very high specificity for detecting right atrial enlargement.[49] The highest sensitivities are found for cases with a P wave initial force in lead V_1 of over 0.06 mm-sec (38 percent) or with low-amplitude QRS complexes in lead V_1 (33 percent).

CLINICAL SIGNIFICANCE.

ECG findings of right atrial abnormality are found in patients with chronic obstructive pulmonary disease. Patients with this ECG pattern have more severe pulmonary dysfunction, as well as significantly reduced survival.[50] However, comparison of ECG and hemodynamic parameters has not demonstrated a close correlation of P wave patterns and right atrial hypertension.[51]

Other Atrial Abnormalities

Patients with abnormalities in both atria--that is, biatrial abnormality--may have ECG patterns reflecting each defect. Suggestive findings include large biphasic P waves in lead V_1 and tall and broad P waves in leads II, III, and aV_f (see Fig. 5-17) .

P wave and PR segment changes can also be seen in patients with atrial infarction or pericarditis. The changes caused by these conditions will be described later in this chapter.

Ventricular Hypertrophy and Enlargement

Left Ventricular Hypertrophy and Enlargement

ECG ABNORMALITIES.

Left ventricular hypertrophy (LVH) or enlargement produces changes in the QRS complex, the ST segment, and the T wave. The most characteristic finding is increased amplitude of the QRS complex. R waves in leads facing the left ventricle (that is, leads I, aV_l , V_5 , and V_6) are taller than normal, while S waves in leads overlying the right ventricle (that is, V_1 and V_2) are deeper than normal. These changes are illustrated schematically in Figure 5-18 .

ST-T wave patterns vary widely in patients with left ventricular enlargement and hypertrophy. ST segment and T wave amplitudes may be normal or increased in leads with tall R waves. In many patients, however, the ST segment is depressed and followed by an inverted T wave (Fig. 5-19) . Most often, the ST segment slopes downward from a depressed J point and the T wave is asymmetrically inverted. These repolarization changes usually occur in patients with QRS changes but can appear alone. Particularly prominent inverted T waves, or so-called *giant negative T waves*, are characteristic of hypertrophic cardiomyopathy

TABLE 5-3 -- COMMON DIAGNOSTIC CRITERIA FOR LEFT AND RIGHT ATRIAL ABNORMALITIES*

LEFT ATRIAL ABNORMALITY
Prolonged P wave duration of >120 msec in lead II
Prominent notching of the P wave, usually most obvious in lead II, with an interval between the notches of >40 msec (*p mitrale*)
Ratio between the duration of the P wave in lead II and the duration of the PR segment of >1.6
Increased duration and depth of the terminal negative portion of the P wave in lead V_1 (the *P terminal force*) so that the area subtended by it exceeds 0.04 mm-sec
Leftward shift of the mean P wave axis to between -30 and +45 degrees
RIGHT ATRIAL ABNORMALITY
Peaked P waves with amplitudes over 250 muV in lead II (*p pulmonale*)
Rightward shift of the mean P wave axis to above 75 degrees
Increased area under the initial positive portion of the P wave in lead V_1 to >0.06 mm-sec

*In addition to criteria based on P wave morphologies, right atrial abnormalities are suggested by QRS changes, including (1) Q waves (especially qR patterns) in the right precordial leads without evidence of myocardial infarction and (2) low amplitude (under 600 muV) QRS complexes in lead V_1 with a threefold or greater increase in lead V_2 .

Figure 5-18 Left ventricular hypertrophy (LVH) increases the amplitude of electrical forces directed to the left (and posteriorly). In addition, repolarization abnormalities can cause ST segment depression and T wave inversion in leads with a prominent R wave (formerly referred to as a "strain" pattern). Right ventricular hypertrophy (RVH) can shift the QRS vector to the right; this effect is usually associated with an R, RS, or qR complex in lead V_1 , especially when due to severe pressure overload. T wave inversions may be present in the right precordial leads.*(From Goldberger AL:*

Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)

with predominant apical thickening, especially in patients from the Pacific Rim (Yamaguchi syndrome)[52] (see also Fig. 5-48) .

Other ECG changes can also be seen in LVH, including widening and notching of the QRS complex. An increase in QRS duration beyond 110 milliseconds and a delay in the intrinsicoid deflection may reflect the longer duration of activation in a thickened ventricular wall or damage to the ventricular conduction system. Notching of the QRS complex may also be observed.

These ECG features are most typical of LVH induced by pressure or "systolic" overload of the left ventricle. Volume overload or "diastolic overload" can produce a somewhat different ECG pattern, including tall, upright T waves and sometimes narrow (under 25 milliseconds), but deep (0.2 mV or greater) Q waves in leads facing the left side of the septum (Fig. 5-20) . The diagnostic value of these changes in predicting the underlying hemodynamics is, however, very limited.

MECHANISMS FOR ECG ABNORMALITIES.

High voltages may be produced by any of several mechanisms. They may be due directly to an increase in left ventricular mass. This increase in mass is due to an enlargement in cell size, with an increase in surface area increasing transmembrane current flow and an increase in the number of intercalated disks enhancing intercellular current flow. This effect is augmented by an increase in the size of activation fronts moving across the thickened wall; these larger wave fronts subtend larger solid angles and result in higher body surface voltage. The high voltage as well as QRS prolongation may also be due to conduction system delays.[53] The delay in intrinsicoid deflection is a result of the prolonged transmural activation time required to activate the thickened wall, as well as delayed endocardial activation, while notching may be produced by the fractionation of activation wave fronts by intramural scarring associated with wall thickening and damage.

In addition, changes in transmission factors can contribute to ECG abnormalities. Left ventricular enlargement can shift the position of the heart so that the lateral free wall lies closer than normal to the chest wall, which as described above, would increase body surface potentials in accordance with the inverse square law. Also, ventricular dilatation increases the size of the highly conductive intraventricular blood pool.[4] This enhanced blood volume results in an increase in potentials produced by transmural activation fronts, a phenomenon referred to as the *Brody effect*.

Repolarization abnormalities may reflect a primary disorder of repolarization that accompanies the cellular processes of hypertrophy.

Figure 5-19 Marked left ventricular hypertrophy (LVH) pattern with prominent precordial lead QRS voltages. ST depression and T wave inversion may be seen with severe LVH in leads with a predominant R wave (compare with Fig. 5-20) . Left atrial abnormality is also present.

Figure 5-20 Left ventricular hypertrophy with prominent positive anterior T waves from a patient with severe aortic regurgitation. This pattern has been described with "diastolic overload" syndrome but has limited sensitivity and specificity. Serum potassium was normal.

Alternatively, they may reflect subendocardial ischemia. Patients with LVH may have coronary artery disease; hypertension--a major cause of ventricular hypertrophy--is a risk factor for coronary atherosclerosis. Ischemia may be induced in the absence of coronary artery disease by the combination of high oxygen demand caused by high wall tension and limited blood flow to the subendocardium of the thickened wall.

DIAGNOSTIC CRITERIA.

Several sets of diagnostic criteria for LVH have been developed on the basis of these ECG abnormalities. Details of widely used criteria are presented in Table 5-4 . Most commonly used methods assess the presence or absence of LVH as a binary function based on an empirically determined set of criteria. For example, the Sokolow-Lyon and the Cornell[54] voltage criteria require that voltages in specific leads exceed certain values. The Romhilt-Estes point score system assigns point values to amplitude and other criteria; definite LVH is diagnosed if 5 points are computed and probable LVH is diagnosed if 4 points are computed. The Cornell voltage-duration method[55] includes measurement of QRS duration as well as amplitudes.

Other methods seek to quantify left ventricular mass as a continuum. Diagnosis of LVH can then be based on a computed mass that exceeds an independently determined threshold. Two recently developed sets of criteria applying this approach are the Cornell regression equation[54] and the Novacode[56] system.

DIAGNOSTIC ACCURACY.

The relative diagnostic accuracy of these methods has been tested by radiographic, echocardiographic, and autopsy measurements of left ventricular size as standards.[54] [55] In general, these studies have reported low sensitivity and high specificity. Sensitivities are lowest (approximately 10 to 30 percent) for the Sokolow-Lyon and Romhilt-Estes criteria and higher for the Cornell voltage and voltage-duration criteria and for the Cornell and Novacode regression methods (35 to 50 percent). Specificities, in contrast, for all measures vary from 85 percent to 95 percent. Thus, all methods are limited as screening tests in which high sensitivities (few false-negatives) are critical but have good reliability as diagnostic tests when few false-positives are desired.

TABLE 5-4 -- COMMON DIAGNOSTIC CRITERIA FOR LEFT VENTRICULAR HYPERTROPHY

Sokolow-Lyon index	
S_{V1} +(R_{V5} or R_{V6})>3.5 mV	
R_{aVl} >1.1 mV	
Romhilt-Estes point score system *	
Any limb lead R wave or S wave 2.0 mV	3 points
S_{V1} or S_{V2} 3.0 mV	3 points
R_{V5} to R_{V6} 3.0 mV	3 points
ST-T wave abnormality (no digitalis therapy)	3 points
ST-T wave abnormality (digitalis therapy)	1 point
P terminal force in V_1 >4 mV-msec	3 points
Left axis deviation	1 point
Intrinsicoid deflection in V_5 or V_6 50 msec	1 point
Cornell voltage criteria [54]	
S_{V3} +R_{aVl} 2.8 mV (for men)	
S_{V3} +R_{aVl} 2.0 mV (for women)	
Cornell regression equation[54]	

Risk=1/(1+e^{-exp})

Where

$$exp=4.558-0.092\ (R_{aV1}+S_{V3})-0.306\ T_{V1}-0.212\ QRS-0.278\ PTF_{V1}-0.859\ (sex)$$

Where voltages are in mV, QRS is QRS duration in mV, PTF is the area in the P terminal force in lead V_1 (in mm-sec), and sex=1 for men and 2 for women; LVH is present if exp is less than -1.55

Cornell voltage-duration measurement[55]

QRS duration×Cornell Voltage>2436

QRS duration×sum of voltages in all 12 leads>17,472

Novacode criterion (for men) [56]

LVMI (gm/m^2)=-36.4+0.010 R_{V5} +0.20 S_{V1} +0.28 S_{III} + 0.182 $T_{(neg)}$ V_6 -0.148 $T_{(pos)}$ aV_r + 1.049 $QRS_{duration}$

where neg and pos refer to amplitudes of the negative and positive portions of the T waves, respectively; S indicates the amplitude of the S, Q, and QS wave, whichever is larger

*Probable left ventricular hypertrophy is diagnosed if 4 points are present and definite left ventricular hypertrophy is diagnosed if 5 or more points are present.

LVH=left ventricular hypertrophy; LVMI=left ventricular mass index.R/S in V_1 >1 with R >0.5 mV SENSITIVITY SPECIFICITY

Several reasons may be suggested for the limited accuracy of these criteria. Many of the clinical studies that were used to define the criteria included a disproportionate number of white men, thus limiting applicability of the tests to other populations; LVH is more common among blacks.[57] In addition, the criteria for dichotomous tests such as the Sokolow-Lyon and Cornell voltage criteria are based on quantitative differences in normally occurring measures, i.e., QRS voltage, between normal and abnormal cohorts; these tests by their nature are limited to detecting only the extreme end of the spectrum of LVH because milder degrees overlap with normal populations.[58] Finally, these voltage measurements are subject to the influence of many noncardiac factors, such as body habitus, which blurs the distinction between normal and abnormal.[59] [59A]

CLINICAL SIGNIFICANCE.

The presence of ECG criteria for LVH identify a subset of the general population with a significantly increased risk for cardiovascular morbidity and mortality.[56] [57] [58] [59] [59A] [60] This increased risk is particularly true in women and if ST-T wave abnormalities are present; the relative risk of cardiovascular events for patients with LVH voltage criteria alone is approximately 2.8, whereas the relative risk increases to over 5.0 if ST segment depression is also present.[57] [61] [62]

In patients with cardiac disease, the ECG finding of LVH correlates with more severe disease, including higher blood pressure in hypertensives and greater ventricular dysfunction in patients with hypertension or coronary artery disease.[63] In contrast, effective treatment of hypertension reduces ECG evidence of LVH and decreases the associated risk of cardiovascular mortality.[61] Patients with repolarization abnormalities have, on average, more severe degrees of LVH and more commonly have symptoms of left ventricular dysfunction,[64] in addition to a greater risk of cardiovascular events.[61]

Right Ventricular Hypertrophy and Enlargement

ECG ABNORMALITIES.

The ECG changes invoked by RVH or right ventricular enlargement are different from those produced by left ventricular enlargement because the right ventricle is considerably smaller than the left ventricle and produces electrical forces that are largely canceled by those generated by the larger left ventricle. Thus, for RVH to be manifested on the ECG, it must be severe enough to overcome the canceling effects of the larger left ventricular forces. In addition, increasing dominance of the right ventricle changes the ECG in fundamental ways, whereas an enlarged left ventricle produces predominantly quantitative changes in underlying normal waveforms.

ECG changes associated with moderate to severe concentric hypertrophy of the right ventricle[65] include abnormally tall R waves in anteriorly and rightward directed leads (leads aV_r , V_1 , and V_2) and deep S waves and abnormally small r waves in leftward directed leads (I, aV_l , and lateral precordial leads) (see Figs. 5-18 and 5-21) . These changes result in a reversal of normal R wave progression in the precordial leads, a shift in the frontal plane QRS axis to the right, and sometimes the presence of S waves in leads I, II, and III (*so-called S_1 S_2 S_3 pattern*).

Several other ECG patterns of RVH also exist. Less severe hypertrophy, especially when limited to the outflow tract of the right ventricle that is activated late during the QRS complex, produces less marked changes. ECG abnormalities may be limited to an rSr pattern in V_1 and persistence of s (or S) waves in the left precordial leads. This pattern is typical of right ventricular volume overload as produced by an atrial septal defect.

Chronic obstructive pulmonary disease can induce ECG changes by producing RVH, changes in the position of the heart within the chest, and hyperinflation of the lungs (Fig. 5-22). QRS changes caused by the insulating and positional changes produced by hyperinflation of the lungs include reduced amplitude of the QRS complex, right axis deviation in the frontal plane, and delayed transition in the precordial leads (probably reflecting a vertical and caudal shift in heart position because of hyperinflation and a flattened diaphragm). Evidence of true RVH includes (1) marked right axis deviation (more positive than 110 degrees), (2) deep S waves in the lateral precordial leads,

Figure 5-21 Right ventricular hypertrophy pattern most consistent with severe pressure overload. Note the combination of findings, including (1) a tall R wave in V_1 (as part of the qR complex), (2) right axis deviation, (3) T wave inversion in V_1 through V_3 , (4) delayed precordial transition zone (rS in V_6), and (5) right atrial abnormality. An S_1 Q_3 pattern is also present and can occur with acute or chronic right ventricular overload syndrome.

Figure 5-22 Pulmonary emphysema simulating anterior infarction in a 58-year-old man with no clinical evidence of coronary disease. Note the relative normalization of R wave progression with placement of the chest leads an interspace below their usual position ($5V_1$, $5V_2$, and so forth). *(From Chou TC: Pseudo-infarction (noninfarction Q waves). In Fisch C [ed]: Complex Electrocardiography. Vol 1. Philadelphia, FA Davis, 1973.)*

and (3) *an S_1 Q_3 T_3 pattern*, with an S wave in lead I (as an RS or rS complex), an abnormal Q wave in lead III, and an inverted T wave in the inferior leads.

Finally, acute right ventricular pressure overload such as produced by pulmonary embolism may produce a characteristic ECG pattern (Fig. 5-23) , including (1) a QR or qR pattern in the right ventricular leads; (2) an S_1 Q_3 T_3 pattern with an S wave in lead I and new or increased Q waves in

Figure 5-23 Acute cor pulmonale secondary to pulmonary embolism simulating inferior and anterior infarction. This tracing exemplifies the classic pseudoinfarct patterns sometimes seen: an S_1 Q_3 T_3 ,

a QR in V_1 with poor R wave progression in the right precordial leads ("clockwise rotation"), and right precordial to midprecordial T wave inversion (V_1 to V_4). Sinus tachycardia is also present. The S_1 Q_3 pattern is usually associated with a QR or QS complex, but not an rS, in aV_f. Furthermore, acute cor pulmonale per se does not cause prominent Q waves in II (only in III and aV_f). *(From Goldberger AL: Myocardial Infarction: Electrocardiographic Differential Diagnosis. 4th ed. St Louis, Mosby-Year Book, 1991.)*

TABLE 5-5 -- COMMON DIAGNOSTIC CRITERIA FOR RIGHT VENTRICULAR HYPERTROPHY

CRITERION	SENSITIVITY(%)	SPECIFICITY(%)
R in V_1 0.7 mV	<10	--
QR in V_1	<10	--
R/S in V_1 >1 with R >0.5 mV	25	89
R/S in V_5 or V_6 <1	<10	--
S in V_5 or V_6 0.7 mV	17	93
R in V_5 or V_6 0.4 mV with S in V_1 0.2 mV	<10	--
Right axis deviation (+90 degrees)	14	99
S_1 Q_3 pattern	11	93
S_1 S_2 S_3 pattern	<10	--
P pulmonale	11	97

From Murphy ML, Thenabadu PN, de Soyza N, et al: Reevaluation of electrocardiographic criteria for left, right and combined cardiac ventricular hypertrophy. Am J Cardiol 53:1140-1147, 1984.

lead III and sometimes aV_f, with T wave inversions in those leads; (3) ST segment deviation and T wave inversions in leads V_1 to V_3; and (4) incomplete or complete right bundle branch block (RBBB). Sinus tachycardia is usually present. Arrhythmias such as atrial fibrillation can also occur. However, even with major pulmonary artery obstruction, the ECG is notoriously deceptive and may show little more than minor or nonspecific waveform changes, or it may even be normal.[66] The classic S_1 Q_3 T_3 pattern occurs in only about 10 percent of cases of acute pulmonary embolism. Furthermore, the specificity of this finding is limited since it can occur acutely with other causes of pulmonary hypertension.

DIAGNOSTIC CRITERIA.

These ECG abnormalities form the basis for the diagnostic criteria for RVH. The most commonly relied on criteria for the ECG diagnosis of RVH are listed in Table 5-5 .

MECHANISMS FOR ECG ABNORMALITIES.

These ECG patterns result from three effects of RVH. First, current fluxes between hypertrophied cells are stronger than normal and produce higher than normal voltage on the body surface. Second, activation fronts moving through the enlarged right ventricle are larger than normal and produce higher surface potentials as predicted by the solid angle theorem.[67] Third, the activation time of the right ventricle is prolonged.[67] This last effect is particularly important in producing ECG changes; right ventricular activation now ends after the completion of left ventricular activation, so its effects are no longer canceled by the more powerful forces of the left ventricle and may merge in the ECG. Because the right ventricle is located anterior as well as to the right of the left ventricle, the effects produce increased potentials in leads directed anteriorly and to the right, especially late during the QRS complex. As noted above, changes in cardiac position in patients with obstructive lung disease can produce ECG changes without intrinsic cardiac electrophysiological derangements.

DIAGNOSTIC ACCURACY.

The sensitivity and specificity of the individual ECG criteria are also shown in Table 5-5 . As in the case of ECG criteria for other abnormalities, the sensitivities of individual criteria are low and specificities are high. If any one feature is present, the sensitivity rises to over 50 percent with a specificity of over 90 percent; requiring any two features to make a diagnosis markedly reduces the sensitivity and raises the specificity to very high levels. These low sensitivities may reflect the marked degree of hypertrophy required to produce ECG abnormalities.

CLINICAL SIGNIFICANCE.

ECG evidence of RVH has limited value in assessing the severity of pulmonary hypertension or lung disease. QRS changes do not generally appear until ventilatory function is significantly depressed, with the earliest change commonly being a rightward shift in the mean QRS axis, and correlation with either ventilatory function or hemodynamics is poor. The presence of either right atrial abnormality, an S_1 S_2 S_3 pattern, or both is associated with reduced survival, especially if an increased arterial-alveolar oxygen gradient is also present.[52] ECG findings of acute right ventricular overload in patients with pulmonary embolism correspond to obstruction of over 50 percent of the pulmonary arterial bed and significant pulmonary hypertension.

Biventricular Enlargement

Enlargement or hypertrophy of both ventricles produces complex ECG patterns.[67A] In contrast to biatrial enlargement, the result is not the simple sum of the two sets of abnormalities. The effects of enlargement of one chamber may cancel the effects of enlargement of the other; for example, anterior forces produced by RVH may be canceled by enhanced posterior forces generated by LVH. In addition, the greater left ventricular forces generated in LVH increase the degree of RVH needed to overcome the dominance of the left ventricle.

Because of these factors, specific ECG criteria for either RVH or LVH are seldom observed with biventricular enlargement. Rather, ECG patterns are usually modification of the features of LVH and include (1) tall R waves in both the right and left precordial leads, (2) vertical heart position or right axis deviation in the presence of criteria for LVH, (3) deep S waves in the left precordial leads in the presence of ECG criteria for LVH, or (4) a shift in the precordial transition zone to the left in the presence of LVH. The presence of prominent left atrial abnormality or atrial fibrillation with evidence of right ventricular or biventricular enlargement (especially LVH with a vertical or rightward QRS axis) should suggest chronic rheumatic valvular disease (Fig. 5-24) (see Chap. 46) .

Intraventricular Conduction Delays and Preexcitation

The ECG patterns described in this section reflect abnormalities in the conduction system (see Chaps. 22 , 23 , and 25 .)

Fascicular Blocks

Under normal conditions, activation of the left ventricle begins simultaneously at the insertion sites of the fascicles. Delayed conduction in a fascicle--*fascicular block*--results in activation of these sites sequentially rather than simultaneously and produces an abnormal sequence of early left ventricular activation. This altered sequence produces characteristic ECG patterns. Even modest delays in conduction through the affected structure may be enough to alter ventricular activation

patterns sufficiently to produce characteristic ECG patterns; complete block of conduction is not required.

LEFT ANTERIOR FASCICULAR BLOCK.

Damage to the left anterior fascicle is a very common occurrence because of the delicate nature of the structure. The ECG features of left anterior fascicular block (LAFB) are listed in Table 5-6 and illustrated in Figure 5-25. The most characteristic finding is marked left axis deviation. However, LAFB is not synonymous with left axis deviation. Axis shifts to between -30 and -45 degrees commonly reflect other conditions, e.g., LVH, without conduction system damage and are best referred to as *left axis deviation* rather than LAFB.

Left axis shift is a result of delayed activation of the anterosuperior left ventricular wall. Delayed activation causes unbalanced inferior and posterior forces early during ventricular activation and unopposed anterosuperior forces later during the QRS complex. The abnormal pattern results in initial r waves followed by deep S waves in the inferior

Figure 5-24 This electrocardiogram from a 45-year-old woman with severe mitral stenosis shows multiple abnormalities. The rhythm is sinus tachycardia. Right axis deviation and a tall R wave in lead V_1 are consistent with right ventricular hypertrophy. The very prominent biphasic P wave in lead V_1 indicates left atrial abnormality/enlargement. The tall P waves in lead II suggest concomitant right abnormality. Nonspecific ST-T changes and incomplete right bundle branch block are also present. The combination of right ventricular hypertrophy and marked left or biatrial abnormality is highly suggestive of mitral stenosis. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)*

TABLE 5-6 -- COMMON DIAGNOSTIC CRITERIA FOR UNIFASCICULAR BLOCKS

LEFT ANTERIOR FASCICULAR BLOCK
Frontal plane mean QRS axis of -45 to -90 degrees with rS patterns in leads II, III, and aV_f and a qR pattern in lead aV_l
QRS duration less than 120 msec
LEFT POSTERIOR FASCICULAR BLOCK
Frontal plane mean QRS axis of 120 degrees
RS pattern in leads I and aV_l with qR patterns in inferior leads
QRS duration of less than 120 msec
Exclusion of other factors causing right axis deviation (e.g., right ventricular overload patterns, lateral infarction)

leads (left axis deviation with rS patterns) and a qR pattern in left-looking leads (leads aV_l and usually V_5 and V_6). Initial q waves in these leads reflect the normal left-to-right activation of the septum. The overall QRS duration is not prolonged; fascicular block only alters the sequence of left ventricular activation but does not by itself prolong the overall duration of ventricular excitation or the QRS complex. LAFB usually does not produce prominent changes in the precordial leads. V_1 and V_3 are usually unchanged; V_4 through V_6 commonly show deep S waves related to superiorly directed late QRS forces.[68]

LAFB is common in persons without overt cardiac disease, as well as a wide range of diseases, and has minimal or no independent prognostic significance. Commonly associated

Figure 5-25 Diagrammatic representation of fascicular blocks in left ventricles. Interruption of the left anterior fascicle (LAF) *(left)* results in an initial inferior (1) followed by a dominant superior (2) direction of activation; interruption of the left posterior fascicle (LPF) *(right)* results in an initial superior (1) followed by a dominant inferior (2) direction of activation. AVN=atrioventricular node; HB=His bundle; LB=left bundle; RB=right bundle. *(Courtesy of C. Fisch, M.D.)*

cardiac and systemic conditions include myocardial infarction, especially occlusion of the left anterior descending coronary artery,[69] LVH, hypertrophic and dilated cardiomyopathy, and degenerative diseases. The development of LAFB with rS complexes in II, III, and aV_f can mask the Q waves of a prior inferior myocardial infarction.

LEFT POSTERIOR FASCICULAR BLOCK.

Conduction delay in the left posterior fascicle is considerably less common than delay in the anterior fascicle because of its thicker structure and more protected location near the left ventricular inflow tract. The conduction delay results in sequential activation of the anterosuperior left ventricular free wall, followed by activation of the inferoposterior aspect of the left ventricle, that is, the reverse of the pattern observed with LAFB.

ECG features of left posterior fascicular block (LPFB), listed in Table 5-6 and illustrated in Figure 5-25 , reflect this altered activation pattern. Right axis deviation with rS patterns in leads I and aV_l , as well as qR complexes in the inferior leads, is the result of early unopposed activation forces from the anterosuperior aspect of the left ventricle (producing the initial q and r waves) and late unopposed forces from the inferoposterior free wall (generating the late S and R waves). As in the case of LAFB, the overall activation time of the ventricles is not prolonged and the QRS duration remains normal.

LPFB, like LAFB, can occur in almost any cardiac disease but is unusual in otherwise healthy persons. Other conditions that enhance electrical forces from the right ventricle, such as right ventricular enlargement and extensive lateral infarction, can produce similar ECG patterns and must be excluded before a diagnosis of LPFB is made.

Figure 5-26 Comparison of typical QRS-T patterns in right bundle branch block (RBBB) and left bundle branch block (LBBB) with the normal pattern in leads V_1 and V_6 . Note the secondary T wave inversions (*arrows*) in leads with an rSR
complex with RBBB and in leads with a wide R wave with LBBB. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)*

TABLE 5-7 -- COMMON DIAGNOSTIC CRITERIA FOR BUNDLE BRANCH BLOCKS

COMPLETE LEFT BUNDLE BRANCH BLOCK
QRS duration 120 msec
Broad, notched R waves in lateral precordial leads (V_5 and V_6) and usually leads I and aV_l
Small or absent initial r waves in right precordial leads (V_1 and V_2) followed by deep S waves
Absent septal q waves in left-sided leads
Prolonged intrinsicoid deflection (>60 msec) in V_5 and V_6 [*]

Complete Right Bundle Branch Block
QRS duration 120 msec
Broad, notched R waves (rsr , rsR , or rSR patterns) in right precordial leads (V_1 and V_2)
Wide and deep S waves in left precordial leads (V_5 and V_6)

*Criterion required by some authors.

Left Bundle Branch Block

Left bundle branch block (LBBB) results from conduction delay or block in any of several sites in the intraventricular conduction system, including the main left bundle branch, in each of the two fascicles, or less commonly, within the fibers of the bundle of His that become the main left bundle branch. The result is extensive reorganization of the activation pattern of the left ventricle.

ECG ABNORMALITIES.

LBBB produces a prolonged QRS duration, abnormal QRS complexes, and ST-T wave abnormalities (Fig. 5-26). Commonly accepted diagnostic criteria for LBBB are listed in Table 5-7 . Basic requirements include a prolonged QRS duration to 120 milliseconds or beyond; broad, sometimes notched R waves in leads I and aV_l and the left precordial leads; narrow r waves followed by deep S waves in the right precordial leads; and absent septal q waves. R waves are typically tall and S waves are deep. The mean QRS axis with LBBB is highly variable; it can be normal or deviated to the left. Left axis deviation is associated with more severe conduction system disease that includes the fascicles as well as the main left bundle.[70] In addition to these features, some electrocardiographers require a delayed intrinsicoid deflection (60 milliseconds) to diagnose LBBB.

ST-T wave changes are also prominent with LBBB. In most cases, the ST wave and the T wave are *discordant* with the QRS complex; that is, the ST segment is depressed and the T wave is inverted in leads with positive QRS waves (leads I, aV_l , V_5 , and V_6), while the ST segment is elevated and the T wave is upright in leads with negative QRS complexes (leads V_1 and V_2).

An incomplete form of LBBB may result from lesser degrees of conduction delay in the left bundle branch system. Left ventricular activation begins, as in complete LBBB, on the right side of the septum, but much of left ventricular activation occurs through the normal specialized conduction system. ECG features include (1) loss of septal q waves (reflecting reversal of the normal pattern of septal activation), (2) slurring and notching of the upstroke of R waves (because of the presence of competing activation fronts), and (3) modest prolongation of the QRS complex (between 100 and 120 milliseconds).

MECHANISMS FOR ECG ABNORMALITIES.

The ECG abnormalities of LBBB result from an almost completely reorganized pattern of left ventricular activation. Initial septal activation occurs on the right (rather than on the left) septal surface, and right ventricular excitation occurs earlier than normal. This sequence of septal activation results in the absence of normal septal q waves in the ECG.

The excitation wave then spreads slowly, by conduction from muscle cell to muscle cell, to the left side of the septum; the earliest left ventricular activation begins as late as 30 to 50 milliseconds into the QRS complex. Endocardial activation of the left ventricle may then require an additional 40 to over 180 milliseconds, depending largely on the functional status of the distal left bundle and Purkinje systems.[71] Thus, the overall QRS complex is prolonged and can be very wide in patients with, for example, ventricular scarring from prior myocardial infarction. Once left ventricular activation begins, it proceeds in a relatively simple and direct manner around the free wall and, finally, to the base of the heart. Direct progression of activation

across the left ventricle projects continuous positive forces to left-sided leads and continuous negative ones to right-sided leads. Spread predominantly through working muscle fibers rather than the specialized conduction system results in notching and slurring as a consequence of discontinuous anisotropy, as described above.

The discordant ST-T wave pattern is a result of the transventricular recovery gradients referred to above. With LBBB, the right ventricle is activated and recovers earlier than the left, so recovery vectors or dipoles are directed toward the right and away from the left. Hence, positive ST-T waves will be registered over the right ventricle and negatives ones over the left ventricle. These transventricular gradients play only a minor role in normal conduction because the simultaneous activation of multiple regions cancels the forces that they produce; with bundle branch block, activation is sequential, so cancellation is reduced. Because the ST-T wave changes with LBBB are generated by abnormalities in conduction, they are called *secondary T wave abnormalities*; as will be discussed below, ST-T wave changes produced by direct abnormalities of the recovery process are referred to as *primary T wave abnormalities.*

CLINICAL SIGNIFICANCE.

LBBB usually appears in patients with underlying heart disease. It is associated with significantly reduced long-term survival, with 10-year survival rates as low as 50 percent, probably reflecting the severity of the underlying cardiac disease. Among patients with coronary artery disease, the presence of LBBB correlates with more extensive disease, more severe left ventricular dysfunction, and reduced survival rates.[72] Patients with associated left axis deviation have more severe clinical manifestations.[73] The paradoxical combination of complete LBBB with right axis deviation has been reported as a marker of severe myocardial disease, especially dilated cardiomyopathy.[74]

In addition to the hemodynamic abnormalities produced by these underlying conditions, the abnormal ventricular activation pattern of LBBB itself induces hemodynamic perturbations,[75] including abnormal systolic function with dysfunctional contraction patterns, reduced ejection fraction and lower stroke volumes, and abnormal diastolic function; reversed splitting of the second heart sound and functional mitral regurgitation are common. In addition, functional abnormalities in phasic coronary blood flow and reduced coronary flow reserve caused by delayed diastolic relaxation[76] often result in septal or anteroseptal defects on exercise perfusion scintigraphy in the absence of coronary artery disease.[77] Pharmacological stress testing with dobutamine or adenosine may be more specific than exercise scintigraphy in diagnosing left anterior descending coronary stenosis in the presence of LBBB.[78]

A major impact of LBBB lies in obscuring or simulating other ECG patterns. The diagnosis of LVH is complicated by the increased QRS amplitude and axis shifts intrinsic to LBBB; in addition, the very high prevalence of anatomical LVH in combination with LBBB makes defining criteria with high specificity difficult. The diagnosis of infarction may be obscured; as will be described, the emergence of abnormal Q waves with infarction is dependent on a normal initial sequence of ventricular activation, which is absent with LBBB. In addition, ECG patterns of LBBB, including low R wave amplitude in the midprecordial leads and ST-T wave changes, can simulate anterior infarct patterns.

Right Bundle Branch Block

RBBB is a result of conduction delay in any portion of the right-sided intraventricular conduction system. The delay can occur in the main right bundle branch itself, in the bundle of His, or in the distal right ventricular conduction system. The latter is the common cause of RBBB after right ventriculotomy performed, for example, to correct the tetralogy of Fallot. The relative fragility of the right bundle branch, as suggested by the development of RBBB after minor trauma produced by right ventricular catheterization, corresponds to the high prevalence of RBBB in the general population.

ECG ABNORMALITIES.

Major features of RBBB are illustrated in Figure 5-26, and commonly used diagnostic criteria are listed in Table 5-7 . As with LBBB, the QRS complex duration exceeds 120 milliseconds. The right precordial leads show prominent and notched R waves with rsr, rsR
, or rSR
 patterns, while leads I, aV_L , and the left precordial leads demonstrate wide S waves that are longer in duration than the preceding R wave. Septal q waves are preserved because the initial ventricular activation remains unchanged. The ST-T waves are, as in LBBB, discordant with the QRS complex, so T waves should be inverted in the right precordial leads (and other leads with a terminal R
 wave) and upright in the left precordial leads and in leads I and aV_L .

The mean QRS axis is not altered by RBBB. Axis shifts can occur, however, as a result of the simultaneous occurrence of fascicular block along with RBBB. This concurrence of RBBB with either LAFB (producing left axis deviation) or LPFB (producing right axis deviation) is termed *bifascicular block*, as described below. The electrophysiological consequences of these abnormalities are discussed in Chapters 22 , 23 , and 25 .

Features indicative of *incomplete right bundle branch block* (IRBBB), produced by lesser delays in conduction in the right bundle branch system, are commonly seen. This finding is most frequently characterized by an rSr
 pattern in lead V_1 with a QRS duration between 100 and 120 milliseconds.

MECHANISMS FOR ECG ABNORMALITIES.

With delay or block in the proximal right bundle branch system, activation of the right side of the septum is initiated after slow transeptal spread of activation from the left septal surface. The right ventricular free wall is then excited slowly, with variable participation of the specialized conduction system. The result is slowed and delayed activation of the right ventricle with much or all of the right ventricle undergoing activation after activation of the left ventricle has been completed. Consequently, the electrical forces generated by the right ventricle are not, as in normal conduction, canceled by the more powerful forces from the left ventricle and emerge in the ECG late in the QRS complex. In addition, because left ventricular activation remains relatively intact, the early portions of the QRS complex are normal. Delayed activation of the right ventricle causes prolongation of the QRS duration, while the late and unopposed emergence of right ventricular forces produces increased anterior and rightward voltage in the ECG. Discordant ST-T wave patterns are generated by same mechanisms as for LBBB; with RBBB, recovery forces are directed toward the earlier-activated left ventricle and away from the right. While these ECG changes of IRBBB are commonly attributed to conduction defects, they can reflect RVH without intrinsic dysfunction of the conduction system.

CLINICAL SIGNIFICANCE.

RBBB is a common finding in the general population, and many persons with it have no clinical evidence of structural heart disease. In this group without overt heart disease, the ECG finding has no prognostic significance. However, the new onset of RBBB does predict a higher rate of coronary artery disease, congestive heart failure, and cardiovascular mortality. When cardiac disease is present, the coexistence of RBBB suggests advanced disease with, for example, more extensive multivessel disease and reduced long-term survival in patients with ischemic heart disease.[79] An apparently specific entity known as the *Brugada syndrome* has been described in which RBBB with persistent ST segment elevation in the right precordial leads is associated with susceptibility to ventricular tachyarrhythmias and sudden cardiac death[80] [81] (see Chapter 25) .

RBBB interferes with other ECG diagnoses, although to a lesser extent than LBBB does. The diagnosis of RVH is more difficult to make with RBBB because of the accentuated potentials in lead V_1 . RVH is suggested, although with limited accuracy, by the presence of an R wave in lead V_1 that exceeds 1.5 mV and a rightward shift of the mean QRS axis. The usual criteria for LVH can be applied but have lower sensitivities than with normal conduction. The combination of left atrial abnormality or left axis deviation with RBBB also suggests underlying LVH.[82]

Figure 5-27 Sinus rhythm at 95 beats/min with 2:1 atrioventricular block. Conducted ventricular beats show a pattern consistent with bifascicular block with delay or block in the right bundle and left anterior fascicle. The patient underwent pacemaker implantation.

Multifascicular Blocks

The term *multifascicular block* refers to conduction delay in more than one of the structural components of the specialized conduction system, that is, the left bundle branch, the left anterior and posterior fascicles, and the right bundle branch. Conduction delay in any two fascicles is called *bifascicular block,* and delay in all three fascicles is called *trifascicular block*.

Bifascicular block can have several forms, including RBBB with LAFB, which is characterized by the ECG pattern of RBBB plus left axis deviation beyond -45 degrees (Fig. 5-27) , or RBBB with LPFB, with an ECG pattern of RBBB and a mean QRS axis deviation to the right of +120 degrees (Fig. 5-28) . LBBB is often considered to reflect unifascicular block, although as discussed above, it can result from delay in both the anterior and posterior fascicles.

Figure 5-28 Sinus rhythm with a 2:1 atrioventricular block. QRS morphology in the conducted leads is consistent with bifascicular block with delay or block in the right bundle and left posterior fascicle. Subsequently, complete heart block was also noted. The patient underwent pacemaker implantation.

Figure 5-29 Multifascicular block manifested by alternating bundle branch blocks and PR intervals. *Top panel,* V_1 right bundle branch block (RBBB) with a PR interval of 280 milliseconds. *Middle panel*, V_1 left bundle branch block (LBBB) with a PR interval of 180 milliseconds. *Lower panel*, RBBB alternating with LBBB, along with alternation of the PR interval. The electrocardiographic records shown in leads I, II, and III (L1 to L3) exhibit left anterior fascicular block. An alternating bundle branch block of this type is consistent with trifascicular conduction delay. *(From Fisch C: Electrocardiography of Arrhythmias. Philadelphia, Lea & Febiger, 1990, p 433.)*

This paradox represents one of the inadequacies of current ECG terminology and the simplification inherent in the trifascicular schema of the conduction system.[83]

Trifascicular block involves conduction delay in the right bundle branch plus delay in either the main left bundle branch or both the left anterior and the left posterior fascicles. The resulting ECG pattern is dependent on (1) the relative degree of delay in the affected structures and (2) the shortest conduction time from the atria to the ventricles through any one fascicle. Ventricular activation begins at the site of insertion of the branch with the fastest conduction time and spreads from there to the remainder of the ventricles. For example, if delay in the right bundle branch is less than the delay in the left main bundle branch, activation will begin in the right ventricle and the QRS pattern will resemble that of LBBB. If the delay were greater in the right bundle branch than in the left bundle branch, the ECG pattern would be that of RBBB. The fascicle with the greatest delay can vary with, for example, the heart rate and lead to changing or alternating conduction patterns, as illustrated in Figure 5-29 .

What distinguishes ECG patterns of trifascicular block from those of bifascicular block is an increased overall AV conduction interval that results specifically from prolongation of the His-ventricular time. In bifascicular block, conduction time through the unaffected fascicle (and hence, overall AV conduction time) is normal. In trifascicular block, however, the delay in conduction through even the least affected fascicle is abnormal and results in relative prolongation of the overall AV conduction interval. (Note that only delay, not block of conduction is required. If block were present in all fascicles, conduction would fail and complete heart block would result. This situation is perhaps best illustrated by cases of alternating bundle branch block [see Fig. 5-29]; if the block were total in one bundle branch, development of block in the other would produce complete AV block rather than a change in bundle branch block patterns.) Thus, a diagnosis of trifascicular block

requires an ECG pattern of bifascicular block *plus* evidence of prolonged AV conduction.

Detecting AV conduction delay is best accomplished by intracardiac recordings as a prolongation of the H-V interval. On the surface ECG, AV conduction delay may be manifested as a prolonged PR interval. However, the PR interval includes conduction time in the AV node, as well as in the intraventricular conduction system. Prolonged intraventricular conduction may be insufficient to extend the PR interval beyond normal limits, while a prolonged PR interval can reflect concomitant delay in the AV node rather than in all three intraventricular fascicles. Thus, the finding of a prolonged PR interval in the presence of an ECG pattern of bifascicular block is not diagnostic of trifascicular block, while the presence of a normal PR interval does not exclude this finding (see Chap. 25) .

The major clinical implication of a multifascicular block is its relation to advanced conduction system disease. It may be a marker for advanced myocardial disease and may identify patients at risk for heart block (see Figs. 5-27 and 5-28), as discussed further in Chapter 25 .

Rate-Dependent Conduction Block (Aberration)

Intraventricular conduction delays can result from the effects of changes in the heart rate, as well as from fixed pathological lesions in the conduction system.[84] *Rate-dependent block* or *aberration* can occur at either high or low heart rates. In *acceleration (tachycardia)-dependent block* or *phase 3 block*, conduction delay occurs when the heart rate exceeds a critical value. At the cellular level, this aberration is the result of encroachment of the impulse on the relative refractory period (usually in phase 3 of the action potential) of the preceding impulse, which results in slower conduction. This form of block is relatively common and can have the ECG pattern of RBBB or LBBB (Figs. 5-30 and 5-31) .

Figure 5-30 Atrial tachycardia with a Wenckebach (type I) atrioventricular (AV) block, ventricular aberration resulting from the Ashman phenomenon, and probably concealed transseptal conduction. The long pause of the atrial tachycardia is followed by five QRS complexes with right bundle branch block (RBBB) morphology. The RBBB of the first QRS reflects the Asman phenomenon. The aberration is perpetuated by concealed transseptal activation from the left bundle (LB) into the right bundle (RB) with block of anterograde conduction of the subsequent sinus impulse in the RB. Foreshortening of the R-R cycle, a manifestation of the Wenckebach structure, disturbs the relationship between transseptal and anterograde sinus conduction, and RB conduction is normalized. In the ladder diagram below the tracing, the solid lines represent the His bundle, the dashes represent the RB, the dots represent the LB, and the solid horizontal bars denote the refractory period. P waves and the AV node are not identified in the diagram. *(Courtesy of C. Fisch, M.D.)*

In *deceleration (bradycardia)-dependent block* or *phase 4 block*, conduction delay occurs when the heart rate falls below a critical level. Although the mechanism is not clearly established, it may reflect abnormal phase 4 depolarization of cells so that activation occurs at lower resting potentials. Deceleration-dependent block is less common than acceleration-dependent block and is usually seen only in patients with significant conduction system disease (Fig. 5-32) .

Other mechanisms of ventricular aberration include concealed conduction (anterograde or retrograde) in the bundle branches (Figs. 5-30 and 5-31), premature excitation, depressed myocardial conduction as a result of drug effects or hyperkalemia (see Fig. 5-51 , top), and the effect of changing cycle length on refractoriness (the *Ashman phenomenon*). The duration of the refractory period is a function of the immediately preceding cycle length: the longer the preceding cycle, the longer the subsequent refractory period. Therefore, abrupt prolongation of the immediately preceding cycle can result in aberration as part of a long cycle-short cycle sequence. These so-called Ashman beats usually have a RBBB morphology (see Fig. 5-30) .

WOLFF-PARKINSON-WHITE PREEXCITATION.

This abnormality is discussed in Chapter 25 .

Figure 5-31 Acceleration-dependent QRS aberration with the paradox of persistence at a longer cycle and normalization at a shorter cycle than what initiated the aberration. The duration of the basic cycle (C) is 760 milliseconds. Left bundle branch block (LBBB) appears at a cycle length of 700 milliseconds (dot) and is perpetuated at cycle lengths of 800 (
) and 840 (
) milliseconds; conduction normalizes after a cycle length of 600 milliseconds. Perpetuation of LBBB at a cycle length of 800 and 840 (
) milliseconds is probably due to transseptal concealment, similar to that described in Figure 5-30. Unexpected normalization of the QRS (S) following the atrial premature contraction is probably due to equalization of conduction in the two bundles; however, supernormal conduction in the left bundle cannot be excluded. *(From Fisch C, Zipes DP, McHenry PL: Rate dependent aberrancy. Circulation 48:714, 1973.)*

Myocardial Ischemia and Infarction (See Chap. 35)

The ECG remains a key test in the diagnosis of acute and chronic coronary syndromes.[85] [86] [87] The findings vary considerably, depending importantly on four major factors: (1) the *duration* of the ischemic process (acute vs. evolving/chronic), (2) its *extent* (transmural vs. subendocardial), (3) its *topography* (anterior vs. inferior-posterior and right ventricular), and (4) the presence of *other underlying abnormalities* (e.g., LBBB, Wolff-Parkinson-White [WPW], or pacemaker patterns) that can mask or alter the classic patterns.

Repolarization (ST-T Wave) Abnormalities

The earliest and most consistent ECG finding during acute ischemia is deviation of the ST segment as a result of a *current-of-injury mechanism*. Under normal conditions, the ST segment is usually nearly isoelectric (i.e., flat along the baseline) because healthy myocardial cells attain approximately the same potential during early repolarization, which corresponds to the plateau phase of the ventricular action potential. Ischemia has complex time-dependent effects on the electrical properties of myocardial cells. Severe, acute ischemia can reduce the resting membrane potential, shorten the duration of the action potential in the ischemic area, and also decrease the rate of rise and amplitude of phase 0 (Fig. 5-33) . These changes cause a voltage

Figure 5-32 Deceleration-dependent aberration. The basic rhythm is sinus with a Wenckebach (type I) atrioventricular (AV) block. With 1:1 AV conduction, the QRS complexes are normal in duration; with a 2:1 AV block or after the longer pause of a Wenckebach sequence, left bundle branch block (LBBB) appears. Slow diastolic depolarization (phase 4) of the transmembrane action potential during the prolonged cycle is implicated as the cause of the LBBB. *(Courtesy of C. Fisch, M.D.)*

Figure 5-33 Acute ischemia may alter ventricular action potentials by inducing lower resting membrane potential, decreased amplitude and velocity of phase 0, and an abbreviated action potential duration (pathological early repolarization). These electrophysiological effects create a voltage gradient between ischemic and normal cells during different phases of the cardiac electrical cycle. The resulting currents of injury are reflected on the surface electrocardiogram by deviation of the ST segment (see Fig. 5-34) .

gradient between normal and ischemic zones that leads to current flow between these regions. These currents of injury are represented on the surface ECG by deviation of the ST segment.

Both *diastolic* and *systolic injury currents* have been invoked to explain ischemic ST elevations (Fig. 5-34). According to the diastolic-current-of-injury hypothesis, ischemic ST elevation is attributable to negative (downward) displacement of the electrical "diastolic" baseline (TQ segment of the ECG). At least partly because of transmembrane leakage of intracellular potassium ions, ischemic cells may remain relatively depolarized during phase 4 of the ventricular action potential (i.e., lower membrane resting potential) (see Fig. 5-33).[88] Depolarized muscle carries a negative extracellular charge relative to repolarized muscle. Therefore, during electrical diastole, current (diastolic current of injury) will flow between the partly or completely depolarized ischemic myocardium and the normally repolarized uninjured myocardium. The *injury current vector* will be directed away from the more negative ischemic zone toward the electropositive normal myocardium. As a result, leads overlying the ischemic zone will record a negative deflection during electrical diastole and produce depression of the TQ segment.

TQ segment depression, in turn, appears as ST segment elevation because the ECG recorders in clinical practice use AC-coupled amplifiers that automatically

"compensate" for any negative shift in the TQ segment. As a result of this electronic compensation, the ST segment will be proportionately elevated. Therefore, according to the diastolic-current-of-injury theory, ST segment elevation represents an *apparent shift.* The true shift, observable only with DC-coupled ECG amplifiers, is the negative displacement of the TQ baseline.

Current evidence suggests that ischemic ST elevations (and hyperacute T waves) are also related to systolic injury currents. Three factors may make acutely ischemic myocardial cells relatively positive in comparison to normal cells with respect to their extracellular charge during electrical systole (QT interval): (1) pathological early repolarization (shortened action potential duration), (2) decreased action potential upstroke velocity, and (3) decreased action potential amplitude (see Fig. 5-33) . The presence of one or more of these effects will establish a voltage gradient between normal and ischemic zones during the QT interval such that the current-of-injury vector will be directed toward the ischemic region. This systolic-current-of-injury mechanism will result in primary ST elevation, sometimes with tall positive (hyperacute) T waves.[89]

When acute ischemia is *transmural* (whether caused by diastolic and/or systolic injury currents), the overall ST vector is usually shifted in the direction of the outer (epicardial) layers, and ST elevation and sometimes tall positive (hyperacute) T waves are produced over the ischemic zone (Fig. 5-35) . Reciprocal ST depressions can appear in leads reflecting the contralateral surface of the heart. (Occasionally, the reciprocal changes can be more apparent than the primary ST elevations.)[90] [91] [92] When ischemia is confined primarily to the *subendocardium*, the overall ST vector typically shifts toward the inner ventricular layer and the ventricular cavity such that the overlying (e.g., anterior precordial) leads show ST segment depression with ST elevation in lead aV_r (see Fig. 5-35). This subendocardial ischemic pattern is the typical finding during spontaneous episodes of angina pectoris or during symptomatic or asymptomatic ("silent") ischemia induced by exercise or pharmacological stress tests (see Chaps. 34 and 35) .

Multiple factors can affect the *amplitude* of acute ischemic ST deviations. Profound ST elevation or depression in multiple leads usually indicates very severe ischemia. Conversely, prompt resolution of ST elevation following thrombolytic therapy[93] [94] [94A] or primary angioplasty[95] is a specific marker of successful reperfusion. However, these relationships are not universal since severe ischemia or even infarction

Figure 5-34 Pathophysiology of ischemic ST elevation. Two basic mechanisms have been advanced to explain the elevation seen with acute myocardial injury. *A, Diastolic current of injury*. In this case (first QRS-T complex), the ST vector will be directed away from the relatively negative, partly depolarized, ischemic region during electrical diastole (TQ interval), and the result will be primary TQ depression. Conventional alternating-current electrocardiograms compensate for the baseline shift, and an apparent ST elevation (second QRS-T complex) results. *B, Systolic current of injury*. In this case, the ischemic zone will be relatively positive during electrical systole because the cells are repolarized early and the amplitude and upstroke velocity of their action potentials may be decreased. This injury current vector will be oriented toward the electropositive zone, and the result will be primary ST elevation. (After Goldberger AL: Myocardial Infarction: Electrocardiographic Differential Diagnosis. 4th ed. St Louis, Mosby-Year Book, 1991.)

Figure 5-35 Current-of-injury patterns with acute ischemia. With predominant subendocardial ischemia *(A)*, the resultant ST vector is directed toward the inner layer of the affected ventricle and the ventricular cavity. Overlying leads therefore record ST depression. With ischemia involving the outer ventricular layer *(B)* (transmural or epicardial injury), the ST vector is directed outward. Overlying leads record ST elevation. Reciprocal ST depression can appear in contralateral leads.

can occur with slight or even absent ST-T changes. Furthermore, a relative increase in T wave amplitude (hyperacute T waves) can accompany or precede the ST elevations as part of the injury current pattern attributable to ischemia with or without infarction[89] (Fig. 5-36) .

QRS Changes

With actual infarction, depolarization (QRS) changes often accompany repolarization (ST-T) abnormalities (Fig. 5-37) . Necrosis of sufficient myocardial tissue can lead to decreased R wave amplitude or Q waves in the anterior, lateral, or inferior leads as a result of loss of electromotive forces in the infarcted area.[85] Local conduction delays caused by acute ischemia can also contribute to Q wave pathogenesis in selected cases. Abnormal Q waves were once considered markers of transmural myocardial infarction, while subendocardial (nontransmural) infarcts were thought to not produce Q waves. However, careful experimental and clinical ECG-pathological correlative studies have indicated that transmural infarcts can occur without Q waves and that subendocardial infarcts can sometimes be associated with Q waves.[96] [97] Accordingly, infarcts are better classified electrocardiographically as "Q wave" or "non-Q-wave" based on the ECG. The findings may be somewhat different with posterior or lateral infarction (Fig. 5-38) . Loss of depolarization forces in these regions can reciprocally *increase* R wave amplitude in lead V_1 and sometimes V_2 , rarely without causing diagnostic Q waves in any of the conventional leads.[98] The differential diagnosis of prominent right precordial R waves is given in Table 5-8 .

Evolution of ECG Changes

When ischemic ST elevation and hyperacute T wave changes occur as the earliest sign of acute infarction, they are typically followed within a period ranging from hours to days by evolving T wave inversion and sometimes Q waves in the same lead distribution (see Fig. 5-37) . T wave

Figure 5-36 Hyperacute phase of extensive anterior-lateral myocardial infarction. Marked ST elevation melding with prominent T waves is present across the precordium, as well as in leads I and aV_l . ST depression, consistent with a reciprocal change, is seen in leads III and aV_f . Q waves are present in leads V_3 through V_6 . Marked ST elevations with tall T waves caused by severe ischemia are sometimes referred to as a monophasic current-of-injury pattern. A paradoxical increase in R wave amplitude (V_2 and V_3) may accompany this pattern. This tracing also shows left axis deviation with small or absent inferior R waves, which raises the possibility of a prior inferior infarct.

Figure 5-37 Sequence of depolarization and repolarization changes with *(A)* acute anterior-lateral and *(B)* acute inferior wall Q wave infarctions. With anterior-lateral infarcts, ST elevation in leads I, aV_l , and the precordial leads may be accompanied by reciprocal ST depression in leads II, III, and aV_f . Conversely, acute inferior (or posterior) infarcts may be associated with reciprocal ST depression in leads V_1 to V_3 . (After Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)

inversion from evolving or chronic ischemia correlates with increased ventricular action potential duration, and these ischemic changes are often associated with QT prolongation. The T wave inversion can resolve after days or weeks or persist indefinitely. The extent of the infarct may be an important determinant of T wave evolution.[98A] In one series, T waves that were persistently negative for more than 1 year in leads with Q waves were associated with a transmural infarction with fibrosis of the entire wall; in contrast, T waves that were positive in leads with Q waves correlated with nontransmural infarction with viable myocardium within the wall.[99]

In the days to weeks or longer following infarction, the QRS changes can persist or begin to resolve. Complete normalization of the ECG following Q wave infarction is uncommon but can occur, particularly with smaller infarcts and when the left ventricular ejection fraction and regional wall motion improve. The latter is usually associated with spontaneous recanalization or good collateral circulation[100] and is a good prognostic sign. [101] In contrast, persistent Q waves and ST elevation several weeks or more after an infarct correlate strongly with a severe underlying wall motion disorder (akinetic or dyskinetic zone), although not necessarily a frank ventricular aneurysm. The presence of

Figure 5-38 Evolving inferoposterolateral infarction. Note the prominent Q waves in II, III and aV_f , along with ST elevation and T wave inversion in these leads, as well as V_3 through V_6 . ST depression in I, aV_r , V_1 , and V_2 is consistent with a reciprocal change. Relatively tall R waves are also present in V_1 and V_2 .

TABLE 5-8 -- DIFFERENTIAL DIAGNOSIS OF TALL R WAVES IN V_1 /V_2

Physiological/positional factors

an rSR
or similar complex in the midleft chest leads or lead I is another reported marker of ventricular aneurysm (*el-Sherif sign*).

OTHER ISCHEMIC ST-T PATTERNS.

Reversible transmural ischemia caused, for example, by coronary vasospasm may cause transient ST segment elevation (Fig. 5-39). This pattern is the ECG marker of Prinzmetal variant angina (see Chap. 36) . Depending on the severity and duration of such noninfarction ischemia, the ST elevation can either resolve completely within minutes or be followed by T wave inversion that can persist for hours or even days. Some patients with ischemic chest pain have deep *coronary* T wave inversion in multiple precordial leads (e.g., V_1 through V_4), with or without cardiac enzyme elevations. This finding is typically caused by severe ischemia associated with a high-grade stenosis in the proximal left anterior descending coronary artery system (*LAD-T wave* pattern).[102] The T wave inversion may actually be preceded by a transient ST elevation that resolves by the time that the patient arrives at the hospital. These T wave inversions, in the setting of unstable angina, can correlate with segmental hypokinesis of the anterior wall and suggest a "myocardial stunning" syndrome.[103] The natural history of this syndrome is unfavorable, with a high incidence of recurrent angina and myocardial infarction. On the other hand, patients whose baseline ECG already shows abnormal T wave inversion can experience paradoxical T wave normalization (pseudonormalization) during episodes of acute transmural ischemia[85] [89] (Fig. 5-40) . (Postinfarction regional pericarditis can also cause T wave normalization.[104]) The four major classes of acute ECG-coronary artery syndromes in which myocardial ischemia leads to different ECG findings are summarized in Figure 5-41 .

ISCHEMIC U WAVE CHANGES.

Alterations in U wave amplitude or polarity have been reported with acute ischemia or infarction. For example, exercise-induced transient inversion of precordial U waves has been correlated with severe stenosis of the left anterior descending coronary artery.[105] Rarely, U wave inversion may be the earliest ECG sign of acute coronary syndromes.[106]

QT INTERVAL DISPERSION.

Increasing interest has been shown in the effects of acute myocardial ischemia and infarction on the disparity among QT intervals in various ECG leads, referred to as QT dispersion.[38] [107] [108] [109] The greater the difference between maximum and minimum QT intervals, i.e., increased QT dispersion, the greater the variability in myocardial repolarization. An increased index has been proposed as a marker of arrhythmia risk after myocardial infarction[110] and as a marker of acute ischemia with atrial pacing.[111] The practical utility of QT dispersion measurements, in coronary syndromes[111A] [111B] and certain other cardiac pathologies, [38] is a focus of current investigation (see Chap. 25) .

Localization of Ischemia or Infarction

The ECG leads are more helpful in localizing regions of transmural than subendocardial ischemia. As examples, ST elevation and/or hyperacute T waves are seen in (1) one or more of the precordial leads (V_1 through V_6) and in leads I and aV_l with acute transmural anterior or anterolateral wall ischemia; (2) leads V_1 to V_3 with anteroseptal ischemia; (3) leads V_4 to V_6 with apical or lateral ischemia; (4) leads II, III, and aV_f with inferior wall ischemia; and (5) right-sided precordial leads with right ventricular ischemia. Posterior wall infarction, which induces ST elevation in leads placed over the back of the heart, e.g., leads V_7 to V_9 ,[8] [112] [113]

Figure 5-39 *A,* Prinzmetal angina with ST segment and T wave alternans. *B,* ST segment and T wave alternans associated with nonsustained ventricular tachycardia. *(Courtesy of C. Fisch, M.D.)*

Figure 5-40 Pseudo (paradoxical) T wave normalization. *A,* The baseline electrocardiogram of a patient with coronary artery disease shows ischemic T wave inversion. *B,* T wave "normalization" during an episode of ischemic chest pain. *C,* Following resolution of the chest pain, the T waves have reverted to their baseline appearance. *(From Goldberger AL: Myocardial Infarction: Electrocardiographic Differential Diagnosis. 4th ed. St Louis, Mosby-Year Book, 1991.)*

can be induced by lesions in the right coronary artery or left circumflex artery. These lesions can produce both inferior and posterior-lateral injury, which may be indirectly recognized by reciprocal ST depression in leads V_1 to V_3 . [114] Similar ST changes can also be the primary ECG manifestation of anterior subendocardial ischemia. Posterior inferior wall infarction with reciprocal changes can be differentiated from primary anterior wall ischemia by the presence of ST segment elevations in posterior leads.

The ECG can also provide more specific information about the location of the occlusion within the coronary system. In patients with an inferior wall myocardial infarction, the presence of ST segment elevation in lead III exceeding that in lead II, particularly when combined with ST elevation in V_1 , may be a useful predictor of an occlusion in the proximal to midportion of the right coronary artery[115] (Fig. 5-42) . Right-sided ST elevation is indicative of acute right ventricular injury[116] [117] [117A] and usually correlates with occlusion of the proximal right coronary artery.[117] Of note is the finding that acute right ventricular infarction can project an injury current pattern in leads V_1 through V_3 or even V_4 and simulate anterior infarction. [118] In other cases, simultaneous ST elevation in V_1 (V_2 R) and ST depression in V_2 (V_1 R) can occur[119] (see Fig. 5-42) . These and other criteria proposed for localization of the site of coronary occlusion based on the initial ECG[120] [121] [122] [123] [124] [125] [125A] require additional validation in test populations. In some cases, ischemia can affect more than one region of the myocardium (e.g., inferolateral) (see Fig. 5-38) .[125B] Not uncommonly, the ECG will show the characteristic findings of involvement in each region. Sometimes, however, partial normalization can result from cancellation of opposing vectorial forces. Inferior lead ST segment elevation accompanying acute anterior wall infarction suggests occlusion of a left anterior descending artery that extends onto the inferior wall of the left ventricle ("wrap around" vessel). [126]

Figure 5-41 Variability of electrocardiogram (ECG) patterns with acute myocardial ischemia. The ECG may also be normal or nonspecifically abnormal. Furthermore, these categorizations are not mutually exclusive. For example, a non-Q-wave infarct can evolve into a Q wave infarct, ST elevation can be followed by a non-Q-wave infarct, or ST depression and T wave inversion can be followed by a Q wave infarct. *(Modified from Goldberger AL: Myocardial Infarction: Electrocardiographic Differential Diagnosis. 4th ed. St Louis, Mosby-Year Book, 1991.)*

Figure 5-42 Acute right ventricular infarction with acute inferior wall infarction. Note the ST elevation in the right precordial leads, as well as in leads II, III, and aV_f , with reciprocal change in I and aV_l . ST elevation in lead III greater than in lead II[115] and right precordial ST elevation are consistent with proximal to middle occlusion of the right coronary artery. The combination of ST elevation in conventional lead V_1 (V_2 R here) and ST depression in lead V_2 (lead V_1 R here) has also been reported with acute right ventricular ischemia/infarction.[119]

ECG Diagnosis of Bundle Branch Blocks and Myocardial Infarction

The diagnosis of myocardial infarction is often more difficult in cases in which the baseline ECG shows a bundle branch block pattern, or a bundle branch block develops as a complication of the infarct.[85] The diagnosis of Q wave infarction is not usually impeded by the presence of RBBB, which affects primarily the terminal phase of ventricular depolarization. The net effect is that the criteria for the diagnosis of a Q wave infarct in a patient with RBBB are the same as in patients with normal conduction (Fig. 5-43) . The diagnosis of infarction in the presence of LBBB is considerably more complicated and confusing since LBBB alters both the early and the late phases of ventricular depolarization and produces secondary ST-T changes. These changes may both mask and mimic the findings of myocardial infarction. As a result, considerable attention has been directed to the problem of diagnosing acute and chronic myocardial infarction in patients with LBBB[85] [127] [128] [129] (Fig. 5-44) .

Infarction of the left ventricular free (or lateral) wall ordinarily results in abnormal Q waves in the midprecordial to lateral precordial leads (and selected limb leads). However, the initial septal depolarization forces with LBBB are directed from right to left. These leftward forces produce an initial R wave in the midprecordial to lateral precordial leads, usually masking the loss of electrical potential (Q waves) caused by the infarction. Therefore, acute or chronic left ventricular free wall infarction by itself will not usually produce diagnostic Q waves in the presence of LBBB. Acute or chronic infarction involving both the free wall and the septum (or the septum itself) may produce abnormal

Figure 5-43 Right bundle branch block with acute anterior infarction. Loss of anterior depolarization forces results in QR-type complexes in the right precordial to midprecordial leads, with ST elevations and evolving T wave inversions (V_1 through V_6).

Figure 5-44 Complete left bundle branch block with acute inferior myocardial infarction. Note the prominent ST segment elevation in leads II, III, and aV_f , with reciprocal ST segment depression in I and aV_l superimposed on secondary ST-T changes. The underlying rhythm is atrial fibrillation.

Q waves (usually as part of the QRS complex or QrS types of complexes) in leads V_4 to V_6 . These initial Q waves probably reflect posterior and superior forces from the spared basal portion of the septum (Fig. 5-45). Thus, a wide Q wave (0.04 second) in one or more of these leads is a more reliable sign of underlying infarction. The sequence of repolarization is also altered in LBBB, with the ST segment and T wave vectors being directed opposite the QRS complex. These changes can mask or simulate the ST segment changes of actual ischemia.

The following points summarize the ECG signs of myocardial infarction in LBBB: (1) ST segment elevation with tall positive T waves are frequently seen in the right precordial leads with uncomplicated LBBB. Secondary T wave inversions are characteristically seen in the lateral precordial leads. However, the appearance of ST elevations in the lateral leads or ST depressions or deep T wave inversions in leads V_1 to V_3 strongly suggests underlying ischemia. More marked ST elevations (0.5 mV) in leads with QS or rS waves may also be due to acute ischemia.[127] (2) The presence of QR complexes in leads I, V_5 , or V_6 or in II, III, and aV_f with LBBB strongly suggests underlying infarction, and (3) chronic infarction is also suggested by notching of the ascending part of a wide S wave in the midprecordial leads (*Cabrera sign*) or the ascending limb of a wide R wave in V_5 or V_6 (*Chapman sign*).[127] Similar principles may apply to the diagnosis of acute and chronic infarction in the presence of right ventricular pacing.[130] Comparison between

Figure 5-45 *A,* With uncomplicated left bundle branch block, early septal forces are directed to the left. Therefore, no Q waves will be seen in V_5 and V_6 (*right panel*). *B,* With left bundle branch block complicated by anteroseptal infarction, early septal forces may be directed posteriorly and rightward (*left panel*). Therefore, prominent Q waves may appear in V_5 and V_6 as a paradoxical marker of septal infarction (*right panel*). *(Adapted from Dunn MI, Lipman BS: Lipman-Massie Clinical Electrocardiography. 8th ed. Chicago, Year Book, 1989.) C,* Anterior wall infarction (involving septum) with left bundle branch block. Note the presence of QR complexes in leads I, aV_l , V_5 , and V_6 .

an ECG exhibiting the LBBB prior to the infarction and the present ECG is often helpful to show these changes.

Atrial Infarction

A number of ECG clues to the diagnosis of atrial infarction have been suggested, including localized deviations of the PR segment (e.g., PR elevation in V_5 or V_6), changes in P wave morphology, and atrial arrhythmias.[131] However, the sensitivity and specificity of these signs are limited. Diffuse PR segment changes (PR elevation in aV_r with depression in the inferolateral leads) with acute infarction usually indicate concomitant pericarditis (see below).

ECG Differential Diagnosis of Ischemia and Infarction

The ECG has important limitations in both sensitivity and specificity in the diagnosis of coronary syndromes. An initially normal ECG does not exclude ischemia or even acute infarction. However, a normal ECG throughout the course of an alleged acute infarct is distinctly uncommon. As a result, prolonged chest pain without diagnostic ECG changes should always prompt a careful search for noncoronary causes of chest pain (see Chap. 35) . Pathological Q waves may be absent even in patients with depressed left ventricular function caused by severe coronary disease and a previous infarct.[132] As noted, the diagnosis of acute or chronic infarction can be completely masked by ventricular conduction disturbances, especially those resulting from LBBB, as well as ventricular pacing and WPW preexcitation. On the other hand, diagnostic confusion can arise because Q waves, ST elevation, ST depression, tall positive T waves, and deep T wave inversion can be seen in a wide variety of noncoronary settings.[85]

Noninfarction Q Waves

Q waves simulating coronary artery disease can be related to one (or a combination) of the following four factors (Table 5-9) : (1) physiological or positional variants, (2) altered ventricular conduction, (3) ventricular enlargement, and (4) myocardial damage or replacement. Depending on the electrical axis, prominent Q waves (as part of QS- or QR-type complexes) can also appear in the limb leads (aV_l with a

Progressive decrease in R wave amplitude from V_1 to the midlateral precordial leads.

vertical axis and III and aV_f with a horizontal axis). A QS complex can appear in lead V_1 as a normal variant and rarely in leads V_1 and V_2 . Prominent Q waves can be associated with a variety of other positional factors that alter the orientation of the heart vis-a-vis a given lead axis. Poor R wave progression, sometimes with actual QS waves, can be due solely to improper placement of chest electrodes above their usual position. In dextrocardia, provided that no underlying structural abnormalities are present, normal R wave progression can be restored by recording leads V_2 to V_6 on the right side of the chest. A rightward mediastinal shift in left pneumothorax can contribute to the apparent loss of left precordial R waves. Other positional factors associated with poor R wave progression include pectus excavatum, congenitally corrected transposition of the great vessels, and congenital absence of the left pericardium.

An intrinsic change in the sequence of ventricular depolarization can lead to pathological, noninfarct Q waves. The two most important conduction disturbances associated with pseudoinfarct Q waves are LBBB and the WPW preexcitation patterns. With LBBB, QS complexes can appear in the right precordial to midprecordial leads and occasionally in one or more of leads II, III, and aV_f .. Depending on the location of the bypass tract, WPW preexcitation can mimic anteroseptal, lateral, or inferior-posterior infarction. LAFB is often cited as a cause of anteroseptal infarct patterns. However, LAFB has only minor effects on the QRS complex in horizontal plane leads. Probably the most common findings are relatively prominent S waves in leads V_5 and V_6 . Poor R wave progression is not a routine feature of LAFB, although some authors have reported minuscule q waves in leads V_1 to V_3 in this setting. These small q waves can become more apparent if the leads are recorded one interspace above their usual position and disappear in leads one interspace below their usual position.[68] However, as a general clinical rule, prominent Q waves (as part of QS or QR complexes) in the right precordial to midprecordial leads should *not* be attributed to LAFB alone.

In contrast, poor R wave progression is commonly observed with LVH and with acute or chronic right ventricular overload. Q waves in such settings can reflect a variety of mechanisms, including a change in the balance of early ventricular depolarization forces and altered cardiac geometry and position. A marked loss of R wave voltage, sometimes with frank Q waves from V_1 to the lateral chest leads, may be seen with chronic obstructive pulmonary disease (see Fig. 5-22). The presence of low limb voltage and P pulmonale can serve as additional diagnostic clues. This loss of R wave progression may, in part, reflect right ventricular dilation. Furthermore, downward displacement of the heart in an emphysematous chest may play a major role in the genesis of poor R wave progression in this syndrome. Partial or complete normalization of R wave progression may be achieved in such cases simply by recording the chest leads an interspace lower than usual (see Fig. 5-22) .

A variety of pseudoinfarct patterns can occur with acute cor pulmonale caused by pulmonary embolism. Acute right ventricular overload in this setting can cause poor R wave progression and sometimes right precordial to midprecordial T wave inversion (right ventricular "strain") mimicking anterior infarction. The classic S_1 Q_3 T_3 pattern can occur but is neither sensitive nor specific. A prominent Q wave (usually as part of a QR complex) can also occur in lead aV_f along with this pattern (see Fig. 5-23) . However, acute right overload by itself does not cause a pathological Q wave in lead II. Right heart overload, acute or chronic, may also be associated with a QR complex in lead V_1 and simulate anteroseptal infarction.

Pseudoinfarct patterns are an important finding in patients with hypertrophic cardiomyopathy, and the ECG can simulate anterior, inferior, posterior, or lateral infarction.[85] [133] The pathogenesis of depolarization abnormalities in this cardiomyopathy is not certain. Prominent inferolateral Q waves (II, III, aV_f , and V_4 to V_6) and tall right precordial R waves are probably related to increased depolarization forces generated by the markedly hypertrophied septum (Fig. 5-46) . Abnormal septal depolarization may also contribute to the bizarre QRS complexes.

Loss of electromotive force associated with myocardial necrosis contributes to R wave loss and Q wave formation in myocardial infarction. This mechanism of Q wave pathogenesis, however, is not specific for coronary artery disease with infarction. Any process, acute or chronic, that causes sufficient loss of regional electromotive potential can result in Q waves. For example, replacement of myocardial tissue by electrically inert material such as amyloid or tumor may cause noninfarction Q waves. A variety of dilated cardiomyopathies associated with extensive myocardial fibrosis may be characterized by pseudoinfarct patterns. Ventricular hypertrophy can also contribute to Q wave pathogenesis in this setting. Finally, Q waves caused by myocardial injury, whether ischemic or nonischemic in origin, can appear transiently and do not necessarily signify irreversible heart muscle damage.[85] Severe ischemia can cause regional loss of electromotive potential without actual cell death ("electrical stunning" phe

Figure 5-46 Hypertrophic cardiomyopathy simulating inferolateral infarction. This 11-year-old girl had a family history of hypertrophic cardiomyopathy. St Louis, Mosby-Year Book, 1991.)*

nomenon). Transient conduction disturbances can also cause alterations in ventricular activation and result in noninfarctional Q waves. In some cases, transient Q waves may represent unmasking of a prior Q wave infarct. New, but transient Q waves have been described with severe hypotension from a variety of causes, as well as with tachyarrhythmias, myocarditis, Prinzmetal's angina, protracted hypoglycemia, phosphorus poisoning, and hyperkalemia.[85]

ST-T Changes Simulating Ischemia

The differential diagnosis of ST segment elevation includes acute pericarditis (Fig. 5-47), acute myocarditis, normal-variant "early repolarization" (see Fig. 5-15), and a number of other conditions[85] [134] [134A] [135] [135A] listed in Table 5-10 . Acute pericarditis, in contrast to acute myocardial infarction, typically induces diffuse ST segment elevation, usually in most of the chest leads and also in leads I, aV_l , II, and aV_f . Reciprocal ST depression is seen in lead aV_r . An important clue to acute pericarditis, in addition to the diffuse nature of the ST elevation, is the frequent presence of PR segment elevation in aV_r , with reciprocal PR segment depression in other leads, caused by a concomitant atrial current of injury[136] (see Fig. 5-47). Abnormal Q waves do not occur with acute pericarditis, and the ST elevation may be followed by T wave inversion after a variable period (see Chap. 50) . Myocarditis (see Chap. 48) can, in some patients, exactly simulate the ECG pattern of acute myocardial infarction, including ST elevation and Q waves. In one series,[137] these pseudoinfarct findings were associated with a rapidly progressive course and increased mortality.

A variety of factors such as digitalis, ventricular hypertrophy, hypokalemia, and hyperventilation can cause ST segment depression mimicking subendocardial ischemia. Similarly, tall positive T waves do not invariably represent hyperacute ischemic changes but can reflect normal variants, hyperkalemia, cerebrovascular injury, and left

ventricular volume loads resulting from mitral or aortic regurgitation, among other causes.[85] ST elevation and tall positive T waves are also common findings in leads V_1 and V_2 with LBBB or LVH patterns. In addition, tall T waves may be seen occasionally in the left chest leads with LVH, especially with volume (diastolic) overload syndrome (see Fig. 5-20) .

T WAVE INVERSION.

When caused by physiological variants, T wave inversion is sometimes mistaken for ischemia. T waves in the right precordial leads can be slightly inverted, particularly in leads V_1 and V_2 . Some adults show persistence of the *juvenile T wave pattern* (see Fig. 5-14), with more prominent T wave inversion in right precordial to midprecordial leads showing an rS or RS morphology. The other normal variant that may be associated with prominent T wave inversion is the early repolarization pattern (see Fig. 5-15). Some subjects with this variant have prominent, biphasic T wave inversion in association with the ST elevation. This pattern, which may simulate the

*Usually localized to V_1 to V_2 .

Figure 5-47 *Top,* Acute pericarditis is often characterized by two apparent injury currents: one atrial, the other ventricular. The atrial injury current vector (ST_a) is usually directed upward and to the right and produces PR segment elevation in aV_r with reciprocal PR depression in II, V_5 , and V_6 . The ventricular injury current (ST_V) is directed downward and to the left, associated with ST elevation in II, V_5 , and V_6 with reciprocal ST depression in aV_r . This characteristic PR-ST segment discordance is illustrated in the *Bottom*, Note the diffuse distribution of ST segment elevation in acute pericarditis (e.g., I, II, and V_2 through V_6 , with reciprocal changes in aV_r and perhaps minimally in V_1). initial stages of an evolving infarct, is most prevalent in young adult black males and among athletes. These functional ST-T changes are probably due to regional disparities in repolarization and can be normalized by exercise.[85]

Primary and Secondary T Wave Inversions.

A variety of pathological factors can alter repolarization and cause prominent T wave inversion (see Fig. 5-48). As noted above, T wave alterations are usefully classified as primary or secondary. Primary T wave changes are caused by alterations in the duration or morphology of ventricular action potentials in the absence of changes in the activation sequence. Examples include ischemia, drug effects, and metabolic factors. Prominent primary T wave inversion (or in some cases, tall positive T waves) is also a well-described feature of the ECG in cerebrovascular accidents (CVAs), particularly with subarachnoid hemorrhage. The "CVA T wave pattern" is characteristically diffuse, with a widely splayed appearance usually associated with marked QT prolongation (Fig. 5-48). Some studies have implicated structural damage (myocytolysis) in the hearts of patients with such T wave changes, probably induced by excessive sympathetic stimulation mediated via the hypothalamus.[138] A role for concomitant vagal activation in the pathogenesis of such T wave changes, which are usually associated with

Figure 5-48 Deep T wave inversion can be due to a variety of causes (see Table 5-11) . Note the marked QT prolongation in conjunction with the cerebrovascular accident (CVA) T wave pattern caused here by subarachnoid hemorrhage. Apical hypertrophic cardiomyopathy (HCM) is another cause of deep T wave inversion that can be mistaken for coronary disease. *(From Goldberger AL: Deep T wave inversions. ACC Curr J Rev Nov/Dec:28-29, 1996.)*

bradycardia, has also been postulated. Similar T wave changes have been reported after truncal vagotomy, radical neck dissection, and bilateral carotid endarterectomy.[109] In addition, the massive diffuse T wave inversion seen in some patients following Stokes-Adams syncope may be related to a similar neurogenic mechanism. Patients with subarachnoid hemorrhage may also show transient ST elevation, as well as arrhythmias, including torsades de pointes. Ventricular dysfunction may even occur.[139] [140]

In contrast to these primary T wave abnormalities, secondary T wave changes are caused by altered ventricular activation, without changes in action potential characteristics. Examples include bundle branch block, WPW preexcitation, and ventricular ectopic or paced beats. In addition, altered ventricular activation (associated with QRS interval prolongation) can induce persistent T wave changes that appear after normal ventricular depolarization has resumed. The term "cardiac memory T wave changes" has been used in this context to describe repolarization changes subsequent to depolarization changes caused by ventricular pacing, intermittent LBBB, intermittent WPW preexcitation, and other alterations of ventricular activation.[141] [142] Finally, the designation idiopathic *global T wave inversion* has been applied[143] in cases in which no identifiable cause for often marked, diffuse repolarization abnormalities can be defined. An unexplained female preponderance has been reported.[144] Major causes of prominent T wave inversion are summarized in Table 5-11 , with selected examples in Figure 5-48 .

Drug Effects

Numerous drugs can affect the ECG, often in association with nonspecific ST-T alterations. More marked changes, as well as AV and intraventricular conduction disturbances, may occur with selected agents. The proarrhythmic effects of "antiarrhythmic" medications are described in Chapter 23 .

Digitalis effect refers to the relatively distinctive "scooped" appearance of the ST-T complex and shortening of the QT interval, which correlates with abbreviation of the ventricular action potential duration (Fig. 5-49). Digitalis-related ST-T changes may be accentuated by an increased heart rate during exercise and result in false-positive stress test results (see Chap. 6) . Digitalis effect may occur with therapeutic or toxic doses of the drug. The term *digitalis toxicity* refers specifically to systemic effects (nausea and anorexia among other effects) or conduction disturbances and arrhythmias caused by drug excess or increased sensitivity (see Chap. 23) .

Idiopathic global T wave inversion
Secondary T wave alterations: bundle branch blocks, Wolff-Parkinson-White patterns
Intermittent left bundle branch block, preexcitation, or ventricular pacing ("memory T waves")
Modified from Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.

Figure 5-49 *Top,* Digitalis effect. Digitalis glycosides characteristically produce shortening of the QT interval with a "scooped" or downsloping ST-T complex. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.) Bottom, Digitalis effect in combination with digitalis toxicity. The underlying rhythm is atrial fibrillation. A "group beating" pattern of QRS complexes with shortening of the R-R intervals is consistent with nonparoxysmal junctional tachycardia with exit (atrioventricular Wenckebach) block. ST segment depression and "scooping" (V_6) are consistent with digitalis effect, although ischemia or left ventricular hypertrophy cannot be excluded. Findings are strongly suggestive of digitalis excess; the serum digoxin level was greater than 3 ng/ml. Digitalis effect does not necessarily imply digitalis toxicity, however.*

ECG effects and toxicities of other cardioactive agents may be anticipated, in part, from ion channel effects (see Chap. 22) . Inactivation of sodium channels by class 1 agents (e.g., quinidine, procainamide, disopyramide, flecainide) can cause QRS prolongation. Class 1A and class 3 agents (e.g., sotalol, amiodarone) can induce an acquired long QT(U) syndrome (see Chap. 23) . Psychotropic drugs (e.g., tricyclic antidepressants and phenothiazines), which have class 1A-like properties, can also lead to QRS and QT(U) prolongation.[144A] Toxicity may produce asystole or torsades de pointes. Right axis shift of the terminal 40-millisecond frontal plane QRS axis was reported to be a helpful marker of tricyclic antidepressant overdose.[145]

Electrolyte and Metabolic Abnormalities

In addition to the structural and functional cardiac conditions already discussed, numerous systemic metabolic aberrations affect the ECG,[86] including electrolyte abnormalities and acid-base disorders, as well as systemic hypothermia.

CALCIUM.

Hypercalcemia and hypocalcemia predominantly alter the action potential duration. An increased extracellular calcium concentration shortens the ventricular action potential duration by shortening phase 2 of the action potential. In contrast, hypocalcemia prolongs phase 2 of the action potential. These cellular changes correlate with abbreviation and prolongation of the QT interval (ST segment portion) with hypercalcemia and hypocalcemia, respectively (Fig. 5-50) . Severe hypercalcemia (e.g., serum Ca^{2+}
15 mg/dl) can also be associated with decreased T wave amplitude, sometimes with T wave notching or inversion.[146] Hypercalcemia sometimes produces a high takeoff of the ST segment in leads V_1 and V_2 and can thus simulate acute ischemia (see Table 5-10) .

POTASSIUM.

Hyperkalemia is associated with a distinctive sequence of ECG changes (Fig. 5-51 *A*). The earliest effect is usually narrowing and peaking (*tenting*) of the T wave. The QT interval is shortened at this stage associated with decreased action potential duration. Progressive extracellular hyperkalemia reduces atrial and ventricular resting membrane potentials, thereby inactivating sodium channels, which decreases Vmax and conduction velocity. The QRS begins to widen and P wave amplitude decreases. PR interval prolongation can occur, followed sometimes by second- or third-degree AV block. Complete loss of P waves may be associated with a junctional escape rhythm or *sinoventricular rhythm*. In the latter instance, sinus rhythm persists with conduction between the SA and AV nodes and occurs without producing an overt P wave. Moderate to severe

Figure 5-50 Prolongation of the QT interval (ST segment portion) is typical of hypocalcemia. Hypercalcemia may cause abbreviation of the ST segment and shortening of the QT interval.*(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)*

hyperkalemia occasionally induces ST elevations in the right precordial leads (V_1 and V_2) and simulates an ischemic current-of-injury pattern. However, even severe hyperkalemia can be associated with atypical or nondiagnostic ECG findings.[147] [148] Very marked hyperkalemia leads to eventual asystole, sometimes preceded by a slow undulatory (sine-wave) ventricular flutter-like pattern. The ECG triad of (1) peaked T waves (from hyperkalemia), (2) QT prolongation (from hypocalcemia), and (3) LVH (from hypertension) is strongly suggestive of chronic renal failure.[149]

Figure 5-51 Electrocardiographic changes in hyperkalemia *(A)* and hypokalemia *(B). A,* On day 1, at a K^+ level of 8.6 mEq/liter, the P wave is no longer recognizable and the QRS complex is diffusely prolonged. Initial and terminal QRS delay is characteristic of K^+ -induced intraventricular conduction slowing and is best illustrated in leads V_2 and V_6 . On day 2, at a K^+ level of 5.8 mEq/liter, the P wave is recognizable with a PR interval of 0.24 seconds, the duration of the QRS complex is approximately 0.10 seconds, and the T waves are characteristically "tented." *B,* On day 1, at a K^+ level of 1.5 mEq/liter, the T and U waves are merged. The U wave is prominent and the QU interval prolonged. On day 4, at a K^+ level of 3.7 mEq/liter, the tracing is normal. *(Courtesy of C. Fisch, M.D.)*

The electrophysiological changes associated with hypokalemia, in contrast, include hyperpolarization of myocardial cell membranes and increased action potential duration. The major ECG manifestations are ST depression with flattened T waves and increased U wave prominence (Fig. 5-51 *B*). The U waves can exceed the amplitude of T waves. Hypokalemia is an important cause of acquired long QT(U) syndrome that predisposes to torsades de pointes (see Chap. 25) . Hypokalemia also predisposes to tachyarrhythmias from digitalis (see Chap. 23) .

MAGNESIUM.

Specific ECG effects of mild to moderate isolated abnormalities in magnesium ion concentration are not well characterized. Severe hypermagnesemia can cause AV and intraventricular conduction disturbances that may culminate in complete heart block and cardiac arrest (Mg^{2+} >15 mEq/L).[150] Hypomagnesemia is usually associated with hypocalcemia or hypokalemia. Hypomagnesemia can potentiate certain digitalis toxic arrhythmias (see Chap. 23) . The role of magnesium deficiency in the pathogenesis and treatment of the acquired long QT(U) syndrome with torsades de pointes is discussed in Chapters 23 and 25 .

OTHER FACTORS.

Isolated hypernatremia or hyponatremia does not produce consistent effects on the ECG. Acidemia and alkalemia are often associated with hyperkalemia and hypokalemia, respectively. *Systemic hypothermia* may be associated with the appearance of a distinctive convex elevation at the junction (J point) of the ST segment and QRS complex (*J wave* or *Osborn wave*) (Fig. 5-52) . The cellular mechanism of this type of pathological *J wave* appears to be related to an epicardial-endocardial voltage gradient associated with the localized appearance of a prominent epicardial action potential notch.[151]

Nonspecific QRS and ST-T Changes

Low QRS voltage is said to be present when the total amplitude of the QRS complexes in each of the six extremity leads is 0.5 mV or less or 1.0 mV or less in leads V_1 through V_6 . Low QRS voltage can relate to a variety of mechanisms (Table 5-12) , including increased insulation of the heart by air (chronic obstructive pulmonary disease) or adipose tissue (obesity); replacement of myocardium, for example, by fibrous tissue (ischemic or nonischemic cardiomyopathy), amyloid, or tumor; or short-circuiting effects (pericardial or pleural effusions). The combination of relatively low limb voltage (QRS voltage
0.8 mV in each of

Figure 5-52 Systemic hypothermia. The arrows (V_3 through V_6) point to the characteristic convex J waves, termed Osborn waves. Prominent sinus bradycardia is also present.*(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)*

the limb leads), relatively prominent QRS voltage in the chest leads (SV_1 or SV_2 +RV_5 or RV_6
3.5 mV), and poor R wave progression (R wave less than the S wave in V_1 through V_4) has been reported as a relatively specific, but not sensitive sign of dilated-type cardiomyopathies (*ECG-congestive heart failure triad*).[152]

Multiple factors in addition to ischemia (e.g., postural changes, meals, drugs, hypertrophy, electrolyte and metabolic disorders, central nervous system lesions, infections, pulmonary diseases) can affect the ECG.[85] Ventricular repolarization is particularly sensitive to these effects, which can lead to a variety of *nonspecific ST-T changes*. The term is usually applied to slight ST depression or T wave inversion or to T wave flattening without evident cause. Care must be taken to not overinterpret such changes, especially in subjects with a low prior probability of heart disease. At the same time, subtle repolarization abnormalities can be markers of coronary or hypertensive heart disease or other types of structural heart disease and probably account for the association of relatively minor but persistent nonspecific ST-T changes with increased cardiovascular mortality in middle-aged men.[153]

TABLE 5-12 -- CAUSES OF LOW-VOLTAGE QRS COMPLEXES

Adrenal insufficiency
AnasarcaArtifactual or spurious, e.g., unrecognized standardization of the electrocardiogram at half the usual gain (i.e., 5 mm/mV)
Cardiac infiltration or replacement (e.g., amyloidosis, tumor)
Cardiac transplantation, especially with acute or chronic rejection
Cardiomyopathies, idiopathic or secondary*
Chronic obstructive pulmonary disease
Constrictive pericarditis
Hypothyroidism (usually with sinus bradycardia)
Left pneumothorax (mid-left chest leads)
Myocardial infarction, extensive
Myocarditis, acute or chronic
Normal variant
Obesity
Pericardial tamponade (usually with sinus tachycardia)
Pleural effusions

*Dilated cardiomyopathies may be associated with a combination of relatively low limb lead voltage and prominent precordial voltage.[152]

Alternans Patterns

The term *alternans* applies to conditions characterized by the sudden appearance of a periodic beat-to-beat change in some aspect of cardiac electrical or mechanical behavior. These abrupt changes (AAAA
ABAB pattern) are reminiscent of a generic class of subharmonic (period-doubling) bifurcation patterns, well described in perturbed *nonlinear control systems*. [21] [154] [155] Many different examples of electrical alternans have been described clinically[156] [157] [158] [159] [160] [160A] (Table 5-13) ; a number of others have been reported in the laboratory.[161] Most familiar is total electrical alternans with sinus tachycardia, a specific but not highly sensitive marker of pericardial effusion with tamponade physiology[162] (Fig. 5-53) (see Chap. 50) . This finding is associated with an abrupt transition from a 1:1 to a 2:1 pattern in the "to-fro" swinging motion of the heart in the effusion.[163] Other alternans patterns are due to primary electrical rather than mechanical causes. ST-T alternans has long been recognized as a marker of electrical instability in acute ischemia, where it may precede ventricular tachyarrhythmia[164] (see Fig. 5-39) . Considerable interest has recently been shown in the detection of microvolt T wave (or ST-T) alternans as a noninvasive marker of the risk of ventricular tachyarrhythmia in patients with chronic heart disease[165] [166] [167] [168] [169] (see Chap. 23) . Similarly, TU wave alternans (Fig. 5-54) may be a marker of imminent risk of a ventricular tachyarrhythmia such as torsades de pointes in hereditary or acquired long QT syndromes.[170] [171]

CLINICAL ISSUES IN ELECTROCARDIOGRAPHIC INTERPRETATION

These principles and diagnostic ECG guidelines are, finally, subject to appropriate use in the clinical setting. Their effectiveness as a diagnostic tool depends on factors such as the indications for the procedure, the clinical context in which the ECG is used, and proper technique and skills of the ECG reader.

INDICATIONS FOR AN ECG.

Little attention has been paid to the indications for an ECG, probably because of its seeming simplicity and low cost. However, the cumulative expense of low-cost tests

performed at high volume is significant, and the risk to the patient of false diagnoses of

TABLE 5-13 -- EXAMPLES OF ALTERNANS PATTERNS IN ECG DIAGNOSIS

PATTERN	COMMENT
P wave alternans	Rarely reported; e.g., in pulmonary embolism [159]
"Total" electrical alternans (P-QRS-T) with sinus tachycardia	Swinging-heart mechanism in pericardial effusion/tamponade* (see Fig. 5-53)
PR interval alternans	Dual AV nodal pathway physiology; alternating bundle branch block (see Fig. 5-29)
ST segment alternans	Can precede ischemic ventricular tachyarrhythmias (see Fig. 5-39)
T wave (or ST-T) alternans	Can precede nonischemic ventricular tachyarrhythmias
TU wave alternans	Can precede torsades de pointes in long QT(U) syndromes, congenital or acquired (see Fig. 5-54)
QRS alternans in supraventricular or ventricular tachycardia	Most common with AV reentrant tachycardia (concealed bypass tract)
R-R (heart rate) alternans	With sinus rhythm, e.g., in congestive heart failure[157] With non-sinus rhythm tachyarrhythmias, e.g., PSVT
Bidirectional tachycardias	Usually ventricular in origin; may be caused by digitalis excess
Intermittent bundle branch/fascicular blocks or Wolff-Parkinson-White patterns	Rarely occur on beat-to-beat basis (see Fig. 5-29)

AV=atrioventricular; PSVT=paroxysmal supraventricular tachycardia.

*Also case report of QRS-T alternans with sinus tachycardia in acute pulmonary embolism.[160]

cardiac disease can be damaging. Specific indications for the use of ECGs have been proposed and evaluated.[172] [172A] [173] [174] In patients with known cardiac disease, ECGs are warranted as part of a baseline examination; after therapy known to produce ECG changes that correlate with therapeutic responses, progression of disease, or adverse effects; and for intermittent follow-up with changes in signs or symptoms or relevant laboratory findings or after significant intervals (usually 1 year or longer), even in the absence of clinical changes. In patients suspected of having cardiac disease or at high risk for cardiac disease, an ECG is appropriate as part of an initial evaluation in the presence of signs or symptoms suggesting cardiac disease; in patients with important risk factors such as cigarette abuse, diabetes mellitus, peripheral vascular disease, or a family history of cardiac disease (including long QT interval syndromes and ventricular preexcitation); during therapy with cardioactive medications; and during follow-up if clinical events develop or at prolonged intervals (usually 1 year or more) if clinically stable. Preoperative tracings are appropriate for patients with known or suspected cardiac disease, although this application too may be questioned, especially if the cardiac condition is hemodynamically insignificant or the procedure is simple.[174]

It has been common practice to include an ECG as part of routine health examinations, before any surgical procedure, and on any admission to a hospital in patients without current evidence of cardiac disease and without major risk factors. These ECGs are assumed to be of value in detecting any unknown abnormalities, serving as a baseline against which to compare later tracings, and assessing future risk of cardiovascular events. There is little evidence to support these practices. The overall sensitivity of the ECG for identifying specific patients who will have future events and the number of therapeutic or diagnostic changes provoked by routine ECG findings are too low to warrant universal screening.[57] [172] In these cases, use of the ECG should be based on clinical judgment rather than rigid protocol

Figure 5-53 Total electrical alternans (P-QRS-T) caused by pericardial effusion with tamponade. This finding, particularly in concert with sinus tachycardia and relatively low voltage, is a highly specific, although not sensitive marker of cardiac tamponade.

Figure 5-54 The QT(U) interval is prolonged and measures approximately 600 milliseconds with TU wave alternans. The tracing was recorded in a patient with chronic renal disease shortly following dialysis. This type of repolarization alternans may be a precursor to torsades de pointes. *(Courtesy of C. Fisch, M.D.)*

requirements. Flexible guidelines for ordering ECGs on general hospital admission and preoperatively have been proposed on the basis of age, gender, medical history, and physical examination.[172] [172A]

KNOWLEDGE OF THE CLINICAL CONTEXT AND PRIOR ECG FINDINGS.

Although most ECGs are read without a priori knowledge of the clinical condition of the patient, the accuracy and the value of the interpretation are enhanced by having clinical information about the patient. Such knowledge may include, for example, information about drug therapy, which may be a cause of observed ECG abnormalities, or prior myocardial infarction, which may produce ECG changes mimicking acute ischemia.[175] [176]

Similarly, the availability of prior ECGs can improve the clinical value of the ECG. For example, knowledge of prior ECG patterns can improve diagnostic accuracy and triage decisions for patients with current ECG and clinical evidence of ischemia or infarction, as well as improve the proper interpretation of, for example, bundle branch block in the setting of acute infarction.[177] [178] [178A]

TECHNICAL ERRORS AND ARTIFACTS.

Technical errors can lead to significant diagnostic mistakes that can result in false diagnoses that place patients at risk for unneeded and potentially dangerous diagnostic tests and treatments and unnecessarily use limited health care resources.[179] Misplacement of one or more ECG electrodes is a common cause for errors in ECG interpretation. Some misplacements produce ECG patterns that can aid in identification of the error.[180] [181] [182] Reversal of the two arm electrodes, for example, results in an inverted waveform in lead I but not in lead V_6 , two leads that would normally be expected to have similar polarities. Others are not as obvious. For example, placing the right precordial electrodes too high on the chest can yield patterns that mimic those produced by anterior myocardial infarction (poor R wave progression) or intraventricular conduction delay (rSr
patterns). Electrical or mechanical artifacts such as produced by poor electrode contacts or tremors can simulate life-threatening arrhythmias[179] (Fig. 5-55) , and excessive body motion can cause excessive baseline wander that may simulate an ST segment shift of myocardial ischemia or injury.

READING ERRORS.

Errors in interpreting ECGs are common.[182] Studies assessing the accuracy of routine interpretations have demonstrated significant numbers of errors that can lead to clinical mismanagement, including failure to appropriately detect and triage patients with acute myocardial ischemia and other life-threatening situations.[183] Organizations such as the American College of Cardiology have proposed minimal training and experience standards for electrocardiographers to help reduce these potentially serious errors.[184]

A final issue concerns overreliance on computerized interpretations. Computer systems have facilitated storage and retrieval of large numbers of ECGs and, as diagnostic algorithms have become more accurate, have provided important adjuncts to the clinical interpretation of ECGs. However, the current systems are not sufficiently accurate,[185] [186] especially in the presence of rhythm disturbances or complex abnormalities, to be relied on in critical clinical environments without expert

review. New analysis techniques based upon artificial intelligence concepts may lead to future improvements,[187] [187A] and new hardware technology may result in expanded deployment of systems for prompt expert interpretation.[187B]

Figure 5-55 Artifacts simulating serious arrhythmias. *A,* Motion artifact mimicking ventricular tachyarrhythmia. Partly obscured normal QRS complexes (arrows) can be seen with a heart rate of about 100 beats/min. *B,* Parkinsonian tremor causing baseline oscillations mimicking atrial fibrillation. The regularity of QRS complexes may provide a clue to this artifact.

GUIDELINES ELECTROCARDIOGRAPHY

Thomas H. Lee

Electrocardiograms (ECGs) are among the most commonly performed tests in medicine and are "the procedure of first choice" in the evaluation of patients with chest pain, syncope, or dizziness. Guidelines published in 1992 by a task force of the American College of Cardiology and American Heart Association (ACC/AHA) described conditions for which it is generally agreed that ECGs are useful (Class I); conditions for which opinion differs with respect to their usefulness (Class II); and conditions for which it is generally agreed that ECGs are of little or no usefulness (Class III).[1] These guidelines addressed categories of patients defined by whether they had known, suspected, or no evidence of cardiovascular disease. For each patient category, the guidelines evaluated use of the ECG as a baseline test, for evaluation of response to therapy, for follow-up, and before surgery (Table 5-G-1). Further discussion of some of the ongoing controversies and disagreements regarding use of the ECG in clinical settings is given in the chapter.

Patients with Known Cardiovascular Disease or Dysfunction

The ECG is so critical to the evaluation of all patients with a cardiovascular condition that this test was considered appropriate (Class I) for all patients during the initial evaluation and to evaluate the short- and long-term responses to therapies known to produce ECG changes. The guidelines offer no specific recommendations about the frequency of follow-up ECGs but noted that for several acute cardiovascular problems, serial ECGs are warranted until the patient has returned to a stable condition. Even in the absence of new symptoms or signs, ECGs were considered appropriate for the follow-up of patients with several conditions, including syncope or near syncope, chest pain, and unexplained fatigue (see Table 5-G-1). The ECG was not considered appropriate for patients with mild chronic cardiovascular conditions that were not considered likely to progress (e.g., mild mitral valve prolapse). ECGs at *each* visit were considered inappropriate for patients with stable heart disease who were seen frequently (e.g., within 4 months) and had no evidence of clinical change.

Before cardiac or noncardiac surgery, the ACC/AHA guidelines considered ECGs appropriate for all patients with known cardiovascular disease or dysfunction, except those with insignificant or mild conditions such as mild systemic arterial hypertension.

Patients with Suspected or at High Risk for Cardiovascular Disease

The ECG was considered an appropriate baseline test for all patients with suspected cardiovascular conditions and those at high risk for the development of such conditions. It was also considered an appropriate test after the administration of any drug known to influence cardiac

TABLE 5-5-G-1 -- ACC/AHA GUIDELINES FOR ELECTROCARDIOGRAPHY (1992)

Setting	Class I (appropriate)	Class II (equivocal)	Class III (inappropriate)
Patients with Known Cardiovascular Disease or Dysfunction			
Baseline or initial evaluation	All patients	None	None
Response to therapy	Patients in whom prescribed therapy is known to produce ECG changes that correlate with therapeutic responses or progression of disease Patients in whom prescribed therapy may produce adverse effects that may be predicted from or detected by ECG changes	None	Patients receiving pharmacological or nonpharmacological therapy not known to produce ECG changes or to affect conditions that may be associated with such changes

Follow-up	Patients with a change in symptoms, signs, or relevant laboratory findings	None	Adult patients whose cardiovascular condition is benign and unlikely to progress (e.g., patients with mild mitral prolapse, mild hypertension, or premature contractions in the absence of organic heart disease
	Patients with an implanted pacemaker or antitachycardia device		Adult patients with chronic stable heart disease seen at frequent intervals (i.e., 4 mo) and who have no new or unexplained findings
	Patients with syndromes such as the following conditions, even in the absence of new symptoms of signs, after an interval of time appropriate for the condition or disease: Syncope and near syncope Unexplained change in the usual pattern of angina pectoris Chest pain New or worsening dyspnea Extreme and unexplained fatigue, weakness, and prostration Palpitations New signs of congestive heart failure A new organic murmur or pericardial friction rub New findings suggesting pulmonary hypertension Acceleration or poorly controlled systemic arterial hypertension Evidence of a recent cerebrovascular accident Unexplained fever in patients with known valvular disease New onset of cardiac arrhythmis or inappropriate heart rate Chronic known congenital or acquired cardiovascular disease		
Before surgery	All patients with known cardiovascular disease or dysfunction, except as noted under Class II	Patients with hemodynamically insignificant heart disease, mild systemic arterial hypertension, or infrequent premature complexes in the absence of organic heart disease	None
Patients Suspected of Having or Who Are at Increased Risk for Cardiovascular Disease or Dysfunction			
Baseline or initial evaluation	All patients suspected of having or at increased risk for cardiovascular disease	None	None
	Patients who may have used cocaine, amphetamines, or other illicit drugs known to have cardiac effects		
	Patients who may have received an overdose of a drug known to have cardiac effects		
Response to therapy	To assess therapy with cardioactive drugs in patients with suspected cardiac disease	To assess the response to administration of any agent known to alter serum electrolyte concentrations	To assess the response to administration of agents known not to influence cardiac structure or function
	To assess response to the administration of any agent known to result in cardiac abnormalities or ECG abnormalities (e.g., antineoplastic drugs, lithium, antidepressant agents)		
Follow-up	The presence of any change in clinical status or laboratory findings suggesting interval development of cardiac disease or dysfunction	None	Follow-up ECGs more often than once yearly are not indicated in patients who remain clinically stable, who are not at increased risk for the development of cardiac disease, and who have not been demonstrated to have cardiac disease with previous studies
	Periodic follow-up (e.g., every 1--5 yr) of patients known to be at increased risk for heart disease		
	Follow-up of patients after resolution of chest pain		
Before surgery	As part of the preoperative evaluation of any patient with suspected or at increased risk for cardiac disease or dysfunction	None	None
Patients with No Apparent or Suspected Heart Disease or Dysfunction			
Baseline or initial evaluation	Persons aged 40 or more yr undergoing physical examination	To evaluate competitive athletes	Routine screening or baseline ECGs in asymptomatic persons younger than 40 yr with no risk factors
	Before administration of pharmacological agents known to have a high incidence of cardiovascular effects (e.g., antineoplastic agents)		
	Before exercise stress testing		
	People of any age who are in special occupations that require very high cardiovascular performance (e.g., fire fighters, police officers) or whose cardiovascular performance is linked to public safety (e.g., pilots, air traffic controllers, critical process operators, bus or truck drivers, and railroad engineers)		
Response to therapy	To evaluate patients in whom prescribed therapy (e.g., doxorubicin) is known to produce cardiovascular effects	None	To assess treatment that is known to not produce any cardiovascular effects
Follow-up	To evaluate asymptomatic persons > 40 yr of age	None	To evaluate asymptomatic adults who have had no interval change in symptoms, signs, or risk factors and who have had a normal ECG with the recent past
Before surgery	Patients >40 yr of age	Patients 30--40 yr of age	Patients younger than 30 yr with no risk factors for coronary artery disease
	Patients being evaluated as a donor for heart transplantation or as a recipient of a noncardiopulmonary transplant		

Class I: Conditions for which or patients for whom it is generally agreed that electrocardiography is useful (appropriate).
Class II: Conditions for which or patients for whom electrocardiography is frequently used but opinion differs with respect to its usefulness (equivocal).
Class III: Conditions for which or patients for whom it is generally agreed that electrocardiography is of little or no usefulness (inappropriate).

structure or function. Follow-up ECGs more often than once per year were not recommended for patients who remained clinically stable, as long as they had not been

previously demonstrated to have cardiac disease. However, for patients known to be at increased risk for the development of heart disease, ECGs every 1 to 5 years were considered appropriate (Class I). ECGs were considered appropriate before cardiac or noncardiac surgery for all patients in this population.

Patients Without Known or Suspected Heart Disease

For patients without evidence suggesting cardiovascular disease, ECGs were considered appropriate during the baseline evaluation in the ACC/AHA guidelines for those aged 40 years or older. The ACC/AHA guidelines also recommended ECGs for patients for whom drugs with a high incidence of cardiovascular effects (e.g., chemotherapy) or exercise testing was planned and for people of any age in occupations with high cardiovascular demands or whose cardiovascular status might affect the well-being of many other people (e.g., airline pilot). These guidelines are similar to those of the U.S. Preventive Services Task Force,[2] which suggested ECG screening for those with occupations in which their cardiovascular health might jeopardize the lives of others.

Guidelines vary on the performance of baseline ECGs. An American Heart Association panel recommended in 1987 that ECGs be obtained at ages 20, 40, and 60 years in persons with normal blood pressure,[3] while a task force assembled by the Canadian government has discouraged the use of any screening ECGs.[4]

Before cardiac or noncardiac surgery, the ACC/AHA guidelines recommend ECGs for all people aged 40 years or older,[1] and ECGs are considered equivocal in appropriateness (Class II) for surgical patients aged 30 to 40 years. Guidelines issued by the American College of Physicians[5] recommend ECGs preoperatively and upon hospital admission for men aged 40 years or older and women aged 50 years or older, as well as all patients having elective intrathoracic, intraperitoneal, or aortic surgery; elective major neurosurgery; or emergency operations under general or regional anesthesia.

Chapter 6 - Exercise Stress Testing

BERNARD R. CHAITMAN

Exercise is a common physiological stress used to elicit cardiovascular abnormalities not present at rest and to determine adequacy of cardiac function.[1] [2] [3] [4] [5] [6] [7] [8] [9] Exercise electrocardiography (ECG) is one of the most frequent noninvasive modalities used to assess patients with suspected or proven cardiovascular disease. The test is mainly used to estimate prognosis and to determine functional capacity, the likelihood and extent of coronary artery disease (CAD), and the effects of therapy.[5] [6] Hemodynamic and ECG measurements combined with ancillary techniques such as metabolic gas analysis, radionuclide imaging, and echocardiography enhance the information content of exercise testing in selected patients.[9] [10] [11]

EXERCISE PHYSIOLOGY (See also Chap. 39)

Anticipation of dynamic exercise results in an acceleration of ventricular rate due to vagal withdrawal, increase in alveolar ventilation, and increased venous return primarily as a result of sympathetic venoconstriction.[12] In normal persons, the net effect is to increase resting cardiac output before the start of exercise. The magnitude of hemodynamic response during exercise depends on the severity and amount of muscle mass involved. In the early phases of exercise in the upright position, cardiac output is increased by an augmentation in stroke volume mediated through the use of the Frank-Starling mechanism and heart rate; the increase in cardiac output in the latter phases of exercise is primarily due to a sympathetic-mediated increase in ventricular rate. At fixed submaximal workloads below anaerobic threshold, steady-state conditions are usually reached after the second minute of exercise, following which heart rate, cardiac output, blood pressure, and pulmonary ventilation are maintained at reasonably constant levels.[7] During strenuous exertion, sympathetic discharge is maximal and parasympathetic stimulation is withdrawn, resulting in vasoconstriction of most circulatory body systems, except for that in exercising muscle and in the cerebral and coronary circulations. Venous and arterial norepinephrine release from sympathetic postganglionic nerve endings, as well as plasma renin levels, is increased; the catecholamine release enhances ventricular contractility. As exercise progresses, skeletal muscle blood flow is increased, oxygen extraction increases by as much as threefold, total calculated peripheral resistance decreases, and systolic blood pressure, mean arterial pressure, and pulse pressure usually increase. Diastolic blood pressure does not change significantly. The pulmonary vascular bed can accommodate as much as a sixfold increase in cardiac output with only modest increases in pulmonary artery pressure, pulmonary capillary wedge pressure, and right atrial pressure; in normal individuals, this is not a limiting determinant of peak exercise capacity.

Cardiac output increases by four- to sixfold above basal levels during strenuous exertion in the upright position, depending on genetic endowment and level of training.[12] The maximum heart rate and cardiac output are decreased in older individuals, partly because of decreased beta-adrenergic responsivity.[13] [14] [15] Maximum heart rate can be estimated from the formula 220 - age (years) with a standard deviation of 10 to 12 beats/min. The age-predicted maximum heart rate is a useful measurement for safety reasons. However, the wide standard deviation in the various regression equations used and the impact of drug therapy limit the usefulness of this parameter in estimating the exact age-predicted maximum for an individual patient.

In the postexercise phase, hemodynamics return to baseline within minutes of termination. Vagal reactivation is an important cardiac deceleration mechanism after exercise and is accelerated in well-trained athletes but blunted in patients with chronic heart failure.[16] Intense physical work or significant cardiorespiratory impairment may interfere with achievement of a steady state, and an oxygen deficit occurs during exercise. The total oxygen uptake in excess of the resting oxygen uptake during the recovery period is the oxygen debt.

PATIENT'S POSITION.

At rest, the cardiac output and stroke volume are higher in the supine than in the upright position. With exercise in normal supine persons, the elevation of cardiac output results almost entirely from an increase in heart rate with little augmentation of stroke volume. In the upright posture, the increase in cardiac output in normal individuals results from a combination of elevations in stroke volume and heart rate. A change from supine to upright posture causes a decrease in venous return, left ventricular end-diastolic volume and pressure, stroke volume, and cardiac index. Renin and norepinephrine levels are increased. End-systolic volume and ejection fraction are not significantly changed. In normal individuals, end-systolic volume decreases and ejection fraction increases to a similar extent from rest to exercise in the supine and upright positions. The magnitude and direction of change in end-diastolic volume from rest to maximum exercise in both positions are small and may vary according to the patient population studied. The net effect on exercise performance is an approximate 10 percent increase in exercise time, cardiac index, heart rate, and rate pressure product at peak exercise in the upright as compared with the supine position.

Cardiopulmonary Exercise Testing

Cardiopulmonary exercise testing involves measurements of respiratory oxygen uptake ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$), and ventilatory parameters during a symptom-limited exercise test. During testing, the patient usually wears

a nose clip and breathes through a nonrebreathing valve that separates expired air from room air. Important measurements of expired gas are PO_2 , PCO_2 , and airflow. Ventilatory measurements include respiratory rate, tidal volume, and minute ventilation ($\dot{V}E$) PO_2 and PCO_2 are sampled breath by breath or by use of a mixing chamber. The $\dot{V}O_2$ and $\dot{V}CO_2$ can be computed on line from ventilatory volumes and differences between inspired and expired gases.[9] Under steady-state conditions, $\dot{V}O_2$ and $\dot{V}CO_2$ measured at the mouth are equivalent to total-body oxygen consumption and carbon dioxide production. The relationship between work output, oxygen consumption, heart rate, and cardiac output during exercise is linear (Fig. 6-1) . $\dot{V}O_2$ max is the product of maximal arterial-venous oxygen difference and cardiac output and represents the largest amount of oxygen a person can use while performing dynamic exercise involving a large part of total muscle mass. The $\dot{V}O_2$ max decreases with age, is usually less in women than in men, and can vary between individuals as a result of genetic factors.[14] [15] $\dot{V}O_2$ max is diminished by degree of cardiovascular impairment and by physical inactivity. In untrained persons, the arterial-mixed venous oxygen difference at peak exercise is relatively constant (14 to 17 vol percent), and

O_2 max is an approximation of maximum cardiac output. Measured
O_2 max can be compared with predicted values from empirically derived formulas based on age, sex, weight, and height.[9] [17] Most clinical studies that use exercise as a stress to assess cardiac reserve report peak
O_2 that is the highest
O_2 attained during graded exercise testing rather than
O_2 max. Peak exercise capacity is decreased when the ratio of measured to predicted
O_2 max is less than 85 to 90 percent. Oximetry, performed noninvasively, can be used to monitor arterial oxygen saturation, and the value normally does not decrease by more than 5 percent during exercise. Estimates of oxygen saturation during strenuous exercise using pulse oximetry may be unreliable in some patients.[18]

ANAEROBIC THRESHOLD.

Anaerobic threshold is a theoretical point during dynamic exercise when muscle tissue switches over to anaerobic metabolism as an additional energy source. All tissues do not shift simultaneously, and there is a brief interval during which exercise muscle tissue shifts from predominantly aerobic to anaerobic metabolism.[9] [12] [17] [19] Lactic acid begins to accumulate when a healthy untrained subject reaches about 50 to 60 percent of the maximal capacity for aerobic metabolism. The increase in lactic acid becomes greater as exercise becomes more intense, resulting in metabolic acidosis. As lactate is formed, it is buffered in the serum by the bicarbonate system, resulting in increased carbon dioxide excretion, which causes reflex hyperventilation. The gas exchange anaerobic threshold is the point at which
V_E increases disproportionately relative to
O_2 and work; it occurs at 40 to 60 percent of
O_2 max in normal, untrained individuals.[9] Below the anaerobic threshold, carbon dioxide production is proportional to oxygen consumption. Above the anaerobic threshold, carbon dioxide is produced in excess of oxygen

Figure 6-1 Cardiopulmonary exercise test in a healthy 53-year-old man using the Bruce protocol. The progressive linear increase in work output, heart rate, and oxygen consumption (O_2) is noted, with steady-state conditions reached after 2 minutes in each of the first two stages *(top panel).* Open arrows indicate the beginning of each new 3-minute stage. The subject completed 7 minutes and 10 seconds of exercise, and peak
O_2 was 3.08 liters/min. The anaerobic threshold (AT_{ge}), determined by the V-slope method, is the point at which the slope of the relative rate of increase in
CO_2 relative to
O_2 changes; it occurred at a
O_2 of 1.5 liters/min, or 49 percent of peak
O_2 , within predicted values for a normal sedentary population *(bottom panel).* The AT_{ge} determined by the point at which the
O_2 and
CO_2 slopes intersect (1.8 liters/min) *(top panel)* is slightly greater than the AT_{ge} determined by the V-slope method *(bottom panel).* The V-slope method usually provides a more reproducible estimate of AT_{ge} . $PETO_2$ = end-tidal pressure of oxygen; RER = respiratory exchange ratio; VE/
O_2 = ratio ventilation to oxygen uptake.

consumption. There are several methods to determine anaerobic threshold, which include (1) the V-slope method, the point at which the rate of increase in
CO_2 relative to
O_2 increases (see Fig. 6-1) ; (2) the point at which the
O_2 and
CO_2 slopes intersect; and (3) the point at which the ratio of V_E/
O_2 and end-tidal oxygen tension begins to increase systematically without an immediate increase in the V_E/
O_2 (see Fig. 6-1) . The anaerobic threshold is a useful parameter because work below this level encompasses most activities of daily living. Anaerobic threshold is often reduced in patients with significant cardiovascular disease. An increase in anaerobic threshold with training can enhance an individual's capacity to perform sustained submaximal activities, with consequent improvement in quality of life and daily living. Changes in anaerobic threshold and peak
O_2 with repeat testing can be used to assess disease progression, response to medical therapy, and improvement in cardiovascular fitness with training.

VENTILATORY PARAMETERS.

In addition to peak
O_2 , minute ventilation and its relation to
CO_2 and oxygen consumption are useful indices of cardiac and pulmonary function. The respiratory exchange ratio represents the amount of carbon dioxide produced divided by the amount of oxygen consumed. The respiratory exchange ratio ranges from 0.7 to 0.85 at rest and is partly dependent on the predominant fuel used for cellular metabolism (e.g., respiratory exchange rate for predominant carbohydrate use is 1.0, whereas respiratory exchange ratio for predominant fatty use is 0.7). At high exercise levels, carbon dioxide production exceeds
O_2 , and a respiratory exchange ratio greater than 1.0 often indicates that the subject has performed at maximal effort.

METABOLIC EQUIVALENT.

The current use of the term metabolic equivalent (MET) refers to a unit of sitting, resting oxygen uptake; 1 MET is equivalent to 3.5 ml $O_2 \cdot kg^{-1} \cdot min^{-1}$ of body weight. Measured
O_2 in ml/min/kg divided by 3.5 ml $O_2 \cdot kg^{-1} \cdot min^{-1}$ determines number of METs associated with activity. Work activities can be calculated in multiples of METs; this measurement is useful to determine exercise prescriptions, assess disability, and standardize the reporting of submaximal and peak exercise workloads when different protocols are used. An exercise workload of 3 to 5 METs is consistent with activities such as raking leaves, light carpentry, golf, and walking at 3 to 4 mph. Workloads of 5 to 7 METs are consistent with exterior carpentry, singles tennis, and light backpacking. Workloads in excess of 9 METs are compatible with heavy labor, handball, squash, and running at 6 to 7 mph. Estimating
O_2 from work rate or treadmill time in individual patients may lead to misinterpretation of data if exercise equipment is not correctly calibrated, when the patient holds onto the front handrails, if the patient fails to achieve steady state, is obese, or has peripheral vascular disease, pulmonary vascular disease, or cardiac impairment.
O_2 does not increase linearly in some patients with cardiovascular or pulmonary disease as work rate is increased, and
O_2 may thus be overestimated.[9] The measurements obtained with cardiopulmonary exercise testing are useful in understanding an individual patient's response to exercise and can be useful in the diagnostic evaluation of a patient with dyspnea.[9] [19] [20]

EXERCISE PROTOCOLS

The main types of exercise are isotonic or dynamic exercise, isometric or static exercise, and resistive (combined isometric and isotonic) exercise. Dynamic protocols most frequently are used to assess cardiovascular reserve, and those suitable for clinical testing should include a low-intensity warm-up phase. In general, 6 to 12 minutes of continuous progressive exercise during which the myocardial oxygen demand is elevated to the patient's maximal level is optimal for diagnostic and prognostic purposes.[1] [2] [3] The protocol should include a suitable recovery or cool-down period. If the protocol is too strenuous for an individual patient, early test termination results and will not allow an opportunity to observe clinically important responses. If the exercise protocol is too easy for an individual patient, the prolonged procedure tests endurance and not aerobic capacity. Thus, exercise protocols should be individualized to accommodate a patient's limitations. Protocols may be set up at a fixed duration of exercise for a certain intensity to meet minimal qualifications for certain industrial tasks or sports programs.

STATIC EXERCISE.

This form of isometric exercise generates force with little muscle shortening and produces a greater blood pressure response than with dynamic exercise. Cardiac output does not increase as much as with dynamic exercise because increased resistance in active muscle groups limits blood flow. In a common form of static exercise, the patient's maximal force on a hand dynamometer is recorded. The patient then sustains 25 to 33 percent of maximal force for 3 to 5 minutes while ECG and blood pressures are recorded. The increase in myocardial

O_2 is often insufficient to initiate an ischemic response.

ARM ERGOMETRY.

Arm crank ergometry protocols involve arm cranking at incremental workloads of 10 to 20 W for 2- or 3-minute stages. The heart rate and blood pressure responses to a given workload of arm exercise usually are greater than those for leg exercise. A bicycle ergometer with the axle placed at the level of the shoulders is used, and the subject sits or stands and cycles the peddles so that the arms are alternately fully extended. The most common frequency is 50 rpm. In normal individuals, maximal O_2 and $E$for arm cycling approximates 50 to 70 percent of leg cycling. Peak heart rate is approximately 70 percent of that during leg testing. Arm ergometry exercise protocols are useful for risk stratification of patients with suspected or documented CAD before noncardiac surgery when leg exercise is not possible or insufficient to test cardiac reserve.

BICYCLE ERGOMETRY.

Bicycle protocols involve incremental workloads calibrated in watts or kilopond/meters/minute (kpm). One watt is equivalent to approximately 6 kpm. Because exercise on a cycle ergometer is not weight bearing, kpm or watts can be converted to oxygen uptake in milliliters per minute. In mechanically braked bicycles, work is determined by force and distance and requires a constant pedaling rate of 60 to 80 rpm, according to the patient's preference. Electronically braked bicycles provide a constant workload despite changes in pedaling rate and are less dependent on a patient's cooperation. They are more costly than a mechanically braked bicycle but are preferred for diagnostic and prognostic assessment. Most protocols start with a power output of 10 or 25 W (150 kpm/min), usually followed by increases of 25 W every 2 or 3 minutes until endpoints are reached. Younger subjects may start at 50 W, with 50-W increments every 2 minutes. A ramp protocol differs from the staged protocols in that the patient starts at 3 minutes of unloaded pedaling at a cycle speed of 60 rpm. Work rate is increased by a uniform amount each minute, ranging from 5- to 30-W increments, depending on a patient's expected performance.[9] Exercise is terminated if the patient is unable to maintain a cycling frequency above 40 rpm. In the cardiac catheterization laboratory, hemodynamic measurements may be made during supine bicycle ergometry at rest and at one or two submaximal workloads.

The bicycle ergometer is associated with a lower maximal O_2 and anaerobic threshold than the treadmill; maximal heart rate, maximal E, and maximal lactate values are often similar. The bicycle ergometer has the advantage of requiring less space than a treadmill; it is quieter and permits sensitive precordial measurements without much motion artifact. However, in North America, treadmill protocols are more widely used in the assessment of patients with coronary disease.

TREADMILL PROTOCOL.

The treadmill protocol should be consistent with the patient's physical capacity and the purpose of the test. In healthy individuals, the standard

Bruce's protocol is popular, and a large diagnostic and prognostic data base has been published.[1] [2] [3] [4] Bruce's multistage maximal treadmill protocol has 3-minute periods to allow achievement of a steady state before workload is increased (Figs. 6-1 and 6-2) . In older individuals or those whose exercise capacity is limited by cardiac disease, Bruce's protocol can be modified by two 3-minute warm-up stages at 1.7 mph and 0 percent grade and 1.7 mph and 5 percent grade. A limitation of Bruce's protocol is the relatively large increase in O_2 between stages and the additional energy cost of running as compared with walking at stages in excess of Bruce's stage III. The Naughton and Weber protocols use 1- to 2-minute stages with 1-MET increments between stages; these protocols may be more suitable for patients with limited exercise tolerance such as patients with congestive heart failure. The Asymptomatic Cardiac Ischemia Pilot trial (ACIP) and modified ACIP (mACIP) protocols use 2-minute stages with 1.5-MET increments between stages after two 1-minute warm-up stages with 1-MET increments. The ACIP protocols were developed to test patients with established CAD and result in a linear increase in heart rate and O_2 , distributing the time to occurrence of ST segment depression over a wider range of heart rate and exercise time than protocols with more abrupt increments in workload between stages.[21] [22] The mACIP protocol produces a similar aerobic demand as the standard ACIP protocol for each minute of exercise and is well suited for short or elderly individuals who cannot keep up with a walking speed of 3 mph (see Fig. 6-2) .

Ramp protocols start the patient at relatively slow treadmill speed, which is gradually increased until the patient has a good stride. The ramp angle of incline is progressively increased at fixed intervals (e.g., 10 to 60 seconds), starting at zero grade with the increase in grade calculated on the basis of the patient's estimated functional capacity such that the protocol will be complete at between 6 and 12 minutes.[2] [3] [4] In this type of protocol, the rate of work increase is continuous and steady-state conditions are not reached. A limitation of ramp protocols is the requirement to estimate functional capacity from an activity scale; underestimation or overestimation of functional capacity occasionally results in an endurance test or premature cessation. One formula for estimating O_2 from treadmill speed and grade is

$$O_2\ (\text{ml } O_2 \cdot kg^{-1} \cdot min^{-1}) = (\text{mph} \times 2.68) + (1.8 \times 26.82 \times \text{mph} \times \text{grade} \div 100) + 3.5$$[23]

The peak O_2 is usually the same regardless of treadmill protocol used; the difference is the rate of time at which the peak O_2 is achieved.

It is important to encourage patients not to grasp the handrails of the treadmill during exercise. Functional capacity can be overestimated by as much as 20 percent in tests in which handrail support is permitted, and O_2 is decreased. Because the degree of handrail support is difficult to quantify from one test to another, more consistent results can be obtained during serial testing when handrail support is not permitted.

The *6-minute walk test* can be used for patients who have marked left ventricular dysfunction or peripheral arterial occlusive disease and who cannot perform bicycle or treadmill exercise.[24] [25] Patients are instructed to walk down a 100-foot corridor at their own pace, attempting to cover as much ground as possible in 6 minutes. At the end of the 6-minute interval, the total distance walked is determined and the symptoms experienced by the patient are recorded. The 6-minute walk test as a clinical measure of ambulatory function requires highly skilled personnel following a rigid protocol to elicit reproducible and reliable results. The coefficient of variation for distance walked during two 6-minute walk tests was 10 percent in one series of patients with peripheral arterial occlusive disease.[25]

Figure 6-2 Estimated oxygen cost of bicycle ergometer and selected treadmill protocols. The standard Bruce protocol starts at 1.7 mph and 10 percent grade (5 METs), with a larger increment between stages than protocols such as the Naughton, ACIP, and Weber protocols, which start at less than 2 METs at 2 mph and increase by 1- to 1.5-MET increments between stages. The Bruce protocol can be modified by two 3-minute warm-up stages at 1.7 mph and 0 percent grade and 1.7 mph and 5 percent grade.*(Adapted from Fletcher GF, Balady G, Froelicher VF, et al: Exercise standards. A statement for healthcare professionals from the American Heart Association. Circulation 91:580, 1995. Copyright 1995 American Heart Association.)*

TECHNIQUES.

Patients should be instructed not to eat, drink caffeinated beverages, or smoke for 3 hours before testing and to wear comfortable shoes and loose-fitting clothes. Unusual physical exertion should be avoided before testing. A brief history and physical examination should be performed, and patients should be advised about the risks and benefits of the procedure. A written informed consent form is usually required.[7] [8] The indication for the test should be known. In many laboratories, the presence or absence of atherosclerotic risk factors is noted and cardioactive medication recorded. A 12-lead ECG should be obtained with the electrodes at the distal extremities. The timing of cardioactive medication ingestion before testing depends on the test indication.

After the standard 12-lead ECG is recorded, a torso ECG should be obtained in the supine position and in the sitting or standing position. Postural changes can elicit labile ST-T wave abnormalities. Hyperventilation is not recommended before exercise. If a false-positive test result is suspected, hyperventilation should be performed

after the test, and the hyperventilation tracing compared with the maximal ST segment abnormalities observed. The ECG and blood pressure should be recorded in both positions, and patients should be instructed on how to perform the test.

Adequate skin preparation is essential for high-quality recordings, and the superficial layer of skin needs to be removed to augment signal-to-noise ratio. The areas of electrode application are rubbed with an alcohol-saturated pad to remove oil and rubbed with free sandpaper or a rough material to reduce skin resistance to 5000 ohms or less. Silver chloride electrodes with a fluid column to avoid direct metal-to-skin contact produce high-quality tracings; these electrodes have the lowest offset voltage.

Cables connecting the electrodes and recorders should be light, flexible, and properly shielded. In a small minority of patients, a fishnet jersey may be required over the electrodes and cables to reduce motion artifact. The electrode-skin interface can be verified by tapping on the electrode and examining the monitor or by measuring skin impedance. Excessive noise indicates that the electrode needs to be replaced; replacement before the test rather than during exercise can save time. The ECG signal can be digitized systematically at the patient's end of the cable by some systems, reducing power line artifact. Cables, adapters, and junction box have a finite life span and require periodic replacement to obtain the highest quality tracings. Exercise equipment should be calibrated regularly. Room temperature should be between 64 and 72°F (18 and 22°C) and humidity less than 60 percent.

Treadmill walking should be demonstrated to the patient. The heart rate, blood pressure, and ECG should be recorded at the end of each stage of exercise, immediately before and immediately after stopping exercise, at the onset of an ischemic response, and for each minute for at least 5 to 10 minutes in the recovery phase. A minimum of three leads should be displayed continuously on the monitor during the test. There is some controversy about optimal patient position in the recovery phase. In the sitting position, less space is required for a stretcher, and patients are more comfortable immediately after exertion. The supine position increases end-diastolic volume and has the potential to augment ST segment changes.[26]

ELECTROCARDIOGRAPHIC MEASUREMENTS

LEAD SYSTEMS.

The Mason-Likar modification of the standard 12-lead ECG requires that the extremity electrodes be moved to the torso to reduce motion artifact. The arm electrodes should be located in the most lateral aspects of the infraclavicular fossae, and the leg electrodes in a stable position above the anterior iliac crest and below the rib cage. The Mason-Likar modification results in a right-axis shift and increased voltage in the inferior leads and may produce a loss of inferior Q waves and the development of new Q waves in lead aV_L . Thus, the body torso limb lead positions cannot be used to interpret a diagnostic rest 12-lead ECG. The more cephalad the leg electrodes are placed, the greater is the degree of change and the greater is the augmentation of R wave amplitude, potentiating exercise-induced ST segment changes.

Bipolar lead groups place the negative or reference electrode over the manubrium (CM_5), right scapula (CB_5), RV_5 (CC_5), or on the forehead (CH_5), and the active electrode at V_5 or proximate location to optimize R wave amplitude. In bipolar lead ML, which reflects inferior wall changes, the negative reference is at the manubrium and the active electrode in the left leg position. Bipolar lead groups may provide additional diagnostic information, and in some medical centers, lead CM_5 is substituted for lead aV_r in the Mason-Likar modified lead system (Fig. 6-3) . Bipolar leads are frequently used when only a limited ECG set is required (e.g., in cardiac rehabilitation programs). In one series of patients, the use of right precordial leads (V3-5 R) increased the sensitivity to detect exercise-induced ST segment shifts.[27] The use of more elaborate lead set systems is usually reserved for research purposes.

Types of ST Segment Displacement

In normal persons, the PR, QRS, and QT intervals shorten as heart rate increases. P amplitude increases, and the PR

Figure 6-3 J point depression of 2 to 3 mm in leads V_4 to V_6 with rapid upsloping ST segments depressed approximately 1 mm 80 msec after the J point. The ST segment slope in leads V_4 and V_5 is 3.0 mV/sec. This response should not be considered abnormal.

segment becomes progressively more downsloping in the inferior leads. J point, or junctional, depression is a normal finding during exercise (see Fig. 6-3) . In patients with myocardial ischemia, however, the ST segment usually becomes more horizontal (flattens) as the severity of the ischemic response worsens. With progressive exercise, the depth of ST segment depression may increase, involving more ECG leads, and the patient may develop angina. In the immediate postrecovery phase, the ST segment displacement may persist, with downsloping ST segments and T wave inversion, gradually returning to baseline after 5 to 10 minutes (Figs. 6-4 and 6-5) . Ischemic ST segment displacement may be seen only during exercise, emphasizing the importance of adequate skin preparation and electrode placement to capture high-quality recordings during maximum exertion (see Fig. 6-6) . In about 10 percent of patients, the ischemic response may appear only in the recovery phase. The prevalence of recovery-onset ischemic ST segment changes is higher in asymptomatic populations compared with those with symptomatic CAD.[28] Patients should not leave the exercise laboratory area until the postexercise ECG has returned to baseline. Figure 6-7 illustrates eight different ECG patterns seen during exercise testing.[29]

MEASUREMENT OF ST SEGMENT DISPLACEMENT.

For purposes of interpretation, the PQ junction is usually chosen as the isoelectric point. The TP segment represents a true isoelectric point but is an impractical choice for most routine clinical measurements. The development of 0.10 mV (1 mm) or greater of J point depression measured

Figure 6-4 Bruce protocol. In lead V_4 , the exercise ECG result is abnormal early in the test, reaching 0.3 mV (3 mm) of horizontal ST segment depression at the end of exercise. The ischemic changes persist for at least 1 minute and 30 seconds into the recovery phase. The right panel provides a continuous plot of the J point, ST slope, and ST segment displacement at 80 msec after the J point (ST level) during exercise and in the recovery phase. Exercise ends at the vertical line at 4.5 min. The computer trends permit a more precise identification of initial onset and offset of ischemic ST segment depression. This type of ECG pattern, with early onset of ischemic ST segment depression, reaching more than 3 mm of horizontal ST segment displacement and persisting several minutes into the recovery phase, is consistent with a severe ischemic response.

Figure 6-5 Bruce protocol. In this type of ischemic pattern, the J point at peak exertion is depressed 2.5 mm, the ST segment slope is 1.5 mV/sec, and the ST segment level at 80 msec after the J point is depressed 1.6 mm. This "slow upsloping" ST segment at peak exercise indicates an ischemic pattern in patients with a high coronary disease prevalence pretest. A typical ischemic pattern is seen at 3 minutes of the recovery phase when the ST segment is horizontal and 5 minutes after exertion when the ST segment is downsloping. Exercise is discontinued at the vertical line in the right panel at 7.5 minutes.

from the PQ junction, with a relatively flat ST segment slope (<1 mV/sec), depressed greater than or equal to 0.10 mV 80 msec after the J point (ST 80) in three consecutive beats with a stable baseline is considered to be an abnormal response (Fig. 6-8) . When the ST 80 measurement is difficult to determine at rapid heart rates (e.g., >130 beats/min), the ST 60 measurement should be used. The ST segment at rest may occasionally be depressed. When this occurs, the J point and ST 60 or ST 80 measurements should be depressed an additional 0.10 mV or greater to be considered abnormal.

When the degree of resting ST segment depression is 0.1 mV or greater, the exercise ECG becomes less specific, and myocardial imaging modalities should be considered.[5] [11] In patients with early repolarization and resting ST segment elevation, return to the PQ junction is normal. Therefore, the magnitude of exercise-induced ST segment depression in a patient with early repolarization should be determined from the PQ junction and not from the elevated position of the J point before exercise. Exercise-induced ST segment depression does *not* localize the site of myocardial ischemia, *nor* does it provide a clue about which coronary artery is involved. For example, it is not unusual for patients with isolated right CAD to exhibit exercise-induced ST segment depression only in leads V_4 to V_6 , nor is it unusual for patients with disease of the left anterior descending coronary artery to exhibit exercise-induced ST segment displacements in leads II, III, and aV_f . Exercise-induced ST segment elevation is relatively specific for the territory of myocardial ischemia and the coronary artery involved.

UPSLOPING ST SEGMENTS.

Junctional or J point depression is a normal finding during maximal exercise, and a

Figure 6-6 Bruce protocol. The exercise ECG result is not yet abnormal at 8:50 minutes but becomes abnormal at 9:30 minutes (horizontal arrow *right*) of a 12-minute exercise test and resolves in the immediate recovery phase. This ECG pattern in which the ST segment becomes abnormal only at high exercise workloads and returns to baseline in the immediate recovery phase may indicate a false-positive result in an asymptomatic individual without atherosclerotic risk factors. Exercise myocardial imaging would provide more diagnostic and prognostic information if this were an older person with several atherosclerotic risk factors.

rapid upsloping ST segment (>1 mV/sec) depressed less than 0.15 mV (1.5 mm) after the J point should be considered to be normal. Occasionally, however, the ST segment is depressed 0.15 mV (1.5 mm) or greater at 80 msec after the J point. This type of slow upsloping ST segment may be the only ECG finding in patients with well-defined obstructive CAD and may depend on the lead set used (see Fig. 6-5) . In patient subsets with a high CAD prevalence, a slow upsloping ST segment depressed 0.15 mV or greater at 80 msec after the J point should be considered to be abnormal. The importance of this finding in asymptomatic individuals or those with a low CAD prevalence is less certain. Increasing the degree of ST segment depression at 80 msec after the J point to 0.20 mV (2.0 mm) or greater in patients with a slow upsloping ST segment increases specificity but decreases sensitivity.[29]

ST SEGMENT ELEVATION.

Exercise-induced ST segment elevation may occur in an infarct territory where Q waves are present or in a noninfarct territory. The development of 0.10 mV (1 mm) or greater of J point elevation, persistently elevated greater than 0.10 mV at 60 msec after the J point in three consecutive beats with a stable baseline, is considered an abnormal response (see Fig. 6-7) . This finding occurs in approximately 30 percent of patients with anterior myocardial infarctions and 15 percent of those with inferior ones tested early (within 2 weeks) after the index event and decreases in frequency by 6 weeks. As a group, postinfarct patients with exercise-induced ST segment elevation have a lower ejection fraction than those without, a greater severity of resting wall motion abnormalities, and a worse prognosis. Exercise-induced ST segment elevation in leads with abnormal Q waves is *not* a marker of more extensive CAD and rarely indicates myocardial ischemia. Exercise-induced ST-segment elevation may occasionally occur in a patient who has regenerated embryonic R waves after an acute myocardial infarction; the clinical significance of this finding is similar to that observed when Q waves are present.

When ST segment elevation develops during exercise in a non-Q wave lead in a patient without a previous myocardial infarction, the finding should be considered as likely evidence of transmural myocardial ischemia caused by coronary vasospasm or a high-grade coronary narrowing (Fig. 6-9) . This finding is relatively uncommon, occurring in approximately 1 percent of patients with obstructive CAD. The ECG site of ST segment elevation is relatively specific for the coronary artery involved, and myocardial perfusion scintigraphy usually reveals a defect in the territory involved.

T WAVE CHANGES.

The morphology of the T wave is influenced by body position, respiration, hyperventilation, drug therapy, and myocardial ischemia/necrosis. In patient populations with a low CAD prevalence, pseudonormalization of T waves (inverted at rest and becoming upright with exercise) is a nondiagnostic finding (Fig. 6-10) . In rare instances, this finding may be a marker for myocardial ischemia in a patient with documented CAD, although it would need to be substantiated by an ancillary technique, such as the concomitant finding of a reversible myocardial perfusion defect.[30]

OTHER ELECTROCARDIOGRAPHIC MARKERS.

Changes in R wave amplitude during exercise are relatively nonspecific and are related to the level of exercise performed. When the R wave amplitude meets voltage criteria for left ventricular hypertrophy, the ST segment response *cannot* be used reliably to diagnose CAD, even in the absence of a left ventricular strain pattern. Loss of R wave amplitude, commonly seen after myocardial infarction, reduces the sensitivity of the ST segment response in that lead to diagnose obstructive CAD. Adjustment of the extent of ST segment depression by R wave height in individual leads has not been consistently shown to improve the diagnostic value of the exercise ECG for CAD. U wave inversion may occasionally be seen in the precordial leads at heart rates of 120 beats/min. Although this finding is relatively specific for CAD, it is relatively insensitive.[31]

COMPUTER-ASSISTED ANALYSIS

The use of computers has facilitated the routine analysis and measurements required from exercise ECG and can be performed on line as well as off line.[32] When the raw ECG data are high quality, the computer can filter and average or select median complexes from which the degree of J point displacement, ST segment slope, and ST displacement 60 to 80 msec after the J point (ST 60 to 80) can be measured. The selection of ST 60 or ST 80 depends on the heart rate response. At ventricular rates greater than 130 beats/min, the ST 80 measurement may fall on the upslope of the T wave, and the ST 60 measurement should be used instead. In some computerized systems, the PQ junction or isoelectric interval is detected by scanning before the R wave for the 10-msec interval with the least slope. J point, ST slope, and ST levels are determined (see Figs. 6-4 , 6-5 , and 6-6) ; the ST integral can be calculated from the area below the isoelectric line from the J point to ST 60 or ST 80.[29] Computerized treatment of ECG complexes permits reduction of motion and myographic artifacts. However, the averaged or median beats may occasionally be erroneous because of ECG signal distortion caused by noise, baseline wander, or changes in conduction, and identification of the PQ junction and ST segment onset may be imperfect. Therefore, it is crucial to ensure that the computer-determined averages or median complexes reflect the raw ECG data, and physicians should program the computer to print out raw data during exercise and inspect the raw data to be certain that the QRS template is accurately reproduced before accepting the automatic measurements.

ST/HEART RATE SLOPE MEASUREMENTS.

Heart rate adjustment of ST segment depression appears to improve the sensitivity of the exercise test, particularly the prediction of multivessel CAD.[33] The ST/heart rate slope depends on the type of exercise performed, number and location of monitoring electrodes, method of measuring ST segment depression, and clinical characteristics of the study population. Calculation of maximal ST/heart rate slope in mV/beats/min is performed by linear regression analysis relating the measured amount of ST segment depression in individual leads to the heart rate at the end of each stage of exercise, starting at the end of exercise. An ST/heart

Figure 6-7 Illustration of eight typical exercise ECG patterns at rest and at peak exertion. The computer-processed incrementally averaged beat corresponds with the raw data taken at the same time point during exercise and is illustrated in the last column. The patterns represent worsening ECG responses during exercise. In the column of computer-averaged beats, ST 80 displacement (top number) indicates the magnitude of ST segment displacement 80 msec after the J point relative to the PQ junction or E point. ST segment slope measurement (bottom number) indicates the ST segment slope at a fixed time point after the J point to the ST 80 measurement. At least three noncomputer average complexes with a stable baseline should meet criteria for abnormality before the exercise ECG result can be considered abnormal (see Fig. 6-9) . The normal and rapid upsloping ST segment responses are normal responses to exercise. J point depression with rapid upsloping ST segments is a common response in an older, apparently healthy population. Minor ST depression can occur occasionally at submaximal workloads in patients with coronary disease; in this illustration, the ST segment is depressed 0.09 mV (0.9 mm) 80 msec after the J point. The slow upsloping ST segment pattern often demonstrates an ischemic response in patients with known coronary disease or those with a high pretest clinical risk of coronary disease. Criteria for slow upsloping ST segment depression include J point and ST 80 depression of 0.15 mV or more and ST segment slope of more than 1.0 mV/sec. Classic criteria for myocardial ischemia include horizontal ST segment depression observed when both the J point and ST 80 depression are 0.1 mV or more and ST segment slope is within the range of 1.0 mV/sec. Downsloping ST segment depression occurs when the J point and ST 80 depression are 0.1 mV and ST segment slope is -1.0 mV/sec. ST segment elevation in a non-Q wave noninfarct lead occurs when the J point and ST 60 are 1.0 mV or greater and represents a severe ischemic response. ST segment elevation in an infarct territory (Q wave lead) indicates a severe wall motion abnormality and in most cases is not considered an ischemic response.*(From Chaitman BR: Exercise electrocardiographic stress testing. In Beller GA [ed]: Chronic Ischemic Heart Disease. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 5. Chronic Ischemic Heart Disease. Philadelphia, Current Medicine, 1995, pp 2.1-2.30.)*

rate slope of 2.4 mV/beats/min is considered abnormal, and values that exceed 6 mV/beats/min are suggestive evidence of three-vessel CAD. The use of this measurement requires modification of the exercise protocol such that increments in heart rate are gradual, as in the Cornell protocol, as opposed to more abrupt increases in heart rate between stages, as in the Bruce's or Ellestad's protocols, which limit the ability to calculate statistically valid ST segment heart rate slopes. The

measurement is not accurate in the early postinfarction phase. A modification of the ST segment/heart rate slope method is the ST segment/heart rate index calculation, which represents the average change of ST segment depression with heart rate throughout the course of the exercise test. The ST/heart rate index measurements are less than the ST/heart rate slope measurements, and a ST/heart rate index of 1.6 is defined as abnormal. A slight increase in the prognostic content of ST segment/heart rate slope measurements as compared with standard criteria was demonstrated in the Multiple Risk Factor Interventional Trial.[34] [35]

MECHANISM OF ST SEGMENT DISPLACEMENT

PATHOPHYSIOLOGY OF THE MYOCARDIAL ISCHEMIC RESPONSE.

Myocardial oxygen consumption (M_2) is determined by heart rate, systolic blood pressure, left ventricular end-diastolic volume, wall thickness, and contractility (see Chap. 34) .[2] [7] [12] The rate-pressure or double product (heart rate × systolic blood pressure) increases progressively with increasing work and can be used to estimate the myocardial perfusion requirement in normal persons and in many patients with coronary artery disease. The heart is an aerobic organ with little capacity to generate energy through anaerobic metabolism. Oxygen extraction in the coronary circulation is nearly maximal at rest. The only significant mechanism available to the heart to increase oxygen consumption is to increase perfusion, and there is a direct linear relationship between M_2 and coronary blood flow in normal individuals. The principal mechanism for increasing coronary blood flow during exercise is to decrease resistance at the coronary arteriolar level.[36] In

Figure 6-8 Magnified ischemic exercise-induced ECG pattern. Three consecutive complexes with a relatively stable baseline are selected. The PQ junction (1) and J point (2) are determined; the ST 80 (3) is determined at 80 msec after the J point. In this example, average J point displacement is 0.2 mV (2 mm) and ST 80 is 0.24 mV (24 mm). The average slope measurement from the J point to ST 80 is -1.1 mV/sec.

patients with progressive atherosclerotic narrowing of the epicardial vessels, an ischemic threshold occurs, and exercise beyond this threshold can produce abnormalities in diastolic and systolic ventricular function, ECG changes, and chest pain. The subendocardium is more susceptible to myocardial ischemia than the subepicardium because of increased wall tension, causing a relative increase in myocardial oxygen demand in the subendocardium.

Dynamic changes in coronary artery tone at the site of an atherosclerotic plaque may result in diminished coronary flow during static or dynamic exercise; i.e., perfusion pressure distal to the stenotic plaque actually falls as during exercise, resulting in reduced subendocardial blood flow.[37] Thus, regional left ventricular myocardial ischemia may result not only from an increase in myocardial oxygen demand during exercise but also from a limitation of coronary flow as a result of coronary vasoconstriction and inability of vessels to dilate near the site of an atherosclerotic plaque.

In normal persons, the action potential duration of the endocardial region is longer than that of the epicardial region, and ventricular repolarization is from epicardium to endocardium. The action potential duration is shortened in the presence of myocardial ischemia, and electrical gradients are created, resulting in ST segment depression or elevation, depending on the surface ECG leads.[38] Increased myocardial oxygen demand associated with a failure to increase or an actual decrease in regional coronary blood flow usually causes ST segment depression; ST segment elevation may occasionally occur in patients with more severe coronary flow reduction.

NONELECTROCARDIOGRAPHIC OBSERVATIONS

The ECG is only one part of the exercise response, and abnormal hemodynamics or functional capacity is just as important if not more so than ST segment displacement.

BLOOD PRESSURE.

The normal exercise response is to increase systolic blood pressure progressively with increasing workloads to a peak response ranging from 160 to 200 mm Hg, with the higher range of the scale in older patients with less compliant vascular systems.[2] [7] As a group, African American patients--here and elsewhere--tend to have a higher systolic blood pressure response than do whites.[39] At high exercise workloads, it is sometimes difficult to obtain a precise determination of systolic blood pressure by auscultation.[40] In normal persons, the diastolic

Figure 6-9 A 48-year-old man with several atherosclerotic risk factors and a normal rest ECG result developed marked ST segment elevation (4 mm [arrows]) in leads V_2 and V_3 with lesser degrees of ST segment elevation in leads V_1 and V_4 and J point depression with upsloping ST segments in lead II, associated with angina. This type of ECG pattern is usually associated with a full-thickness, reversible myocardial perfusion defect in the corresponding left ventricular myocardial segments and high-grade intraluminal narrowing at coronary angiography. Rarely, coronary vasospasm produces this result in the absence of significant intraluminal atherosclerotic narrowing.*(From Chaitman BR: Exercise electrocardiographic stress testing. In Beller GA [ed]: Chronic Ischemic Heart Disease. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 5. Chronic Ischemic Heart Disease. Philadelphia, Current Medicine, 1995, pp 2.1-2.30.)*

Figure 6-10 Pseudonormalization of T waves in a 49-year-old man referred for exercise testing. The patient had previously been seen for typical angina. The rest electrocardiogram in this patient with coronary artery disease shows inferior and anterolateral T wave inversion, an adverse long-term prognosticator. The patient exercised to 8 METs, reaching a peak heart rate of 142 beats/min and a peak systolic blood pressure of 248 mm Hg. At that point, the test was stopped because of hypertension. During exercise, pseudonormalization of T waves occurs, and it returns to baseline (inverted T wave) in the postexercise phase. The patient denied chest discomfort, and no arrhythmia or ST segment displacement was noted. Transient conversion of a negative T wave at rest to a positive T wave during exercise is a nonspecific finding in patients without prior myocardial infarction and does not enhance the diagnostic or prognostic content of the test; however, the ability to exercise to 8 METs without ischemic changes in the ST segment places this patient into a subset of lower risk.*(From Chaitman BR: Exercise electrocardiographic stress testing. In Beller GA [ed]: Chronic Ischemic Heart Disease. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 5. Chronic Ischemic Heart Disease. Philadelphia, Current Medicine, 1995, pp 2.1-2.30.*

blood pressure does not usually change significantly. Failure to increase systolic blood pressure beyond 120 mm Hg, or a sustained decrease greater than 10 mm Hg repeatable within 15 seconds, or a fall in systolic blood pressure below standing rest values is abnormal and reflects either inadequate elevation of cardiac output because of left ventricular systolic pump dysfunction or an excessive reduction in systemic vascular resistance.[41] An abnormal systolic blood pressure response in patients with a high prevalence of CAD is associated with more extensive CAD and more extensive myocardial perfusion defects; exertional hypotension ranges from 3 to 9 percent and is higher in patients with three-vessel or left main CAD. Conditions other than myocardial ischemia that have been associated with the failure to increase or an actual decrease in systolic blood pressure during progressive exercise are cardiomyopathy, cardiac arrhythmias, vasovagal reactions, left ventricular outflow tract obstruction, ingestion of antihypertensive drugs, hypovolemia, and prolonged vigorous exercise.[42]

It is important to distinguish between a decline in blood pressure in the postexercise phase and a decrease or failure to increase systolic blood pressure *during* progressive exercise. The incidence of postexertional hypotension in asymptomatic subjects was 1.9 percent in 781 asymptomatic volunteers in the Baltimore Longitudinal Study on Aging, with a 3.1 percent incidence noted in subjects younger than 55 years and 0.3 percent incidence in patients older than 55 years.[43] In this series, most hypotensive episodes were symptomatic, and only two patients had hypotension associated with bradycardia and vagal symptoms. Although ST segment abnormalities suggestive of ischemia occurred in one-third of the patients with hypotension, none of the patients had a cardiac event during 4 years of follow-up. Rarely, in young patients, vasovagal syncope can occur in the immediate postexercise phase, progressing through sinus bradycardia to several seconds of asystole and hypotension before reverting to sinus rhythm.

MAXIMAL WORK CAPACITY.

This variable is one of the most important prognostic measurements obtained from an exercise test.[44] [45] [46] [47] [48] Maximal work capacity in normal individuals is influenced by familiarization with the exercise test equipment, level of training, and environmental conditions at the time of testing. In patients with known or suspected CAD, a limited exercise capacity is associated with an increased risk of cardiac events, and in general, the more severe the limitation, the worse the CAD extent and

prognosis. In estimating functional capacity, the amount of work performed (or exercise stage achieved) should be the parameter measured and not the number of minutes of exercise. Estimates of peak functional capacity for age and gender have been well established for most of the exercise protocols in common use, subject to the limitations described in the section on cardiopulmonary testing. Comparison of an individual's performance against normal standards provides an estimate of the degree of exercise impairment. There is a rough correlation between observed peak functional capacity during exercise treadmill testing and estimates derived from clinical data and specific activity questionnaires.[49]

Serial comparison of functional capacity in individual patients to assess significant interval change requires a careful examination of the exercise protocol used during both tests, of drug therapy and time of ingestion, of systemic blood pressure, and of other conditions that might influence test performance. All these variables need to be considered before attributing changes in functional capacity to progression of CAD or worsening of left ventricular function. Major reductions in exercise capacity usually indicate significant worsening of cardiovascular status; modest changes may not.

SUBMAXIMAL EXERCISE.

The interpretation of exercise test results for diagnostic and prognostic purposes requires

consideration of maximal work capacity. When a patient is unable to complete moderate levels of exercise or reach at least 85 to 90 percent of age-predicted maximum, the level of exercise performed may be inadequate to test cardiac reserve. Thus, ischemic ECG, scintigraphic, or ventriculographic abnormalities may not be evoked and the test may be nondiagnostic. Nondiagnostic test results are more common in patients with peripheral vascular disease, orthopedic limitation, or neurological impairment and in patients with poor motivation. Pharmacologic stress imaging studies should be considered in this setting.[5] [6] [11]

HEART RATE RESPONSE.

The sinus rate increases progressively with exercise, mediated in part through sympathetic and parasympathetic innervation of the sinoatrial node and circulating catecholamines. In some patients who may be anxious about the exercise test, there may be an initial overreaction of heart rate and systolic blood pressure at the beginning of exercise, with stabilization after approximately 30 to 60 seconds. An inappropriate increase in heart rate at low exercise workloads may occur in patients who are in atrial fibrillation, physically deconditioned, hypovolemic, or anemic or who have marginal left ventricular function; this increase may persist for several minutes in the recovery phase. The term *chronotropic incompetence* refers to a heart rate increment per stage of exercise that is less than normal or a peak heart rate below predicted at maximal workloads.[50] [51] This finding may indicate sinus node disease, may be present with drug therapy such as beta blockers or in patients with compensated congestive heart failure, or may indicate a myocardial ischemic response. In a series of 2953 low-risk subjects who were referred for treadmill exercise myocardial perfusion imaging and who were not taking beta-adrenergic blocking drugs, failure to achieve 85 percent of age-predicted maximal heart rate, or a low chronotropic index (<80% of heart rate reserve at peak exercise) was associated with an approximate two-fold increased risk of death during 2 years of follow-up)[50] (Fig 6-11) .

RATE-PRESSURE PRODUCT.

The heart rate-systolic blood pressure product, an indirect measure of myocardial oxygen demand, increases progressively with exercise, and the peak rate pressure product can be used to characterize cardiovascular performance. Most normal individuals develop

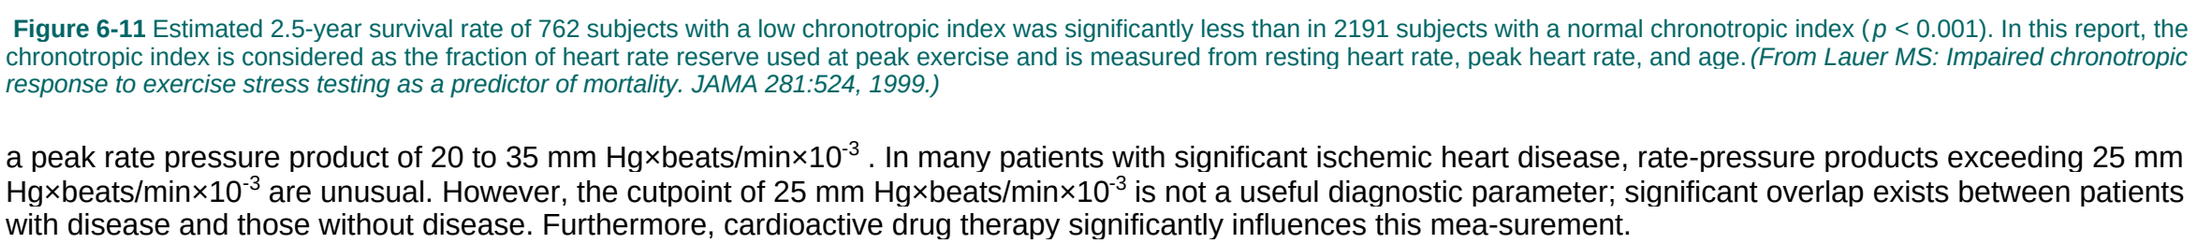

Figure 6-11 Estimated 2.5-year survival rate of 762 subjects with a low chronotropic index was significantly less than in 2191 subjects with a normal chronotropic index ($p < 0.001$). In this report, the chronotropic index is considered as the fraction of heart rate reserve used at peak exercise and is measured from resting heart rate, peak heart rate, and age. *(From Lauer MS: Impaired chronotropic response to exercise stress testing as a predictor of mortality. JAMA 281:524, 1999.)*

a peak rate pressure product of 20 to 35 mm Hg×beats/min×10^{-3} . In many patients with significant ischemic heart disease, rate-pressure products exceeding 25 mm Hg×beats/min×10^{-3} are unusual. However, the cutpoint of 25 mm Hg×beats/min×10^{-3} is not a useful diagnostic parameter; significant overlap exists between patients with disease and those without disease. Furthermore, cardioactive drug therapy significantly influences this mea-surement.

CHEST DISCOMFORT.

Characterization of chest discomfort during exercise can be a useful diagnostic finding, particularly when the symptom complex is compatible with typical angina pectoris. In some patients, the exercise level during the test may exceed that which the patient exhibits in day-to-day activities. Exercise-induced chest discomfort usually occurs after the onset of ischemic ST segment abnormalities and may be associated with diastolic hypertension.[52] However, in some patients, chest discomfort may be the only signal that obstructive CAD is present. In patients with chronic stable angina, exercise-induced chest discomfort occurs less frequently than ischemic ST segment depression. The severity of myocardial ischemia in a patient with exercise-induced angina and a normal ECG can often be assessed using a myocardial imaging technique.[5] [6] [11] The new development of an S_3 , holosystolic apical murmur, or basilar rates in the early recovery phase of exercise enhances the diagnostic accuracy of the test.

Exercise Test Indications

The most frequent indications for exercise testing are to aid in establishing the diagnosis of CAD, in determining functional capacity, and in estimating prognosis. The indications continue to evolve, with some that are uniformly accepted and others that are more controversial. The American Heart Association (AHA) and American College of Cardiology (ACC) Exercise Task Force determined several categories of test indications drawn from a large body of published literature on exercise testing[5] (see Guidelines Section, p. 155). Exercise testing should not be used to screen very low-risk, asymptomatic individuals because the test has limited diagnostic and prognostic value in this situation, and the resultant undesirable consequences of a false-positive exercise test result may result in unnecessary follow-up, additional procedures, anxiety, and exercise restrictions.[5] [6] Most asymptomatic subjects who are enrolled in an exercise screening program for CAD and who die suddenly of cardiac causes have had a previous normal exercise test result. In patients with established CAD, low-risk patients with an estimated annual mortality less than 1 percent per year do not require repeat testing for several years after their initial evaluation. Higher-risk patients (estimated annual mortality >3%) might require more frequent follow-up testing on an annual basis in the absence of a change of symptoms.[53]

DIAGNOSTIC USE OF EXERCISE TESTING

Appreciation of the noninvasive test literature to diagnose CAD requires an understanding of standard terminology such as sensitivity, specificity, and test accuracy[1] [2] [3] [4] [5] [6] (Tables 6-1 and 6-G-2) . The sensitivity of the exercise ECG in patients with CAD is approximately 68 percent, and specificity is 77 percent.[2] In patients with single-vessel disease, the sensitivity ranges from 25 to 71 percent, with exercise-induced ST displacement most frequent in patients with left anterior descending CAD, followed by those with right CAD and those with isolated left circumflex CAD. In patients with multivessel CAD, sensitivity is approximately 81 percent and specificity is 66 percent.[2] The sensitivity and specificity for left main or three-vessel CAD are approximately

TABLE 6-1 -- TERMS USEFUL IN EVALUATION OF TEST RESULTS

True positive (TP)=abnormal test results in individual with disease
False positive (FP)=abnormal test results in individual without disease
True negative (TN)=normal test result in individual without disease
False negative (FN)=normal test result in individual with disease
Sensitivity: percentage of patients with CAD who have an abnormal result=TP/(TP+FN)

Specificity: percentage of patients without CAD who have a normal result=TN/(TN+FP)
Predictive value: percentage of patients with abnormal result who have CAD=TN/(TN+FN)
Test accuracy: percentage of true test results=(TP+TN)/total number tests performed
Likelihood ratio: odds of a test result being true: of an abnormal test: sensitivity/(1-specificity); of a normal test: specificity/(1-sensitivity)

CAD=coronary artery disease.

86 percent and 53 percent. The exercise ECG tends to be less sensitive in patients with extensive anterior wall myocardial infarction and when a limited exercise ECG lead set is used. Approximately 75 to 80 percent of the diagnostic information on exercise-induced ST segment depression in patients with a normal rest ECG is contained in leads V_4 to V_6 . Exercise ECG is less specific when patients in whom false-positive results are more common are included--i.e., those with valvular heart disease, left ventricular hypertrophy, marked resting ST segment depression, or digitalis therapy.[5] Table 6-2 lists the more common causes of noncoronary exercise-induced ST segment depression.

The traditional reference standard against which the exercise ECG has been measured is a qualitative assessment of the coronary angiogram using 50 to 70 percent obstruction of the luminal diameter as the angiographic cutpoint. Limitations are inherent in angiographic classification of patients into one-, two-, and three-vessel CAD, and the length of the coronary artery narrowing and the impact of serial lesions are not accounted for in correlative studies comparing diagnostic exercise testing with coronary angiographic findings. Other approaches, including intracoronary Doppler flow studies and quantitative coronary angiography, have been proposed to assess coronary vascular reserve; these may be more accurate than qualitative assessment of the angiogram.[54] [55] [56] [57] [58] In patients with ischemic-appearing ST segment depression during exercise and normal findings on coronary angiography (syndrome X), coronary endothelial dysfunction as measured by coronary vasomotor responsiveness to acetylcholine does not account for the ischemic ST segment response.[59]

TABLE 6-2 -- NONCORONARY CAUSES OF ST SEGMENT DEPRESSION

Severe aortic stenosis	Glucose load
Severe hypertension	Left ventricular hypertrophy
Cardiomyopathy	Hyperventilation
Anemia	Mitral valve prolapse
Hypokalemia	Intraventricular conduction disturbance
Severe hypoxia	Preexcitation syndrome
Digitalis use	Severe volume overload (aortic, mitral regurgitation)
Sudden excessive exercise	Supraventricular tachyarrhythmias

Selective referral of patients with a positive test result for further study both decreases the rate of detection of true negative test results and increases the rate of detection of false-positive results, thus increasing sensitivity and decreasing specificity.[1] [2] [3] [4] Froelicher and colleagues, in a study of 814 consecutive patients who presented with angina pectoris and agreed to undergo both exercise testing and coronary angiography, reported an exercise ECG sensitivity and specificity of 45 percent and 85 percent, respectively for obstructive CAD using visual analysis in this population with reduced work-up bias.[60] Computerized ST segment measurements were similar to visual ST segment measurements in this study. A false-positive result is more common when only the inferior lead group (leads 2, 3, aV_f) is abnormal at high exercise workloads.

BAYESIAN THEORY.

The depth of exercise-induced ST-segment depression and the extent of the myocardial ischemic response can be thought of as continuous variables. Cutpoints such as 1 mm of horizontal or downsloping ST segment depression as compared with baseline cannot completely discriminate patients with disease from those without disease, and the requirement of more severe degrees of ST segment depression to improve specificity will decrease sensitivity. Sensitivity and specificity are inversely related, and false-negative and false-positive results are to be expected when ECG or angiographic cutpoints are selected to optimize the diagnostic accuracy of the test.[1] [2] [3] [4] [5] [6] [61]

The use of Bayesian theory incorporates the pretest risk of disease and the sensitivity and specificity of the test (likelihood ratio) to calculate the posttest probability of coronary disease. The results of a patient's clinical information and exercise test results are used to make a final estimate of the probability of CAD. Atypical or probable angina in a 50-year-old man or a 60-year-old woman is associated with approximately 50 percent probability for CAD before exercise testing is performed. The diagnostic power of the exercise test is maximal when the pretest probability of CAD is intermediate (30 to 70 percent).

MULTIVARIATE ANALYSIS.

Multivariate analysis of noninvasive exercise tests to estimate posttest risk also can provide important diagnostic information. Multivariate analysis offers the potential advantage that it does not require that the tests be independent of each other or that sensitivity and specificity remain constant over a wide range of disease prevalence rates. However, the multivariate technique depends critically on how patients are selected to establish the reference data base. Both Bayesian and multivariate approaches are commonly used to provide diagnostic and prognostic estimates of patients with CAD.

SEVERITY OF ELECTROCARDIOGRAPHIC ISCHEMIC RESPONSE.

The exercise ECG result is more likely to be abnormal in patients with more severe coronary arterial obstruction, with more extensive CAD, and after more strenuous levels of exercise. Early onset of angina, ischemic ST segment depression, and fall in blood pressure at low exercise workloads are the most important exercise parameters associated with an adverse prognosis and multivessel CAD.[62] Additional adverse markers include profound ST segment displacement, ischemic changes in five or more ECG leads, and persistence of the changes late in the recovery phase of exercise (Table 6-3) .

EXERCISE TESTING IN DETERMINING PROGNOSIS

Exercise testing provides not only diagnostic information but also more importantly prognostic data. The value of exercise testing to estimate prognosis must be considered in light of what is already known about a patient's risk status. Left ventricular dysfunction, CAD extent, electrical instability,

TABLE 6-3 -- EXERCISE PARAMETERS ASSOCIATED WITH AN ADVERSE PROGNOSIS AND MULTIVESSEL CORONARY ARTERY DISEASE

Duration of symptom-limiting exercise <6 METs
Failure to increase systolic blood pressure 120 mm Hg, or a sustained decrease 10 mm Hg, or below rest levels, during progressive exercise
ST segment depression 2 mm, downsloping ST segment, starting at <6 METs, involving 5 leads, persisting 5 min into recovery
Exercise-induced ST segment elevation (aV_r excluded)

Angina pectoris at low exercise workloads
Reproducible sustained (>30 sec) or symptomatic ventricular tachycardiaAcute systemic illness (pulmonary embolism, aortic dissection)

and noncoronary comorbid conditions must be taken into consideration when estimating long-term outcome.

ASYMPTOMATIC POPULATION.

The prevalence of an abnormal exercise ECG result in middle-aged asymptomatic men ranges from 5 to 12 percent.[63] [64] [65] [66] The risk of developing a cardiac event such as angina, myocardial infarction, or death in men is nine times greater when the test result is abnormal as when it is normal; however, over 5 years of follow-up, only one in four such men will suffer a cardiac event, and this will most commonly be the development of angina. The risk is slightly greater when the test result is strongly positive. In the LRC Prevention Trial, a strongly positive test result was defined as one in which the ST response was 0.2 mV (2 mm) or greater or occurred during the first 6 minutes of exercise or at heart rate at or below 163 - 0.66 × age. Of 3806 middle-aged asymptomatic men who had a total cholesterol level of 265 mg/dl at entry, 3 percent had a strongly positive test result; the event rate was 2 percent per year over an average of 4 years of follow-up.[63] A positive test result was *not* significantly associated with nonfatal myocardial infarction; this indicates the difficulty in identifying patients destined to develop abrupt changes in plaque morphology.

In the Seattle Heart Watch, Bruce noted that an abnormal ST response to exercise in asymptomatic men did *not* increase the likelihood of developing cardiac events within 6 years in the absence of conventional risk factors. However, the likelihood of developing a cardiac event was increased when the patient had any conventional atherosclerotic risk factor and two or more abnormal responses to exercise, with an abnormal exercise response defined as chest discomfort during the test, exercise duration less than 6 minutes or two stages, failure to achieve 90 percent of age-predicted maximum heart rate, or 0.1 mV (1 mm) or greater of horizontal or downsloping ST depression with exercise in early recovery. Only 1.1 percent of the asymptomatic healthy men in this study were in a high-risk category.[65] In the Baltimore Longitudinal Study on Aging, the 9-year risk of developing a cardiac event (angina pectoris, myocardial infarction, or coronary death) was 3.4 percent in 611 subjects without ischemic ST segment changes, 14.6 percent in 151 subjects with ischemic ST segment changes that started during exercise, and 19 percent in 63 subjects with ischemic ST segment changes that started only in recovery; age, cholesterol level, and presence of ST segment depression were independent predictors of cardiac events, approximately half of which were onset of angina pectoris[28] (Fig. 6-12) . In asymptomatic middle-aged or older men with several atherosclerotic risk factors, a markedly abnormal exercise response is associated with a significantly increased risk of subsequent cardiac events, particularly when there is additional supporting evidence for underlying CAD (e.g., coronary calcification, abnormal results of thallium scan, and the like).[66] [67] Serial change of a negative exercise ECG result to a positive one in an asymptomatic person carries the same prognostic importance as an initially abnormal test result.[68] However, when an asymptomatic individual with an initially abnormal test result has significant worsening of the ECG abnormalities at lower exercise workloads, this finding may indicate significant CAD progression and warrants a more aggressive diagnostic work-up.

The prevalence of an abnormal exercise ECG result in middle-aged asymptomatic women ranges from 20 to 30 percent.[1] [2] In general, the prognostic value of an ST segment shift in women is less than in men. Although the use of multivariate scores to predict CAD in women has improved diagnostic accuracy, false-positive results continue to be a problem in many patients, and supplemental imaging techniques are often necessary to enhance the diagnostic performance of the test.[5] [6] [11]

SYMPTOMATIC PATIENTS.

Exercise testing should be routinely performed (unless this is not feasible or unless there are contraindications) before coronary angiography in patients with chronic ischemic heart disease. Patients who have excellent exercise tolerance (e.g., >10 METs) usually have an excellent prognosis regardless of the anatomical extent of CAD. The test provides an estimate of the functional significance of angiographically documented coronary artery stenoses. The impact of exercise testing in patients with proven or suspected CAD was studied by Weiner and colleagues in 4083 medically treated patients in the CASS study.[69] A high-risk patient subset was identified (12 percent of the population), with an annual mortality of 5 percent a year when exercise workload was less than Bruce's stage I (<4 METs) and the exercise ECG exhibited 0.1 mV (1 mm) or greater ST segment depression. A low-risk patient subset (34 percent of the population) who were able to exercise into Bruce's stage III or greater and who had a normal exercise ECG result had an annual mortality less than 1 percent per year over 4 years of follow-up. Similar ECG and workload parameters were useful in risk

Figure 6-12 Event-free survival (absence of cardiac death, myocardial infarction, or angina) in 825 healthy volunteers (ages 22 to 89 years) without clinical evidence of coronary heart disease enrolled in the Baltimore Longitudinal Study of Aging. The cardiac event rate in patients whose ischemic ST segment response occurred only during the recovery phase was similar to that in subjects who developed the ischemic ST segment response during exercise; the cardiac event rate was significantly greater than in subjects with normal results on an exercise electrocardiogram. *(From Rywik TM, Zink RC, Gittings NS, et al: Independent prognostic significance of ischemic ST segment response limited to recovery from treadmill exercise in asymptomatic subjects. Circulation 97:2117-2122, 1998.)*

stratifying patients with three-vessel CAD likely to benefit from coronary bypass grafting.

Mark and colleagues developed a treadmill score based on 2842 consecutive patients in the Duke data bank with chest pain; these patients underwent treadmill testing using Bruce's protocol and cardiac catheterization.[70] Patients with left bundle branch block (LBBB) or those with exercise-induced ST elevation in a Q wave lead were excluded. The treadmill score is calculated as follows:

Angina index was assigned a value of zero if angina was absent, one if typical angina occurred during exercise, and two if angina was the reason the patient stopped exercising. Exercise-induced ST deviation was defined as the largest net ST displacement in any lead. The 13 percent of patients with a treadmill score of -11 or less had a 5-year survival of 72 percent, compared with 97 percent in the 34 percent of patients at low risk with a treadmill score +5 or greater. The score added independent prognostic information to that provided by clinical data, coronary anatomy, and left ventricular ejection fraction. The stratified annual mortality rates predicted from the treadmill score were less in 613 outpatients referred for exercise testing from the same institution[71] (Fig. 6-13) . Exercise scoring systems can be used to identify prognostic, intermediate-high-risk patients in whom coronary angiography would be indicated to define coronary anatomy.[70] [71] [72] [73] However, the decision to perform coronary revascularization should take into consideration the fact that in patients with less extensive CAD (e.g., one to two vessels narrowed and well-preserved left ventricular function), a similar degree of exercise-induced myocardial ischemia does not carry the same significant increased risk of cardiac events as in patients with more extensive disease (e.g., three vessels narrowed or those with impaired left ventricular function).[48] [74] [75]

SILENT MYOCARDIAL ISCHEMIA (see Chap. 37) .

In patients with documented coronary artery disease, the presence of exercise-induced ischemic ST segment depression confers increased risk of subsequent cardiac events regardless of whether angina occurs during the test.[76] [77] [78] [79] [80] The magnitude of the prognostic gradient in patients with an abnormal exercise ECG result with or without angina varies considerably in the published literature, most likely a feature

Figure 6-13 Nomogram of prognostic relations using the Duke treadmill score, which incorporates duration of exercise (in minutes) - (5 × maximal ST segment deviation during or after exercise) (in mm) - (4 × treadmill angina index). Treadmill angina index is 0 for no angina, 1 for nonlimiting angina, and 2 for exercise-limiting angina. The nomogram can be used to assess the prognosis of ambulatory outpatients referred for exercise testing. In this example, the observed amount of exercise-induced ST segment deviation (minus resting changes) is marked on the line for ST segment deviation during exercise (1). The degree of angina during exercise is plotted (2), and the points are connected. The point of intersect on the ischemic reading line is noted (3). The number of METs (or minutes of exercise if the Bruce protocol is used) is marked on the exercise duration line (4). The marks on the ischemia reading line and duration of exercise line are connected, and the intersect on the prognosis line determines 5-year survival rate and average annual mortality for patients with these selected specific variables. In this example, the 5-year prognosis is estimated at 78 percent in this patient with exercise-induced 2-mm ST depression, nonlimiting exercise angina, and peak exercise workload of 5 METs. *(Adapted from Mark DE, Shaw L, Harrell FE Jr, et al: Prognostic value of a treadmill exercise score in outpatients with suspected coronary artery disease. N Engl J Med 325:849, 1991. Copyright Massachusetts Medical Society.)*

of patient selection. In the CASS data bank, 7-year survival in patients with silent or symptomatic exercise-induced myocardial ischemia was similar in patients stratified by coronary anatomy and left ventricular function, with the worst survival in patients with the most extensive CAD. In the ACIP trial, coronary revascularization was a more effective treatment strategy to reduce exercise-induced myocardial ischemia than was medical therapy.[79]

UNSTABLE ANGINA (see Chap. 36) .

The incidence of exercise-induced angina or ischemic ST segment abnormalities in patients who have unstable angina and who undergo a predischarge low-level protocol ranges from 30 to 40 percent. The finding of ischemic ST segment changes or limiting chest pain is associated with a significantly increased risk of subsequent cardiac events in men and postmenopausal women.[81] [82] [83] The absence of these findings identifies a low-risk patient subset. Exercise testing should be considered in the outpatient evaluation of low-risk patients with unstable angina and should be performed in hospitalized low-to-intermediate-risk ambulatory patients who are free of angina or heart failure symptoms for at least 48 hours.[82] Prognostic risk assessment should incorporate clinical and serum markers to optimize mortality and morbidity estimates[83] (Fig. 6-14) .

MYOCARDIAL INFARCTION.

Exercise testing after myocardial infarction is useful to determine (1) risk stratification and assessment of prognosis, (2) functional capacity for activity prescription after hospital discharge, and (3) assessment of adequacy of medical therapy and need to use supplemental diagnostic or treatment options.[1] [2] [3] [4] [5] [6] [7] The incidence of fatal or nonfatal cardiac events associated with exercise testing after myocardial infarction is low. The risk of events is approximately twofold greater for symptom-limited protocols compared with submaximal tests, although the overall fatal event rate is extremely low with both types of exercise protocols. A low-level exercise test (achievement of 5 to 6 METs or 70 to 80 percent of age-predicted maximum) is frequently performed before hospital discharge to

Figure 6-14 Rate of cardiac death or myocardial infarction after 5 months in relation to exercise test (ET) response and maximum troponin T (TnT) level in patients hospitalized for unstable angina. High-risk response: ST segment depression in
3 leads and maximal workload <90/70 W (men/women); intermediate risk response: ST segment depression in
3 leads and maximal workload <90/70 W (men/women); and low risk response: no ST segment depression in
3 leads or maximal workload >90/70 W (men/women). *(From Lindahl B: Noninvasive risk stratification in unstable coronary artery disease: Exercise test and biochemical markers. Am J Cardiol 80:40E, 1997.)*

Figure 6-15 One-year mortality of patients assigned to the conservative strategy enrolled in the Thrombolysis in Myocardial Infarction (TIMI) II trial. All patients were treated with thrombolytic therapy within 4 hours of symptom onset. Patients unable to perform the exercise test were compared with individuals able to complete 200 kpm (stage 2) or 200 to 400 kpm (stage 2) on a supine bicycle ergometry study performed within 2 weeks of the index event. Although the absolute mortality rates are less than patient series studied in the prethrombolytic era, a similar gradient of worsening prognosis is noted in patients unable to perform the low-level exercise test within 2 weeks of the index event, patients able to perform the test but unable to complete the protocol, and patients able to complete the low-level exercise test.*(From Chaitman BR: Impact of treatment strategy on predischarge exercise test in the Thrombolysis in Myocardial Infarction [TIMI] II trial. Am J Cardiol 71:131, 1993.)*

establish the hemodynamic response and functional capacity.[84] [85] [86] [87] [88] [89] [90] The ability to complete 5 to 6 METs of exercise or 70 to 80 percent of age-predicted maximum in the absence of abnormal ECG or blood pressure abnormalities is associated with a 1-year mortality of 1 to 2 percent and may help guide the timing of early hospital discharge[91] (Fig. 6-15) . Parameters associated with increased risk include inability to perform the low-level predischarge exercise test, poor exercise capacity, inability to increase or a decrease in exercise systolic blood pressure, and angina or exercise-induced ST segment depression at low workloads.[1] [2] [3] [4] [5] [6] [48] Many postinfarct patients referred for exercise testing have been prescribed beta-adrenergic blocking agents and angiotensin-converting enzyme inhibitors. Although beta-adrenergic blocking drugs may attenuate the ischemic response, they do not interfere with poor functional capacity as a marker of adverse prognosis and should be continued in patients referred for testing.[7] The relative prognostic value of a 6-week postdischarge exercise test is minimal once clinical variables and the results of the low-level predischarge test are adjusted for. For this reason, the timing of the exercise test after the infarct event favors predischarge exercise testing to allow implementation of a definitive treatment plan in patients in whom coronary anatomy is known as well as risk stratification of patients in whom coronary anatomy has not yet been determined.[48] [86] There is a trend toward early predischarge exercise testing (within 3 to 5 days) in uncomplicated cases after acute myocardial infarction. A 6-week test is useful in clearing patients to return to work in occupations involving physical labor and to provide a better estimate of cardiovascular reserve at peak exercise performance.

The goals and basic principles of the predischarge evaluation have not been changed by the advent of reperfusion or direct percutaneous transluminal coronary angioplasty

---

(PTCA) therapy for acute infarction. After receiving intravenous thrombolytic therapy or direct coronary angioplasty, patients with uncomplicated myocardial infarct tend to exhibit exercise-induced angina and ST segment depression less frequently than do consecutive postinfarct patients before these treatment strategies were widely applied. The occurrence of reciprocal ST segment depression associated with exercise-induced ST segment elevation in patients who undergo testing approximately 6 to 8 weeks after Q wave infarction with single-vessel disease may indicate residual tissue viability in the infarct-related area.[92] In patients with negative T waves after infarction, stress-induced normalization of the T waves may also indicate higher coronary flow reserve than in patients unable to normalize their T waves.[30]

RISK STRATIFICATION IN THE EMERGENCY DEPARTMENT.

Patients who present to the emergency department are a heterogeneous population with a large range of pretest risk for CAD. Clinical algorithms can identify lower-risk persons who can safely be further risk stratified using exercise testing. The cost-effectiveness of this approach has been demonstrated in both low- and intermediate-risk patients. The accuracy of exercise testing in the emergency department setting follows Bayesian principles, with the greatest diagnostic and prognostic estimates in intermediate-risk clinical patient subsets. Exercise testing in the emergency department should not be performed when (1) new or evolving ECG abnormalities are noted on the rest tracing, (2) the levels of cardiac enzymes are abnormal, (3) the patient cannot adequately perform exercise, (4) the patient reports worsening or persistent chest pain symptoms, or (6) clinical risk profiling indicates imminent coronary angiography is likely. Several series of clinically low-risk subjects reported 6-month cardiac event rates less than 1 percent with a normal exercise test result.[93] [94] [95]

PREOPERATIVE RISK STRATIFICATION BEFORE NONCARDIAC SURGERY (see Chap. 61) .

Exercise ECG before elective noncardiac surgery provides an objective measurement of functional capacity and the potential to identify likelihood of perioperative myocardial ischemia in patients with a low ischemic threshold. In patients with intermittent claudication and no prior history of cardiac disease, approximately 20 to 25 percent will have an abnormal exercise ECG result. In patients with a prior history of myocardial infarction or abnormal rest ECG, 35 to 50 percent will have an abnormal exercise ECG result. The risk of perioperative cardiac events and adverse long-term outcome is significantly increased in patients with an abnormal exercise ECG results at low workloads, and coronary angiography with revascularization when feasible should be considered before the noncardiac operative intervention.[96] [97] [98]

CONGESTIVE HEART FAILURE.

Cardiac and peripheral compensatory mechanisms are activated in patients with chronic congestive heart failure to partly or fully restore impaired left ventricular performance. Abnormal baroreflex function and increased norepinephrine spillover, sympathetic discharge, downregulation of beta-adrenergic receptors, and depletion of myocardial sympathetic stores characterize the disease process resulting in the hemodynamic response to exercise.[99] [100] [101] [102] [103] [104] [105] [106] [107] [108] [109] [110] [111] [112] [113] [114] [115] [116] [117] [118] There is a wide range of exercise capacity in patients who have a markedly reduced ejection fraction, with some patients having near-normal peak exercise capacity. The magnitude of exercise capacity impairment is a function of abnormalities in skeletal muscle metabolism, which may be the predominant cause of functional limitation in a significant proportion of patients with heart failure. Fatigue may be related to altered skeletal muscle metabolism secondary to chronic physical deconditioning as well as impaired perfusion.[101] [109] Symptoms in patients with congestive heart failure are related to an excessive increase in blood lactate during low exercise levels, reduction in quantity of oxygen consumed at peak exertion, and disproportionate increase in ventilation at submaximal and peak workloads. The increased ventilatory requirement assessed by the hyperventilatory response to exercise and increase in pulmonary dead space leads to rapid, shallow breathing

during exercise. Dyspnea and fatigue are the usual reasons for exercise termination.

Peak o_2 measurements in patients with compensated congestive heart failure are useful in risk stratifying patients with congestive heart failure to determine the subsequent incidence of cardiac events[102] [104] [108] [118] (Fig. 6-16) . The ability to achieve a peak o_2 of greater than 20 ml O_2 $\cdot kg^{-1} \cdot min^{-1}$ and anaerobic threshold greater than 14 ml O_2 $\cdot kg^{-1} \cdot min^{-1}$ is associated with a relatively good long-term prognosis and maximal cardiac output greater than 8 liters/min/m^2 . Patients who are unable to achieve a peak o_2 of 10 ml O_2 $\cdot kg^{-1} \cdot min^{-1}$ and anaerobic threshold of 8 ml O_2 $\cdot kg^{-1} \cdot min^{-1}$ have a poor prognosis, and their maximal exercise cardiac output is usually less than 4 liters/min/m^2 . Failure of o_2 to decrease within 30 seconds after peak exertion is associated with more severe reductions in left ventricular ejection fraction and moderate to severe impairment of pulmonary gas exchange. Inability to increase oxygen pulse (milliliters of oxygen per beat) is related to lack or minimal increase of stroke volume. A blunted heart rate response is not uncommon in patients with congestive heart failure caused by postsynaptic desensitization of beta-adrenergic receptors.

Exercise protocols that limit exercise duration to 5 to 7 minutes are associated with the most reproducible peak o_2 measurements in patients with heart failure. The interpretation of cardiopulmonary exercise test results in patients with heart failure can occasionally be difficult, because some patients hyperventilate during exercise, producing falsely low peak oxygen consumption, and it can be difficult to distinguish patients who are deconditioned from those who have impaired exercise performance and low peak o_2 due to cardiac pathology. Randomized controlled trials of long-term moderate exercise training in chronic heart failure report a 15 to 20 percent improvement in peak o_2 and prolonged onset of anaerobic metabolism.[109] Thus, clinical decisions such as listing a patient for cardiac transplantation based on peak o_2 measurements need to take into consideration interval training effects.[107] [109] [110] The 6-minute walk test also can be used to evaluate functional capacity and to estimate prognosis in patients unable to exercise on a bicycle ergometer or treadmill.[24]

CARDIAC ARRHYTHMIAS AND CONDUCTION DISTURBANCES

The genesis of cardiac arrhythmias includes reentry, triggered activity, and enhanced automaticity (see Chap. 22) . Increased catecholamines during exercise accelerate impulse conduction velocity, shorten the myocardial refractory period, increase the amplitude of afterpotentials, and increase the slope of phase 4 spontaneous depolarization of the action potential. Other potentiators of cardiac rhythm disturbance include metabolic acidosis and exercise-induced myocardial ischemia. Ventricular premature complexes occur frequently during exercise testing and increase with age. Repetitive forms occur in 0 to 5 percent of asymptomatic subjects without suspected cardiac disease and are not associated with an increased risk of cardiac death. Exercise-induced ventricular ectopic activity is not a useful diagnostic marker of ischemic heart disease in the absence of ischemic ST segment depression. Suppression of ventricular ectopic activity during exercise is a nonspecific finding and may occur in patients with CAD as well as in normal subjects. The prognostic importance of ventricular arrhythmias in patients with chronic ischemic heart disease

Figure 6-16 Cardiopulmonary exercise test in a 51-year-old man with cardiomyopathy in New York Heart Association Class III. A modified Bruce protocol was used. The patient reached a peak o_2 of 14 ml O_2 $\cdot kg^{-1} \cdot min^{-1}$ (4 METs), 44 percent of predicted for age, gender, and weight *(top panel).* Anaerobic threshold (AT_{ge}) occurred at a o_2 of 977 ml/min *(bottom panel).* The blunted cardiopulmonary response is typical for a patient with severe cardiomyopathy and marked impairment of cardiac reserve. This patient was listed for cardiac transplantation.

after adjustment for baseline, clinical, and left ventricular function characteristics is small. Approximately 20 percent of patients with known heart disease and 50 to 75 percent of sudden cardiac death survivors have repetitive ventricular beats induced by exercise. In patients with a recent myocardial infarction, the presence of exercise-induced repetitive forms is associated with an increased risk of subsequent cardiac events.

Exercise-induced ventricular arrhythmias tend to be more frequent in the recovery phase of exercise because peripheral plasma norepinephrine levels continue to increase for several minutes after cessation of exercise and vagal tone is high in the immediate recovery phase. Beta-adrenergic blocking times may suppress exercise-induced ventricular arrhythmias.

EVALUATION OF VENTRICULAR ARRHYTHMIAS.

Exercise testing is useful in the assessment of patients with ventricular arrhythmias and has an important adjunctive role along with ambulatory monitoring and electrophysiological studies. Exercise testing provokes repetitive ventricular premature beats in most patients with a history of sustained ventricular tachyarrhythmia, and in approximately 10 to 15 percent of such patients, spontaneously occurring arrhythmias are observed only during exercise testing (Fig. 6-17) . The test is useful in evaluating the effects of antiarrhythmic drugs, detecting supraventricular arrhythmias, treating patients with chronic atrial fibrillation to test for ventricular rate control, and exposing possible drug toxicity in patients placed on antiarrhythmic drugs. Paradoxical prolongation of the QT_C interval greater than 10 msec with exercise identifies patients likely to develop a proarrhythmic effect on type 1A antiarrhythmic drugs.[119] Exercise-induced widening of the QRS complex in patients using type 1C drugs may favor reentry induction of ventricular tachycardia. Amiodarone therapy increases the QRS duration during exercise by approximately 6 percent in patients with a QRS duration less than 110 msec, compared with 15 percent in patients with a QRS duration greater than 110 msec.[120]

SUPRAVENTRICULAR ARRHYTHMIAS.

Supraventricular premature beats induced by exercise are observed in 4 to 10 percent of normal persons and up to 40 percent of patients with underlying heart disease. Sustained supraventricular tachyarrhythmias occur in only 1 to 2 percent of patients, although the frequency may approach as much as 10 to 15 percent in patients referred for management of episodic supraventricular arrhythmias. The presence of supraventricular arrhythmias is not diagnostic for ischemic heart disease.[121]

ATRIAL FIBRILLATION.

Patients with chronic atrial fibrillation tend to have a rapid ventricular response in the initial stages of exercise, and 60 to 70 percent of the total change in heart rate usually occurs within the first few minutes of exercise (Fig. 6-18) . The effect of digitalis preparations and beta-adrenergic and selected calcium antagonists such as diltiazem on attenuating this rapid increase in heart rate for individual patients can be measured using exercise testing. Pharmacological control of the ventricular rate does not necessarily result in a significant increase in

Figure 6-17 A 67-year-old man with ischemic cardiomyopathy referred for exercise testing had a left bundle branch block and first-degree atrioventricular (AV) block on the resting ECG. There was no worsening of the AV conduction disturbance immediately before ventricular tachycardia (VT) onset (arrow). At 4:55 minutes into the test, a 27-beat run of VT was noted, reproducing the patient's symptoms of dizziness and chest pounding. The exercise test proved useful in directing subsequent patient management to treatment of the ventricular arrhythmia.

exercise capacity, which in many patients is related to the underlying cardiac disease process and not adequacy of control of the ventricular rate.

SICK SINUS SYNDROME.

In general, patients with sick sinus syndrome have a lower heart rate at submaximal and maximal workloads compared with control subjects. However, as many as 40 to 50 percent of patients will have a normal exercise heart rate response.

ATRIOVENTRICULAR BLOCK.

Exercise testing may help determine the need for atrioventricular (AV) sequential pacing in selected patients. In patients with congenital AV block, exercise-induced heart rates are low and some patients develop symptomatic rapid junctional rhythms that can be suppressed with DDD devices. In patients with acquired conduction disease, exercise can occasionally elicit advanced AV block.

LEFT BUNDLE BRANCH BLOCK.

Exercise-induced ST segment depression is found in most patients with LBBB and cannot be used as a diagnostic or prognostic indicator regardless of the degree of ST segment abnormality. In patients who are referred to a tertiary center and in whom exercise testing is carried out, the new development of exercise-induced transient left hemiblock is 0.3 percent and LBBB is 0.4 percent, with a slightly greater incidence in older patients.[122] The relative risk of death or other major cardiac events in patients with exercise-induced LBBB is increased approximately threefold compared with patients without this abnormality. In one series, permanent LBBB was reported in approximately half the patients who developed transient LBBB during exercise and who were monitored for an average of 6.6 years. High-grade AV block did not develop in any of the patients in this 15-patient series.[123] The development of ischemic ST segment depression before the LBBB pattern appears or in the recovery phase after the LBBB has resolved does not attenuate the diagnostic yield of the ST segment shift. The ventricular rate at which the LBBB appears and disappears can be significantly different (Fig. 6-19) .

RIGHT BUNDLE BRANCH BLOCK.

The resting ECG in right bundle branch block (RBBB) is frequently associated with T wave and ST segment changes in the early anterior precordial leads (V_1 to V_3). Exercise-induced ST depression in leads V_1 to V_4 is a common finding in patients with RBBB and is nondiagnostic (Fig. 6-20) . The new development of exercise-induced ST segment depression in leads V_5 and V_6 or leads 2 and aV_f , reduced exercise capacity, and inability to adequately increase systolic blood pressure are useful in detecting patients who have CAD and a high clinical pretest risk of disease.[5] The presence of RBBB decreases the sensitivity of the test.[124] The new development of exercise-induced RBBB is relatively uncommon, occurring in approximately 0.1 percent of tests.

Figure 6-18 A 75-year-old woman with chronic atrial fibrillation and a 6-month history of atypical chest pain underwent mitral valve repair 1 year before testing, at which time nonobstructive coronary disease was noted. The patient exercised for 6 minutes, achieving a peak heart rate of 176 beats/min and peak blood pressure of 170/90 mm Hg. The resting ECG shows atrial fibrillation with a controlled ventricular response and minor ST segment depression. At peak exertion, marked ST segment depression is seen in the anterior leads, consistent with either digitalis effect or myocardial ischemia. In this type of patient, initial exercise testing with myocardial perfusion tracers or echocardiography would provide more useful diagnostic information than exercise testing alone.

Figure 6-19 A 58-year-old hypertensive diabetic man with prior history of cigarette smoking was referred for evaluation of dyspnea and early fatigability during exercise. At 6:48 minutes into the test, the patient developed a rate-related left bundle branch block (LBBB) at a heart rate of 133 beats/min, which persisted during exercise and resolved at 1:36 minutes into the postexercise phase. The abnormal 2.5- to 3-mm downsloping ST segment depression in lead 2 during the LBBB is nondiagnostic for coronary artery disease because of the conduction disturbance. The test was stopped because of dyspnea at a peak heart rate of 138 beats/min (85 percent of predicted) and estimated workload of 6 METs. Peak blood pressure at end exercise was 174/94 mm Hg. Time to onset and offset of LBBB occurred at different ventricular rates related to fatigue in the left bundle, a common finding.

PREEXCITATION SYNDROME.

The presence of Wolff-Parkinson-White (WPW) syndrome invalidates the use of ST segment analysis as a diagnostic method for detecting CAD in preexcited as well as normally conducted beats; false-positive ischemic changes are frequently registered (Fig. 6-21) . In patients with persistent preexcitation, exercise may normalize the QRS complex, with disappearance of the delta wave in 20 to 50 percent of cases, depending on the series studied.[125] Abrupt disappearance of the delta wave is presumptive evidence of a longer anterograde effective refractory period of the accessory pathway. Progressive disappearance of the delta wave is less reassuring and occurs when the improvement in AV node conduction is greater than in the accessory pathway; this finding does not preclude a possible significant or even critical shortening of the anterograde effective refractory period in the accessory pathway under the influence of sympathetic stimulation. Exercise-induced disappearance of the delta wave is more frequent with left sided than right sided accessory pathway positions. Although tachyarrhythmias appearing during an exercise test in patients with WPW syndrome are rare, when they do occur, they provide an opportunity to evaluate AV conduction velocity. The presence of WPW syndrome does not cause a limitation of physical work capacity.

CARDIAC PACEMAKERS AND IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR DEVICES.

The exercise protocol used to assess chronotropic responsiveness in patients before and after cardiac pacemaker insertion should adjust for the fact that many such patients are older individuals and may not tolerate high exercise workloads or abrupt and relatively large increments in work between stages of exercise. An optimal physiological cardiac pacemaker should normalize the heart rate response to exercise in proportion to oxygen uptake and should increase heart rate 2 to 4 beats/min for an increase in
o_2 of 1 ml $O_2 \cdot kg^{-1} \cdot min^{-1}$, with a slightly steeper slope for patients with severe left ventricular function impairment.[126] [127]

When testing patients with an implantable cardioverter-defibrillator (ICD) device, the program detection interval of

Figure 6-20 Exercise-induced ST segment depression is noted in leads V_2 to V_3 (arrows) in this patient with a resting right bundle branch block pattern. Exercise-induced horizontal or downsloping ST segment responses in the early anterior precordial leads (V_1 through V_4) are common in patients with right bundle branch block and are secondary to the conduction disturbance. The presence of this finding in leads V_1 through V_4 is not diagnostic of obstructive coronary disease; however, if ischemic changes are seen in leads II, aV_F , or in leads V_5 or V_6 , the specificity for coronary disease is improved.

Figure 6-21 A 61-year-old man with atypical angina and a hiatal hernia was referred for diagnostic exercise testing. The test was stopped because of dyspnea. The standing rest ECG shows an intermittent Wolff-Parkinson-White pattern (arrows). In the nonpreexcited beats, ST segment depression does not occur either at peak exercise or in the postexercise phase. However, in the preexcited beats (arrows), an additional 1.3 mm of downsloping ST segment depression is noted as compared with baseline during and after exertion.

the device should be known. If the ICD device is implanted for ventricular fibrillation or fast ventricular tachycardia, the rate will normally exceed that attainable during sinus tachycardia and the test can be terminated as the heart rate approaches 10 beats/min below the detection interval of the device. In patients with slower programmed detection rates, the ICD may be reprogrammed to a faster rate to avoid accidental discharge during exercise testing or may be temporarily deactivated by a magnet. Exercise testing may be used to test the efficacy of tachycardic detection algorithms that apply criteria such as suddenness of onset and R-R variability.

SPECIFIC CLINICAL APPLICATIONS

INFLUENCE OF DRUGS AND OTHER FACTORS.

Patients with CAD demonstrate individual variability in time to onset of exercise-induced angina, time to onset of exercise-induced ischemic ST segment depression of 0.1 mV or greater, and cardiovascular efficiency during exercise testing.[2] [5] [22] The average individual variability in time to onset of exercise-induced myocardial ischemia or peak anaerobic capacity approximates as much as 20 percent in placebo-controlled trials of antianginal drugs. Variability can be reduced by patients'

familiarization with the exercise protocol and equipment, controlling for antianginal drug therapy at the time of testing, and stable test performance conditions. When two or three exercise tests are conducted within weeks of each other, the greatest increase in exercise time usually occurs between test one and test two.[128] In one series of 24 subjects with stable angina less than class II, exercise time was increased by approximately 1 minute, and time to onset of angina or ischemic ST segment depression by 3 minutes when two exercise tests were performed 15 minutes apart.[129] The mechanisms of the attenuation response with reexercise may be the results of ischemic preconditioning, familiarization with the exercise protocol, and improved musculoskeletal efficiency but do not appear to be dependent on exercise protocol intensity or downregulation of myocardial contractility induced by the initial ischemic stimulus. In cold-sensitive individuals, exercise testing in a cooler environment results in onset of ischemic ST segment depression earlier than under normal temperature-controlled conditions.[130] Conditions that increase carbon monoxide levels, such as chronic cigarette smoking, lower the ischemic response threshold.

Digitalis glycosides can produce exertional ST segment depression even if the effect is not evident on the resting ECG and can accentuate ischemic exercise-induced ST segment changes, particularly in older individuals. Absence of ST segment deviation during an exercise test in a patient receiving a cardiac glycoside is considered a valid negative response. Hypokalemia in patients on long-term diuretic therapy may be associated with exercise-induced ST segment depression. Antiischemic drug therapy with nitrates, beta-blocking drugs, or calcium channel blocking drugs prolongs the time to onset of ischemic ST segment depression, increases exercise tolerance, and, in a small minority of patients (10 to 15 percent), may normalize the exercise ECG response in patients with documented CAD.[1] [2] [22] The time and dose of drug ingestion may affect exercise performance. In some laboratories, cardioactive drug therapy is withheld for three to five half-lives and digitalis for 1 to 2 weeks before diagnostic testing. However, this is impractical in many cases. Heparin therapy may increase total exercise duration and ability to achieve a higher rate pressure product before the onset of angina and at peak exertion.[131]

WOMEN.

The sensitivity and specificity of exercise-induced ST segment depression for obstructive CAD are less in women than in men. The decreased diagnostic accuracy results in part from a lower prevalence and extent of CAD in young and middle-aged women. Women tend to have a greater release of catecholamines during exercise, which could potentiate coronary vasoconstriction and augment the incidence of abnormal exercise ECGs results, and false-positive results have been reported to be more common during menses or preovulation. In a series of 976 symptomatic women referred for exercise testing and coronary angiography, a low- moderate- and high-risk Duke treadmill score were associated with CAD of 75 percent or greater luminal narrowing in 19.1, 34.9, and 89.2 percent of subjects, respectively. The frequency of three-vessel disease 75 percent or greater or left main CAD was 3.5, 12.4, and 46 percent respectively.[131] In a retrospective population-based cohort study of 1452 men and 741 women, exercise-induced angina, ischemic ECG changes, and workload were strongly associated with all-cause mortality and cardiac events in both sexes. The relationship between workload and outcome was linear, with an increment of 1 MET in workload associated with a 20 to 25 percent reduction in risk of death and cardiac events.[132] Alexander and colleagues compared the Duke treadmill score in 976 women and 2249 men; the 2-year mortality for women was 1, 2.2, and 3.6 percent for low- moderate- and high-risk scores, compared with 1.7, 5.8, and 16.6 percent in men. In this report, women had a similar frequency of angina on the treadmill as men, but exertional angina in women was less often correlated with CAD presence.[133] Thus, in women with established

CAD, exercise testing provides useful prognostic information for risk stratification and identification of low and higher-risk patient subsets.[131] [133] [134] [135]

HYPERTENSION.

Exercise testing has been used in an attempt to identify patients who have an abnormal blood pressure response and are destined subsequently to develop hypertension. In asymptomatic normotensive individuals, an exaggerated exercise systolic and diastolic blood pressure response during exercise or exaggerated peak systolic blood pressure response to 214 mm Hg or greater or an elevated systolic or diastolic blood pressure at the third minute of recovery is associated with significant increased long-term risk of hypertension[136] [137] (Fig. 6-22) . Severe systemic hypertension may interfere with subendocardial perfusion and cause exercise-induced ST segment depression in the absence of atherosclerosis, even when the rest ECG does not show significant ST or T wave changes.[138] Beta and calcium channel blocking drugs decrease submaximal and peak systolic blood pressure in many hypertensive patients. Exercise tolerance is decreased in patients with poor blood pressure control.[139]

ELDERLY PATIENTS.

Maximal aerobic capacity (O_2 max) declines 8 to 10 percent per decade in sedentary men and women, with approximately 50 percent reduction in exercise capacity between the ages of 30 and 80 years.[15] The exercise protocol in elderly patients should be selected according to estimated aerobic capacity. In patients with limited exercise tolerance, the test should be started at the slowest speed with a 0 percent grade and adjusted according to the patient's ability. Older patients may need to grasp the handrails for support. The frequency of abnormal exercise ECG patterns is greater in older than younger individuals, and the risk of cardiac events is significantly increased because of a concomitant increase in prevalence of more extensive CAD.[140] [141] The greater test sensitivity of the exercise ECG in elderly individuals is accompanied by a slight reduction in specificity. Cardiac arrhythmias, chronotropic incompetence, and hypertensive responses are more common in older individuals.

DIABETES MELLITUS.

Coronary atherosclerosis and peripheral vascular disease are significantly increased in adult diabetic as compared with nondiabetic patients; the likelihood of atherosclerosis correlates closely with duration of diabetes. In patients with autonomic dysfunction and sensory neuropathy, anginal threshold may be increased, and abnormal exercise-induced heart rate and blood pressure responses are common.[142] Once CAD disease is established, the incidence of exercise-induced ECG changes is similar to that of nondiabetic persons.[143] The probability of an adverse cardiac outcome in a diabetic as compared with a nondiabetic individual for a similar abnormal exercise test result is likely to be increased because of the increased risk of dyslipidemia, impaired fibrinolysis, and hypertension associated with the diabetic process. Further research is required to determine optimal noninvasive test procedures to diagnose early endothelial dysfunction in diabetic patients and the presence and extent of obstructive CAD.

VALVULAR HEART DISEASE AND HYPERTROPHIC CARDIOMYOPATHY.

The hemodynamics of exercise provide an excellent opportunity to measure gradients across stenotic valves, to assess ventricular function in patients with primary valvular regurgitation or mixed lesions, and to assess pulmonary and systemic vascular resistance[144] [145] [146] (see Chap. 46) . The use of echocardiographic Doppler techniques (see Chap. 7) is particularly valuable in evaluating patients whose symptoms are out of proportion to the degree of valvular disease observed and in assessing the results of valvulotomy or valve replacement.[146A] [146B] Clinical and exercise noninvasive assessment of patients with valvular heart disease can provide useful information on the timing of operative intervention and help achieve a more precise estimate of a patient's degree of incapacitation than can assessment of symptoms alone.[145] Studies of adults with moderate to severe aortic stenosis (e.g., valve area 0.5 to 1.5 cm^2 and mean gradients of 18 to 64 mm Hg) show that exercise testing can be safely performed when appropriate exercise protocols and precautions are used. In patients with mitral stenosis, excessive heart rate response to relatively low levels of exercise, reduction of cardiac output with exercise (exercise-induced hypotension), and chest pain (ischemia secondary to low output or pulmonary hypertension) are indicators that favor earlier valve repair. In patients with mitral valve prolapse without regurgitation at rest, exercise-induced mitral regurgitation has been associated with the subsequent development of progressive mitral regurgitation, heart failure symptoms, or syncope.

Peak O_2 and anaerobic threshold are reduced in symptomatic patients with hypertrophic cardiomyopathy compared

Figure 6-22 Probability of developing systemic hypertension within 8 years after exercise testing as a function of exercise-induced systolic and diastolic blood pressure responses in men and women. *Left panel:* Exercise systolic blood pressure. *Right panel:* Exercise diastolic blood pressure. Crude probabilities of developing hypertension are displayed for mean systolic or diastolic blood pressure value for each of exercise response during the second stage of treadmill testing.*(From Singh JP, Larson MG, Manolio TA, et al: Blood pressure response during treadmill testing is a risk factor for new onset hypertension. The Framingham Heart Study. Circulation 99:1831-1836, 1999.)*

with sedentary subjects (see Chap. 48) . In a 50-patient series of hypertrophic cardiomyopathy, 59 percent of symptomatic subjects were unable to achieve a peak O_2 60 percent of predicted; only two patients achieved a peak

o_2 greater than 80 percent of predicted.[147] [148] In 20 symptomatic patients with hypertrophic cardiomyopathy, 9 who had an abnormal exercise blood pressure response before transcoronary alcoholic septal ablation normalized their blood pressure response after treatment; exercise time was only mildly increased.[149]

CORONARY REVASCULARIZATION

Coronary Bypass Grafting (see Chap. 37) .

The degree of improvement in exercise-induced myocardial ischemia and aerobic capacity after coronary bypass grafting depends in part on the degree of revascularization achieved and left ventricular function.[150] [151] Exercise-induced ischemic ST segment depression may persist when incomplete revascularization is achieved, albeit at higher exercise workloads, and in approximately 5 percent of patients in whom complete revascularization has been achieved.[152] [153] [154] It usually takes at least 6 weeks of convalescence before maximum exercise can be performed. The natural history of saphenous vein grafts and internal mammary artery conduits is different, and serial conversion from an initially normal to abnormal exercise ECG result over time depends in part on the type of conduit used and CAD progression in nongrafted vessels. The diagnostic and prognostic utility of exercise testing late after coronary revascularization (e.g., 5 to 10 years) is much greater than early (<1 year) testing, because a late abnormal exercise response is more likely to indicate graft occlusion, stenosis, or progression of CAD. In selected patients with severe left ventricular dysfunction and symptomatic heart failure, coronary bypass surgery is associated with a significant increase in exercise capacity when a large amount of viable myocardium (e.g., >25% of left ventricular mass) can be determined using positron emission tomography.[155]

Percutaneous Coronary Intervention (see Chap. 38) .

After PTCA, restenosis occurs in approximately 20 to 40 percent of patients, usually within the first 6 months, and is more common in patients with proximal left anterior descending CAD, in patients with long coronary artery narrowings, in diabetic patients, in patients with multivessel or multilesion dilation, and those in whom post-PTCA luminal obstruction exceeds 50 percent. The restenosis rate is less in patients who have a coronary stent placed. In the early post-PTCA phase (<1 month), an abnormal exercise ECG result may be secondary to a suboptimal PTCA result, impaired coronary vascular reserve in a successfully dilated vessel, or incomplete revascularization.[156] [157] The optimal time to perform an exercise test after PTCA depends in part on the success of the procedure and the degree of revascularization obtained. Exercise testing early after PTCA (within days) can often be used to help determine the need for a staged procedure and to provide a reference baseline for subsequent follow-up. In an otherwise asymptomatic patient, a 6-month postprocedure test allows sufficient time to document restenosis should it occur and allows the dilated vessel an opportunity to heal. Serial conversion of an initially normal exercise test result after PTCA to an abnormal result in the initial 6 months after the procedure, particularly when it occurs at a lower exercise workload, is usually associated with restenosis. The use of exercise myocardial imaging in selected patients enhances the diagnostic content of the test and can help localize the territory of myocardial ischemia and guide indications for repeat coronary angiography in patients who have undergone multivessel/multilesion PTCA.[11] In a small uncontrolled series of patients who had end-stage CAD and who underwent transmyocardial laser revascularization, exercise capacity was significantly increased by 26 W.[158]

CARDIAC TRANSPLANTATION (see Chap. 20) .

Cardiopulmonary exercise testing is useful in selecting patients with end-stage heart failure for cardiac transplantation. A peak
o_2 of less than 12 to 14 ml $O_2 \cdot kg^{-1} \cdot min^{-1}$ or 40 to 50 percent of predicted
o_2 is associated with 2-year survival rates ranging from 30 to 50 percent (Fig. 6-23) .[159] The use of percent of predicted
o_2 , which adjusts an individual patient's peak
o_2 for age, gender, and weight rather than weight alone, has been shown to further enhance prognostic estimates in patients who have a low peak exercise
o_2 [102] [104] In patients awaiting heart transplantation, with initial poor exercise capacity, ability to increase peak oxygen uptake with increased peak oxygen pulse identifies a relatively lower-risk group in whom cardiac transplantation may be able to be deferred if the patient's clinical status is stable. Exercise performance in transplant recipients is influenced by the fact that the donor heart is surgically denervated without efferent parasympathetic or sympathetic innervation and by the occurrence of rejection and scar formation, systemic and pulmonary vascular resistance, level of training, and development of coronary atherosclerosis in the graft.[160] [161] [162] [163] Maximal oxygen uptake and work capacity are reduced after cardiac transplantation compared with age-matched controls but usually are markedly improved compared with preoperative findings. Abnormalities of the ventricular rate response include a resting tachycardia due to parasympathetic denervation, a slow heart rate response during mild to moderate exercise, a more rapid response during more strenuous exercise, and a more prolonged

Figure 6-23 The 3-year survival of patients with congestive heart failure referred for cardiac transplant evaluation with a peak
o_2
14 ml $O_2 \cdot kg^{-1} \cdot min^{-1}$ stratified according to percent predicted peak
o_2 > 50 percent or
50 percent. The 91 ± 5 percent 3-year survival rate of the 44 patients with a percent predicted
o_2 > 50 percent was similar to the survival rates of patients with a peak
o_2
14 ml $O_2 \cdot kg^{-1} \cdot min^{-1}$ and significantly greater than the 61 ± 5 percent of the 110 patients with a peak
o_2
50 percent. The data indicate that a low peak
o_2 and percent predicted
o_2 identify high-risk patients with congestive heart failure whose survival may be improved by cardiac transplantation. *(From Osada N, Chaitman BR, Miller LW, et al: Cardiopulmonary exercise testing identifies low risk patients with heart failure and severely impaired exercise capacity considered for heart transplantation. J Am Coll Cardiol 31:577, 1998.)*

time for the ventricular rate to return to baseline during recovery. The transplanted heart relies heavily on the Frank-Starling mechanism to increase cardiac output during mild to moderate exercise. Systemic vascular resistance may be increased because of cyclosporine therapy. The exercise ECG is relatively insensitive in detecting coronary artery vasculopathy after cardiac transplantation.[160] [162] However, the new development of an abnormal exercise ECG result several years after cardiac transplantation may indicate focal intraluminal narrowing.

SAFETY AND RISKS OF EXERCISE TESTING

Exercise testing has an excellent safety record. The risk is determined by the clinical characteristics of the patient referred for the procedure. In nonselected patient populations, the mortality is less than 0.01 percent and morbidity less than 0.05 percent.[164] The risk is greater when the test is performed soon after an acute ischemic event. In a survey of 151,941 tests conducted within 4 weeks of an acute myocardial infarction, mortality was 0.03 percent, and 0.09 percent of patients either had a nonfatal reinfarction or were resuscitated from cardiac arrest.[165] The relative risk of a major complication is about twice as great when a symptom-limited protocol is used as compared with a low-level protocol. Nevertheless, in the early postinfarction phase, the risk of a fatal complication during symptom-limited testing is only 0.03 percent. The risk is less for low-risk patients who are seen in the emergency department and who undergo exercise testing for risk stratification.[93] Exercise testing can be safely performed in patients with compensated congestive heart failure, with no major complications reported in 1286 tests in which a bicycle ergometer was used.[166] The risk of exercise testing in patients referred for life-threatening ventricular arrhythmias was examined by Young and colleagues[167] in a series of 263 patients who underwent 1377 tests; 2.2 percent developed sustained ventricular tachyarrhythmias that required cardioversion, cardiopulmonary resuscitation, or antiarrhythmic drugs to restore sinus rhythm. The ventricular arrhythmias were more frequent in tests performed on antiarrhythmic drug therapy as compared with the baseline drug-free state. In contrast to the high risk in the aforementioned patient subsets, the risk of complications in asymptomatic subjects is extremely low, with no fatalities reported in several series.[1] [2] [3] [4] [5] [6]

The risk of incurring a major complication during exercise testing can be reduced by performing a careful history and physical examination before the test and observing patients closely during exercise with monitoring of the ECG, arterial pressure, and symptoms. The standard 12-lead ECG should be verified before the test for any acute or recent change. The contraindications to exercise testing are well defined (Table 6-4) . Patients with critical obstruction to left ventricular outflow are at increased risk of cardiac events during exercise. In selected patients, low-level exercise can be useful in determining the severity of the left ventricular outflow tract gradient. The cool-down period should be prolonged to at least 2 minutes in patients with

TABLE 6-4 -- CONTRAINDICATIONS TO EXERCISE TESTING

Acute myocardial infarction (<2 d)

Unstable angina with recent rest pain
Untreated life-threatening cardiac arrhythmias
Advanced atrioventricular block
Acute myocarditis or pericarditis
Critical aortic stenosis
Severe hypertrophic obstructive cardiomyopathy
Uncontrolled hypertension
Acute systemic illness (pulmonary embolism, aortic dissection)

TABLE 6-5 -- INDICATIONS FOR TERMINATING EXERCISE TESTING

ABSOLUTE INDICATIONS
Drop in systolic blood pressure of >10 mm Hg from baseline blood pressure despite an increase in workload, when accompanied by other evidence of ischemia
Moderate to severe angina (grade ¾)
Increasing nervous system symptoms (e.g., ataxia, dizziness, or near-syncope)
Signs of poor perfusion (cyanosis or pallor)
Technical difficulties in monitoring ECG or systolic blood pressure
Subject's desire to stop
Sustained ventricular tachycardia
ST elevation (1.0 mm) in noninfarct leads without diagnostic Q waves (other than V_1 or aV_r)
RELATIVE INDICATIONS
Drop in systolic blood pressure of 10 mm Hg from baseline blood pressure despite an increase in workload, in the absence of other evidence of ischemia
ST or QRS changes such as excessive ST depression (>3 mm of horizontal or downsloping ST segment depression) or marked axis shift
Arrhythmias other than sustained ventricular tachycardia, including multifocal PVCs, triplets of PVCs, supraventricular tachycardia, heart block, or bradyarrhythmias
Fatigue, shortness of breath, wheezing, leg cramps, or claudication
Development of bundle branch block of intraventricular conduction delay that cannot be distinguished from ventricular tachyardia
Increasing chest pain
Hypertensive response
ECG=electrocardiogram; PVCs=premature ventricular contractions. *Modified from Fletcher GF: Exercise standards: A standard for healthcare professionals from the American Heart Association Writing Group. Circulation 91:580, 1995.*

stenotic valves to avoid sudden pressure-volume shifts that occur in the immediate postexercise phase.

Uncontrolled systemic hypertension is a contraindication to exercise testing. Patients should continue antihypertensive drug therapy on the day of testing. Patients who present with systemic arterial pressure readings of 220/120mm Hg or greater should rest for 15 to 20 minutes, and their blood pressure should be remeasured. If blood pressure remains at these levels, the test should be postponed until the hypertension is better controlled.

A resuscitator cart and defibrillator should be available in the room where the test procedure is carried out, as should appropriate cardioactive medication available to treat cardiac arrhythmias, AV block, hypotension, and persistent chest pain. An intravenous line should be started in high-risk patients such as those being tested for adequacy of control of life-threatening ventricular arrhythmias. The equipment and supplies in the cart should be checked on a regular basis. A previously specified routine for cardiac emergencies needs to be determined; this includes patient transfer and admission to a coronary care unit if necessary.

Clinical judgment is required to determine which patients can be safely tested in an office as opposed to a hospital-based setting. High-risk patients, such as those with evident left ventricular dysfunction, severe angina pectoris, a history of cardiac syncope, and significant ambient ventricular ectopy on the pretest examination, should be tested in the hospital. Low-risk patients, such as asymptomatic individuals and those with a low pretest risk of disease, may be tested by specially trained nurses or physician assistants who have received advanced cardiac life support certification, with a physician in close proximity.

TERMINATION OF EXERCISE.

The use of standard test indications to terminate an exercise test reduces risk (Table 6-5) .

TABLE 6-6 -- EXERCISE TEST REPORT INFORMATION

Demographic data: name, patient identifier, date of birth/age, gender, weight, height, test date
Indication(s) for test
Patient descriptors: atherosclerotic risk profile, drug usage, resting ECG findings
Exercise test results
Protocol used
Reason(s) for stopping exercise
Hemodynamic data: rest and peak heart rate, rest and peak blood pressure, percent maximum achieved heart rate, maximum rate of perceived exertion (Borg's scale), peak workload, peak METs, total exercise duration in minutes
Evidence for myocardial ischemia: time to onset and offset of ischemic ST segment deviation or angina, maximum depth of ST segment deviation, number of abnormal exercise ECG leads, abnormal systemic blood pressure responses
General comments
ECG=electrocardiogram.

Termination of exercise should be determined in part by the patient's recent activity level. The rate of perceived patient exertion can be estimated by the Borg's scale. The scale is linear, with values of 9, very light; 11, fairly light; 13, somewhat hard; 15, hard; 17, very hard; and 19, very, very hard. Borg's readings of 14 to 16 approximate anaerobic threshold, and readings of 18 or greater approximate a patient's maximum exercise capacity. It is helpful to grade exercise-induced chest discomfort on a 1 to 4 scale, with 1 indicating the initial onset of chest discomfort and 4 the most severe chest pain the patient has ever experienced. The exercise technician should note the onset of grade 1 chest discomfort on the work sheet, and the test should be stopped when the patient reports grade 3 chest pain. In the absence of symptoms, it is prudent to stop exercise when a patient demonstrates 0.3 mV (3 mm) or greater of ischemic ST segment depression or 0.1 mV (1 mm) or greater of ST segment elevation in a noninfarct lead without an abnormal Q wave. Significant worsening of ambient ventricular ectopy during exercise or the unsuspected appearance of ventricular tachycardia is an indication to terminate exercise. A progressive, reproducible decrease in systolic blood pressure of 10 mm Hg or more may indicate transient left ventricular dysfunction or an inappropriate decrease in systemic vascular resistance and is an indication to terminate exercise. The test should be stopped if the arterial blood pressure is 250 to 270/120 to 130 mm Hg or greater. Ataxia may indicate cerebral hypoxia.

The exercise test report should contain basic demographic data, the indication for testing, a brief description of the patient's profile, and exercise test results (Table 6-6) .

GUIDELINES
USE OF EXERCISE TOLERANCE TESTING

Thomas H. Lee

Guidelines for the use of exercise testing were published by an American College of Cardiology/American Heart Association (ACC/AHA) task force in1997.[1] These guidelines consider the usefulness of exercise testing for (1) diagnosis (2) risk stratification in patients with chronic coronary artery disease or after acute myocardial infarction, and (3) several specific populations. This document updated prior guidelines from the ACC/AHA from 1986[2] and drew on other guidelines and position statements on topics related to exercise testing from the ACC/AHA and drew on other guidelines and position statements on topics related to exercise testing from the ACC/AHA and other organizations.

PERFORMANCE OF THE TEST.

The ACC/AHA guidelines agreed with prior recommendations that exercise testing should be supervised by an appropriately trained physician.[3] The test itself can be performed by properly trained nonphysician personnel, but these personnel should be working under the supervision of a physician who should be in the immediate vicinity and available for emergencies. The guidelines note that exercise tests do not always require the involvement of a cardiologist.

Absolute and relative contraindications to exercise testing were adapted from a prior statement from the AHA[4] (Table 6-G-1) . The guidelines note that for some patients with relative contraindications, the benefits of exercise testing outweigh the risks; in such patients, testing may be appropriate. Absolute and relative indications for terminating exercise are summarized in Table 6-5 , p. 151.

DIAGNOSIS OF OBSTRUCTIVE CORONARY ARTERY DISEASE.

Exercise testing is considered clearly appropriate for the purpose of diagnosis of coronary artery disease in most adults with an intermediate probability of coronary artery disease (Table 6-G-2) . The focus on the use of this test in patients with an intermediate probability of coronary disease recognizes that testing is unlikely to change the diagnosis for patients with either a low or a high probability of coronary disease based on age and other clinical data. The guidelines provided a framework for qualitative assessment of the probability of coronary disease on the basis of such information (Table 6-G-3) .

The ACC/AHA guidelines specifically note that exercise testing is appropriate in patients with a complete right bundle branch block or less than 1 mm of resting ST depression. They also conclude that cessation of therapy with digoxin or beta blockers is not necessary before exercise testing, even though the effects of these agents can sometimes complicate interpretation of test results.

RISK STRATIFICATION IN PATIENTS WITH PROBABLE CORONARY DISEASE.

Even if the evidence for coronary disease is so clear for a patient that an exercise test cannot influence the diagnosis, testing may improve management through risk stratification. Exercise testing is especially likely to be valuable as part of the initial evaluation of patients with suspected or known coronary disease (see Table 6-G-2) since the results may help identify high-risk subsets of patients who are likely to have their survival improved with coronary artery bypass graft surgery or coronary angioplasty. Exercise testing is also appropriate in patients who have had a significant change in clinical status because the test may clarify whether the new symptoms are due to coronary artery

TABLE 6-6-G-1 -- CONTRAINDICATIONS TO EXERCISE TESTING (ACC/AHA GUIDELINES)

Absolute	Relative*
Acute myocardial infarction (within 2d)	Left main coronary stenosis
Unstable angina not previously stabilized by medical therapy	Moderate stenotic valvular heart disease
	Electrolyte abnormalities
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise	Severe arterial hypertension
Symptomatic severe aortic stenosis	
Uncontrolled symptomatic heart failure	Tachyarrhythmias or bradyarrhythmias
Acute pulmonary embolus or pulmonary infarction	Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
Acute myocarditis or pericarditis	Mental or physical impairment leading to an inability to exercise adequately
Acute aortic dissection	High-degree atrioventricular block

From Gibbons RJ, Balady GJ, Beasley FW, et al: ACC/AHA guidelines for exercise testing: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Exercise Testing). J Am Coll Cardiol 30:260-315, 1997; modified from Fletcher GF, Balady G, Froelicher VF, et al: Exercise standards: A statement for healthcare professionals from the American Heart Association Writing Group. Special Report. Circulation 91: 580-615, 1995.

*Relative contraindications can be superseded if the benefits of exercise outweigh the risks.

The appropriate timing of testing depends on the level of risk of unstable angina.

In the absence of definitive evidence, the committee suggests systolic blood pressure greater than 200 mm Hg and/or diastolic blood pressure greater than 110 mm Hg.

TABLE 6-6-G-2 -- APPROPRIATENESS OF EXERCISE TESTING FOR SPECIFIC PATIENT SUBSETS AND INDICATIONS

Indication	Class I: Appropriate	Class IIa: Probably Appropriate	Class IIb: Probably Not Appropriate	Class III: Inappropriate

Exercise testing in diagnosis of obstructive CAD	Adult patients (including those with complete right bundle branch block or less than 1 mm of resting ST depression) with an intermediate pretest probability of CAD (see Table 6-G-3) based on gender, age, and symptoms (specific exceptions are noted in Classes II and III)	Patients with vasospastic angina	Patients with a high pretest probability of CAD by age, symptoms, and gender	Patients with the following baseline ECG abnormalities: Preexcitation (Wolff-Parkinson-White) syndrome Electronically paced ventricular rhythm Greater than 1 mm of resting ST depression Complete left bundle branch block
			Patients with a low pretest probability of CAD by age, symptoms, and gender	Patients with a documented myocardial infarction or prior coronary angiography demonstrating significant disease have an established diagnosis of CAD; however, ischemia and risk can be determined by testing
			Patients with less than 1 mm of baseline ST depression and taking digoxin	
			Patients with ECG criteria for left ventricular hypertrophy and less than 1 mm of baseline ST depression	
Risk assessment and prognosis in patients with symptoms or a prior history of CAD	Patients undergoing initial evaluation with suspected or known CAD. Specific exceptions are noted below in Class IIb	None	Patients with the following ECG abnormalities: Preexcitation (Wolff-Parkinson-White) syndrome Electronically paced ventricular rhythm Greater than 1 mm of resting ST depression Complete left bundle branch block	Patients with severe comorbidity likely to limit life expectancy and/or candidacy for revascularization
	Patients with suspected or known CAD previously evaluated with significant change in clinical status		Patients with a stable clinical course who undergo periodic monitoring to guide treatment	
After myocardial infarction	Before discharge for prognostic assessment, activity prescription, and evaluation of medical therapy (submaximal at about 4 to 7 d)	After discharge for activity counseling and/or exercise training as part of cardiac rehabilitation in patients who have undergone coronary revascularization	Before discharge in patients who have undergone cardiac catheterization to identify ischemia in the distribution of a coronary lesion of borderline severity	Severe comorbidity likely to limit life expectancy and/or candidacy for revascularization
	Early after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the predischarge exercise test was not done (symptom limited/about 14-21 d)		Patients with the following ECG abnormalities: Complete left bundle branch block Preexcitation syndrome Left ventricular hypertrophy Digoxin therapy Greater than 1 mm of resting ST segment depression Electronically paced ventricular rhythm	
	Late after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the early exercise test was submaximal (symptom limited/about 3-6 wk)		Periodic monitoring in patients who continue to participate in exercise training or cardiac rehabilitation	
Exercise testing using ventilatory gas analysis	Evaluation of exercise capacity and response to therapy in patients with heart failure who are being considered for heart transplantation	Evaluation of exercise capacity when indicated for medical reasons in patients whom subjective assessment of maximal exercise in unreliable	Evaluation of the patient's response to specific therapeutic interventions in which improvement in exercise tolerance is an important goal or endpoint	Routine use to evaluate exercise capacity
	Assistance in the differentiation of cardiac vs. pulmonary limitations as a cause of exercise-induced dyspnea or impaired exercise capacity when the cause is uncertain		Determination of the intensity of exercise training as part of comprehensive cardiac rehabilitation	
Exercise testing in asymptomatic persons without known CAD	None	None	Evaluation of persons with multiple risk factors (see the text)	Routine screening of asymptomatic men or women
			Evaluation of asymptomatic men older than 40 yr and women older than 50 yr Who plan to start vigorous exercise (especially if sedentary) *or* Who are involved in occupations in which impairment might have an impact on public safety *or* Who are at high risk for CAD because of other diseases (e.g., chronic renal failure)	
Valvular heart disease	None	None	Evaluation of exercise capacity of patients with valvular heart disease	Diagnosis of CAD is patients with valvular heart disease

Exercise testing before and after revascularization	Demonstration of ischemia before revascularization	After discharge for activity counseling and/or exercise training as part of cardiac rehabilitation in patients who have undergone coronary revascularization	Detection of restenosis in selected, high-risk asymptomatic patients within the first months after angioplasty	Localization of ischemia for determining the site of intervention
	Evaluation of patients with recurrent symptoms suggesting ischemia after revascularization		Periodic monitoring of selected, high-risk asymptomatic patients for restenosis, graft occlusion, or disease progression	Routine, periodic monitoring of asymptomatic patients after percutaneous transluminal coronary angioplasty or coronary artery bypass graft surgery without specific indications
Investigation of heart rhythm disorders	Identification of appropriate settings in patients with rate-adaptive pacemakers	Evaluation of patients with known or suspected exercise-induced arrhythmias	Investigation of isolated ventricular ectopic beats in middle-aged patients without other evidence of CAD	Investigation of isolated ectopic beats in young patients
		Evaluation of medical, surgical, or ablative therapy in patients with exercise-induced arrhythmias (including atrial fibrillation)		

CAD = coronary artery disease; ECG = electrocardiogram.

disease. Exercise testing for patients with unstable angina is recommended as soon as the patient has stabilized clinically. In contrast, the ACC/AHA guidelines do not offer strong support for routine exercise testing of patients with a stable clinical course (see Table 6-G-3) .

The ACC/AHA guidelines explicitly state that the exercise test should be the standard initial mode of stress testing for risk stratification of patients with a normal electrocardiogram who are not taking digoxin. The guidelines assert that "There is no compelling evidence in patients who are classified as low risk based on clinical and exercise testing information that an imaging modality adds significant new prognostic information to a standard exercise test." In intermediate-risk patients, the text acknowledges that myocardial perfusion imaging appears to add value for risk stratification.

AFTER MYOCARDIAL INFARCTION.

The ACC/AHA guidelines are strongly supportive of one to two exercise tests for risk stratification after acute myocardial infarction (see Table 6-G-3) . Submaximal tests are appropriate prior to discharge from the hospital. If predischarge testing is not performed, symptom-limited tests about 14 to 21 days after the myocardial infarction are appropriate. If predischarge testing was performed, a full symptom-limited test 3 to 6 weeks after infarction is appropriate.

These guidelines indicated that cardiac rehabilitation should be "considered standard care that should be integrated into the treatment plan of patients with" coronary artery disease, and they supported exercise testing for this purpose. However, the guidelines indicated that the appropriateness of some uses of exercise testing as part of cardiac rehabilitation was not established. Use of exercise testing after patients have undergone coronary revascularization was considered uncertain, but supported by most evidence (Class IIa). However, periodic monitoring with exercise testing in patients who are participating in cardiac rehabilitation programs was considered to have less support from research data.

USE OF VENTILATORY GAS ANALYSIS.

The ACC/AHA guidelines were explicitly supportive of the use of ventilatory gas analysis for certain specific indications in patients with cardiovascular and pulmonary disease. The most clearly appropriate indications were when cardiac transplantation was being considered or when differentiation between cardiac and pulmonary limitations in functional status was uncertain because of other clinical data. Some evidence exists to support the appropriateness of such testing when patients' subjective assessment of maximal exercise is unreliable (Class IIa). Routine use of ventilatory gas analysis to assess exercise capacity was considered inappropriate.

EXERCISE TESTING IN WOMEN.

The guidelines recommend that strategies for exercise testing in women be the same as those used in men. The text acknowledged problems with false-positive results but indicated that the data were insufficient to support routine stress imaging as the initial test for coronary disease in women.

ASYMPTOMATIC PATIENTS WITHOUT KNOWN CORONARY ARTERY DISEASE.

The ACC/AHA guidelines were generally not supportive of the use of exercise testing to screen for coronary artery disease in asymptomatic patients. The guideline authors acknowledged that this assessment was discordant with widespread practice patterns but concluded that existing data indicate that such screening leads to a high rate of false-positive results. This lack of support for screening asymptomatic patients with exercise testing is consistent with guidelines from the U.S. Preventive Services Task Force[5] and the American College of Physicians.[6]

The ACC/AHA guidelines identified some indications of uncertain appropriateness for which the weight of evidence was not strong. One such "Class IIb" indication was evaluation of patients with multiple risk factors, which was defined as hypercholesterolemia (>240 mg/dl), hypertension (systolic blood pressure >140 mm Hg or diastolic blood pressure >90 mm Hg), smoking, diabetes, and a family history of heart attack or sudden cardiac death in a first-degree relative younger than 60 years. An alternative approach is to select patients with a Framingham risk score consistent with at least a moderate risk of serious cardiac events within 5 years.

Exercise testing was also considered to be of marginal (Class IIb) appropriateness for men older than 40 years or women older than 50 who (1) were starting a vigorous exercise program, (2) might endanger the safety of others if they had a sudden cardiac event, or (3) had a high risk for coronary disease because of other diseases. A minority of the ACC/AHA committee favored a Class III recommendation for exercise testing in patients with multiple risk factors or people starting

TABLE 6-6-G-3 -- PROBABILITY OF CORONARY ARTERY DISEASE BY AGE, GENDER, AND SYMPTOMS (FROM ACC/AHA GUIDELINES)

Age* (yr)	Gender	Typical/Definite Angina Pectoris	Atypical/Probable Angina Pectoris	Nonanginal Chest Pain	Asymptomatic
30-39	Men	Intermediate	Intermediate	Low	Very low
	Women	Intermediate	Very low	Very low	Very low
40-49	Men	High	Intermediate	Intermediate	Low
	Women	Intermediate	Low	Very low	Very low
50-59	Men	High	Intermediate	Intermediate	Low
	Women	Intermediate	Intermediate	Low	Very low
60-69	Men	High	Intermediate	Intermediate	Low
	Women	High	Intermediate	Intermediate	Low

*No data exist for patients younger than 30 or older than 69 years, but it can be assumed that prevalence of coronary artery disease increases with age. In a few cases, patients with ages at the extremes of the decades listed may have probabilities slightly outside the high or low range. High indicates 90 percent; intermediate, 10 to 90 percent; low, less than 10 percent; and very low, less than 5 percent.

exercise programs. Support for these positions is provided by guidelines from the American College of Sports Medicine, which recommends exercise electrocardiography for men older than 40 years, women older than 50, and other asymptomatic persons with multiple cardiac risk factors prior to beginning a vigorous exercise program.[7]

VALVULAR HEART DISEASE.

The ACC/AHA guidelines supported only limited use of exercise testing as part of the routine care of patients with valvular heart disease. The primary value of exercise testing in such patients is to assess atypical symptoms, exercise capacity, and the extent of disability (Class IIb). However, use of the exercise test to screen for coronary artery disease was considered inappropriate.

The guidelines noted that exercise testing may sometimes be useful and appropriate in patients with aortic stenosis. Although severe symptomatic aortic stenosis is considered a contraindication to exercise testing, this evaluation can be safely performed under close observation by an experienced physician.

BEFORE AND AFTER REVASCULARIZATION.

The ACC/AHA guidelines were supportive of the use of exercise testing to demonstrate ischemia before revascularization or to evaluate the significance of recurrent symptoms afterward. However, routine periodic testing of asymptomatic patients was considered inappropriate (Class III). The appropriateness of testing was considered equivocal in patients who were undergoing cardiac rehabilitation after revascularization or in asymptomatic patients who were considered to be at high risk for restenosis, graft occlusion, or disease progression.

INVESTIGATION OF HEART RHYTHM DISORDERS.

Exercise testing was considered to have narrow appropriate indications for use in the evaluation of rhythm disorders, including the assessment of settings for rate-adaptive pacemakers. Patients with known or suspected exercise-induced arrhythmias were considered reasonably appropriate (Class IIa) candidates for exercise testing. Exercise testing was also considered reasonably appropriate for assessment of therapy in patients who had been shown to have exercise-induced arrhythmias. Use of exercise testing for assessment of isolated ectopic beats was discouraged.

Chapter 7 - Echocardiography

WILLIAM F. ARMSTRONG
HARVEY FEIGENBAUM

Echocardiography is a group of interrelated applications of ultrasound including two-dimensional anatomical imaging, M-mode echocardiography, Doppler techniques, and contrast echocardiography. Echocardiography uses sound in the frequency range of 1 to 10 MHz. Typically when imaging adult patients, frequencies range from 2 to 5 MHz. For pediatric and some specialized adult applications higher frequencies of 7.5 and 10 MHz may also be used.

PRINCIPLES OF CARDIAC ULTRASONOGRAPHY

IMAGE GENERATION

The underlying premise of cardiac ultrasonography is that the speed of sound through tissue is equal to that in water (1450 m/sec). Ultrasound scanners emit a series of ultrasound bursts at a given frequency. The number of bursts or pulses per second is the "pulse repetition frequency." The ultrasound energy is then reflected from cardiac and other structures and returned to the transducer. By determining the time required for round trip transit, the distance of a reflective object from the transducer can be calculated. The returning strength of the ultrasound signal is directly proportional to the reflective intensity of the object and likewise is integrated into the displayed image. The resolution with which structures can be defined is dependent on the transducer frequency, with higher resolution provided by high-frequency transducers but at the cost of reduced depth of penetration. The nature of the image that is acquired and displayed is determined by the number of ultrasound interrogation lines and the manner in which they are processed.

M-mode echocardiography was the earliest form of cardiac ultrasonography used clinically. M-mode echocardiography relies on interrogation along a single line of ultrasound either emitted from an independent transducer or along a cursor within a two-dimensional image. The M-mode echocardiogram only provides information with respect to the distance of each object from the transducer and provides no information in the lateral dimension (Fig. 7-1) . M-mode echocardiography was once the mainstay of echocardiography, but in modern laboratories it is relegated to a secondary role. It may still have some incremental value for highly precise measurements, and its temporal resolution far exceeds that of two-dimensional scanning.

A two-dimensional echocardiogram is created when a fan-shaped array, consisting of multiple interrogation lines, is emitted typically over a 90-degree sector from the transducer and analyzed. There are two methods by which the fan-shaped sector of ultrasound beams can be created. Most widely used is a phased-array system in which a linear array of ultrasound crystals is electronically steered through an imaging arc. The second method relies on high-speed mechanical rotation of one or usually more ultrasound crystals to mechanically steer the ultrasound beam through the predefined arc.

Doppler ultrasonography relies on analysis of a shift in the frequency of the ultrasound beam due to interaction with moving targets. The Doppler shift data can be displayed as a velocity profile or a color flow image. In the following sections we first discuss the methods by which anatomical images are recorded and then discuss Doppler methodology. The actual clinical echocardiographic examination consists of simultaneous and integrated two-dimensional and Doppler evaluation, supplemented by other specific and goal-oriented imaging modalities.

Figure 7-1 Normal M-mode echocardiogram in which the M-mode beam is swept from the aortic valve through the mitral valve and to the level of the papillary muscles. Note the normal boxlike opening of the aortic valve and the biphasic, "M"-shaped opening pattern of the mitral valve. There is posterior motion of the ventricular septum synchronous with anterior motion of the posterior wall. AV = aortic valve; DAo = descending aorta; LA = left atrium; LV = left ventricle; MV = mitral valve; RV = right ventricle.

Figure 7-2 Schematic of the transducer orientation used for acquiring parasternal views. The scanning plane of the ultrasound beam is superimposed on a schematic of the heart. Plane 1 represents a parasternal long-axis view in which the right ventricular outflow tract, proximal portion of the aorta and aortic valve, anterior ventricular septum, cavity of the left ventricle containing the mitral valve, and inferoposterior wall of the left ventricle can be visualized. Scanning plane 1 results in an ultrasound image as noted in Figure 7-1 . Scanning plane 2 is obtained by rotating the transducer 90 degrees and can be used to obtain a family of short-axis views of the heart. *(From Feigenbaum H: Echocardiography, 4th ed. Malvern, PA, Lea & Febiger, 1986.)*

THE ANATOMICAL ECHOCARDIOGRAPHIC EXAMINATION (SeeChap. 3.)

The mainstay of the echocardiographic examination is transthoracic two-dimensional echocardiography (TTE). The fan-shaped scan plane is directed into the chest to provide tomographic imaging planes (Figs. 7-2 , 7-3 , 7-4 , 7-5 , 7-6 , and 7-7). Each returning ultrasound signal is then registered and converted to a two-dimensional image of the interrogated plane. This process is repeated 20 to 120 times per second, resulting in a frame rate of 20 to 120 Hz. The sequence of imaged frames results in a real-time moving image of the heart. The frame rate for two-dimensional imaging is dependent on line density and scanning depth. Smaller areas can be imaged at substantially higher (100-120 Hz) frame rates than can be larger sectors, which typically are imaged at 30 Hz.

For the transthoracic examination, patients are typically placed in a left lateral position and scanned from several different left intercostal spaces. The standard transthoracic views (Table 7-1) are recorded from parasternal and apical transducer positions. Subcostal and suprasternal transducer positions can also be used. From any transducer position, the Doppler modalities, including pulsed, continuous-wave, and color flow imaging, can be recorded. Other imaging windows, such as the right sternal border, can be used for specific examinations.

Traditionally, two-dimensional echocardiograms and Doppler echocardiograms have been recorded on videotape for subsequent analysis and activities. In modern ultrasound equipment the image is acquired in a digital format and stored as such (Fig. 7-8) . Digital images can be displayed side by side or as a quad screen containing multiple views for visualization simultaneously. Digital images are free from degradation seen when the source image is transferred to analog videotape and can be transmitted to remote sites for review.[1] [2]

Figure 7-3 Parasternal long-axis view of the left ventricle in diastole *(top)* and systole *(bottom)*. Chambers and cardiac structures are as noted. This view corresponds to plane 1 of Figure 7-1 . AO = aorta; LA = left atrium; LV = left ventricle; RV = right ventricular outflow tract; MV = mitral valve.

Figure 7-4 Schematic showing the relationship of the parasternal long- and short-axis views of the heart. The central figure is a schematized parasternal long-axis view. Images 1 through 4 can be obtained by rotating the probe 90 degrees from the long axis and then angling the probe through the positions noted as 1 through 4 on the central schematic. Echocardiograms recorded from these different planes are presented in Figure 7-5 . *(From Feigenbaum H: Echocardiography. 4th ed. Malvern, PA, Lea & Febiger, 1986.)*

Figure 7-5 Short-axis two-dimensional echocardiograms recorded in planes depicted in Figure 7-4 . The two left panels are recorded at the level of the papillary muscles in diastole *(top)* and systole *(bottom)*. Note the symmetrical thickening of the myocardium and inward motion of the endocardium representing normal ventricular function in systole. The top right panel is recorded at the level of the aortic valve, and the bottom right panel is recorded at the level of the mitral valve in diastole. Abbreviations are as per other figures; TV = tricuspid valve; RA = right atrium; PA = pulmonary artery; IVC = inferior vena cava.

Figure 7-6 Schematic of the ultrasound scanning planes for apical four- and two-chamber views. With the scanning plane directed as in plane 1, all four chambers are intersected. Scanning plane 1 results in an image as presented in the left panel of Figure 7-7 . By rotating the probe approximately 90 degrees, scanning plane 2 intersects only the left ventricle and left atrium, as is noted in the right panel of Figure 7-7 . *(From Feigenbaum H: Echocardiography. 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

Examination and Appearance of the Normal Heart

PARASTERNAL LONG-AXIS VIEW.

In this view (see Fig. 7-3) , both the inferoposterior wall and interventricular septum are visualized, each of which is mildly concave toward the other. The normal ascending aorta is visualized, including its annulus, sinus of Valsalva, and proximal portion of the ascending aorta. The anterior and posterior leaflets of the mitral valve can be visualized in the parasternal long-axis position, with the anterior leaflet appearing more elongated. Typically, the posterolateral papillary muscle is also visualized from this transducer position. Anterior to the aorta, a portion of the right ventricular outflow tract is visualized. By medially angulating the transducer the right ventricular inflow tract can be visualized in which the inferior vena cava, right atrium, tricuspid valve, and right ventricle are visualized (Fig. 7-9) . From the parasternal transducer position a short-axis view of the heart can be obtained by rotating the transducer 90 degrees (see Figs. 7-4 and 7-5) . At the base of the heart, the circular aorta and the aortic valve with three equally sized leaflets are visualized, as well as the right ventricular outflow tract, which is seen as an inverted "U" overlying the aorta. By angling the transducer toward the apex, a short-axis view of the mitral valve can be visualized from which the actual orifice can be seen and quantified. With further angulation, the circular cavity of the left ventricle is visualized, including both of the papillary muscles. The normal short-axis geometry of the left ventricle is circular, whether it is visualized at the level of the mitral valve, papillary muscle, or apex. In the

Figure 7-7 Apical four- and two-chamber views of the left ventricle corresponding to the schematic presented in Figure 7-6 . Note the normal "bullet shape" geometry of the left ventricle and the more triangular right ventricle. Note also the more apical insertion of the tricuspid valve compared with the mitral valve. Abbreviations are as per other figures.

short-axis projections at the level of the mitral valve and below, the right ventricle appears as a more trabeculated crescent-shaped structure.

FOUR-CHAMBER VIEW.

From this view, the left ventricle has a normal bullet-shaped geometry. The anterior and posterior mitral valve leaflets can be visualized. The left atrium and pulmonary veins are visualized in high-quality studies as well (see Fig. 7-7) . In the four-chamber view, the right ventricle appears as a triangular structure. The

tricuspid valve inserts into the annulus of the right ventricle at a position slightly more apical than the mitral valve. This results in a small portion of the ventricular septum (the atrioventricular septum) falling between the septal leaflets of the tricuspid and mitral valves. By rotating the transducer 90 degrees from the four-chamber view, a two-chamber view of the left ventricle and atrium can be obtained (see Fig. 7-7) .

SUBCOSTAL AND SUPRASTERNAL VIEWS.

In addition to parasternal and apical transducer positions, subcostal and suprasternal positions also provide imaging windows in adult patients. The subcostal transducer position can be very effective in patients with chronic lung disease in whom parasternal and apical views are obscured by intervening lung tissue. Typically, patients are imaged in the supine position with the knees bent and the transducer placed in the subxiphoid position. Imaging during held inspiration often is effective at bringing the heart into optimal position. Views similar to a four-chamber view as well as a series of short-axis views can be obtained from this transducer position. The subcostal views also provide excellent visualization of the atrial septum and the connection between the inferior vena cava (IVC) and right atrium (Fig. 7-10) .

SUPRASTERNAL VIEWS.

These views are obtained by placing the transducer in the suprasternal notch. This transducer position may be somewhat uncomfortable for many patients. It provides a view of the arch of the aorta and includes the great vessels in the majority of patients and portions of the main pulmonary artery (Fig. 7-11) .

Anatomical Variants

Several well-recognized anatomical and developmental variants can be seen with echocardiography. It is important to recognize these as normal variants to avoid confusion with pathological processes.[3] [4]

MUSCLE TRABECULATIONS.

The right ventricle is more heavily trabeculated than the left, and, similarly, the right atrium is more trabeculated than the left atrium. High-resolution scanning virtually always detects multiple muscle trabeculations in the right ventricle, the most prominent of which is the moderator band, which is a muscular structure traversing from the lateral wall to the septum of the right ventricle near the apex (Fig. 7-12) . On occasion, secondary

Figure 7-8 Demonstration of quad screen format for displaying of digitized echocardiograms. This format allows simultaneous display in real time (here depicted as still images) of four different images of the heart for immediate evaluation and comparison.

muscle bundles are likewise noted. In any situation in which right ventricular hypertrophy occurs the trabeculations become more prominent. It is important to recognize this phenomenon to avoid confusing a heavily trabeculated right ventricle with tumor, vegetation, thrombus, or other mass.

The left ventricle is typically less trabeculated than the right, and other than the papillary muscles it is infrequent to note muscle trabeculations in the left ventricle. Occasionally, a trabeculated left ventricular apex is encountered, the degree of which rarely approaches that seen in the right ventricle. Not infrequently, pseudochordae are seen in the left ventricular apex. Anatomically, these are structures similar to mitral valve chordae but take an aberrant course,

Figure 7-9 Two-dimensional echocardiogram of the right ventricular inflow tract, recorded from the parasternal transducer position. Abbreviations are as per other figures.

typically across the apex of the left ventricle. They are less often seen in the left ventricular outflow tract. They are more easily visualized in patients with cardiomyopathy and dilated hearts than in normal hearts, where they may lie against the endocardium and therefore not be visible.

RIGHT AND LEFT ATRIAL STRUCTURES.

Several developmental remnants can be noted in the right atrium. These include the eustachian valve (Fig. 7-13) and Chiari network. In the embryo, a continuous membrane courses from the IVC to the coronary sinus to direct oxygenated blood from the IVC directly across the foramen ovale. During cardiac development this membrane reabsorbs. In the majority of patients a small remnant known as the eustachian valve can be seen at the margin of the right atrial-IVC junction. A second remnant is occasionally seen attached to the coronary sinus. This is known as a Chiari network and consists of a fine filamentous membrane, with multiple perforations attached to the coronary sinus. On rare occasions, the complete eustachian valve is seen as a linear echo coursing from the IVC to the coronary sinus. In this instance it has multiple perforations and rarely, if ever, is truly obstructive. Either the eustachian valve or a Chiari network can result in redirection of blood flow within the atrium and unusual patterns of blood flow noted with contrast echocardiography.

The right atrial appendage is typically visualized only with transesophageal echocardiography (TEE). It is a more trabeculated structure than the left atrial appendage, and, on occasion, trabeculae in the right atrial appendage have been confused for thrombi. Recognizing the full range of appearance of the right atrial appendage is essential to avoid this error.

The left atrium has a smoother wall than the right atrium. The left atrial appendage is occasionally visualized from TTE, either in the apical two-chamber view or in a parasternal short-axis view. It is optimally visualized with TEE, where it has the appearance of a "dog's ear" (Fig. 7-14) . A substantial percentage of individuals have a multilobed

Figure 7-10 Two-dimensional echocardiograms recorded from the subcostal transducer position. The upper panel is a subcostal four-chamber view in which all four cardiac chambers are visualized as well as the plane of the mitral and tricuspid valves. The interatrial septum is visualized in its entire length in this view. The lower panel is recorded in a short-axis view at the level of the aortic valve from the subcostal position. The right atrium, tricuspid valve, right ventricle, and pulmonary artery are visualized as well as the circular aorta. The interatrial septum and inferior vena cava are both visualized in this view as well. Abbreviations are as per other figures; IVC = inferior vena cava; IAS = interatrial septum.

left atrial appendage, which can result in a confusing appearance because the septation between the two lobes may be confused for thrombus.[4]

ATRIAL SEPTUM.

The normal interatrial septum is visualized both in its primum and more superior portions, connected by thin tissue of the foramen ovale. There is substantial variation in the thickness and prominence of the more muscular primum and superior portions of the atrial septum. A commonly encountered anomaly of the atrial septum is lipomatous atrial hypertrophy in which there is benign infiltration by lipomatous tissue of the primum and superior atrial septum (Fig. 7-15) . The valve of the foramen ovale is spared, resulting in a "dumbbell" configuration of the atrial septum. The amount of infiltration is highly variable and can range from less than 1.0 cm to 5 cm or more. The tissue is homogeneous and somewhat brighter than the normal atrial septum. It should not be confused with intracardiac tumor or thrombus.

Figure 7-11 Two-dimensional echocardiogram recorded from a suprasternal transducer position. The arch of the aorta as well as a portion of the ascending and descending aorta can be visualized. Note also the great vessels arising from the arch (arrows). DA = descending aorta; LCA = left carotid artery; LSA = left subclavian artery.

Quantification of Ventricular Performance

Echocardiography provides an excellent method for quantification of ventricular function. Linear measurements such as wall thickness, internal chamber dimension, and the derived parameters such as fractional shortening traditionally have been obtained from M-mode echocardiography. Normal values for adults and children are well established (Table 7-2) .[5] [6] [7] [53A] [55A] [55B] [65A] Global ventricular function and cardiac volumes can be measured with a variety of algorithms using two-dimensional echocardiography.[7A] The most commonly

Figure 7-12 Apical four-chamber view of the heart revealing a prominent moderator band. The moderator band (arrow) appears as a muscle density structure traversing the apex of the right ventricle (arrow). This is a normal anatomical structure that should not be confused with a pathological process.

Figure 7-13 Transthoracic parasternal echocardiograms recorded in a patient with a prominent eustachian valve (EV). This is a normal anatomical variant that should not be confused for a mass, vegetation, or other pathological structure. The top panel is a right ventricular inflow tract view recorded from the left sternal border. Both the right atrium and right ventricle can be seen, and the tricuspid valve is closed. Note the linear echo arising from the junction of the right atrium and inferior vena cava coursing into the body of the right atrium. In real time this linear echo has highly mobile motion, mimicking valvular motion. The bottom panel is recorded in a parasternal short-axis view at the base of the heart. The same linear echo is noted in the bottom of the right atrium (arrow).

employed method for quantitation of ventricular volume is Simpson's rule (Fig. 7-16) . Once the chamber volumes have been determined, ejection fraction can be calculated. Calculation of ejection fraction represents only a small aspect of quantification of ventricular performance. Determination of left ventricular volume requires manual tracings of the endocardial border in diastole and systole. Instrumentation exists that can automatically determine the endocardial border and calculate volumes and ejection fraction (Fig. 7-17)[8] Application of this technology requires high-quality images with a favorable signal-to-noise ratio. These automatically determined ventricular volumes can be combined with arterial pressure measurements to create pressure-volume loops for more sophisticated evaluation of ventricular performance.[9] [10]

Figure 7-14 Transesophageal echocardiogram recorded at a 30-degree angle demonstrating the appearance of normal left atrial appendage. The body of the left atrium is at the apex of the scan and the normal "ear-shaped" left atrial appendage can be seen communicating with the body of the left atrium (arrow).

Figure 7-17 Apical four-chamber image in which an algorithm for automatic border detection has been used to determine instantaneous left ventricular volume. The white line outlining the endocardial border has been automatically drawn by the ultrasound machine. A graphic output of instantaneous ventricular volume and calculated ejection fraction is presented below the echocardiographic image.

Left ventricular mass can be measured by several different methods. One of the earliest was the "cube" method, which used M-mode septal, posterior wall, and left ventricular internal dimensions and assumed normal ventricular geometry.[7] [11] [11A] More recently, several two-dimensional

Figure 7-15 Transesophageal echocardiogram recorded in a patient with lipomatous atrial septum. From the transthoracic view, marked homogeneous thickening of the atrial septum is noted. In the transesophageal echocardiogram this can be appreciated as disproportionate infiltration and thickening of the basal and primum portions of the atrial septum with relative sparing of the area of the foramen ovale.

TABLE 7-2 -- NORMAL VALUES OF M-MODE ECHOCARDIOGRAPHIC MEASUREMENTS IN ADULTS

	RANGE (cm)	MEAN (cm)	NO. OF SUBJECTS
Age (years)	13 to 54	26	134
Body surface area (M^2)	1.45 to 2.22	1.8	130
RVD--flat	0.7 to 2.3	1.5	84
RVD--left lateral	0.9 to 2.6	1.7	83
LVID--flat	3.7 to 5.6	4.7	82
LVID--left lateral	3.5 to 5.7	4.7	81
Posterior LV wall thickness	0.6 to 1.1	0.9	137
Posterior LV wall amplitude	0.9 to 1.4	1.2	48
IVS wall thickness	0.6 to 1.1	0.9	137
Mid IVS amplitude	0.3 to 0.8	0.5	10
Apical IVS amplitude	0.5 to 1.2	0.7	38
Left atrial dimension	1.9 to 4.0	2.9	133
Aortic root dimension	2.0 to 3.7	2.7	121
Aortic cusps' separation	1.5 to 2.6	2.9	93
Percentage of fractional shortening-	34% to 44%	36%	20%
Mean rate of circumferential shortening (Vcf) or mean normalized shortening velocity	1.02 to 1.94 circ/sec	1.3 circ/sec	38

RVD = right ventricular dimension; LVID = left ventricular internal dimension; d = end diastole; s = end systole; LV = left ventricle; IVS = interventricular septum.

methods have been shown to provide enhanced accuracy, especially in abnormally shaped ventricles.[12]

Normal wall motion consists of simultaneous myocardial thickening and inward motion of the endocardium toward the center of the chamber.[13] The most common cause of a regional wall motion abnormality is myocardial ischemia or infarction. The extent of a wall motion abnormality can be measured in several different ways. Echocardiography is a tomographic technique that visualizes all of the cardiac walls. Traditionally for quantitative purposes the left ventricle is divided into 16 segments.[14] Each segment can be attributed to one of the three major epicardial coronary arteries (Fig. 7-18) . There is substantial overlap in the posterior segments and inferior and lateral apical segments. For each of these 16 segments a wall motion score can be assigned (Fig. 7-19) . This is a unitless hierarchical number in which 1 represents normal motion; 2, hypokinesis; 3, akinesis;

Figure 7-16 Apical four-chamber view from which left ventricular volume has been calculated using Simpson's rule. The endocardium has been traced and automatically subdivided into a series of discs. The volume of each of the discs is then calculated as disc area (pir^2) multiplied by the height of each disc. The volume of each separate disc is then summed to provide the volume of the ventricle (116 ml).

and 4, dyskinesis. Each wall is then assigned a score, and the average score for the 16 segments is then calculated. This number is directly proportional to the extent and severity of wall motion abnormalities. There are several variations on a wall motion score, including addition of scores for aneurysm, mild hypokinesis, and hyperkinesis. The wall motion score can be calculated for all 16 segments of the left ventricle or separately for anterior and posterior segments, representing the left anterior descending and right plus circumflex coronary artery territories, respectively. An M-mode interrogation line can be used to quantify endocardial excursion and myocardial thickening in any targeted segment (Fig. 7-20) .

There are several more complex methods for quantification of left ventricular function. Most rely on tracing the endocardial border in diastole and systole in either a short-axis or apical view. Radians are then constructed from the center of mass, and either changes in radian length or changes in area subtended by an arc are then quantified. [15]

ABNORMALITIES OF SEPTAL MOTION.

The interventricular septum is a shared wall between the right and left ventricles, and thus its motion can be affected by processes in either ventricle. Myocardial ischemia and infarction cause a fairly characteristic absence of systolic thickening and dyskinesis of the septum. There are multiple nonischemic causes for septal wall motion abnormalities as well.

Conduction Disturbances.

Both left bundle branch block and Wolff-Parkinson-White syndrome,[16] with a septal pathway, can result in abnormalities of septal motion. Left bundle branch block characteristically causes an early systolic downward motion followed by relaxation of the ventricular septum and a secondary downward contraction. This is best appreciated with M-mode echocardiography. This phenomenon is most common in the proximal anterior septum and is less prominent in the distal septum. A similar pattern is seen in patients with ventricular pacing; however, the maximum location of abnormal motion is highly variable, depending on the location of the pacemaker lead.

Wolff-Parkinson-White syndrome results in ventricular preexcitation in a localized area of the left or right ventricle. The preexcited area contracts slightly earlier than the remainder of the heart and can be seen in the ventricular septal posterior or lateral walls. The abnormality associated with Wolff-Parkinson-White syndrome is less dramatic than that seen with left bundle branch block. Although newer

Figure 7-18 Schematic representation of a 16-segment division of the left ventricle and the associated coronary artery distributions.

two-dimensional scanning instruments have temporal resolution sufficient to detect an abnormality of wall motion due to a conduction disturbance, the high temporal resolution of M-mode echocardiography may be necessary for precise identification of the wall motion abnormalities.

CONSTRICTIVE PERICARDITIS (see Chap. 50) .

Constrictive pericarditis interferes with the normal sequence of right and left ventricular filling and results in subtle septal wall motion abnormalities.[17] This typically causes early downward motion of the septum, followed by paradoxical motion. Multiple patterns of septal motion abnormalities have been noted in constrictive pericarditis. As with electrical conduction disturbances, these may be best identified with M-mode echocardiography.

VENTRICULAR OVERLOAD.

Either a volume or pressure overload of the right ventricle results in a ventricular septal motion abnormality.[18] In each instance the right ventricle is dilated. In a pure volume overload there is diastolic flattening of the ventricular septum so that the left ventricular geometry in diastole assumes a "D" shape rather than circular geometry. Because this is a low pressure phenomenon the left ventricle becomes circular in early systole before onset of ventricular ejection (Fig. 7-21) . A right ventricular pressure overload results in flattening of the septum not only in diastole but also in systole. The degree of flattening is directly proportional to the elevation in right ventricular systolic pressure. Frank reversal of septal curvature is seen in individuals with systemic level right-sided heart pressures.

A final septal motion abnormality that is commonly encountered is the "postoperative septum." This abnormality is characterized by paradoxical anterior motion of the septum in systole, with preserved myocardial thickening. Often posterior wall excursion appears exaggerated.[19] This phenomenon may be seen in any form of cardiac surgery in which the pericardium has been opened. It often resolves 3 to 5 years after surgery.

Doppler Principles and Equations

The Doppler principle states that the frequency of ultrasound reflected from a stationary object is identical to the transmitted frequency. If an object is moving toward the transducer, the reflected frequency will be higher than the transmitted frequency; and conversely if an object is moving away from the transducer, the reflected frequency will be lower. The difference between the transmitted and received frequencies is the Doppler shift (Fig. 7-22) . The magnitude of the Doppler shift is determined by the velocity and direction of the moving object and can be calculated by the Doppler equation. The Doppler equation relates the angle of interrogation, the Doppler shift, or change in frequency between the transmitted and reflected frequency, and a constant that is equal to the speed of sound in water, to the velocity and direction of the moving object (Fig. 7-23) . A major contributor to this equation is the angle theta, with which the interrogating beam intercepts flow. For

Figure 7-19 Typical wall motion score presentation. For each of the 16 segments a score of 1 to 4 has been assigned, representing normal or abnormal wall motion. The scores are then summed and averaged to calculate an overall wall motion score that is directly proportionate to the size and severity of the wall motion abnormality.

maximum accuracy, interrogation should be directly in the line of flow, that is, theta = 0 degrees. Because the cosine of 0 degrees = 1.0, solving the Doppler equation is a fairly straightforward process. With increasing angle theta the cosine becomes progressively less than 1.0 and when incorporated into the equation results in a systematic and increasingly severe underestimation of the true velocity. For practical purposes an angle of interrogation less than 20 degrees is essential to ensure clinically accurate information. Most modern instrumentation contains algorithms for correcting theta when it is not equal to 0 degrees. Unfortunately, the true direction of the laminar flow is often not known, and attempts at correction are likely to result in creation of additional error. For the purposes of cardiac imaging, Doppler echocardiography is most commonly employed for determining the direction and velocity of red blood cells moving

Figure 7-20 M-mode echocardiogram recorded in a patient with severe left ventricular systolic dysfunction. Note the dilated left ventricle and a decreased excursion of the septum and posterior wall compared with the normal example seen in Figure 7-1 . There is additional evidence of left ventricular systolic dysfunction in that the mitral valve E point septal separation is increased (double-headed arrow). Evidence of elevated end-diastolic pressure is noted in the "B bump" (arrowhead), which delays final closure of the mitral valve.

Figure 7-21 Short-axis two-dimensional echocardiogram depicting a right ventricular volume overload pattern. Compare the normal geometry of the left ventricle in a short-axis view (see Fig. 7-5) to that noted here. In the right ventricular volume overload pattern there is dilation of the right ventricle and flattening of the ventricular septum (downward pointing arrows) so that in diastole the ventricle takes on a "D"-shaped configuration rather than circular geometry. With systole there is restitution of normal circular geometry (upward arrows).

within the cardiovascular system. By convention, motion toward the transducer is recorded as a signal above the zero velocity line and motion away from the transducer as a signal below this line (Fig. 7-24) .

CALCULATION OF PRESSURE GRADIENTS.

Once the velocity of the target has been determined, this information can be used to determine pressure gradients across a restrictive orifice using the Bernoulli equation.[20] The Bernoulli equation contains multiple elements, including convective acceleration and viscous friction (Fig. 7-25) . Of note, convective acceleration and viscous friction are relatively weak contributors in most biological systems and can

Figure 7-22 Demonstration of the Doppler effect. In each instance the transmitted ultrasound beam is denoted emanating from the upper transducer and the returning beam off of the reflecting object (dark circle) coming to the lower transducer. The upper panel depicts a stationary target in which the transmit frequency (f_t) is equal to the returning frequency (f_r) and there is no Doppler shift. The middle panel depicts an object moving toward the transducer in which the returning frequency (f_r) is greater than the transmit frequency (f_t). In the lower schematic the object is moving away from the transducer and the returning frequency (f_r) is less than the transmit frequency (f_t). The Doppler shift (f_d) equals the difference between these two frequencies. *(From Feigenbaum H: Echocardiography. 4th ed. Malvern, PA, Lea & Febiger, 1986.)*

be effectively ignored. The Bernoulli equation in its simplest form states that DeltaP (the pressure gradient across a restrictive orifice) = $4V^2$, where V = the peak instantaneous velocity of flow through the restrictive orifice. In reality, the equation incorporates not only the peak instantaneous velocity at the restrictive orifice but also the velocity noted

Figure 7-23 Demonstration of the Doppler equation for determining the velocity of a moving object. The Doppler shift (f_d) is calculated as the difference between the returning (f_r) and transmit (f_t) frequencies. The Doppler equation relates the Doppler shift (f_d) to the transmit frequency, the angle of interrogation (theta), the velocity of the moving object (V), and the speed of sound (C). The equation can be rearranged to solve for velocity as is noted in the third equation above. *(From Feigenbaum H: Echocardiography. 4th ed. Malvern, PA, Lea & Febiger, 1986.)*

Figure 7-24 Combination of aortic stenosis and aortic insufficiency demonstrating the directional nature of spectral Doppler. The continuous-wave Doppler is recorded from the apex of the left ventricle along a line oriented through the aortic valve. Aortic stenosis is present with a peak velocity of 4 m/sec (400 cm/sec) that is directed away from the transducer and hence recorded below the zero crossing line. Aortic insufficiency is also present and is noted as a diastolic signal recorded above the zero crossing line. AI = aortic insufficiency; AS = aortic stenosis.

in the acceleration zone, V2. For most clinically relevant conditions such as severe aortic stenosis, V1 is substantially greater than V2 and hence V2 can effectively be ignored. There are several instances in which the V2 velocity must be included. These include the obvious case of a serial obstruction, as well as other situations in which V2 is relatively large compared with V1, such as in milder degrees of aortic stenosis and aortic stenosis combined with aortic insufficiency.

THE BASIC DOPPLER EXAMINATION: NORMAL FLOW PATTERNS.

All four cardiac valves can be interrogated using either pulsed or continuous-wave Doppler and substantial physiological data derived from the recorded signals.[20] Figure 7-26 is a representation of normal Doppler flow patterns across the aortic and mitral valves. Highly sensitive Doppler instrumentation frequently picks up mild amounts of physiological regurgitation, which is more common for the tricuspid and pulmonic than the aortic and

Figure 7-25 The Bernoulli equation can be used to calculate a pressure gradient across any restrictive orifice. The components of the Bernoulli equation are convective acceleration, flow acceleration, and viscous friction. The full equation can be modified to P1 - P2 = $V_2^{\ 2}$ - $V_1^{\ 2}$ ×4 and further simplified in the absence of a significant V_1 velocity to DeltaP = $4V^2$. P2 = pressure diastole to an obstruction; V_2 = Doppler velocity diastole to an obstruction; V_1 = velocity proximal to an obstruction; P1 = pressure proximal to an obstruction. *(From Feigenbaum H: Echocardiography. 4th ed. Malvern, PA, Lea & Febiger, 1986.)*

Figure 7-26 Pulsed Doppler spectral recordings of normal mitral and aortic valve flows. The top panel is recorded from the left ventricular apex and shows normal mitral valve inflow with a relatively higher E than A velocity. The bottom panel is also recorded from the left ventricular apex and shows flow moving away from the transducer in the left ventricular outflow tract with a peak velocity of approximately 1 m/sec.

mitral valves. In the normal heart under physiological circumstances, the maximum velocity typically encountered is approximately 1.6 m/sec. Pulmonary vein and hepatic vein flows can also be recorded in the majority of patients (Fig. 7-27) .

PULSED VERSUS CONTINUOUS-WAVE DOPPLER.

Doppler ultrasonography is used in two basic methods. The first is pulsed Doppler, which can be considered a "steerable stethoscope" in which a sample volume of variable size can be superimposed on the two-dimensional echocardiographic image. Range gating is used to ensure that only Doppler shifts from one discrete site are interpreted for velocity calculations. Thus, pulsed Doppler allows determination of direction and flow velocity at a precise point within the cardiac system. It is limited, however, in its maximum velocity by the Nyquist limit. The Nyquist limit is defined as the pulse repetition frequency divided by 2. For typical imaging systems the maximum recordable velocity with a pulsed rate system is 1.5 to 2 m/sec. Many stenotic and regurgitant velocities exceed this limit, at which point the spectral display is paradoxically recorded as a velocity in the opposite direction of the moving target. This phenomenon is known as "aliasing" (Fig. 7-28) . [21]

Continuous-wave Doppler imaging continuously interrogates the returning ultrasound beam for Doppler shifts. The line of interrogation is identifiable; however, the precise location of the maximum velocity must be deduced by integrating the interrogation line direction with known cardiac anatomy. Whereas continuous-wave Doppler imaging provides less precise localization of gradients, it is not limited by velocity limits and hence can record velocities exceeding those anticipated in a biological system.

MULTIGATE DOPPLER.

In an effort to increase the maximum velocity detectable with pulsed Doppler, a technique of multigating can be employed in which multiple pulsed gates are simultaneously employed, thus increasing the effective Nyquist limit.[22] Multigate Doppler allows detection of velocities as high as 3.5 to 5 m/sec with the ability to identify one of the gates as the site of origin. In large part, multigate Doppler has been fully supplanted by steerable continuous-wave Doppler methodology.

COLOR FLOW DOPPLER.

Color flow Doppler imaging represents a variation on multigate pulsed Doppler imaging and thus is subject to its velocity limitations. In color flow Doppler, instead of only a single site being interrogated for a Doppler shift, a variable-sized matrix of sampling points can be created and used to simultaneously interrogate velocity

Figure 7-27 Normal pulmonary (upper panel) and hepatic (lower panel) vein flows. Nearly continuous, multiphasic flow is seen in the normal pulmonary and hepatic veins. Note that there is higher velocity of pulmonary vein inflow during ventricular systole then during diastole.

Figure 7-28 Pulsed *(top)* and continuous-wave *(bottom)* Doppler recording of mitral regurgitation. The lower panel recorded with continuous-wave Doppler is free of the aliasing phenomenon, and the true peak velocity of the mitral regurgitation jet (5.5 m/sec) is fully displayed. The top panel was recorded in pulsed Doppler, which results in "aliasing." Once the velocity has exceeded the Nyquist limit (in this case 1.6 m/sec) the signal is paradoxically displayed above the zero crossing line.

over a large area of the heart. Because this represents multiple pulsed sample volumes, each of which must be independently interrogated, frame rates are relatively low in Doppler flow imaging. Color flow imaging is the display solution for managing the data that are derived from thousands of sample sites simultaneously. The typical color flow display algorithm involves displaying velocities toward the transducer in varying shades of red and those heading away from the transducer in varying shades of blue with either the intensity or hue paralleling the actual velocity.[23] [24] If multiple velocity shifts are present at an interrogation point, this is defined as "variance" and may be colored in a yellow or green confetti-like image. Normal color flow Doppler findings include the ability to track mitral and tricuspid inflow patterns and left and right ventricular outflow. Normal mitral inflow appears as a red encoded signal moving from the mitral orifice along the lateral wall to the left ventricular apex, where it reverses course and appears as a blue encoded signal along the septum. The flow profile accelerates with atrial systole. With systole the organized flow in the left ventricular outflow tract appears as a series of color shifts as the accelerating flow exceeds the relatively low Nyquist limit of color Doppler imaging. Pathological flow will be detected either as turbulence due to a restricted orifice, as pathological flow through an abnormal communication (e.g., an atrial septal defect), or as a regurgitant flow signal in a downstream chamber. The above represents traditional color flow imaging algorithms. In reality, multiple different color schemes and variance maps can be employed. It should be emphasized that the visualized jet area is heavily dependent on Doppler gain settings. At higher heart rates, the relatively low frame rate of color flow imaging also compromises accuracy. Substantial experience and attention to technical detail is essential to provide accurate clinical information from color flow Doppler imaging.

DOPPLER CALCULATION OF RIGHT VENTRICULAR SYSTOLIC PRESSURE.

Obviously, application of the Bernoulli equation allows calculation of gradients across stenotic valves, but likewise it can be used to calculate a gradient between any high-pressure and low-pressure chamber. A commonly used application of the Bernoulli equation is the determination of the right ventricular systolic pressure.[25] Tricuspid regurgitation is very common in many disease states. By determining the peak velocity of a tricuspid regurgitation jet one can then calculate the right ventricular to right atrial pressure gradient (Fig. 7-29) . A key component of this is estimation of right atrial pressure. Approaches to this determination include assigning an empirical constant, assigning a floating constant of 5, 10, or 15 mm Hg (depending on the size of the right atrium, severity of regurgitation, and appearance of the inferior vena cava), or assigning a floating constant of 10 percent of the peak gradient. Each of these methodologies appears to result in satisfactory estimation of intercardiac pressure.

CALCULATION OF FLOW.

Because the Doppler spectral profile provides a highly accurate measure of the velocity of the moving blood, this value when combined with a measured or calculated area can provide data regarding actual volumetric flow (Fig. 7-30) . Multiplying the cross-sectional area of the flow times the velocity time integral yields the actual volume of flow during that pulse interval. If the left ventricular outflow tract is interrogated, this value then represents the stroke volume of the left ventricle.[26] [27] This, in turn, can be used to calculate cardiac output. The greatest source of error in this calculation is often determination of the cross-sectional area of the left ventricular outflow tract, which may not assume circular geometry. Additionally, because of the formula for determining area from diameter ($A = pir^2$), any error in measuring the diameter of the flow channel is squared. Thus, determination of stroke volume and cardiac output may have greater clinical value in following serial trends than in precise

Figure 7-29 Measurement of right ventricular systolic pressure using the tricuspid regurgitation jet. The gradient between the right ventricle and right atrium ($P_1 - P_2$) can be calculated from the velocity of the tricuspid regurgitation jet using the modified Bernoulli equation ($DeltaP = 4V^2$). Actual right ventricular systolic pressure is then calculated as the sum of the pressure gradient between the two chambers and an assumed right atrial pressure (P_{ra}). Right atrial pressure can be estimated from examination of the jugular veins, by evaluation of the inferior vena cava for collapse during inspiration, or by using an empirical or floating constant (see text for further details). *(From Feigenbaum H: Echocardiography. 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

Figure 7-30 Principle of Doppler determination of volumetric flow. Flow through the tubular object can be calculated as area (A) times mean velocity (V). This phasic flow times the heart rate (HR) equals cardiac output (CO) in a biological system. The velocity is determined from the pulsed Doppler signal. The instantaneous stroke volume can be determined on a beat-by-beat basis; in addition, stroke volume multiplied times heart rate yields cardiac output. The cross section or area can be either directly measured or calculated from the diameter of the circular structure. *(From Feigenbaum H: Echocardiography. 4th ed. Philadelphia, Lea & Febiger, 1986.)*

determination of volumetric flow. For clinical purposes, however, this remains a valuable technique. Similar calculations of flow volume can be performed for the pulmonic and mitral valves as well.[28]

An expansion of volume flow calculation involves the "continuity equation" (Fig. 7-31) . The underlying principle of the continuity equation is that the volume of flow entering a channel must equal the volume of flow exiting that channel.[29] If the cross-sectional area is equal at the entrance and exit points, then flow velocity will likewise be equal at those two points. If, however, the cross-sectional area decreases at the downstream site, then, of necessity, velocity must increase to maintain the same volumetric flow. The continuity equation can be applied for determination of aortic valve area in aortic stenosis and less often for mitral valve area or other conditions.

The relatively low Nyquist limit of color Doppler flow imaging can be used to determine volumetric flow as well. Flow converging on a relatively restrictive area will accelerate as it nears the downstream exit. Because of the relatively low Nyquist limit of color flow Doppler imaging, this results in a series of aliasing lines where the color flow signal will alternately change from blue to red. By purposely utilizing relatively low Nyquist limits and expanded views, the echocardiographer can determine the distance from the actual flow exit point to one of the aliasing lines. Because the velocity at which flow aliases is known, the velocity of flow at that point is likewise known. If one assumes that flow converges at equal velocities symmetrically toward an orifice, then by applying the geometric formula for a hemisphere one can determine the surface area of flow in motion at any of the aliasing points that represents identifiable velocities (Fig. 7-32). From this, one can then calculate the actual volume of flow from this proximal isovelocity surface area as velocity times surface area.[30] [31] In general terms, for any given Nyquist limit the larger the proximal isovelocity surface area, the greater the amount of flow involved. Therefore, quantitation of proximal isovelocity surface area allows an additional clue as to the volume of regurgitant flow. Proximal isovelocity surface area calculations can be performed for any flow that accelerates toward a relatively restrictive orifice, including mitral regurgitation, aortic insufficiency, and shunt lesions. The major limitation of the use of proximal isovelocity surface area is the assumption that flow moves in a hemispherical manner. This assumption is true only for flow converging on a relatively flat surface. If flow is channeled through a funnel, corrections must be made for a surface area less than a full hemisphere.

Figure 7-32 Demonstration of the proximal isovelocity surface area method for determining flow. The figure on the right is a color flow image of the acceleration of flow toward a regurgitant orifice in a patient with mitral regurgitation. Note the sequential shift in color from blue to red and back to blue. The boundary between blue and red represents an aliasing line at which velocity has exceeded the Nyquist limits, which are displayed on the color bar. The schematic on the left outlines the calculations necessary to determine flow. For any given aliasing line a hemisphere of flow is assumed. The

surface area of a hemisphere is calculated as 2 pir^2 . Flow is equal to the product of the surface area times the velocity, which is determined from the Nyquist limit.

Close inspection of a regurgitant jet between either ventricle and its corresponding atrium can also provide clues to ventricular performance. It should be recognized that in early systole ventricular pressure exceeds atrial pressure by a wide margin and thus ejection of blood into the downstream atrium is at low resistance, resulting in a high dP/dt that corresponds to the forcefulness of ventricular contraction.[32] [33] If myocardial failure occurs, the ability of the ventricle to eject forcefully is compromised and dP/dt decreases. This is also noted in spectral Doppler echocardiography of continuous-wave ejection parameters by a decrease in the ejection velocity slope (Fig. 7-33). Actual dP/dt can be calculated by determining the time in milliseconds between a regurgitant velocity of 1 and 3 m/sec. This corresponds to a pressure difference of 32 mm Hg. If the time over which this pressure difference is obtained is measured, a noninvasive dP/dt can be calculated.

Figure 7-31 Principle of using Doppler calculations for the continuity equation to determine the area of the stenotic orifice. The continuity equation stipulates that the volume of flow entering a tubular chamber must equal that exiting it. Because flow equals volume times area at each end of the flow stream, the calculation for flow at each end can be solved for the unknown restricted orifice area (A_2). A_1 = area proximal to the stenosis; A_2 = area of stenosis; V_1 = velocity proximal to the stenosis; V_2 = velocity through the stenosis.

Figure 7-33 Use of the mitral regurgitation spectral display to determine positive and negative dP/dt of left ventricular contraction. The spectral mitral regurgitation jet is displayed at high sweep speed to maximize temporal resolution. The time in milliseconds required for velocity to increase from 1 to 3 m/sec is then measured. This time is then divided into 32 mm Hg (the pressure difference between 1 and 3 m/sec) to determine dP/dt noninvasively.

The continuous-wave spectral profile can also provide clues as to the nature of obstruction in many disease states. It should be emphasized that the spectral profile provides high temporal resolution for determining the timing of pressure gradients. Thus, the contour of the spectral profile provides clues as to whether an obstruction is fixed or develops over time, in which case the peak gradient will occur late rather than early.[34] The latter is classic for dynamic obstruction in hypertrophic cardiomyopathy. Close examination of a regurgitant profile can also reveal evidence that atrial pressure has acutely elevated toward the end of ejection when velocities taper off rapidly in the latter half of systole.

Much attention has been paid to mitral valve inflow patterns as they relate to diastolic function of the left ventricle.[35] [36] [37] [37A] This assessment must be done in patients who are in sinus rhythm, during which there are discrete E and A wave velocities of the mitral valve inflow. In normal individuals, early velocities exceed later velocities and the E to A ratio is typically greater than 1.2. With impaired relaxation of the left ventricle this ratio declines and the rate of decay of the E wave velocity likewise decreases. Figure 7-34 schematizes several mitral valve Doppler inflow patterns. There are a number of other influences on the E to A ratio, including age and heart rate. With a pathological increase in left ventricular stiffness accompanied by excess volume, there is an augmentation of the normal E to A ratio. This increased E to A ratio is classic for a restrictive cardiomyopathy and constrictive pericarditis but is also typically seen in patients with end-stage heart disease of virtually any type who have markedly elevated diastolic pressures. It is imperative to incorporate the anatomical and other Doppler information into an assessment of mitral valve inflow patterns in an effort to provide clinically relevant information. Evaluation of mitral valve closure patterns with M-mode echocardiography can provide additional information on intracardiac hemodynamics.[38]

Doppler can be used to evaluate the inflow patterns of the hepatic and pulmonary veins as well.[39] [40] Both hepatic and pulmonary vein inflow are biphasic with predominant flow in ventricular systole (see Fig. 7-27) . Examination of the flow patterns can provide valuable clues in a variety of disease states, including mitral regurgitation, restrictive and constrictive processes, and other diseases that elevate left ventricular diastolic pressure.

Figure 7-34 Schematic depiction of mitral valve and pulmonary vein inflow patterns. *A,* A normal mitral valve inflow pattern with both early (E) and atrial contraction related (A) flow velocities. Note that the E velocity exceeds the A velocity in the normal situation. The isovolumetric relaxation time (IVRT) is as noted. The deceleration time (DT) is defined as the milliseconds from peak E-wave velocity to zero velocity. *B,* The same, normal mitral valve inflow pattern on which normal pulmonary vein flow velocities have been superimposed. Note that systolic pulmonary vein flow (PVs) exceeds the velocity of diastolic pulmonary vein flow (PVd) and that there is a normal amount of retrograde pulmonary vein flow (PVa) related to atrial contraction. *C,* The mitral valve inflow and pulmonary vein flow pattern in a noncompliant stiff ventricle with poor relaxation. There is a characteristic decrease in the E to A ratio of the mitral valve inflow pattern associated with a decrease in the diastolic component of pulmonary vein flow. *D,* The example of "restrictive physiology" with decreased left ventricular compliance and high left atrial pressures. Note the exaggerated E to A ratio and the short deceleration time of mitral valve E-wave flow. The diastolic component of pulmonary vein flow is accentuated and the systolic component decreased, and the pulmonary vein retrograde flow during atrial contraction is also accentuated. *E,* The situation of "pseudo-normalization" in which the mitral valve inflow pattern falls between that seen in *C* and *D* and thus mimics the normal mitral valve inflow seen in *A.* Pulmonary vein flow, however, remains abnormal, with a relative predominance of diastolic pulmonary vein flow compared with the systolic flow. There is also accentuation of pulmonary vein retrograde flow during atrial systole.

SPECIFIC IMAGING FORMATS AND TECHNIQUES

TRANSESOPHAGEAL ECHOCARDIOGRAPHY.

For this technique the ultrasound transducer has been miniaturized and mounted on the tip of a flexible gastroscope-like instrument. The mechanics of the instrument allow both flexion and lateral motion of the tip to optimize views. Early TEE probes provided only a single plane of interrogation, with subsequent probes providing two perpendicularly oriented planes that could be viewed in alternate fashion. Modern TEE probes contain an array of ultrasound crystals at the tip of the probe that allow rotation of the ultrasound scanning plane through 360 degrees.

There are specific indications and contraindications to TEE as well as well-recognized inherent risks. TEE is indicated in patients in whom TTE is either unlikely to provide diagnostic information or has been nondiagnostic. Specific examples in which TEE is of proven incremental yield include detection of aortic dissection, evaluation of the mechanism of mitral regurgitation, and evaluation of patients for source of cardiac emboli. TEE is relatively contraindicated in individuals with significant esophageal pathology.

TEE is typically performed under intravenous conscious sedation after local anesthesia of the oropharynx. The exact choice of intravenous agents is institutionally dependent but frequently consists of a combination of narcotics and a benzodiazepine agent. Complications associated with TEE include those associated with the agents used for conscious sedation as well as complications related to the mechanical aspects of probe insertion. The latter can involve trauma to any aspect of the teeth, gums, oropharynx, or esophagus. Esophageal complications are most likely to arise in individuals with preexisting esophageal disorders; and trauma to the oropharynx, teeth, and gums is more likely in patients who are uncooperative.

There are a family of fairly standardized views that are obtained during the TEE examination.[41] Most echocardiographers begin by examining the heart from behind the left atrium because this view provides a fairly rapid means for

Figure 7-39 Routine gray scale and color B-mode scans demonstrating the enhanced visual sensitivity for faint signals. The upper panels are two views of a left atrial appendage recorded in a patient with atrial fibrillation; the left panel is recorded in routine gray scale. There are very vague ;qosmokelike;qc echoes swirling within the body of the left atrial appendage consistent with stagnant blood. The right-hand panel was recorded in the same patient at the same gain and dynamic range settings but using color encoded imaging. Note the greater ease with which the low intensity echoes are visually depicted. The two bottom panels represent spectral Doppler of aortic insufficiency recorded in gray scale *(bottom left)* and in B-color *(bottom right),* again demonstrating the greater ease of visual detection with the color encoded signal.

orienting the operator. Figures 7-35 and 7-36 outline views in the horizontal and longitudinal planes that correspond to 0- and 90-degree scanning planes using a multidirectional rotating transducer. Figures 7-37 and 7-38 are transesophageal echocardiograms recorded from several of the transducer positions schematized in Figures 7-35 and 7-36 .

COLOR B-MODE SCANNING.

In an effort to enhance visual detection of anatomical boundaries and spectral Doppler signals, the fundamental gray scale image can be colorized.[42] This has shown promise for detection and tracking of endocardial boundaries and for visualization of faint spectral Doppler signals (Fig. 7-39).

HARMONIC IMAGING.

A recent adaptation of cardiac ultrasonography relies on the generation of harmonic frequencies during transmission of the ultrasound beam.[43] [44] [45] [45A] [45B] Traditionally, transducers have had narrow bandwidth ultrasound elements that transmit and receive at narrowly defined frequencies. Modern transducers have a wide bandwidth that allows transmission and receipt of ultrasound over a broad range of frequencies. The traditional view of harmonics is that an object once insonated with ultrasound may resonate and hence reflect back ultrasound not only at the fundamental, transmitted frequency but also at harmonics of that frequency. In the traditional view of harmonics an object can be imaged at 2 MHz but reflect ultrasound back at 2 MHz and at 4- and 8-MHz harmonics. Recently, it has been recognized that the transmission of ultrasound through tissue actually creates harmonic frequencies during propagation. Because the transmitted frequency is not a narrow discrete frequency but rather a broad range of frequencies, the full range of reflected frequencies and the resultant harmonics are likewise substantially broader than originally conceived. This is the premise for what has been termed *tissue harmonic imaging.* Harmonic frequencies increase in strength with depth of penetration but represent

Figure 7-35 Schematic demonstrating the transesophageal echocardiographic images that can be obtained in a horizontal plane. Figures 2A and 2B are obtained from the transgastric location, 3A and 3B from the midesophageal position, and 1A and 1B from the upper esophageal position. (Images can be displayed with the apex of the sector either up [A figures] or the apex down [B figures].) Echocardiographic images corresponding to figures 1A, 2A, and 3A are presented in Figure 7-37 . RPA = right pulmonary artery; SVC = superior vena cava; LPA = left pulmonary artery; IVC = inferior vena cava; S = stomach; FO = fossa ovalis; other abbreviations are as per previous figures. *(From Feigenbaum H: Echocardiography. 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

Figure 7-36 Transesophageal echocardiographic views obtained in the longitudinal transducer position. The A series of figures are recorded with the apex down and the B series with the apex up. 3A and 3B are recorded in the gastric position, 2A and 2B from the midesophagus, and 1A and 1B from the upper esophagus. LUPV = left upper pulmonary vein; LAA = left atrial appendage; other abbreviations are as per previous figures. *(From Feigenbaum H: Echocardiography, 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

only a small portion of the total reflected ultrasound energy. The advantage of the reflected harmonic frequencies is that they are free of near-field reverberation and shadowing effect. This results in an increased signal-to-noise ratio of the harmonic signal (Fig. 7-40) . This type of imaging shows tremendous promise for improved visualization of the myocardium but at the cost of a minor reduction in resolution. Additionally, tissue signature is brighter than usual and there is loss of detail for evaluation of fine valvular structures.

COLOR M-MODE.

Color M-mode echocardiography combines routine M-mode scanning with superimposed color Doppler information. As with M-mode echocardiography, the *x* axis represents time and the *y* axis represents distance from the transducer. The M-mode component is identical to that previously discussed for routine M-mode echocardiography. Along the single line of interrogation, Doppler information is then color encoded and superimposed on the M-mode display (Fig. 7-41). This technique provides high temporal resolution for timing cardiac events and can have particular value in determining the timing of a regurgitant valvular lesion and in determining the rate of inflow into the left ventricle.[45C] [45D] It is limited in that it provides information regarding velocity of flow in only one dimension.

CONTRAST ECHOCARDIOGRAPHY.

Ultrasound reflects off all structures but increasingly off structures with different acoustic properties.[46] Thus, a tissue fluid interface is a more potent reflector of ultrasound than the interior of a solid structure. An even more potent reflector of ultrasound is a gas/fluid interface, such as can be created by microcavitations or bubbles. Contrast echocardiography is a complex field currently in evolution. The simplest contrast agent is agitated saline, created by forcefully injecting saline mixed with a small quantity of air between two syringes. This creates a solution of microbubbles that are 30 to 200 mum in diameter. The resultant microbubbles are intrinsically unstable and subject to coalescence, and their effect is relatively transient. Their large size precludes passage through the pulmonary bed. Agitated saline contrast is the standard technique for detection of intracardiac shunts.[47] Because

Figure 7-41 Color M-mode echocardiography. With this methodology color flow imaging is superimposed on an M-mode echocardiogram. This provides excellent temporal resolution for timing intracardiac events. The left panel was recorded in a normal, disease-free individual from the apex of the left ventricle. Notice that both early and late (E and A) mitral inflow can be detected. The systolic interval (white arrowheads) is devoid of flow. The right panel was recorded in a patient with mitral valve prolapse and late systolic mitral regurgitation. Note the prominent early flow velocity through the mitral valve and a late systolic regurgitant flow (white arrowheads).

saline microbubbles are too large to pass through the pulmonary capillary bed,[48] their appearance in the left side of the heart is indirect evidence of a pathological intracardiac shunt.[49]

Attempts at creating a more stable population of microbubbles have been undertaken for a number of years and have included stabilizing agitated saline with indocyanine green dye and creation of manufactured microbubbles. The available manufactured microbubbles have been based on albumin[50] or other protein spheres, and more recently the air has been substituted with a perfluorocarbon.[51] [52] Perfluorocarbon agents have low diffusibility and intense echo-reflective properties. These agents provide full and complete opacification of the left ventricular cavity after intravenous injection (Fig. 7-42) .[45A] [45B] [51] [52] [53] [53A] These agents can also be used to enhance spectral Doppler signals of both right- and left-sided valves.[54] [55] A role in detection of left ventricular and atrial appendage thrombus has recently been suggested.[55A] [55B] They have also shown tremendous promise for evaluation of myocardial perfusion. Myocardial perfusion echocardiography should be considered a developmental tool of immense promise rather than a routine clinical tool at this time.

Specialized imaging techniques are necessary to optimize contrast detection. Compared with fundamental imaging, harmonic imaging is substantially more sensitive for detection of contrast medium in the ventricular cavity and myocardium. It has recently been recognized that contrast microbubbles are destroyed by interaction with the ultrasound beam, especially at high-energy levels.[56] Intermittently triggering the imaging beam avoids this destruction and results in more effective detection of ultrasound contrast.[57] [58] Use of a low mechanical index also results in less bubble destruction.

THREE-DIMENSIONAL ECHOCARDIOGRAPHY.

There are two basic approaches to three-dimensional echocardiography. The first is to compile a series of sequential two-dimensional scans using either an external frame of reference or internal transducer locator to then create a three-dimensional matrix of the cardiac image.[59] [60] [61] This can then be surface rendered to create an actual three-dimensional image of the cardiac structures (Fig. 7-43) , or the three-dimensional data set can be "resliced" to provide a secondary two-dimensional image along any imaging plane. The second approach to three-dimensional imaging has

Figure 7-37 Transesophageal echocardiograms recorded in a horizontal plane. The upper and lower panels were recorded in a true 0-degree plane at a high level behind the left atrium and at a midesophageal level, respectively. In the left atrial view a typical four-chamber view of the heart is obtained in which all four cardiac chambers as well as the mitral and tricuspid valves are clearly visualized. The lower panel was recorded at 0 degrees with the probe inserted deeper in the esophagus. A typical short-axis view of the left ventricle is obtained in which a circular left ventricle and crescent-shaped right ventricle are seen. This view is analogous to a parasternal short-axis view; however, the orientation is inverted such that the inferior wall is at the top of the image and the anterior wall at the bottom. The bottom panel was recorded at 35 degrees and with pull back of the transducer slightly from the position needed for the upper panel. This provides a short-axis view at the base

of the heart at which the circular aorta with an open aortic valve is clearly visualized.

been real-time three-dimensional imaging in which a transducer creates an actual three-dimensional volume of interrogation.[62] [63] [64] This three-dimensional data set can then be rendered into a three-dimensional image, or secondarily two-dimensional imaging planes can be derived. Three-dimensional imaging has advantages with respect to quantitative precision in unusually shaped ventricles and in accurate anatomical description of complex anatomy such as complex congenital heart disease.[60] [61] [65] [65A] It is still limited by relatively low frame rates and/or the time required for processing the three-dimensional image.

INTRAVASCULAR ULTRASONOGRAPHY.

Intracardiac ultrasonography is a discipline largely employed by the invasive

Figure 7-38 Transesophageal echocardiographic images recorded in view orthogonal to the horizontal images seen in Figure 7-37 . The top panel is recorded at the same level in the esophagus as the top panel in Figure 7-37 at a 95-degree angle. In this view the left atrium and left ventricle as well as left atrial appendage (LAA) are clearly visualized. Distinct scallops of the closed mitral valve are also well seen. The middle panel is likewise recorded at the same level in the esophagus with rotation of the probe clockwise. In this view the left atrium and right atrium as well as inferior vena cava (IVC) and superior vena cava (SVC) are clearly visualized. The bottom panel was recorded at 135 degrees. This view provides excellent visualization of the left ventricular outflow tract and proximal aorta.

Figure 7-40 Parasternal long-axis view recorded in both fundamental *(top)* and second harmonic imaging *(bottom).* The orientation of this image is identical to that in Figure 7-3 . Note the marked increase in echogenicity of the septum and posterior wall, as well as increased echo density of the aortic and mitral valves. In this example, tissue harmonic imaging has provided an obvious distinction between the blood pool and myocardium, compared with fundamental imaging. Abbreviations are as per previous figures.

cardiologist in the catheterization laboratory. This ultrasound technique relies on ultraminiaturization of ultrasound transducers that are then incorporated into the tip of intracardiac catheters. The catheters can be as small as 5 French for intracoronary work or as large as 10 or 12 French, which can be used inside cardiac chambers.[66] [67] Typically, either a phased array of crystals is placed circumferentially around the catheter tip or a single crystal, often reflected by a mirror, is mechanically rotated at the tip of a catheter. In either instance, high frequencies of 10 to 40 MHz are used. The smaller catheters can be placed, through a guiding catheter, into epicardial coronary arteries. They provide a high-resolution view of intracardiac anatomy (Fig. 7-44) and have provided previously unavailable visualization of morphology within the coronary artery and characterization of the intracoronary tissue.[68] [69] [70] Calcification and atherosclerosis can be identified and the eccentric or concentric nature of plaque likewise determined. Intracoronary ultrasonography has been instrumental in determining the success of interventions such as stent deployment in coronary artery disease.[71] [71A] [71B] Figure 7-45 (Figure Not Available) depicts intracoronary ultrasound studies demonstrating increasing degrees of severity of atherosclerosis. A closely related technology is the use of miniaturized Doppler wires for monitoring intracoronary flow velocity.[72] [73] Intravascular ultrasonography has also been used in the evaluation of patients with known or suspected aortic dissection, in which case it provides a high-resolution intraluminal view of dissection pathology and yields incremental information with respect to the origin of branch vessels. It has been instrumental in refining the techniques of emergent fenestration in stenting for acute type III dissections.

TISSUE CHARACTERIZATION.

Tissue characterization refers to the detailed evaluation of the entire reflected ultrasound signal in an effort to extract information regarding actual tissue character. Typically, this has relied on evaluation of data in the radiofrequency signal component before processing into a diagnostic, visual image. One of the more promising applications has been in evaluating the cyclic variation in returning ultrasound signal intensity (cyclic variation in backscatter) as a marker of myocardial ischemia.[74]

DOPPLER TISSUE INTERROGATION.

With specific alteration in Doppler filters, the myocardium can be targeted for Doppler interrogation. The resulting Doppler signals can be color encoded and incorporated into the two-dimensional image, thus displaying directional information. Additionally, quantitative data regarding velocity of motion in diastole and systole can be extracted.[75] [76] [76A] [76B] [76C]

Advantages and Limitations of Echocardiography

As with any diagnostic technique, echocardiography has distinct advantages and disadvantages. Cardiac ultrasonography itself carries no risk to the patient, operator, bystanders, pregnant women, or fetus. Specialized examinations such as contrast echocardiography, TEE, and stress echocardiography carry the minimal risk associated with the procedural modifications necessary for their undertaking. Modern ultrasound instruments are capable of visualizing all four cardiac chambers, all four cardiac valves, and the great vessels. They provide high-resolution tomographic views in unlimited planes, which facilitates the ability to diagnose virtually all forms of anatomical cardiovascular disease. The addition of Doppler interrogation allows determination of physiological parameters as they relate to blood flow and myocardial velocities.

Echocardiography does have specific limitations. Because ultrasound does not transmit well through calcified structures or bone, an appropriate acoustic window is necessary for optimal visualization. In neonates and infants, ultrasound can pass through noncalcified cartridge and the windows available exceed those in adults. In the adult population a noncalcified window must be obtained that typically is in the intercostal spaces or from the subxiphoid positions. In patients with narrow intercostal spaces, imaging can be problematic. A greater limitation is the degree to which the air-filled structures reflect ultrasound. Intervening lung tissue in patients with obstructive lung disease can result in suboptimal or even inadequate imaging. Another area of concern for echocardiography is its potential for overuse. Because it is low cost and carries no risk, the tendency for its overuse or inappropriate use is substantial.

The American College of Cardiology, American Heart Association, and American Society of Echocardiography have outlined recommendations for appropriate training in echocardiography[77] and likewise recommendations on its appropriate clinical use.[78]

Figure 7-42 Demonstration of left ventricular contrast medium enhancement after intravenous injection of a perfluorocarbon-based agent. The panels on the left are recorded before administration of contrast agent, and those on the right after opacification of the left ventricular cavity. Note the enhanced ability to identify the left ventricular cavity and distinguish it from the endocardial border after opacification.

ACQUIRED VALVULAR HEART DISEASE (see Chap. 46)

Mitral Valve Disease

Virtually all types of mitral valve disease can be characterized anatomically using echocardiography. Doppler techniques provide accurate physiological information that complements the anatomical assessment. Figure 7-46 outlines the motion pattern of the normal mitral valve and the valve in multiple disease states, each of which are discussed.

Mitral Stenosis

Mitral stenosis was the first valvular lesion to be comprehensively evaluated with echocardiography. Two-dimensional echocardiography and Doppler ultrasonography remain the mainstay of diagnosis and characterization of this lesion. In the vast majority of adult patients, mitral stenosis is the result of rheumatic heart disease, with rarer cases of congenital mitral stenosis being encountered in adult patients. Rarely, heavy calcification of the mitral annulus results in functional restriction of the left

ventricular inflow and can result in a left atrial to left ventricular gradient mimicking valvular mitral stenosis.

Figure 7-43 Surface-rendered three-dimensional echocardiogram showing a normal aortic valve. The panel on the left shows the valve in the open position, and a roughly triangular orifice is seen. The image has been captured at mid opening. At the right the valve is seen in the closed position and the right, left, and noncoronary cusps are clearly visualized.

Figure 7-44 Intracardiac ultrasound image recorded from within the cavity of the right atrium. Note the fairly thick tissue at the primum and more superior aspect of the atrial septum and the very thin valve of the foramen ovale.

The hallmark of mitral stenosis on two-dimensional echocardiography is thickening and restriction of motion of both mitral valve leaflets, with the predominant pathological process being at the tips of the leaflets and proximal chordae (Fig. 7-47) . In more advanced cases, the body of the leaflet itself may become involved; and in even more advanced cases substantial calcification occurs within the leaflet itself and on the subvalvular apparatus, including the chordae and papillary muscle tips (Fig. 7-48) . The earliest effect of rheumatic disease on the mitral valve is the result of inflammation and thickening of leaflet tips that restricts the motion of the tips while allowing free motion of the body of the leaflets. This results in a characteristic "doming" diastolic motion of the mitral valve. The motion

Figure 7-45 (Figure Not Available) Intracoronary ultrasonic images demonstrating the different severity of coronary atherosclerosis. *A,* Small rim of thickened endothelium (arrow). *B,* Larger amount of eccentric endothelial thickening (arrows). *C,* Massive atherosclerotic plaque that is wider (arrows) than the residual lumen. *D,* Calcification in the plaque (CA) produces shadowing (S). *(From Feigenbaum H: Echocardiography. 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

Figure 7-46 Schematic outlining both normal and abnormal mitral valve closure patterns. See text for details.

Figure 7-47 Parasternal long-axis view of a patient with mitral stenosis and a pliable noncalcified mitral valve leaflet. Note the "doming" motion of the mitral valve leaflets (arrowheads). Valves with these morphologic features are excellent candidates for percutaneous balloon valvotomy.

of the anterior leaflet has also been described as a "hockey stick" configuration. Restriction of the tips effectively results in a funnel-like mitral valve apparatus with the restrictive orifice being at the tips of the leaflets. This appearance is easily recognized from TTE in both the parasternal long-axis and apical four-chamber views. With careful attention to detail, the actual restrictive orifice of the mitral valve can be visualized and planimetered from a parasternal short-axis view (Fig. 7-49) . This planimetered area correlates well with the area determined in the catheterization laboratory. M-mode echocardiography was the initial diagnostic tool for evaluation of mitral stenosis. By using this technique, the thickened leaflets could be identified as well as the restricted motion. The restricted motion pattern resulted in a flattening of the E-F slope of the mitral valve (Fig. 7-50) . The E-F slope can be quantified and tracked as a measure of stenosis severity but provides no truly quantitative value by today's standards.

ASSESSMENT OF SEVERITY.

In addition to determining the anatomical extent and severity of the stenotic lesion, assessment of physiological significance is made using Doppler echocardiography.[79] [79A] Color flow imaging is instrumental in determining the degree of concurrent mitral regurgitation. Both continuous-wave and pulsed Doppler echocardiography can be obtained at rest and with exercise and provide accurate quantification of the transvalvular gradient (Fig. 7-51) . [80] Determination of the transvalvular gradient should be performed in patients both at rest and with modest degrees of exercise. A population of symptomatic patients exists who have relatively unimpressive gradients at rest that increase dramatically with mild exercise.

A second Doppler method for determining the severity of mitral stenosis involves calculating the pressure half time ($P_{½}$ t), which is the time in milliseconds required for the peak pressure gradient to decline to one half of its original value. The pressure half time can be related to an anatomical valve area by the formula: mitral valve area =P ½ t ÷ 220 milliseconds. This relationship is probably valid only for isolated mitral stenosis and is not accurate for quantitation of the mitral valve orifice if concurrent mitral regurgitation[81] or significant aortic insufficiency is present.[82] The relationship also has diminished accuracy in instances in which left ventricular diastolic compliance is markedly abnormal, such as in patients with severe hypertension or aortic stenosis[83] and immediately after mitral balloon valvotomy.[84]

Other more detailed methods for determining the mitral valve area involve determination of quantitative mitral valve flow. This can be performed using the continuity equation in a manner analogous to that for aortic stenosis.[85] Either flow and dimensions at the level of the mitral valve annulus or forward going flow in the left ventricular outflow tract can be used in this equation. Obviously this approach has limitations in patients with concurrent regurgitation or multivalve disease.

Figure 7-48 Parasternal long-axis view in diastole *(top)* and systole *(bottom)* in a patient with rheumatic heart disease and mitral stenosis. In the top panel note the diffuse thickening of the mitral valve. The reduced orifice can be seen in this end-diastolic frame (arrow). The bottom panel was recorded in systole and provides a view of the chordal apparatus, which can be seen to be diffusely thickened and fibrotic. Valves with this appearance are less ideal candidates for percutaneous intervention than the valve presented in Figure 7-47 .

Figure 7-49 Parasternal short-axis view at the level of the mitral valve orifice recorded in a patient with mitral stenosis. The frame was recorded in end diastole, and the actual orifice of the stenotic mitral valve can be visualized and in this instance has been planimetered. The measured mitral valve area is approximately 1.1 cm^2 .

In addition to determining the presence and severity of mitral stenosis, it is important to evaluate the heart for secondary effects. Secondary effects of mitral stenosis include left atrial dilation with subsequent stasis and thrombus formation and secondary pulmonary hypertension. Evaluation of the left atrium for blood stasis and thrombus requires TEE (Fig. 7-52) . The aortic, tricuspid, and pulmonic valves can likewise be directly interrogated for evidence of rheumatic involvement. The most common significant sequelae of mitral stenosis is development of secondary pulmonary hypertension with subsequent right-sided heart dysfunction and tricuspid regurgitation. As with other diseases in which the right side of the heart is evaluated, the tricuspid regurgitation jet can be interrogated for determination of right ventricular systolic and, presumably, pulmonary artery systolic pressures.

It is important to fully evaluate the anatomical features of mitral stenosis in patients in whom a mitral balloon valvotomy is contemplated. Four features of mitral valve anatomy have been identified that correlate with success of this procedure. These include valve pliability, thickening, calcification, and subvalvular involvement. Each of these can be quantified on a score of 0 to 4 and a total score tabulated. Scores above 14 represent valves unlikely to be successfully treated with a percutaneous approach.[86] [87] There is a disproportionate impact of calcification and subvalvular involvement on the likelihood of successful valvotomy.

Mitral Regurgitation

Two-dimensional echocardiography and Doppler techniques can be used to detect the presence of mitral regurgitation, to determine its severity, and also to determine the etiology of regurgitation and look for secondary effects. Mitral

Figure 7-50 M-mode echocardiogram recorded in a patient with typical mitral stenosis. Compare this mitral valve opening pattern to the mitral valve motion in Figure 7-1 . With mitral stenosis there is thickening at the leaflets and flattening of the E-F slope.

Figure 7-51 Transmitral Doppler recordings obtained in a patient with mitral stenosis at rest *(top)* and with exercise *(bottom).* Heart rate has increased from 85 to 110 beats/min, resulting in an increase in the mean pressure gradient from 6.3 to 13.6 mm Hg. Abbreviations are as per previous figures.

Figure 7-52 Transesophageal echocardiogram recorded in a patient with severe mitral stenosis. Note the marked thickening of the mitral valve (arrows), including involvement of the chordal apparatus. The left ventricle and right ventricle are small, and the left atrium is massively dilated. Note the homogeneous echoes filling the right and left atria. In real-time scanning these are appreciated as a swirling, "smokelike" echo signal consistent with stagnant blood. Abbreviations are as per previous figures.

regurgitation can be due to a wide variety of cardiac conditions, some of which are presented in schematic form in Figure 7-46 . Typically, mitral regurgitation will first be documented using Doppler color flow imaging. In the presence of significant mitral regurgitation, volume overload of left ventricle and left atrium occurs, resulting in chamber dilation, the degree of which is dependent on both the severity and duration of mitral regurgitation.[88] The etiology of mitral regurgitation is determined by assessing the anatomy of the left ventricle and the mitral valve apparatus. Many forms of mitral regurgitation are due to intrinsic disease of the mitral valve, examples of which would be mitral regurgitation concurrent with mitral stenosis, myxomatous degeneration with mitral valve prolapse, chordal rupture, endocarditis, and infarct-related papillary muscle rupture. Functional forms of mitral regurgitation also occur in which the mitral valve may be anatomically normal but fails to coapt because of dilation of the left ventricle.[88] This can occur due to either cardiomyopathy or coronary artery disease. In the vast majority of instances the anatomical and functional abnormality responsible for mitral regurgitation can be documented with TTE. On occasion, TEE is necessary to refine the anatomical assessment and may be particularly helpful in identifying rupture of a papillary muscle head and flail leaflets and in detecting smaller vegetations or perforations.[89] [90]

ASSESSMENT OF SEVERITY.

Doppler color flow imaging is used to determine the severity of mitral regurgitation. The severity of mitral regurgitation is directly proportional to the size of the regurgitant jet within the left atrium.[91] [92] [93] Multiple studies have confirmed the relationship between the size of the regurgitant jet and the severity of regurgitation determined with angiography or other techniques. Typically, the size of the jet is indexed to the size of the left atrium. Figure 7-53 demonstrates examples of mitral regurgitation. Jets that are peripheral or impinging on a wall, rather than central, cause predictable problems with assessment of severity.[94] [95] Owing to the Coanda effect, a regurgitant jet impinging on a wall results in a smaller color flow area than an equivalent central regurgitant volume. The underlying

Figure 7-53 Four panels depicting varying degrees of mitral regurgitation; the two top panels are apical four-chamber transthoracic views showing, on the left, mild mitral regurgitation and, on the right, moderate to severe mitral regurgitation. On the left note the relatively narrow jet directed from the tips of the mitral valve toward the posterior left atrial wall. On the right note the larger jet, filling approximately 40 percent of the left atrial cavity. The two bottom panels are transesophageal echocardiograms. On the left note the mitral regurgitation occurring in two discrete jets and, on the right, the highly eccentric jet, which courses along the extreme lateral wall of the left atrium. Abbreviations are as per previous figures.

mechanism of this phenomenon is that a regurgitant volume "recruits" the adjacent blood flow into motion. As color Doppler flow detects cells in motion, irrespective of their origin, the visualized regurgitant jet is the sum of the regurgitant volume and the recruited blood cells. A centrally located jet recruits in all of its dimensions, whereas a jet adjacent to a wall recruits only on the free surface, hence being relatively smaller than an equal volume of central regurgitation. A jet impinging on a wall underestimates the regurgitant volume by approximately 40 percent. In cases of moderate and severe mitral regurgitation, flow in the pulmonary veins may reverse direction in systole.[96] A variation on this finding is attenuation of normal forward flow in the pulmonary vein during ventricular systole. More recently, three-dimensional reconstruction of mitral regurgitation jets has been shown to be feasible.[97] [98] The incremental value of this method has not yet been shown.

Several characteristics of a regurgitant jet can give clues as to the etiology. In the presence of chamber dilation due to cardiomyopathy, leaflet coaptation is abnormal and the leaflets are convex into the left ventricular cavity rather than concave (Fig. 7-54). In extreme examples of this phenomenon the actual regurgitant orifice, owing to failure of coaptation, can be directly visualized. These jets are typically central in location. By using either color Doppler M-mode or careful interrogation of the spectral display, the timing of the mitral regurgitation jet can also be determined. Lesions such as mitral prolapse may result in regurgitation confined to mid and late systole.

Anatomical disruption of any portion of the mitral valve will result in regurgitation. This can range from a few ruptured chordae with isolated prolapse of a single scallop to disruption of entire papillary muscle head with flail of an entire leaflet. TEE is often incrementally helpful in determining the precise degree of anatomical disruption of the valve (Fig. 7-55) . Irrespective of the etiology of a flail leaflet the resultant jet is often highly eccentric and its flow is directed opposite of the leaflet bearing the pathology; that is, a flail posterior mitral valve leaflet results in an anteriorly directed jet. An eccentric jet should lead to a higher index of suspicion of a flail leaflet. Three-dimensional echocardiography has shown promise for detailed assessment of mitral valve pathology in mitral regurgitation (Fig. 7-56) .

Quantitation of mitral regurgitation is heavily dependent on the color Doppler flow area. Other techniques for quantifying mitral regurgitation rely on determining the width of the jet at its origin and on evaluation of the proximal isovelocity area. In general terms, for any given Nyquist limit, the larger the size of proximal isovelocity surface area the greater the degree of regurgitation.[99] Calculation of flow volume from proximal isovelocity surface area has already been discussed and can be applied to determine regurgitant volume.

Mitral Valve Prolapse

The detection and characterization of mitral valve prolapse remains a common use of echocardiography. Early studies suggested a prevalence of prolapse of up to 21 percent in otherwise healthy young females. It should be emphasized

Figure 7-54 Apical four-chamber view in a patient with a dilated cardiomyopathy and severe mitral regurgitation due to a dilated annulus and abnormal mitral valve coaptation. The solid horizontal white line represents the plane of the mitral annulus. Note that the mitral valve closes well within the cavity of the left ventricle. The actual origin of the mitral regurgitation jet can be seen as it accelerates toward the regurgitant orifice (arrow) and is likewise displaced into the cavity of the left ventricle.

Figure 7-55 Transesophageal echocardiogram recorded in a patient with a flail posterior mitral valve leaflet. The echocardiogram is recorded in a longitudinal view in which the left atrium, left ventricle, and pulmonary artery are visualized. Because flail leaflets occur in atypical locations, it is often necessary to scan in unusual planes to identify the leaflet. In this projection a substantial portion of the posterior leaflet (arrow) can be seen to protrude into the left atrium, with the tip of the leaflet no longer attached to the chordal apparatus.

that many individuals identified as having mitral prolapse in these earlier studies are recognized today to simply have normal bowing of the mitral valve. The normal mitral valve closure pattern is for the tips of the leaflets to point toward the left ventricular apex and for there to be gentle bowing of the leaflet with a concavity toward the apex of the left ventricle. Based largely on these dimensional reconstruction techniques, the mitral valve annulus is known not to be a planar structure but rather to have complex three-dimensional geometry.[100] Depending on the tomographic plane of interrogation, a portion of one or both leaflets may bow behind the imaginary annular line. In the presence of otherwise anatomically normal thin leaflets, this represents a variation of normal and does not represent pathological mitral valve prolapse.

The most extreme forms of mitral valve prolapse involve myxomatous degeneration of the valves with visible leaflet thickening (defined as greater than 3 to 5 mm in thickness) and either marked symmetrical bowing of the valve behind the majority of the annular plane or highly asymmetrical buckling of one or both leaflets into the

plane of the left atrium (Figs. 7-57 and 7-58) . This will be associated with variable degrees of mitral regurgitation, which may be either wholly systolic or confined to mid to late systole. Because of the eccentric buckling of the myxomatous valve, the mitral regurgitation jet can be eccentric rather than central. The key aspects to the diagnosis of mitral valve prolapse rely not on the mere detection of a valve that buckles into the plane of the left atrium but on characterization of the valve morphology.[101] [102] As mentioned earlier, normal thin leaflets that bow gently into the left atrial plane probably represent no more than a variation of normal closure patterns. Patients with thickened redundant valves and myxomatous changes of the leaflet have a true form of structural heart disease. It is these individuals who are most at risk for endocarditis, spontaneous rupture of chordae, and progressive mitral regurgitation. It also appears that there is a higher than usual incidence of ventricular arrhythmias and neurological events in this subset of patients.

Aortic Valve Disease

Aortic Stenosis

Evaluation of patients with known or suspected aortic valve disease requires integration of anatomical information from two-dimensional echocardiography and physiological information from Doppler studies. Aortic stenosis is most commonly due to one of three pathological processes. These include a bicuspid aortic valve, rheumatic heart disease, and degenerative aortic stenosis. On rare occasions, aortic stenosis can be the result of endocarditis or radiation heart

Figure 7-56 Three-dimensional echocardiogram recorded in a patient with a partial flail mitral anterior leaflet. For both panels the orientation is a view of the mitral valve from within the left atrium. The left panel was recorded in diastole, and the unrestricted orifice can be seen. The right panel was recorded in mid systole. Note the two scallops of the anterior leaflet that protrude into the left atrium (arrows).

Figure 7-57 Parasternal long-axis view in diastole *(top)* and systole *(bottom)* in a patient with mitral valve prolapse and myxomatous changes. In the upper panel note the open mitral valve and the diffuse thickening of the posterior mitral valve leaflet (arrow). The lower panel was recorded in systole. Note that both leaflets prolapse behind the plane of the mitral valve annulus. The prolapse of the posterior leaflet is somewhat more prominent (arrow).

disease. Bicuspid aortic valve typically presents as a hemodynamically significant lesion in the fourth or fifth decade of life and calcific degenerative aortic stenosis in the seventh decade and beyond. Rheumatic aortic valve disease

Figure 7-58 M-mode echocardiogram of the mitral valve recorded in the same patient noted in Figure 7-55 . Note that the posterior leaflet is diffusely thickened and in systole prolapses posteriorly from the normal closure line (arrow).

will virtually always be seen in patients who have concurrent rheumatic mitral valve disease.

The bicuspid aortic valve is the single most common congenital cardiac defect and occurs in approximately 2 percent of the population. There is a broad range of anatomical and physiological abnormalities associated with this condition. The bicuspid aortic valve is commonly thought of as a two-leaflet valve with roughly equal leaflet proportions. There is a range of abnormality in the "bicuspid valve" that includes nearly unicuspid valves and distribution of leaflet tissue other than 50/50 percent. Bicuspid aortic valves are commonly described as having either an anterior-posterior or a lateral orientation of the leaflets. In reality, virtually any direction of the major coaptation can be seen. TTE is a reliable method for detecting the bicuspid aortic valve. With the use of this technique, the hallmark of the bicuspid valve will be eccentric closure of the leaflets within the aorta. In approximately 80 percent of cases, two rather than three leaflets can be directly visualized (Fig. 7-59) . With closer scrutiny by way of TEE, what at first appears to be a true bicuspid valve often is found to represent a three-leaflet valve with unequal leaflet sizes and fusion of one of the three commissures, resulting in a functional bicuspid valve (Fig. 7-60) . It is important to examine the

Figure 7-59 Transthoracic echocardiogram in a patient with bicuspid aortic valve. In the upper panel, note that the leaflets of the aortic valve do not open all the way to the margins of the aorta but are "tethered" in lumen of the proximal aorta. The two bottom panels are recorded in the short-axis view at the base of the heart. The lower left panel was recorded in diastole and reveals the closed bicuspid valve with a single commissure oriented from 10 o'clock to 4 o'clock (arrows). The lower right panel is recorded in systole, and the oval opening of the bicuspid valve can be appreciated within the circular aorta. Abbreviations are as per previous figures.

Figure 7-60 Transesophageal echocardiogram recorded in a patient with an anatomical three-leaflet valve with a fused commissure resulting in a functional bicuspid aortic valve. In the top panel note the three cusps (N = noncoronary, L = left coronary, R = right coronary). The upper frame was recorded in diastole, and the closure lines would suggest presence of three leaflets. The lower panel is recorded in systole; and instead of opening fully to the margins of the aorta with a circular orifice, the valve opens with an oval, fishmouth-shaped orifice. Note the commissure between the right and left cusps is fused, resulting in a functionally bicuspid valve. Abbreviations are as per previous figures.

opening pattern of the aortic valve to determine that it is functionally bicuspid. There is a strong association between coarctation of the aorta and bicuspid valve. When either of these conditions is clinically suspected, the other should also be evaluated.

Degenerative calcific valves appear as three-leaflet structures with marked thickening of the leaflets. Thickening and calcification may be more prominent at the base of the leaflets than at the tips. There is a broad range of immobility and stenosis, depending on the duration and severity of disease (Fig. 7-61) . Rheumatic aortic stenosis typically results in leaflet thickening along the commissural edges. It will be seen almost exclusively in the presence of rheumatic mitral stenosis.

Once aortic stenosis is anatomically defined, secondary effects can also be evaluated. These include poststenotic dilation of the aorta and left ventricular hypertrophy. Assessment of left ventricular systolic function should also be undertaken.

ASSESSMENT OF SEVERITY.

Doppler echocardiography is essential for assessment of the physiological significance of aortic stenosis (see Figs. 7-24 and 7-61) .[103] [103A] [103B] In clinically significant aortic stenosis the gradient is likely to exceed 50 mm Hg. This corresponds to a Doppler velocity of approximately 3.5 m/sec, which is out of the range for accurate quantitation using pulsed-wave Doppler. For this reason, continuous-wave Doppler is essential for quantitation. From continuous-wave Doppler both instantaneous peak and mean gradients can be determined using the Bernoulli equation. Either online or offline outlining of the spectral display and automatic calculation of these values can be performed. In some instances determination of the gradient at rest and with exercise may be beneficial. The gradients determined from Doppler echocardiography correlate very well with simultaneously determined invasive measurements.[103B] This correlation is maximal during simultaneous measurement and when micromanometer tip catheters are used (Fig. 7-62) . The commonly measured "peak to peak" gradient determined in the catheterization laboratory has no basis in physiological reality and will not correspond to either a peak instantaneous or mean gradient determined by either micromanometer catheters or Doppler interrogation. In most instances, cardiac output and hence stroke volume are augmented in the catheterization laboratory compared with rest. For this reason Doppler-determined

Figure 7-61 Echocardiogram recorded in a patient with severe aortic stenosis. The top panel is a parasternal long-axis view recorded in systole. Left ventricular function is diminished. The aortic valve is markedly thickened and partially calcified. Its motion is markedly reduced and in systole it appears that the valve occludes the orifice (arrow). The lower panel is a continuous-wave Doppler recorded from the apex of the left ventricle along a line aimed through the stenotic aortic valve. Note the aortic stenosis signal below the zero crossing line. The peak velocity is 430 cm/sec, which corresponds to a maximum gradient of 77 mm Hg and a mean gradient of 49.4 mm Hg. Abbreviations are as per previous figures.

Figure 7-62 Graphic comparison of Doppler- and catheterization-determined gradients in patients with aortic stenosis. On the left are simultaneously recorded gradients and on the right are nonsimultaneous gradients. Note the stronger correlation between Doppler and catheterization when gradients are obtained in a simultaneous manner. *(From Currie PJ, Hagler DJ, Seward JB, et al: Instantaneous pressure gradient: A simultaneous Doppler and dual catheter correlative study. J Am Coll Cardiol 7:800-806, 1986.)*

gradients in the echocardiography laboratory may be lower than a catheterization-determined gradient.[103B]

On occasion, the Doppler gradient underestimates the gradient measured. This is common with nonsimultaneous recordings as noted earlier but also occurs when the angle of interrogation (theta) exceeds approximately 20 degrees. Off-angle interrogation is the single most common cause for underestimation of an aortic stenosis gradient. In instances in which there is a serial obstruction consisting of both valvular and subvalvular obstruction, both the V1 and V2 components of the Doppler equation must be incorporated.

The actual valve orifice is usually not visualized to a reliable degree from TTE. TEE can be used to obtain a direct measurement of the aortic valve orifice in many patients with aortic stenosis. In severe aortic stenosis, the orifice may be highly irregular and not all portions of it may lie in the same plane. With scrupulous attention to detail it is possible in many instances to directly planimeter the area (Fig. 7-63) .[104]

An additional method for determining the aortic valve area relies on the continuity equation.[105] [106] Typically, in aortic stenosis the left ventricular outflow tract area can be derived from the annulus diameter, assuming circular geometry. Pulsed Doppler is then used to determine the velocity of flow at that site. The product of the two is volumetric flow in the outflow tract. At the stenotic orifice continuous-wave Doppler is used to determine the average velocity. The algebraic equation can then be solved for the aortic valve area. A modification of this technique uses mitral valve flow instead of left ventricular outflow. Because the velocity of flow increases at the restrictive orifice, several investigators have suggested using the V1/V2 ratio

Figure 7-63 Transesophageal echocardiogram recorded in a patient with severe aortic stenosis. In the left panel note the three aortic valve cusps (N = noncoronary, L = left coronary, R = right coronary). The leaflets are diffusely thickened and have restricted opening motion. The right-hand panel is the same systolic frame in which the stenotic area of the aortic valve has been planimetered. Note that the area of the aortic valve is calculated as 0.67 cm^2 , consistent with severe aortic stenosis.

Figure 7-64 Composite of echocardiograms recorded in patients with aortic regurgitation. The two top panels were recorded in the same patient and show, on the left, an apical long-axis view and, on the right, a parasternal short-axis view. In the apical long-axis view note the fairly extensive confetti-like aortic regurgitation jet arising from the proximal aorta and traversing to the left ventricular apex. Note also that the aortic regurgitation jet velocities merge with the mitral inflow velocities, rendering quantitation problematic. The top right hand panel is recorded in the same patient and shows a central aortic regurgitation jet. The bottom left panel is a transesophageal echocardiogram recorded in a longitudinal view. Note the highly eccentric aortic regurgitation jet that appears to fill the entire width of the left ventricular outflow tract. This apparent filling of the left ventricular outflow tract is due to the posterior to anterior jet direction (white arrow) rather than to a substantial true width of the jet. The lower right panel is a color M-mode echocardiogram recorded in a patient with aortic insufficiency in which the normal systolic flow can be appreciated as well as a continuous diastolic flow in the lumen of the aorta that represents aortic insufficiency. The two downward pointing arrows denote the duration of systole, and the two upward pointing arrows indicate the duration of diastole.

as a marker of significant aortic stenosis.[105] Other methods for determining the severity of aortic stenosis involve calculation of aortic valve resistance [107] and using echo-Doppler data in variations of the Gorlin formula.

From a practical standpoint it is often not necessary to determine an aortic valve area. In a patient with thickened restricted leaflets and a mean gradient exceeding 50 mm Hg, the presence of severe aortic stenosis is clinically assured. Likewise, in patients with normal ventricular function and with low gradients the likelihood of significant aortic stenosis becomes negligible. Patients with reduced left ventricular function, typically with ejection fractions of 25 to 35 percent, and a modest transvalvular gradient of 25 to 30 mm Hg are problematic. This situation may either represent mild aortic valve disease and unrelated left ventricular dysfunction or, conversely, critical aortic stenosis with secondary left ventricular dysfunction. In the latter situation, patients will benefit from aortic valve replacement, whereas for the former medical management is indicated. Dobutamine infusion, while monitoring left ventricular function and transvalvular gradients, can be a useful means for separating these two entities.[108] [109] If left ventricular function augments with a dobutamine infusion and the gradient increases to clinically pertinent levels, the diagnosis is most likely severe aortic stenosis with secondary left ventricular dysfunction, and these patients will benefit from valve replacement. Conversely, if ventricular function improves without a change in the gradient it is less likely that the aortic stenosis is the limiting factor.

Aortic Regurgitation

Detection and quantitation of aortic regurgitation relies predominantly on Doppler techniques.[110] [111] Using color flow imaging the regurgitant jet can be visualized in the left ventricular outflow tract from several different planes (Fig. 7-64). In the majority of instances, there will be an underlying anatomical abnormality of the aortic valve such as endocarditis, disease of the aortic root, rheumatic valve disease, or a bicuspid valve.

Several features of the regurgitant jet have been investigated as markers of the severity of aortic regurgitation. Unlike mitral regurgitation, in which the overall jet size correlates

Figure 7-66 Continuous-wave spectral recordings of patients with mild *(top)* and severe *(bottom)* aortic insufficiency. Note the relatively flat slope pressure decay in the mild instance and a steeper slope of pressure decay, denoting near equalization of aortic and left ventricular diastolic pressures, seen in severe aortic insufficiency.

Figure 7-65 Parasternal long-axis two-dimensional echocardiograms in a patient with minimal *(top)* and moderate *(bottom)* aortic regurgitation. In the top panel note the thin color jet of aortic regurgitation that fills less than 10 percent of the left ventricular outflow tract, compared with the wider aortic insufficiency profile, filling over one third of the left ventricular outflow tract in the lower panel. Abbreviations are as per previous figures.

with regurgitation severity, neither the overall size nor depth of penetration of the aortic regurgitation jet correlate strongly with the severity of aortic regurgitation. This is in large part due to the difficulty in separating the regurgitant flow stream from mitral valve inflow. A greater degree of success has been obtained by measuring either the width or cross-sectional area of the regurgitant jet in the outflow tract and indexing this to the width or cross-sectional area of the outflow tract (Fig. 7-65). These measurements are dependent on imaging the jet in its minor axis, and an eccentric jet, crossing across the outflow tract, will result in a disproportionately sized jet compared with its true dimension. TEE often provides more accurate visualization of the true direction and size of the regurgitant jet.

By using continuous-wave Doppler from the apex one can record the actual flow velocity profile of the regurgitant jet (Fig. 7-66) . The velocity of the regurgitant jet is directly related to pressure gradient between the aorta and left ventricle.[112] If this gradient remains high throughout diastole, the slope of velocity and pressure decay is relatively flat. This implies a relatively mild degree of aortic regurgitation in which there has been little equilibration of aortic and left ventricular diastolic pressures.

Conversely, with severe aortic regurgitation there is a greater degree of equilibration of left ventricular and aortic diastolic pressures and the terminal aortic regurgitation velocities are relatively low, resulting in a fairly steep slope of velocity decay over the diastolic pressure curve. The pressure half time of the regurgitant jet, defined as the time in milliseconds required for the initial transvalvular diastolic gradient to decline to one half of its peak value, can be calculated and is inversely related to the severity of aortic regurgitation. A pressure half time less than 400 milliseconds correlates with severe aortic regurgitation. In high-quality studies the continuity equation can be used to calculate the aortic regurgitant volume.[113] Quantitation of aortic regurgitation has also been performed using the proximal isovelocity surface area method.[114]

There are several secondary Doppler and anatomical features that should also be noted in aortic regurgitation. The proximal aorta often has progressive dilation with long-standing aortic regurgitation.[115] Left ventricular dilation is a natural consequence of long-standing hemodynamically significant aortic regurgitation.[116] [117] Left ventricular size can be normal in the acute phase. With moderate and severe aortic regurgitation, diastolic flow reversal in the descending thoracic aorta can frequently be detected from the suprasternal notch. Two-dimensional echocardiography often reveals an indentation of the anterior mitral valve leaflet during diastole. This is due to the impinging regurgitant jet that distorts the symmetrical opening pattern of the mitral leaflet. This is typically seen only in cases of moderate and severe aortic insufficiency. With M-mode echocardiography fine high-velocity flutter of the anterior mitral leaflet and occasionally the septum can be appreciated (Fig. 7-67) .

TIMING OF SURGERY.

Echocardiography plays a significant role in the timing of surgery for aortic regurgitation.[116] [117] This decision is based largely on left ventricular size and performance rather than on the Doppler assessment of severity. Traditional echocardiographic findings that represent indications for surgery have included dilation of the left ventricle beyond 70 mm in diastole or beyond 55 mm in systole with a fractional shortening less than 25 percent. Additionally, progressive dilation of the left ventricle of 1.0 cm or more over a 12-month duration typically represents an indication for valve replacement.

Figure 7-67 M-mode echocardiogram recorded in a patient with aortic insufficiency. Note the fine fluttering of the mitral valve leaflet secondary to impingement by the aortic insufficiency jet. PW = posterior wall.

Finally, left ventricular performance can be monitored with exercise, and a flat or falling ejection fraction likewise represents an indication for surgical intervention.

Tricuspid Valve Disease

TRICUSPID REGURGITATION.

Probably due to the complex closure pattern of the tricuspid valve, minimal and mild degrees of tricuspid regurgitation are commonly seen in normal individuals. The most common form of tricuspid valve disease is annular dilation due to right-sided heart overload, resulting in abnormal leaflet coaptation and tricuspid regurgitation. This is typically secondary to pulmonary hypertension, which most commonly is due to left-sided heart pathology. Tricuspid regurgitation due to annular dilation can be the result of virtually any form of heart disease, resulting in elevation of right ventricular pressure or volume. In these instances, the tricuspid valve typically appears anatomically normal but is found to be regurgitant. Quantitation of tricuspid regurgitation is done in a manner similar to that for mitral regurgitation and in clinical practice is a qualitative assessment (Fig. 7-68).[118] Minimal and mild degrees of tricuspid regurgitation are nearly ubiquitous in adult populations, even in the absence of identifiable structural heart disease.[118] Moderate and severe tricuspid regurgitation and tricuspid regurgitation associated with elevated right ventricular systolic pressure are typically associated with cardiac pathology. Primary tricuspid valve disease can result in tricuspid regurgitation as well. Involvement by rheumatic heart disease,[119] endocarditis, trauma with rupture of a papillary muscle,[120] Ebstein anomaly, radiation heart disease, carcinoid heart disease,[121] [122] and prolapse all have characteristic anatomical features that result in regurgitation. TEE can be useful in determining the feasibility of tricuspid valve repair. Carcinoid heart disease is a rare abnormality but has classic echocardiographic features (Fig. 7-69) . [121] [122] In this syndrome, the leaflets appear stiffened and immobile. The annulus is secondarily dilated and the leaflets may fail to coapt. This lesion is typically associated with severe tricuspid regurgitation without elevation in right ventricular systolic pressure.

Figure 7-68 Two-dimensional echocardiograms with color flow imaging of patients with tricuspid regurgitation. *Top,* Echocardiogram is recorded in a patient with a mild degree of tricuspid insufficiency. *Bottom,* Echocardiogram of a patient with severe tricuspid regurgitation.

Irrespective of the cause of tricuspid regurgitation, one can capitalize on this lesion to accurately calculate right ventricular systolic pressure, as noted in the section on Doppler calculations. In the absence of obstruction to right ventricular outflow, this pressure equals pulmonary artery systolic pressure (see Fig. 7-29) . Calculation of right ventricular systolic pressure can be measured both at rest and with exercise and is a valuable means of noninvasively determining pulmonary artery systolic pressures.

TRICUSPID STENOSIS.

Isolated tricuspid stenosis is a very rare clinical entity. Tricuspid stenosis can be seen in individuals with rheumatic heart disease, in which case concurrent mitral stenosis will invariably be present.[119] The carcinoid syndrome can result in tricuspid stenosis as well. Calculation of transvalvular gradients across the tricuspid valve is done in a manner identical to that for the mitral valve. In the majority of cases, tricuspid valve stenosis is associated with regurgitation.

Pulmonic Valve Disease (See Chaps. 43 and 44.)

Primary disease of the pulmonic valve is uncommon in adult patients. Occasional patients with pulmonic stenosis (Fig. 7-70) , either in isolation or in combination with other congenital lesions, may be encountered in the adult cardiology practice. Congenital pulmonic stenosis results in thickening of the leaflets and restricted motion on two-dimensional echocardiography. Because the orientation of the pulmonary outflow tract is anterior to posterior, Doppler interrogation is quite easily performed within an angle of integration (theta) close to 0 degrees. The degree of stenosis and regurgitation across the pulmonic valve is determined

Figure 7-69 Right ventricular inflow tract view recorded in a patient with carcinoid disease and tricuspid regurgitation. The right atrium and right ventricle are both visualized in this systolic frame. The tricuspid valve leaflets are abnormally dense and immobile. In this systolic frame the leaflets fail to coapt with the leaflet tip separated by approximately 2 cm. In real time the leaflets are nearly immobile.

Figure 7-70 Two-dimensional *(A)* and continuous-wave Doppler *(B)* recorded in a patient with valvular pulmonic stenosis. The two-dimensional study shows a thickened pulmonic valve with restricted motion (arrowheads). The continuous-wave Doppler shows a peak velocity of 4.4 m/sec, which is consistent with a systolic gradient of approximately 78 mm Hg. Abbreviations are as per previous figures. *(From Feigenbaum H: Echocardiography. 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

in a manner analogous to that for the aortic valve. In the presence of pulmonic regurgitation, the pressure gradient between the pulmonary artery and right ventricle in diastole can be calculated, and from this an estimate of pulmonary artery diastolic pressure can be obtained.[123] This is done by calculating the end-diastolic pulmonary artery to right ventricular gradient and adding an assumed right ventricular diastolic pressure.

Several characteristic patterns of pulmonary valve motion should be recognized on M-mode echocardiography. The first is that of pulmonic stenosis in which there is an augmented a wave but otherwise normal motion. In the presence of infundibular stenosis, coarse fluttering of the pulmonic valve is seen. In the presence of significant pulmonary hypertension there is midsystolic notching of the pulmonic valve and loss of the pulmonary valve a wave (Fig. 7-71) . These findings are qualitative and may be seen only in the more advanced or severe forms of pathology. In modern practice, determination of pulmonary artery hemodynamics relies heavily on Doppler interrogation.

Evaluation of the right ventricular outflow tract or pulmonary artery Doppler flow profile can provide valuable clues in patients with known or suspected pulmonary hypertension.[124] Normally, after the onset of ejection, pulmonary artery flow reaches its maximum velocity within 140 milliseconds of the onset of ejection. In pulmonary hypertension this acceleration time is progressively shortened (Fig. 7-72) . There is a linear and inverse correlation between the ejection time, defined as the time from

onset of ejection to reaching peak velocity and pulmonary artery systolic and mean pressures. In general, a pulmonary artery acceleration time less than 70 milliseconds implies presence of a pulmonary artery systolic pressure exceeding 70 mm Hg. Other findings in pulmonary hypertension include notching of the pulmonary artery flow profile on spectral Doppler.

Miscellaneous Valvular Heart Diseases

Several miscellaneous forms of valvular heart disease deserve comment. Recently, attention has been drawn to the association between the use of anorectic drugs, particularly the combination of phentermine and fenfluramine (PhenFen), and development of valvular heart disease.[125] [126] [127] [128] [128A] [128B] [128C] [128D] The exact incidence of drug-related valvular heart disease is unknown. Most studies have suggested that the predominant

Figure 7-71 M-mode echocardiograms of the pulmonic valve recorded in a normal individual *(top)* and in an individual with pulmonic stenosis *(bottom)*. In the top tracing, note that the a wave is approximately 5 mm in depth. In contrast, in the patient with pulmonic stenosis, there is an exaggerated depth of the a wave (arrow) due to right ventricular pressure exceeding pulmonary artery diastolic pressure after atrial contraction.

lesions are similar to that seen in carcinoid or ergot heart disease. The leaflets of the mitral valve and chordae appear thickened and immobile, and mitral regurgitation is present. More commonly, aortic insufficiency has been noted in association with the use of these drugs, and it often appears out of proportion to the anatomical abnormalities noted on the aortic valve.

Radiation therapy can result in valvular dysfunction, most often thickening and insufficiency. The severity of the valvular insufficiency is dependent on the degree of anatomical damage to the valve, and the precise valves involved are dependent entirely on the radiation portal and dose. Typically, more anterior structures are involved and there may be concurrent myocardial dysfunction due to radiation myocarditis.

Evaluation of Prosthetic Heart Valves (See also Chap. 46.)

Two-dimensional echocardiography can be used to determine the appropriate prosthesis size to implant in the aortic position.[129] [130] [131] The evaluation of prosthetic heart valves can be a complex and time-consuming process. Prosthetic heart valves can be divided into three basic groups: mechanical prostheses, such as single or dual disc valves or ball and cage valves; stented bioprostheses, which use either porcine aortic valves or bovine pericardium for valve leaflets; and a newer generation of stentless porcine valves that at this time are approved for use only in the aortic position. Each valve has unique echocardiographic characteristics, and different valves can be evaluated to varying degrees using TTE and TEE. Doppler echocardiography is obviously crucial for determining the presence of regurgitation and the flow characteristics of a valve.[132] [133] It is often not possible to fully evaluate a prosthetic valve with TTE, and TEE is often necessary. This is particularly true for visualization of mitral prostheses. Even with TEE, complete anatomical visualization of an aortic mechanical prosthesis can be problematic. For all but the new stentless aortic prosthesis the sewing ring is characteristically visualized as an echo-dense circular structure within the appropriate annulus.

The ball and cage valve is typically visualized as an echo-dense sewing ring with three wire struts forming the cage and a ball moving within the cage. Depending on the composition of the ball, the ball itself may appear either as a spherical structure or as a single echo-dense line in motion. Single-disc mechanical prostheses are visualized as a sewing ring in which the disc can be seen to move. Typically from the transthoracic route all one sees is a single bright echo-dense line with phasic motion during the cardiac cycle above and into the plane of the sewing ring. The discs of a two-disc valve cast a smaller echo signature, and actual disc motion can be difficult to discern from TTE. Using TEE both leaflets of a two-disc valve are easily visualized in the mitral position and have a characteristic butterfly wing motion (Fig. 7-73) .[134] Identifying motion of both leaflets in the aortic position is more problematic. The stented porcine valves are visualized as a sewing ring, impinging on the actual orifice of the valve annulus in which three separate leaflets can be seen. These leaflets have the characteristics of a normal aortic valve. With fibrosis and degeneration or endocarditis the leaflets may become thickened and brighter than usual (Fig. 7-74) .[135] The newer stentless prosthesis and aortic homograft valves can be difficult to distinguish from a native aortic valve. Depending on the implantation technique, there may be few clues as to the presence of a stentless prosthesis other than subtle echodensities at the line of attachment in the annulus or, if implanted within the native aorta, a double-density aortic wall can be seen.[136] [137]

Figure 7-72 Pulsed-wave Doppler in the right ventricular outflow tract demonstrating varying degrees of pulmonary artery systolic pressure. *A,* Record of a normal individual. Note the normal acceleration time, defined as the time in milliseconds from onset of ejection to reaching peak velocity. In this instance the acceleration time is approximately 200 milliseconds. *B,* Record in a patient with modest pulmonary hypertension. Note the shortened acceleration. *C,* Record in a patient with severe pulmonary hypertension. Note the remarkably short acceleration time as well as the systolic notching in the flow pattern.

Complete evaluation of prosthetic valves requires detailed *Doppler assessment.* Color flow imaging is used to determine the presence and severity of regurgitation.[138] The combination of the sewing ring and/or the mechanical valve itself results in substantial reverberation and shadowing and dramatically reduces the ability to interrogate structures posterior to the mechanical prosthesis or sewing ring with Doppler. There is frequently a minimal amount of physiological regurgitation in mechanical prostheses that represents a combination of the closing velocity of the disc or ball and small physiological leaks at the closure lines. It is not uncommon to see minimal degrees of regurgitation in association with a stented or nonstented bioprosthesis. Valvular regurgitation in prosthetic valves can be quite eccentric, and one must use caution in applying rules for determining

Figure 7-75 Transesophageal echocardiogram recorded in a patient with a St. Jude mitral valve replacement and a paravalvular leak, resulting in moderate mitral regurgitation. *Left,* Recorded in systole. Note the two discs of the St. Jude prosthesis in their closed position (upward-pointing arrows). Immediately outside the boundary of the sewing ring is a distinct color jet (horizontal arrow) representing an eccentric mitral regurgitation jet arising from outside the border of the sewing ring. *Right,* The same image with color suppressed. Again note the closed leaflets of the St. Jude valve. With the color suppressed a distinct gap between the sewing ring and tissue (downward pointing arrow) can be seen, representing partial valve dehiscence.

severity of regurgitation. This is particularly true for paravalvular regurgitation (Fig. 7-75).

Spectral Doppler is used to determine pressure gradients across prosthetic valves. Stentless bioprostheses behave in a manner nearly identical to native aortic valves and typically have a peak gradient of less than 10 to 15 mm Hg.[136] [137] [139] Because of narrowing of the outflow tract by a sewing ring, a stented prosthesis has a higher transvalvular gradient.[139] The magnitude of this gradient is dependent on both flow and the size of the valve. Because of the wide range of anticipated gradients, it is crucial to establish a baseline for prosthetic valves at a time when they are known to be functioning normally. This avoids the problem of subsequent detection of a peak gradient that can be as high as 50 mm Hg. This may be due to the combination of a high flow state and a narrowed orifice due to the sewing ring and may not represent valve deterioration. Doppler evaluation for the gradient across a mechanical prosthesis is complicated by several factors, including phenomena of localized gradients and pressure recovery.[140] [141] As flow accelerates through the noncircular orifice of a mechanical prosthesis, there are areas of rapid flow acceleration that occur over very short distances. This acceleration results in instantaneous peak velocities of 3 to 4 m/sec, corresponding to gradients of 36 to 64 mm Hg. These pathological pressure gradients occur over a very limited distance (1-2 mm) within the sewing ring and do not reflect the true left-ventricular-to-proximal-aorta pressure difference measured in the hemodynamic laboratory. As with a stented bioprosthesis, it is crucial to obtain an early baseline pressure gradient across a mechanical prosthesis at a time when it is known to function normally for subsequent comparison. This is best done by obtaining a full echocardiographic and Doppler examination at the time of the first follow-up visit after implantation.

Dysfunction of prosthetic valves occurs due to valvular dehiscence, in which case a paravalvular leak can be seen (see Fig. 7-75), or there may be endocarditis (see Fig. 7-74) , thrombosis, or pannus interfering with motion of a mechanical valve. Typically, either stenosis or regurgitation can occur. If the mechanical valve becomes obstructed by pannus, vegetation, or thrombus, the transvalvular gradient typically will increase, although in some instances it may remain stable or even decline.[140] Regurgitation is usually seen in conjunction with restriction of the leaflet unless the leaflet has been restricted in a fully closed position. In suspected dysfunction of a prosthesis, TEE adds incremental value and is essential for complete evaluation.

Assessment of Mitral Valve Repair

Transesophageal echocardiography has been instrumental in determining the success of mitral valve repair.[142] [143] The preoperative echocardiogram is highly reliable as a means for determining which patients are candidates for mitral valve repair, and intraoperative monitoring is an integral part of the surgical routine in determining success of repair. In general, patients with elongated redundant valves, those with pathology of the posterior leaflet, and those with smaller vegetations or perforations are excellent candidates for mitral valve repair. A rheumatic etiology and patients with fibrotic leaflets are less likely to have good long-term results.

The intraoperative transesophageal echocardiogram is used to determine transvalvular gradients to exclude iatrogenic mitral stenosis and determine the degree, if any, of residual mitral regurgitation. Other adverse sequelae of mitral

Figure 7-73 Transesophageal echocardiogram of a patient with a normally functioning St. Jude mitral valve prosthesis. The scans are recorded at 0 degrees from behind the left atrium. The left panel is recorded in systole. Note the two closed leaflets of the prosthetic valve (arrows). The right-hand panel is recorded in diastole. Note the two leaflets now have a parallel position, pointing into the cavity of the left ventricle (arrows). Note the substantial shadowing from the sewing ring and discs, which reduces the ability to visualize the left ventricular cavity. Abbreviations are as per previous figures.

valve repair include development of dynamic left ventricular outflow tract obstruction, which likewise can be assessed with TEE before removing the patient from the operating room. Figures 7-55 and 7-76 are examples from a patient before and after successful mitral valve repair.

Infective Endocarditis (See Chap. 47.)

Infective endocarditis represents an invasive infection, usually by a bacterial organism of the endothelial lining of the heart, most commonly on one of the four cardiac valves. Left-sided valves are more commonly involved than right-sided valves. The echocardiographic hallmark of bacterial endocarditis is formation of a vegetation on a valvular surface. Pathologically, a vegetation consists of a combination of thrombus, necrotic valvular debris, inflammatory material, and bacteria. Over time, a vegetation may become sterilized, at which point only the residua of the inflammatory response with variable degrees of the thrombotic component persist. On echocardiography a vegetation has the appearance of an oscillating mass attached to a valve leaflet (Fig. 7-77) . Classically, these are seen on the downstream, low-pressure side of a valve. Therefore, one typically anticipates a vegetation on the left atrial side of the mitral valve and on the left ventricular outflow tract side of the aortic valve. In reality, larger vegetations can exist on both sides of a valve and atypical locations are not uncommon. In screening for vegetations, small unrelated masses or surface irregularities are not infrequently encountered, and thus the specificity for defining a vegetation is not 100 percent. Several large-scale studies have demonstrated that echocardiography may play an incremental role in rapidly establishing the diagnosis of endocarditis,[144] [145] [146] and at least one algorithm for defining endocarditis has used echocardiography as an intrinsic component of the diagnosis.[147] Noninfectious vegetation, such as those seen in association with connective tissue disease, are also detected with echocardiographic imaging.[148] [149]

In addition to detection of a vegetation in patients with suspected endocarditis, echocardiography can be used to determine the functional significance and degree of anatomical impairment due to endocarditis and to evaluate complications of endocarditis. Typically, endocarditis results in valvular regurgitation and only rarely in significant valvular stenosis. Because of the variable location of vegetations and the highly variable degree to which the valvular surface may be interrupted, regurgitant lesions in endocarditis are more likely to be eccentric than in more classic forms of valvular heart disease.

Several studies have attempted to use echocardiographic features of vegetations as a marker for the likelihood of requiring surgery or progressing to heart failure. In general, larger and more mobile vegetations are more likely to be associated with embolic events than are smaller sessile vegetations. Vegetations due to *Staphylococcus aureus* are more likely to result in abscess formation and less likely to be sterilized with antibiotics.

COMPLICATIONS OF ENDOCARDITIS.

These include progressive valvular regurgitation leading to congestive heart failure, abscess formation, failure to sterilize, and embolic phenomena. Intracardiac abscesses are most commonly encountered in the relatively avascular areas of the heart. For aortic valve endocarditis this includes the aorta/mitral valve junction and for mitral and tricuspid valve disease the annular structures. Less commonly, intramyocardial abscess or abscess within a papillary muscle is encountered.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY.

The relative diagnostic value of TTE and TEE has been evaluated in several studies.[150] [151] Because of the higher-quality, higher-resolution

Figure 7-74 Apical four-chamber *(top)* and parasternal short-axis views (lower panel) recorded in a patient with stented porcine bioprostheses in the mitral *(top)* and aortic *(bottom)* positions. In the upper panel, the horizontally oriented arrows denote the struts of the stented porcine valve that protrude in the cavity of the left ventricle. Within the struts note the echo-dense mass that represents vegetation. In the lower panel the three struts of the porcine bioprosthesis can be visualized at 2, 6, and 10 o'clock positions. Within the sewing ring of the bioprosthesis are noted several echo densities that represent vegetations. Abbreviations are as per previous figures.

imaging afforded by TEE, virtually all studies have demonstrated an increased sensitivity for detection of vegetations with TEE (Fig. 7-78) . Often the clinical diagnosis of endocarditis has included detection of vegetations, and, thus, many of these studies tend to overstate the sensitivity of TEE. Most studies have also suggested that when a high-quality, entirely normal transthoracic echocardiogram has been obtained in which there is no evidence of valvular mass or thickening and no evidence of pathological regurgitation, that the yield in proceeding to TEE is relatively low. Because TEE provides a high-resolution view of the heart, it also detects many limited areas of valvular thickening that are not related to an infectious process. Thus, its specificity for excluding the diagnosis of endocarditis may be less than optimal.

There are several proven advantages to TEE in patients with endocarditis. Perhaps the most well established is the detection of abscesses, particularly in the aortic root (Fig. 7-79) .[152] [153] Data suggest that detection rates from the

Figure 7-76 Two-dimensional echocardiogram recorded in a patient after mitral valve repair and annuloplasty ring. The ring is seen as an echo-dense structure in the annulus (arrows). PV = pulmonary vein; DA = descending aorta.

transthoracic approach are under 30 percent, whereas sensitivity for detecting an abscess in the aortic root with TEE exceeds 95 percent. Additionally, TEE provides more accurate characterization of the size and mobility of vegetations

Figure 7-77 Parasternal long-axis view of patient with aortic valve vegetation. Note the relatively echo-dense, irregular mass prolapsing into the left ventricular outflow tract in this diastolic frame (arrow). Abbreviations are as per previous figures.

Figure 7-78 Transthoracic *(top)* and transesophageal echocardiogram *(bottom)* recorded in a patient with a mitral valve vegetation. In the transthoracic parasternal long-axis view, a highly mobile

filamentous echo can be seen prolapsing into the left atrium during systole. This is consistent with a highly mobile vegetation. A systolic frame from the transesophageal echocardiogram is presented in the bottom panel. Again the highly filamentous mobile echo is noted (horizontal arrow). In addition there is a more sessile 8 mm diameter mass attached to the mitral valve (downward pointing arrow). Abbreviations are as per previous figures.

and detection of multiple vegetations in endocarditis. Finally, TEE is more accurate for determining the etiology of valvular regurgitation than is TTE. TEE can identify valvular perforations, ruptured chordae, and flail leaflets with a higher degree of reliability than can TTE.[154]

Calcification of the Mitral Annulus

Fibrosis and calcification of the mitral annulus are common findings with increasing age and can be seen in younger patients with renal disease and other metabolic abnormalities that result in abnormal calcium metabolism (Fig. 7-80) . The degree of calcification can range from limited, focal deposits in the annulus to deposits resulting in a masslike effect.[155] [156] [157] In advanced degrees the basal aspects of the posterior mitral valve leaflet may be involved. In rare situations, annular calcification can result in functional restriction of the mitral valve orifice and a left atrial-left ventricular pressure gradient. Only in advanced and rare cases does the degree of obstruction result in pressure gradients likely to cause symptoms or result in secondary pulmonary hypertension. More commonly, mitral annular calcification is associated with varying degrees of mitral regurgitation. Heavy annular calcification may result in a lower likelihood

Figure 7-79 Transesophageal echocardiogram recorded in a patient with an aortic root abscess, obtained in a longitudinal orientation. Note the thickened aortic valve with superimposed vegetation (arrowhead) and the echo-free space (arrow) between the wall of the aorta and the right ventricular outflow tract, which represents a periaortic abscess. Abbreviations are as per previous figures.

of successful valve replacement and a situation in which paravalvular regurgitation is not uncommon after mitral valve replacement.[146] Statistically, it also has been associated with embolic events.[147]

CONGENITAL HEART DISEASE (See Chaps. 43 and 44.)

Modern two-dimensional echocardiographic techniques provide a comprehensive means for evaluating virtually all

Figure 7-80 Two-dimensional echocardiogram recorded in a patient with renal insufficiency and calcification of the mitral annulus. Mitral annular calcium appears as an echo-dense mass in the mitral annulus.

forms of congenital heart disease found in both adults and children.[158] [159] [160] Additionally, echocardiography can be used to evaluate repaired and palliated congenital heart disease. In the modern era it is unusual for cardiac catheterization or other techniques to be necessary for defining the anatomical anomaly in congenital heart disease.[152] Cardiac magnetic resonance imaging (MRI) may provide incremental information regarding pulmonary artery anatomy and complex venous and great artery connections. Doppler echocardiography often provides the majority of physiological information necessary for the clinical decision-making.

It has become increasingly uncommon to make the diagnosis of congenital heart disease de novo in adult populations. Because of the increased access to well-trained pediatricians, family practitioners, and pediatric cardiologists, the majority of "significant" congenital heart lesions are detected in childhood and adolescence. Thus, the number and nature of lesions "escaping" detection until adulthood has changed over the past several decades. The single most common congenital lesion to be detected in adulthood, other than the bicuspid aortic valve, is the atrial septal defect. There are infrequent cases of ventricular septal defects and other anomalies that escape detection to adulthood. This chapter deals only with the more common entities likely to be encountered in adult populations and evaluation of the more common repaired and palliated lesions.

Intracardiac Shunts

ATRIAL SEPTAL DEFECT.

The most common shunt lesion to be detected de novo in adulthood is the atrial septal defect. Because atrial septal defects result in a relatively innocent murmur, they are often overlooked in childhood and may escape detection until adolescence or adulthood. Atrial septal defects result in a left-to-right shunt at a level of the atrial septum and, consequently, a volume overload of the right ventricle in diastole.[18] [161] The volume overload pattern of the right ventricle is manifest as dilation of the right ventricle and usually the right atrium. Additionally, the septum is "flattened" and the left ventricle, rather than assuming circular geometry, has a "D"-shaped geometry (see Fig. 7-21) . This septal flattening is present predominantly in diastole, and during systole the septum assumes its normal circular geometry. This right ventricular volume overload pattern that is typically seen in atrial septal defects is also seen in any other lesion resulting in right ventricular diastolic volume overload, including significant pulmonary insufficiency, tricuspid regurgitation, and anomalous pulmonary venous return. On M-mode echocardiography the right ventricular volume overload pattern is characterized as paradoxical septal motion. It is now recognized that this "paradoxical" septal motion actually represents restitution of normal circular geometry with the onset of ventricular systole.

Detection of a right ventricular volume overload pattern may be the first clue to the presence of an atrial septal defect, after which further interrogation of the atrial septum should be undertaken to identify the location of the defect. The three most common locations of an atrial septal defect are secundum, primum, and sinus venosus, representing approximately 70 percent, 15 percent, and 15 percent of atrial septal defects, respectively. Rarer forms of atrial septal defect, including the unroofed coronary sinus, are also encountered. Whereas the secundum atrial septal defect is an isolated entity, there are strong associations between sinus venosus atrial septal defect and malalignment of the pulmonary veins, resulting in functional anomalous pulmonary venous return and abnormalities of the mitral valve seen with the primum atrial septal defect. A primum atrial septal defect is best considered a variant of endocardial cushion defect in which a small perimembranous ventricular septal defect and anomalies of the mitral valve may also

Figure 7-81 Transesophageal echocardiograms in two patients with atrial septal defects. In each case there is a distinct loss of tissue in the atrial septum, allowing direct communication between the left atrium and right atrium. The top panel is the same patient presented in the two left panels in Figure 7-82 , and the bottom panel is recorded in the same patient presented in the bottom right panel in Figure 7-82 .

be encountered. The classic mitral valve abnormality to be seen is a cleft mitral valve with varying degrees of mitral regurgitation.

On occasion, a right ventricular volume overload pattern is encountered but no anatomical defect can be visualized. In these instances, contrast echocardiography using agitated saline can be a valuable means of detecting the right-to-left component of interatrial shunting.[42] [162] Of the three common types of atrial septal defect, the sinus venosus defect is most likely to escape direct visualization on a transthoracic echocardiogram. TEE is nearly 100 percent specific and sensitive in detection of all types of atrial septal defects, including sinus venosus defects (Fig. 7-81) .[163] With TEE, the atrial septal defect is visualized as a loss of tissue. The size of the defect can be accurately measured, and color flow imaging can be used to identify abnormal transatrial flow patterns (Figs. 7-81 and 7-82). [164] Often the diagnosis can be established with a degree of accuracy and confidence that catheterization is not necessary before surgical repair.

Once identified, further characterization of the atrial septal defect can be undertaken using two-dimensional echocardiography and Doppler techniques. Three-dimensional

Figure 7-82 Four illustrations of patients with atrial septal defects. *Top left,* Recorded from a subcostal transducer position in a patient with a small atrial septal defect (also illustrated in the lower left panel). From the subcostal transducer position the entire length of the atrial septum can be visualized. There is a defect approximately 7 mm in diameter in the secundum portion of the atrial septum with a color flow signal coursing from the left atrium into the right atrium (arrow) consistent with secundum septal defect. The lower left panel is the transesophageal echocardiogram from the same patient presented on the top left. The size of the defect can be more accurately appreciated, and again there is a distinct color flow image coursing from the left atrium into the right atrium. The upper right panel is a longitudinal view of the atrial septum showing a large patent foramen. Note the margins of the atrial septal tissue (arrows). The atrial septal tissue does not oppose, in this case leaving a 1-cm defect, through which flow shunts from the left atrium to the right atrium. SVC=superior vena cava. The lower right panel is recorded in a patient with a large secundum defect. Note the color flow

image denoting a substantial flow from left atrium to right atrium. The defect is approximately 2 cm in diameter.

echocardiography can provide valuable clues as to the complex shape of an atrial septal defect.[165] [166] TEE can be an invaluable technique for determining the integrity of the tissues surrounding the atrial septal defect and plays a valuable role in determining the feasibility of a percutaneous closure using a button or umbrella device.[167] [168] Defects less than 2 cm in diameter and with relatively firm tissue at the margins are more likely to be successfully closed, compared with large defects and those with fairly thin tissue at the margin or multiple perforations.

Shunt Size.

Numerous attempts have been made to quantify the ratio of pulmonary and systemic flow in intracardiac shunt lesions, including atrial septal defect.[169] The majority of these attempts have been by calculating the instantaneous stroke volume of the pulmonary outflow tract and left ventricular outflow tract (see section on Doppler calculations). This calculation has been fairly reproducible and has correlated with hemodynamic assessment in the animal laboratory and in children. Because of the margin of error for measuring the dimension of the outflow tract, it has seen less use in adult patients. In general, the threshold for recommending closure of an atrial septal defect has diminished to a Qp/Qs (pulmonary/systemic flow ratio) of 1.5 or less. Detection of a right ventricular volume overload pattern in general denotes a shunt of at least this level, and thus the majority of detected atrial septal defects fall into the range that warrant closure.

REPAIRED ATRIAL SEPTAL DEFECT.

Depending on the magnitude of the initial shunt and the age at which an atrial septal defect is repaired, the two-dimensional echocardiogram may revert to normal with respect to chamber sizes or show evidence of residual right-sided heart dilation. In instances in which the defect was large and repaired only late, residual right ventricular dysfunction, varying degrees of pulmonary hypertension, and right ventricular hypertrophy may persist throughout adulthood. Depending on the nature of the repair technique, the atrial septum can appear anatomically normal or can reveal areas of echo density consistent with the type of patch material used. In general, the right ventricular volume overload pattern with paradoxical septal motion resolves but can be replaced by a postoperative septal motion pattern.

OTHER ABNORMALITIES OF THE ATRIAL SEPTUM.

In addition to atrial septal defect anomalies such as aneurysm of the atrial septum,[170] [171] lipomatous atrial hypertrophy and patent foramen ovale[172] can be detected. The aneurysmal atrial septum is not infrequently associated with small perforations and minor degrees of either right-to-left or left-to-right atrial shunting (Fig. 7-83) . Contrast echocardiography can detect minor degrees of right-to-left shunting in both of these situations.[49] [173]

ANOMALOUS PULMONARY VENOUS RETURN.

A final congenital lesion that results in a right ventricular volume overload pattern is anomalous pulmonary venous return. A variation on anomalous return is seen in patients with primum atrial septal defects who have functional anomalous return due to malalignment of the right superior pulmonary vein such that its flow is directed into the superior vena cava and right atrium. True anomalous pulmonary venous return often results in creation of a venous chamber posterior to the left atrium, which then drains to the right atrium.[174] [175]

VENTRICULAR SEPTAL DEFECT.

Whereas the ventricular septal defect represents the most common congenital intracardiac shunt encountered in infants and children, it is a small percentage of those detected de novo in adults. A substantial number of small ventricular septal defects close spontaneously during childhood and thus are not present in adults, whereas the larger defects result in symptoms and are detected in childhood. Furthermore, the smaller persistent defects are associated with prominent pathological murmurs and unlikely to be confused for a flow murmur;

Figure 7-83 Apical four-chamber view recorded in a patient with an atrial septal aneurysm. Note the marked bulging of the atrial septum into the cavity of the left atrium (arrow). The right-hand panel is recorded after injection of saline contrast medium. Note the contrast medium has filled the right ventricular cavity, and there are numerous individual microbubbles seen in the cavity of both the left atrium and left ventricle, consistent with a right-to-left shunt through fenestrations in the atrial septal aneurysm. Abbreviations are as per previous figures.

Figure 7-84 Schematic depicting the location of different ventricular septal defects compared with the different echocardiographic views. *(From Feigenbaum H: Echocardiography. 5th ed. Malvern PA, Lea & Febiger, 1994.)*

and, therefore, individuals come to medical attention promptly. On occasion, patients with small ventricular septal defects escape detection to adulthood, when the defects are found on the basis of a pathological murmur. Ventricular septal defects occur in several different locations, which are denoted echocardiographically in Figure 7-84 . The most common location is a small perimembranous septal defect; however, other locations, including supracristal, are not uncommonly encountered. Muscular defects can occur anywhere within the muscular septum, and small apical defects are frequently multiple.

A ventricular septal defect can be visualized as a dropout of myocardial tissue with communication between the left and right ventricles.[176] The resolution of TTE, using 3- and 5-MHz transducers, is such that most defects below a 3-mm size may not be directly visualized (Fig. 7-85). It is uncommon to directly visualize small muscular defects that may take an angulated or serpiginous course through the ventricular septum. Color Doppler imaging over areas of the septum is a reliable means for detecting the abnormal transseptal flow.[177] [178] It is often necessary to scan in unusual and atypical planes to identify flow through the septum, especially when searching for a muscular defect. For the isolated small perimembranous defect, continuous-wave Doppler can be used to determine the velocity of flow from the left ventricle to the right ventricle and hence the transventricular pressure gradient.[179] This can then be subtracted from arm blood pressure to estimate right ventricular systolic pressure. With the use of this methodology the small restrictive ventricular septal defect can be characterized as a defect resulting in little or no chamber dilation, of small anatomical extent on two-dimensional scanning, and associated with a high transventricular gradient.

Shunt Size.

The magnitude of shunting through a ventricular septal defect can be calculated using several Doppler techniques.[180] [181] Larger ventricular septal defects may be associated with substantial left-to-right shunts and development

Figure 7-85 Parasternal two-dimensional echocardiographic views in a patient with a moderate-sized perimembranous ventricular septal defect. The upper panel is recorded in a parasternal long-axis view and shows the proximal anterior septum. The lower panel is recorded in a short-axis view at the base of the heart. Note in each instance the distinct color jet arising on the left ventricular side of the ventricular septum and coursing in the right ventricular outflow tract. This is consistent with exclusive left-to-right ventricular septal defect flow.

of secondary pulmonary hypertension. In this instance, the right ventricle will be dilated and hypertrophied. By using the tricuspid regurgitation signal, right ventricular systolic pressure can be calculated. In the presence of a ventricular septal defect it is important to look for associated anomalies of the right ventricular outflow tract and pulmonary valve. Pulmonic stenosis and right ventricular outflow tract obstruction are both protective of the pulmonary circuit and will lead to the scenario of elevated right ventricular systolic pressure with normal pulmonary artery pressures. This has obvious clinical implications with respect to surgical intervention.

CLOSED AND REPAIRED VENTRICULAR SEPTAL DEFECT.

As noted earlier, many small ventricular septal defects close spontaneously in infancy and childhood. This occurs by way of two basic mechanisms. The first is adherence of a portion of the tricuspid leaflet to the ventricular septal defect. In this case, one may visualize a very thin membrane closing the actual ventricular septal defect.[182] The second mechanism appears to be growth of additional tissue from the margins of the ventricular septal defect. In this instance, there may be irregular tissue closing the ventricular septal defect, the extent of which can be highly variable. In many instances, a thin-walled aneurysm may be noted in the area of the previous ventricular septal defect. The aneurysm typically bows into the right ventricular outflow tract. A small residual left-to-right shunt may be encountered that often is of little hemodynamic significance but that may result in a murmur and pose a risk for endocarditis.

TETRALOGY OF FALLOT.

Tetralogy of Fallot represents a complex of lesions including a ventricular septal defect with overriding aorta and obstruction to right ventricular outflow tract at either the infundibular or valvular level (Fig. 7-86) . The fourth component is a right-sided aortic arch. Before correction the lesion is characterized by a ventricular septal defect in which the edge of the ventricular septum is directed not at the anterior wall of the aorta but more at the aortic lumen. Varying degrees of right ventricular outflow tract obstruction including true valvular stenosis and infundibular muscular stenosis can be seen. Tetralogy of Fallot represents the most common cyanotic congenital

Figure 7-86 Two-dimensional echocardiogram recorded in a patient with an unrepaired tetralogy of Fallot. Note the fairly large perimembranous ventricular septal defect and the overriding aorta. Because of the overriding aorta both right and left ventricular outflow is directed toward the aorta equally. Abbreviations are as per previous figures. *(From Feigenbaum H: Echocardiography. 4th ed. Malvern PA, Lea & Febiger, 1986.)*

lesion to be encountered that is likely to result in survival to adulthood and, furthermore, the most common complex lesion to be encountered in the adult population after repair.

Preoperatively, tetralogy of Fallot represents a broad spectrum of ventricular septal defect size and outflow tract obstruction. Postoperatively, varying degrees of residual abnormalities may be encountered, ranging from a nearly normal-appearing heart to one in which there are substantial degrees of right ventricular dysfunction and residual right ventricular outflow tract obstruction.[183] [184] Two-dimensional echocardiography and Doppler techniques can be a definitive means for following these individuals with respect to recovery of right ventricular function and development of complications such as recurrent right ventricular outflow tract obstruction and residual ventricular septal defect.[185]

PULMONIC STENOSIS.

Isolated pulmonic stenosis is a relatively common congenital lesion. As with the bicuspid aortic valve, its hemodynamic severity ranges from negligible to severe and life threatening early in infancy. Because of the orientation of the proximal pulmonary artery and pulmonic valve, it is easily interrogated with Doppler. Underestimation of pulmonic valve gradients due to off-angle interrogation is uncommon. Anatomically, the stenotic pulmonary valve appears somewhat thickened and has "doming" motion (see Fig. 7-70) . On M-mode echocardiography there may be an accentuation of the pulmonic valve a wave. In adult patients it is not uncommon for valvular pulmonic stenosis to be associated with secondary infundibular hypertrophy with concurrent right ventricular outflow tract obstruction. Thus, it is important to evaluate both the subvalvular and valvular aspects of the pulmonary valve in adult patients. Less frequently, peripheral pulmonic stenosis will be encountered. Identification and characterization of the peripheral pulmonary arteries in adult populations can be quite problematic and is an area in which MRI can play an incremental and valuable role.

Abnormalities of the Left Ventricular Outflow Tract

The most common abnormality of left ventricular outflow is the bicuspid aortic valve, which has been discussed previously. Additionally, both tunnel and discrete subaortic stenosis are occasionally encountered in adult patients. Tunnel aortic stenosis is visualized as a diffuse narrowing of the left ventricular outflow tract and more often is identified in children. Discrete, membranous subvalvular stenosis occasionally escapes detection until adulthood and is characterized by the presence of a thin membrane or ridge that encircles the left ventricular outflow tract (Fig. 7-87) .[186] Components of the membrane may be attached to the ventricular septum and to the anterior mitral valve leaflet. The membrane itself can be difficult to visualize from transthoracic transducer positions and may require TEE for complete visualization. The obstructing membrane results in turbulence in the left ventricular outflow tract, which can be detected with color Doppler flow imaging and eventually results in secondary pathology of the aortic valve with subsequent aortic insufficiency. M-mode echocardiography often reveals characteristic course systolic fluttering of the aortic valve leaflets. This finding can help distinguish valvular from subvalvular obstruction. This should be contrasted to hypertrophic cardiomyopathy, in which anatomical abnormalities of the aortic valve and aortic insufficiency are uncommon.

The etiology of subvalvular membranes is uncertain, and the lesion may progress from inconsequential and undetectable to significantly obstructive in adult patients. Additionally, if detected in childhood and surgically resected, there is a definite likelihood of recurrence of the lesion in adulthood. On occasion, discrete subvalvular membranes have been seen in association with spontaneously closed ventricular septal defects.

Congenital Abnormalities of the Mitral Valve

Congenital abnormalities of the mitral valve, likely to be encountered in adult populations, include the previously mentioned cleft mitral valve, seen in association with a primum atrial septal defect as well as congenital mitral stenosis. The latter can occur either in the presence of a single papillary muscle, in which all chordae attach to a central point rendering an otherwise unremarkable valve functionally stenotic, or in a valve that is intrinsically stenotic

Figure 7-87 Transesophageal echocardiogram in a longitudinal plane of the left ventricular outflow tract demonstrating a small, discrete subaortic membrane (downward pointing arrow). The aortic leaflets are mildly thickened (horizontal arrows). This small membrane was not visualized from the transthoracic echocardiogram. Abbreviations are as per previous figures.

Figure 7-88 Transthoracic echocardiogram recorded in a patient with cor triatum in the parasternal long-axis view *(top)* and apical views *(bottom)*. A linear echo courses posteriorly from the area of the aorta. From the apical views the membrane can be seen to divide the left atrium into two chambers. PV = pulmonary vein; M = membrane; other abbreviations as per previous figures. *(From Feigenbaum H: Echocardiography. 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

but with two papillary muscle attachments. Functionally, these patients will present in a manner nearly identical to that for rheumatic mitral stenosis. Awareness of the anatomical features of congenital mitral stenosis is necessary to separate it from rheumatic causes. In many instances the congenital lesion will be characterized by an obstructive but eccentrically directed mitral valve orifice without the characteristic chordal and leaflet thickening. Transvalvular gradients can be measured across the congenitally stenotic mitral valve but may require unusual transducer angulations and lines of interrogation.

Cor triatriatum represents membrane within the body of the left atrium that likewise may be obstructive. TTE may suffice for identification of the membrane (Fig. 7-88) , but in many instances TEE, which affords a more accurate view of the left atrium, is necessary.[187] [188] A final congenital abnormality of the mitral valve is the submitral ring or web. This represents a membrane attached near the mitral annulus within the left atrium that is obstructive to flow.

Anomalies of the Tricuspid Valve

The most common congenital tricuspid valve anomaly to escape detection to adulthood is Ebstein anomaly. In this situation the lateral leaflet is elongated and tethered to the lateral wall of the right ventricle and the septal leaflet is relatively small and apically displaced.[189] This results in conversion of a portion of the right ventricle to an "atrialized" right ventricle (Figs. 7-89 and 7-90) . Tricuspid regurgitation is invariably present and results in dilation of the right side of the heart in general but predominantly of the right atrium and atrialized right ventricle. Atrial septal defect is a common association with Ebstein anomaly and

Figure 7-89 Schematic of the anatomical and echocardiographic abnormalities seen in Ebstein anomaly including apical displacement of the septal leaflet and elongation and tethering of the lateral leaflet. Both the functional (FRV) and atrialized right ventricle (AtRV) are noted. *(From Feigenbaum H: Echocardiography. 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

Figure 7-90 Two-dimensional echocardiogram recorded in a patient with Ebstein anomaly. Note the small, apically displayed septal leaflet and the elongated lateral leaflet that is tethered to the myocardium of the right ventricular lateral wall. *(From Feigenbaum H: Echocardiography. 5th ed. Malvern, PA, Lea & Febiger, 1994.)*

should be considered in all instances. Tricuspid regurgitation is present invariably and may provide one of the major clues to the presence of Ebstein anomaly. Because the closure of the tricuspid valve is displaced toward the apex of the right ventricle the apical location of the convergence zone of the tricuspid regurgitation jet may be one of the clues to the presence of this anomaly.

Once identified, it is important to characterize several features of Ebstein anomaly that have direct relevance to the feasibility of surgical repair. Surgical repair can be undertaken in individuals with a relatively large functional right ventricle, compared with the atrialized portion, and in whom there is not extensive tethering of the lateral leaflet. This assessment can be made in a majority of patients using TTE.

Tricuspid Atresia

Tricuspid atresia is usually detected in infancy but after palliation may allow survival to adulthood. In tricuspid atresia there is no functional tricuspid valve tissue, although the tricuspid annulus may be closed by a thin membrane with small perforations.[190] Because of the atretic tricuspid valve, right ventricular hypoplasia coexists. Obviously a complete form of tricuspid atresia is incompatible with life unless a concurrent atrial or ventricular septal defect is present.

Persistent Ductus Arteriosus

Persistent ductus arteriosus represents persistence of the normal communication between the descending thoracic aorta and the left pulmonary artery. The size of the communication varies from 1 or 2 mm to a centimeter or more. The magnitude of left-to-right shunting is dependent on the size of the defect. Initially, persistent ductus results in a continuous left-to-right shunt at the great artery level that subsequently results in a left-sided heart volume overload early in childhood and adolescence. Because of the increased pulmonary flow, pulmonary hypertension may develop, in which case only the systolic component of the shunt persists. Echocardiographic detection of persistent ductus arteriosus is dependent on detection of left-sided heart enlargement and/or abnormal pulmonary artery flow.[191] With the use of suprasternal notch views it is occasionally possible to directly visualize the ductus (Fig. 7-91). More commonly, Doppler interrogation of the proximal pulmonary artery is the initial clue to the presence of a persistent ductus. By using either color Doppler flow imaging or pulsed Doppler one can detect continuous turbulent flow in the proximal pulmonary artery.[191] Further careful interrogation will frequently identify the origin of the abnormal flow from the descending aorta into the left main pulmonary artery.

Figure 7-91 Parasternal short-axis view at the level of the great vessels recorded in a patient with persistent ductus arteriosus. Note the dilated pulmonary artery and the abnormal color flow signal (large arrow) that originates from the area of descending thoracic aorta and flows into the pulmonary artery distal to the pulmonary valve. In this diastolic frame note the small pulmonic insufficiency jet (small white arrow). Abbreviations are as per previous figures.

Coarctation of the Aorta

Narrowing or coarctation of the aorta occurs after the takeoff of the left subclavian artery. It results in reduction of systolic pressure distally and may present in adulthood as a secondary cause of systemic hypertension. The anatomical extent of coarctation may be visualized from the suprasternal notch, and continuous-flow Doppler can be used to determine the coarctation gradient.[192] There is a strong association between coarctation and bicuspid aortic valve; and whenever coarctation is discovered, efforts should be made to define the aortic valve anatomy.

Transposition of the Great Arteries

Transposition refers to the situation in which there is ventricular-arterial discordance. This is defined as a connection of the left ventricle to the pulmonary artery and the right ventricle to the aorta. There are two forms of transposition that may be encountered. D-transposition is an isolated malposition of the great vessels due to failure of the conotruncos to appropriately coil. In this situation the pulmonary artery is attached to the left ventricle, which receives blood from the left atrium. The aorta is attached to the right ventricle, which receives blood from the right atrium. This results in two parallel circulations and is obviously not compatible with life in the absence of an intracardiac shunt such as a persistent ductus or large ventricular or atrial septal defect. This lesion is invariably detected in infancy and is not encountered in adult patients in other than corrected forms. Surgical correction of transposition includes creation of an atrial septal defect early and subsequent surgical creation of a baffle that directs right atrial blood into the left ventricle and left atrial blood flow into the right ventricle. An anatomical switch of the great arteries has become the preferred surgical procedure.

L-transposition occurs when there is both inversion of the ventricles and transposition of the great arteries (Fig. 7-92) .[193] In this situation, blood flows from the anatomical right atrium through an anatomical mitral valve into the anatomical left ventricle and then into the pulmonary artery. Blood returning to the left atrium flows through an anatomical tricuspid valve into an anatomical right ventricle and then to the aorta. This results in "corrected" transposition in which physiological blood flow is maintained. L-transposition is compatible with survival to the fifth or sixth decade and often is first detected in adults. In either type of transposition the great arteries no longer have the circular and crescent orientation but rather arise from the

Figure 7-92 Transesophageal echocardiogram in an adult patient with L-transposition of the great vessels. In the top panel the connection of the anatomical right atrium to the anatomical left ventricle and the communication of the anatomical left atrium, through an anatomical tricuspid valve, into an anatomical right ventricle can be appreciated. Note the normal-appearing left atrial appendage (LAA). Note also the marked hypertrophy of the right ventricular trabeculations, which nearly obliterate the apex of the anatomical right ventricle (arrows). There is apical displacement of the atrioventricular valve contained within the anatomical right ventricle, compared with the atrioventricular (mitral) valve connecting the right atrium to the left ventricle. The lower panel depicts the parallel orientation of the pulmonary artery (PA) and aorta. The more anteriorly placed aorta is in communication with the anatomical right ventricle. Abbreviations are as per previous figures.

heart in a parallel fashion. In adult patients it can be difficult to directly visualize the parallel nature of the great vessels. Clues to the presence of congenitally "corrected" transposition include presence of a trabeculated ventricle with a more apically placed valve in a left and posterior position. L-transposition is compatible with survival into the fourth and fifth decade. After this period of time, substantial hypertrophy of the anatomical right ventricle occurs and right ventricular dysfunction is not uncommon. Regurgitation of the anatomical tricuspid valve in the systemic circuit is also quite common in adult patients.

Complex Congenital Heart Disease

The echocardiographic and clinical evaluation of complex congenital heart disease is best undertaken by individuals with specific interest and training in the area and is beyond the scope of this chapter. Three-dimensional echocardiography has been a valuable adjunct in evaluating the complex anatomy seen in complex lesions (Fig.

7-93) .[194]

DISEASES OF THE PERICARDIUM (See Chap. 50.)

PERICARDIAL EFFUSION.

Detection of pericardial effusion was one of the earliest utilizations of echocardiography, and modern ultrasound techniques remain the predominant diagnostic tool for detection, quantitation, and determination of the physiological significance of pericardial effusion.[195] [196] A pericardial effusion is viewed as an echo-free space surrounding the heart, most commonly seen posteriorly (Fig. 7-94) . Most clinical laboratories document the presence of pericardial effusion and quantify it as minimal, small, moderate, and large. A minimal effusion represents the 5 to 15 ml of normal pericardial fluid seen in disease-free individuals. This is most frequently noted as an echo-free space, confined to the posterior atrioventricular groove. A small pericardial effusion is defined as less than 5 mm in maximum dimension, which is visualized throughout the cardiac cycle. Moderate pericardial effusions typically are 10 to 15 mm in dimension and tend to be more circumferential. Large effusions are defined as those larger than 15 mm. Because patients are scanned in a supine or left lateral position the fluid tends to pool and to be mostly visible in the posterior aspects of the imaging planes. Numerous attempts have been made to quantify the amount of pericardial fluid but have not seen uniform acceptance.[197] The majority of laboratories use the semi-quantitative scheme noted earlier. Three-dimensional echocardiography has shown some promise for enhanced localization and quantitation of pericardial effusion.[198] The most commonly employed technique for quantifying the volume of effusion is to image the effusion in orthogonal planes and determine the intrapericardial volume using Simpson's rule. The entire cardiac silhouette can then likewise be traced and the total cardiac volume determined. The difference between the pericardial and cardiac volumes represents the volume of pericardial fluid. Although theoretically accurate, there are practical limitations to tracing both the cardiac and pericardial volumes that render this technique less than optimal and of little true clinical utility.

Other aspects of a pericardial effusion also can be noted with echocardiography. The presence of soft tissue density masses, thickening of the visceral pericardium, and presence of fibrinous strands can all be identified. All of these features are more common in patients with marked inflammatory or malignant causes for pericardial effusion. Additionally, the nature of the fluid can be further characterized as clear or "cloudy." The hallmark of the benign, idiopathic effusion is a clear echo-free space, whereas malignancy, bacterial infection, and hemorrhagic effusions are more likely to have solid components or stranding.

Cardiac Tamponade.

Several echocardiographic findings are reliable indicators of elevated intrapericardial pressure, which in turn correlate with hemodynamic compromise or clinical tamponade. One of the earliest described was collapse of the right ventricular outflow tract during early diastole. This is best visualized in the parasternal views but can also be appreciated in the four-chamber view. The precise timing and duration of right ventricular collapse can best be determined with M-mode echocardiography. Cardiac tamponade occurs when pericardial effusion of sufficient magnitude has accumulated to result in equilibration of intrapericardial and passively determined intracardiac pressures. Immediately after mechanical systole the ventricle begins to relax, with a greater degree of active relaxation attributed to the left ventricle compared with the right. This results in disproportionate or favored filling of the left ventricle with a transient elevation in intrapericardial pressure. This results in early diastolic collapse of the highly compliant right ventricular outflow tract (Fig. 7-95) . Detection of transient outflow tract collapse is a reliable

Figure 7-93 Three-dimensional echocardiogram of a patient with a ventricular septal defect, transposition, and double outlet right ventricle. Note the small right ventricular cavity and the parallel orientation of the two great vessels.

Figure 7-94 Transthoracic parasternal long-axis echocardiograms recorded in a patient with a small *(top)* pericardial effusion. In the top panel note the echo-free space confined to the area posterior to the heart (arrow). The bottom panel reveals a similar pattern but with a larger echo-free space. Abbreviations are as per previous figures.

marker that intrapericardial pressure is elevated and hemodynamic compromise is present. It is correlated with the presence of overt tamponade but also has been seen in patients who subsequently developed tamponade. The atrial corollary of this phenomenon is exaggerated atrial emptying. Because of elevated intrapericardial pressures, filling of the right ventricle is impeded in early diastole (a manifestation of which is early diastolic right ventricular collapse) and occurs to an exaggerated degree with atrial systole. This results in a delayed and exaggerated contraction of the right atrium with actual invagination of the atrial wall in late diastole (Fig. 7-96) . This echocardiographic sign of hemodynamic compromise is more sensitive than right ventricular diastolic collapse but less specific, because it occurs earlier in the course of intrapericardial pressure elevation. Right ventricular collapse may be absent even in the presence of elevated pericardial pressures in patients with right ventricular hypertrophy or significant pulmonary hypertension. In the presence of loculated effusion or in complex situations, either right- or left-sided chambers may be differentially compressed.[199] [200]

Doppler echocardiography can provide valuable clues as to the hemodynamic significance of pericardial effusions as well.[201] In hemodynamically significant effusions there is an exaggerated interplay between right and left ventricular filling, occurring with phases of the respiratory cycle. Clinically, this is manifest as an exaggerated pulsus paradoxus. Echocardiographically exaggerated respiratory variation can be documented by examining the left ventricular and right ventricular outflow tract flows in systole and noting exaggerated phasic variation in velocities and time velocity ventricles. Similarly, in a hemodynamically significant effusion, ventricular filling is impeded. The normal respiratory variation of the tricuspid valve is 25 percent, with a greater velocity in inspiration than expiration; and the normal mitral valve shows the opposite pattern with a variation of approximately 15 percent. In hemodynamically significant effusions there is a greater than usual variation in this respiratory pattern (Fig. 7-97) .

CONSTRICTIVE PERICARDITIS.

Although chronic constrictive pericarditis remains an elusive diagnosis, echocardiography and Doppler evaluation can provide valuable clues as to its presence.[202] [203] [204] [204A] The classic form of constrictive pericarditis is calcific constrictive pericarditis after tuberculosis infection. In contemporary times, constriction

Figure 7-95 Parasternal short-axis echocardiogram recorded in a patient with a pericardial effusion and evidence of hemodynamic compromise. *A,* Recorded in diastole. Note the normal shape and geometry of the right ventricular wall (RVW). *B,* Recorded in systole. Note that the tricuspid and pulmonic valves are both closed and that the right ventricular outflow tract has normal geometry. *C,* Recorded in early diastole. Note the tricuspid valve is now open and that the distal portion of the right ventricular outflow tract is compressed inward. Abbreviations are as per previous figures. *(From Armstrong WF, Schilt BF, Helper DJ, et al: Diastolic collapse of the right ventricle with cardiac tamponade: An echocardiographic study. Circulation 65:1491-1496, 1982. Copyright 1982, American Heart Association.)*

is more likely to be related to nontuberculous infections or hemorrhagic effusions or be secondary to trauma, cardiac surgery, or irradiation. The clinical presentation and echocardiographic appearance often vary from that classically described with calcific constriction. Numerous attempts have been made to quantify pericardial thickness using echocardiography. Routine transthoracic imaging has not been an accurate means for detecting pericardial thickening. TEE has shown more promise but has not seen clinical acceptance. Intracardiac ultrasonography does provide a high-resolution view of the pericardium but is an invasive

Figure 7-96 Apical four-chamber view recorded in a patient with a moderate pericardial effusion and evidence of hemodynamic compromise. The frame is recorded in early ventricular systole, immediately after atrial contraction. Note that the right atrial wall is indented inward and its curvature is frankly reversed (arrow), implying elevated intrapericardial pressure above right atrial pressure. Abbreviations are as per previous figures.

Figure 7-97 Pulsed-wave spectral Doppler recorded through the left ventricular outflow tract *(top)* and right ventricular outflow tract *(bottom)* in a patient with hemodynamic compromise due to pericardial effusion. Note the respirometry line on the bottom of each tracing. There is exaggerated respiratory velocity of flow in both the left ventricular and right ventricular outflow tracts. Note the

reciprocal nature of the flow variation, with flow increasing during expiration and decreasing in early inspiration for the left ventricular outflow tract and the opposite pattern seen in the right ventricular outflow tract.

Figure 7-98 Pulsed Doppler recording through the mitral valve *(top)* and tricuspid *(bottom)* in a patient with constrictive pericarditis. Note the respirometer tracing for each. There is exaggerated respiratory variation in inflow velocities in both the mitral and tricuspid valves. Note also that the deceleration time is shorter with inspiration (150 msec) than with expiration in the mitral tracing. Reciprocal changes are noted in the tricuspid valve flow patterns. *(From Oh JK, Hatle LK, Seward JB, et al: Diagnostic role of Doppler echocardiography in constrictive pericarditis. J Am Coll Cardiol 23:154-162, 1994.)*

procedure and has been validated in only a small number of patients. Determination of pericardial thickening is probably more accurately done with computed tomography (CT) or MRI.

In the absence of direct ultrasound documentation of thickened pericardium there are indirect signs of pericardial constriction that should be evaluated in suspected cases. These include abnormalities of ventricular septal motion. The abnormalities of septal motion that occur are an exaggerated respiratory variation in septal position with marked bowing of the ventricular septum toward the left ventricle during inspiration. Additionally when viewed from the parasternal long-axis position an abnormality of septal motion is often detected. This frequently is seen as a downward motion of the ventricular septum in early systole, followed by a brief anterior motion, which can be confused with a conduction disturbance and is best detected with M-mode scanning.

The Doppler hallmarks of cardiac constriction include exaggerated respiratory variation of mitral and tricuspid inflows with a pathologically elevated E to A ratio (Fig. 7-98) . Additionally, deceleration time is abnormally short and may vary to a disproportionate degree during the respiratory cycle. Examination of the IVC frequently reveals dilation. The normal multiphasic hepatic vein flow is replaced by monophasic flow, occurring predominantly in systole.

The diagnosis of constrictive pericarditis in large part remains one of exclusion. From an echocardiographic standpoint this diagnosis should be suspected in individuals with symptoms consistent with that diagnosis (i.e., edema, fatigue, and apparent low output state), normal left ventricular systolic function, and no valvular heart disease. Detection of abnormal septal motion, exaggerated respiratory variation, and an elevated E to A ratio provide the majority of the confirmatory evidence of this diagnosis.

MISCELLANEOUS CONDITIONS OF THE PERICARDIUM.

Congenital absence of the pericardium occurs in both partial and complete forms. In the complete form there is a marked abnormality of septal motion with exaggerated intracardiac motion within the thorax. In the partial form, varying degrees of septal motion abnormality can be detected depending on the degree to which the pericardium is anatomically deficient. Pericardial cysts are detected as echo-free spaces adjacent to the heart. The diagnosis should probably be confirmed by CT or MRI as well.

CARDIOMYOPATHIES (See Chap. 48.)

Cardiomyopathies can be divided into three basic types: dilated cardiomyopathy of any etiology, hypertrophic cardiomyopathy, and restrictive cardiomyopathy.

DILATED CARDIOMYOPATHY.

Irrespective of the cause of a dilated cardiomyopathy, left ventricular dilation with global systolic dysfunction is noted (Fig. 7-99) .[205] Depending on the duration of the disease, left atrial dilation likewise occurs; and if significant mitral regurgitation is present, secondary pulmonary hypertension with right-sided heart dilation is common. The range of systolic dysfunction in dilated cardiomyopathy is quite broad, and ejection fraction ranges from less than 10 percent to only mildly diminished. Although dilated cardiomyopathy is a global process, because of regional wall stress and loading conditions regional heterogeneity of function is seen.[206] Typically, the proximal portions of the inferoposterior and posterolateral walls have relatively preserved systolic function whereas the more distal walls, the ventricular septum, and apex appear more severely compromised. This pattern of wall motion may initially be confused with ischemic heart disease. The absence of frank scar or aneurysm and the absence of any truly normally functioning segments should lead the observer to appropriately make a diagnosis of nonischemic cardiomyopathy. The echocardiographic appearance of nonischemic cardiomyopathy is not dependent on its etiology, and patients with alcoholic, doxorubicin (Adriamycin)-induced, idiopathic, and postviral causes will all have a similar echocardiographic appearance.

As a consequence of left ventricular dilation, the bullet-shaped geometry of the left ventricle is often distorted and the left ventricle becomes more spherical.[207] This has the effect of drawing the papillary muscles away from the mitral valve annulus and results in annular functional mitral regurgitation due to abnormal coaptation of the mitral valve (see Fig. 7-54). Mitral regurgitation severity may range from mild to severe; and, as a consequence, left atrial dilation to some degree is invariably present. Because of the diffuse nature of the initial insult, the right ventricle can be primarily affected with dilation and hypokinesis and also secondarily affected due to subsequent pulmonary hypertension. Other complications of dilated cardiomyopathy that should be evaluated include presence of left ventricular thrombus and, in certain circumstances, development of left atrial thrombi. Detection of the latter requires TEE. The magnitude of secondary and pulmonary hypertension can be reliably determined from Doppler tracings of the tricuspid valve. Evaluation of diastolic properties of the left ventricle may provide valuable prognostic information.[208] [209]

HYPERTROPHIC CARDIOMYOPATHY.

Hypertrophic cardiomyopathy comprises a heterogeneous disease in which there is inappropriate and pathological hypertrophy of the

Figure 7-99 Transthoracic two-dimensional echocardiogram recorded in a patient with a dilated cardiomyopathy. The left panel is an apical four-chamber view showing dilation of all four cardiac chambers. Note that the mitral valve protrudes into the left ventricular cavity during systole consistent with papillary muscle dysfunction (arrows). There is also incomplete closure of the tricuspid valve due to annular dilation. The two right panels were recorded in a short-axis view in diastole *(top)* and systole *(bottom)*. Note again the dilated right ventricle in the severe systole dysfunction with global hypokinesis of both chambers when diastolic and systolic frames are compared.

left ventricle and, less commonly, the right ventricle.[210] The classic form of hypertrophic cardiomyopathy has commonly been termed "idiopathic hypertrophic subaortic stenosis" [IHSS]. In this entity there is characteristic disproportionate hypertrophy of the ventricular septum with dynamic left ventricular outflow tract obstruction (Fig. 7-100) . Because hypertrophic cardiomyopathy is a heterogeneous disease the preferred terminology is hypertrophic cardiomyopathy, secondarily described as focal, concentric, apical, and with or without obstruction. Dynamic obstruction classically occurs in the left ventricular outflow tract. From an echocardiographic perspective it is associated with systolic anterior motion of the mitral valve. This results in development of a systolic gradient that develops in the left ventricular outflow tract over the course of systole (Fig. 7-101) .[211] [212] [213] Thus, the maximum gradient is in late systole as opposed to early or mid systole, which is characteristic of a fixed valvular or discrete obstruction. Systolic anterior motion of the mitral valve can be detected either with two-dimensional echocardiography, typically from the parasternal long-axis view, and also with M-mode echocardiography (Fig. 7-102) . Although Doppler echocardiography remains the definitive examination for detection and quantification of outflow tract obstruction, secondary evidence of outflow tract obstruction can be obtained from the M-mode echocardiogram. Systolic anterior motion of the mitral valve that actually remains in contact with the septum for 40 percent of the systolic cycle is more likely to be associated with significant hemodynamic obstruction. Additionally, the outflow tract obstruction results in a characteristic systolic notching pattern on the aortic valve that is best visualized with M-mode echocardiography.

Mitral regurgitation is common in patients with obstructive hypertrophic cardiomyopathy, and the continuous wave of Doppler spectral profile of the mitral regurgitation may occasionally be confused with outflow tract obstruction. It should be kept in mind that the mitral regurgitation velocity will peak relatively early whereas the outflow tract obstruction has a characteristic late-peaking "dagger-like" appearance.

Other variants of hypertrophic cardiomyopathy include mid-cavity obstruction, in which case the maximum gradient is typically at the papillary muscle level. Other distributions of hypertrophy include nearly concentric left ventricular hypertrophy that may have no associated outflow tract obstruction. In this instance, patients can be highly symptomatic because of a relatively small left ventricular cavity with markedly elevated diastolic pressures.[214] Additionally, the small cavity, even with supernormal systolic functions, results in a low stroke volume and cardiac output. A final variant of hypertrophic cardiomyopathy is the apical variant, which is more

common in Asian populations.[215] Deep T wave inversions across the precordium are seen in this variant. By definition it is not obstructive.

Two-dimensional echocardiography and Doppler imaging can be used to follow the status of outflow tract gradients at rest or exercise and after either drug, surgical, or, more recently, transcutaneous ablative therapy.[216] A reduction in both the outflow tract gradient and the severity of mitral regurgitation can be documented after successful therapy. On occasion, patients present with what appears to be a "burned-out" hypertrophic cardiomyopathy. In this instance, unexplained pathological hypertrophy is present with a relatively normal-sized left ventricle that is diffusely hypokinetic. Frequently, systolic function has deteriorated to the point that there is no longer an outflow tract gradient. Any of the forms of hypertrophic cardiomyopathy can result in long-standing elevation of diastolic pressure and secondary pulmonary hypertension.

RESTRICTIVE AND INFILTRATIVE CARDIOMYOPATHY.

Restrictive cardiomyopathies are a family of diseases in which systolic function is relatively preserved until very

Figure 7-100 Parasternal long-axis views recorded in a patient with a hypertrophic cardiomyopathy. The top panel is diastole and the bottom panel is systole. (Note this image has been recorded in tissue harmonic imaging and therefore myocardial signatures and brightness are increased. No assumptions regarding tissue characterization should be made from a tissue harmonic image.) In the top panel note the marked thickening of the ventricular septum (white arrows), which measures approximately 3 cm in thickness. The posterior wall was only mildly hypertrophied. The bottom panel was recorded in systole, and systolic anterior motion of the mitral valve (arrow) is clearly seen.

late stages but ventricular myocardium is pathologically stiff, leading to chronic elevation of diastolic pressure. Symptoms result because of the elevated diastolic pressures. By definition, obstruction is not present, nor is there a primary cause for abnormal myocardial relaxation. The most common form of restrictive cardiomyopathy is the idiopathic restrictive cardiomyopathy in which both atria are dilated, wall thickness tends to be at the upper normal or mildly hypertrophied, systolic function is within normal limits or only mildly depressed, and there is Doppler evidence of abnormal ventricular relaxation. Typically, this is manifest as an elevated E to A ratio without exaggerated respiratory variation.

Other causes of restrictive physiology include infiltrative cardiomyopathies, the most common of which is cardiac amyloidosis. Other rarer etiologies include the glycogen storage diseases[217] and association with other systemic diseases.[218] Cardiac amyloidosis may present as either a primary or a secondary entity and is often associated with amyloid deposits in other organs. Amyloid deposition in the myocardium results in hypertrophy in the absence of hypertension and abnormal myocardial texture, which is noted as a bright "speckling" appearance (Fig. 7-103) .[219] Caution is advised when using second harmonic imaging because this type of instrumentation leads to the appearance of an abnormal myocardial signature as well. There is often evidence of diastolic dysfunction.[220] In the early phases a reduced E to A ratio with a flat deceleration slope is seen. Later, an elevated E to A ratio occurs, associated with a short deceleration time. This pattern has been associated with a worse prognosis. In advanced amyloid, virtually all cardiac structures, including valve leaflets, are involved. In late phases, systolic dysfunction is seen.

DISTINCTION OF RESTRICTIVE AND CONSTRICTIVE PHYSIOLOGY.

The distinction between constrictive pericarditis and a restrictive cardiomyopathy is often clinically problematic. Echocardiography can play several valuable roles in this clinical situation. The first is in the exclusion of primary valvular disease, left ventricular dysfunction, and pulmonary hypertension, which may have resulted in the clinical presentation. Typically, patients in whom this dilemma arises have preserved right and left ventricular

Figure 7-101 Continuous-wave Doppler recorded from the apex of the left ventricle with the interrogation being directed through the left ventricular outflow tract in a patient with an obstructive hypertrophic cardiomyopathy. Note the late peaking systolic gradient with a peak velocity of approximately 3.8 m/sec (corresponding to a peak pressure gradient of 58 mm Hg. Additionally (small arrow), there is evidence of presystolic forward flow in the left ventricular outflow tract, following atrial systole. This is consistent with a hypertrophied and noncompliant ventricle in which atrial contraction results in presystolic flow in the outflow tract.

Figure 7-102 M-mode echocardiogram recorded in the same patient depicted in Figure 7-100 . Note the markedly thickened ventricular septum. The mitral valve as seen directly below the ventricular septum and the E and A waves in diastole are noted. Note in systole there is anterior motion of the mitral valve (black/white arrow).

systolic function with signs and symptoms of biventricular heart failure. Other than detection of cardiac amyloid or patients in whom there are classic findings of constriction, the separation of these two entities relies heavily on Doppler echocardiography. In both cases the E to A ratio is elevated, but in constriction there is a greater than usual respiratory variation in inflow velocities.[221] [222] Deceleration time is short in both but varies to a greater degree in restrictive than in constrictive processes. Examination of pulmonary and hepatic vein flow can be helpful as well. In both instances vein flow is monophasic, but in restriction there is a greater degree of flow reversal in late diastole coincident with inspiration.[223] Newer techniques such as Doppler tissue imaging to interrogate the velocity of myocardial relaxation can also play a role.[224] Most patients with restrictive disease have delayed relaxation and delayed motion of the annulus compared with patients with constrictive pericarditis. The diagnosis of constrictive pericarditis and its separation from restrictive diseases remains problematic even in experienced hands, and many atypical cases of each process exist. Both processes can also coexist, and this combination is not uncommon after radiation therapy, in which there may be a constrictive component in the pericardium but a restrictive component to the right ventricle due to radiation injury.

ISCHEMIC HEART DISEASE (See Chaps. 35 , 36 , and 37 .)

BASIC PRINCIPLES.

Myocardial ischemia and infarction result in regional disturbances of ventricular contraction. After acute reduction in coronary flow, both diastolic[225] and systolic dysfunction occur. Normal systolic contraction consists of both myocardial thickening and inward motion of the endocardium (see Figs. 7-3 and 7-5) . Immediately after the onset of ischemia, myocardial thickening ceases and, depending on the size of the anatomical area and the severity of ischemia, the wall can become frankly dyskinetic (Figs. 7-104 and 7-105) . If blood flow is not restored, myocardial necrosis results and the wall motion abnormality becomes fixed. Over a period of approximately 6 weeks, actual tissue loss occurs and there is replacement by fibrous tissue and a scar forms.

MYOCARDIAL INFARCTION.

As noted earlier, myocardial necrosis, once established, results in a permanent wall motion abnormality. The degree of transmural involvement required before wall motion becomes abnormal is approximately 20 percent.[226] The implication of this is that non-Q-wave myocardial infarction will result in hypokinesis or akinesis of the wall even though the majority of the myocardial mass may still be perfused and viable. A tethering effect of nontransmural infarction or ischemia results in dysfunction of the entire wall thickness. Because the balance of the myocardium is intrinsically normal, it is capable of overriding this effect during either pharmacological stimulation or stress, therefore resulting in substantial cardiovascular reserve in segments that may be akinetic at rest. The regional wall motion score is directly related to the size of the myocardial infarction; however, because of the tethering phenomenon, wall motion abnormalities overestimate the true anatomical extent.

Tethering occurs in several different forms. The most common occurs in substantial size myocardial infarction where the infarcted area may be frankly dyskinetic. During systole the dyskinetic segment drags the normal myocardium outward. Thus, this normal myocardium, which intrinsically has the capacity to contract, is tethered to the abnormal myocardium and is functionally abnormal. The opposite phenomenon can occur in relatively small infarctions where, during cardiovascular stress, the normal healthy adjacent myocardium contracts more vigorously and drags the abnormal segment with it, thus masking the

Figure 7-103 Two-dimensional echocardiogram recorded in a patient with cardiac amyloid. In both the parasternal long-axis view *(top)* and short-axis view *(bottom)* note the homogeneous echo intensity of the myocardium. Both the mitral and aortic valves are also thickened. In real time the myocardium takes on a speckled appearance.

wall motion abnormality. A final form of tethering is "vertical" tethering in which ischemic or infarcted subendocardial layers exert a disproportion of effect on overall myocardial contractility. Because only 20 percent of the myocardium needs to be involved in the ischemic or infarction process for the entire wall to become dysfunctional, nontransmural (non-Q-wave myocardial infarction) results in a wall motion abnormality that is indistinguishable from that of transmural infarction.

Depending on the location and size of the necrotic area, ventricular remodeling will also occur. Remodeling takes several forms and ranges from formation of a frank aneurysm (Fig. 7-106) to progressive left ventricular dilation. Echocardiographically, an aneurysm is defined as a noncontracting area of myocardium with abnormal geometry in both diastole and systole.

In clinical echocardiography a regional wall motion abnormality, conforming to a known coronary distribution, is the hallmark of acute ischemia or myocardial infarction. Detection of a wall motion abnormality with echocardiography can be a valuable adjunct in the diagnosis of ischemia in patients who are presenting with chest pain. After successful reperfusion, wall motion abnormalities typically will resolve. The time course over which the resolve occurs is variable and may range from 12 hours to 2 weeks. Typically, wall motion abnormalities recover within 72 hours if blood flow has been restored in a timely fashion.[227]

At the time of presentation with acute myocardial infarction there are several echocardiographic findings that relate to patient prognosis. As with all imaging techniques, the greater the degree of left ventricular dysfunction, the greater the likelihood of complications such as development of heart failure and death.[228] [229] The size of the myocardial infarction can be approximated with echocardiography by calculating a wall motion score or by calculation of an ejection fraction. Both of these values can be tracked over time to determine the status of recovery. Evaluation of the mitral valve inflow with Doppler echocardiography provides valuable prognostic information as well.[230] [231] Because myocardial ischemia causes immediate diastolic abnormalities, mitral valve inflow patterns become abnormal

Figure 7-104 Transthoracic echocardiogram recorded in a patient with an acute anterior septal myocardial infarction in a parasternal long-axis view. Note the dyskinesis of the anterior septum (upward arrows) when diastolic *(top)* and systolic *(bottom)* frames are compared. Downward arrow indicates normal septum movement.

Figure 7-105 Two-dimensional echocardiogram recorded in a patient with an inferior myocardial infarction complicated by right ventricular infarction. The two left panels are parasternal short-axis views recorded at the level of the papillary muscles. The top left panel is recorded in diastole. Note the full-thickness myocardium and the circular geometry of the left ventricle. In systole *(bottom panel)* the inferior wall (arrows) becomes frankly dyskinetic and fails to show normal systolic thickening whereas the remaining walls thickened appropriately and moved inward. The right panel is an apical four-chamber view demonstrating a dilated right ventricle that is globally hypokinetic in real time. This is consistent with right ventricular involvement.

early in the course of myocardial infarction. One may anticipate an abnormal (typically reduced) E to A ratio in myocardial ischemia. With more substantial areas of ischemia and greater degrees of diastolic dysfunction, an increased E to A ratio, suggesting restrictive physiology, may be seen. The latter is of more ominous prognostic significance.

COMPLICATIONS OF MYOCARDIAL INFARCTION.

Table 7-3 outlines the complications of myocardial infarction

Figure 7-106 Apical two-chamber view of a patient with an inferior myocardial infarction. The proximal third of the inferior wall is thin, with distorted geometry consistent with a basilar aneurysm. The right panel was recorded in systole, and this area can be seen to bulge further compared with the remaining ventricular walls, which contract normally. Abbreviations are as per previous figures.

Figure 7-107 Apical four-chamber views recorded in two different patients with anterior infarct and left ventricular thrombus. The top panel denotes a large laminar thrombus filling a substantial portion of the apex and adherent to the ventricular septum (arrows). The bottom panel denotes a smaller, more spherical thrombus in the apex of the patient with a more limited apical myocardial infarction (arrows). Abbreviations are as per previous figures.

that can be reliably detected using two-dimensional echocardiography. Virtually all mechanical complications are accurately identified.

Left ventricular thrombi may form in the first 24 hours after myocardial infarction and are most commonly seen in anterior infarctions with large areas of apical dyskinesis.[232] [233] They are far less common in inferior wall myocardial infarction. Thrombi can present either as laminar, pedunculated, or mobile masses (Fig. 7-107) . There is a substantially greater likelihood of subsequent embolization in mobile and pedunculated thrombi than in sessile and laminar thrombi.

Infarct expansion is defined as progressive dilation of the infarct zone without recurrent myocardial necrosis.[234] [235] This can occur either acutely, after myocardial infarction, in which case it can be confused with reinfarction, or more chronically over the first 3 to 6 months. When infarct expansion occurs acutely it is seen in the substrate of necrotic and highly friable myocardium. Acute infarct expansion presents as an aneurysm appearing in the first 72 hours, is the anatomical precursor of free wall rupture and ventricular septal defect, and carries a grave prognosis. Chronic infarct expansion occurs over several months, and the likelihood of mechanical complications is low. It does result in tethering of normal walls and progressive chamber dilation with reduction in overall systolic performance. It has been linked to development of both arrhythmias and progressive congestive heart failure.

Pericardial effusion occurs in approximately 40 percent of patients with transmural myocardial infarction. It is often asymptomatic and detected only with echocardiographic scanning. A pericardial effusion occurring in the presence of acute infarct expansion is far more worrisome and may be one of the earlier signs of partial myocardial rupture.

MYOCARDIAL RUPTURE.

The myocardium can rupture in one of three locations. In each case, infarct expansion usually precedes rupture. Free wall rupture complicates approximately 3 percent of acute myocardial infarction and is usually not a survivable event. Clinically, these patients present with recurrent pain and rapidly develop pericardial effusion and tamponade, and death results. In rare instances, echocardiography has been used to document the presence of free wall rupture and allow emergency corrective surgery.[236] A pseudoaneurysm forms when a partial rupture spontaneously seals off, resulting in an extra cardiac chamber the walls of which consist of pericardium and thrombus. It typically connects to the left ventricle with a narrow mouth, distinguishing it from a true aneurysm, which communicates with the left ventricular cavity by way of a wide opening.[237] [238]

Rupture of either a papillary muscle or the ventricular septum results in signs and symptoms of heart failure and a prominent holosystolic murmur, owing to acute mitral regurgitation or ventricular septal defect ((Figs. 7-108). Two-dimensional echocardiography is a highly accurate technique for separating the two entities.[239] [240] Because of the critically ill nature of these individuals, many of them are intubated and TEE may be necessary to establish a diagnosis. Once the diagnosis is established, the degree of mechanical disruption can be determined. Additionally, echocardiography can be used to assess left and right

TABLE 7-3 -- COMPLICATIONS OF MYOCARDIAL INFARCTION DETECTED BY ECHOCARDIOGRAPHY

ventricular function. Both of these are critical components of risk assessment when planning surgical intervention. Ventricular septal defect with concurrent right ventricular dysfunction carries a substantially greater mortality and morbidity.

RIGHT VENTRICULAR INFARCTION.

Some degree of right ventricular dysfunction accompanies a large proportion of patients with inferior infarction due to occlusion of the proximal right coronary artery. Both systolic and diastolic dysfunction occur, and variable degrees of tricuspid regurgitation are common. Depending on which right ventricular branches are involved, the right ventricular wall motion or abnormality can be either apical or more laterally located. Frequently, all that is noted is right ventricular dilation with fairly uniform hypokinesis of the right ventricle.[241] In many instances, right ventricular ischemia is a transient phenomenon and recovery is anticipated. An additional complication of right ventricular infarction is the opening of a patent foramen ovale with subsequent right-to-left shunting. Shunts of significant size can result in arterial oxygen desaturation. The presence of a right-to-left shunt can be reliably documented with saline contrast echocardiography.

In patients with severe multivessel disease, an ischemic cardiomyopathy can develop. This term refers to diffuse global left ventricular systolic dysfunction as a consequence of severe, multivessel coronary artery disease. In many instances there have been multiple unrecognized acute myocardial infarctions. This type of cardiomyopathy presents as a nearly globally hypokinetic ventricle, often with patchy areas of wall thinning but without distinct aneurysm. Secondary mitral regurgitation is common and is due to papillary muscle dysfunction and dilation of the mitral valve annulus.

MYOCARDIAL STUNNING AND HIBERNATION.

There are two phenomena that result in potentially reversible myocardial dysfunction.[242] [243] [244] The first of these is myocardial stunning, which occurs after a severe acute ischemic insult. In this scenario, flow is restored and there is no myocardial necrosis. The exact physiological causes of myocardial stunning are not fully understood, but the syndrome results in spontaneous recovery of myocardial function after restitution of blood flow. Typically, myocardial function recovers in 1 to 7 days. Echocardiography can be used to track recovery of function in this syndrome, and dobutamine stress echocardiography is an excellent means of predicting viability.

Myocardial hibernation is a similar phenomenon seen in a chronic situation.[245] [246] In this situation there is no identifiable recent acute event but diffuse myocardial dysfunction is seen in the presence of normal or near-normal resting blood flow. In many instances what has been termed "myocardial hibernation" may actually represent repetitive stunning. In this scenario, functional recovery of the myocardium occurs after successful revascularization. As in stunning, dobutamine stress echocardiography is an excellent means for detecting hibernating myocardium.

STRESS ECHOCARDIOGRAPHY.

Stress echocardiography is a family of examinations in which two-dimensional echocardiographic monitoring is undertaken before, during, and after cardiovascular stress. It has been shown to be a cost-effective means for evaluating patients presenting with chest pain. The form of cardiovascular stress can include exercise with treadmill[247] [248] [249] [250] [251] [252] [252A] or bicycle ergometry.[253] [254] [255] [256] By evaluating wall motion at rest and then comparing myocardial performance at stress, one obtains indicators of inducible ischemia that can be assigned to specific coronary territory (Figs. 7-18 and 7-109) . Although treadmill exercise is often more familiar to patients, it is limited by the need to image only at rest and after exercise. It is not possible to successfully image an upright walking individual. Bicycle exercise provides the opportunity to image at each sequential stage of stress, and therefore peak exercise images are available.

For patients incapable of physical exercise, pharmacological stress, most commonly employing a dobutamine infusion, can be used.[251] [257] [258] [259] [260] [261] [262] [262A] [262B] [262C] These protocols typically rely on an incremental infusion protocol of 10, 20, 30, and 40 mug/kg/min, augmented by atropine to obtain an adequate heart rate when necessary. Images can be obtained at each stage of dobutamine infusion. Patients with significant obstructive coronary disease develop regional wall motion abnormalities identical to those seen during physical stress. The safety record of dobutamine has been excellent,[262D] and its accuracy appears equivalent to that of exercise echocardiography. An alternative to dobutamine is dipyridamole infusion, which relies on provocation of ischemia by differential vasodilation in normal and descended arteries.[263] [264]

All of the different exercise echocardiography modalities have been validated against coronary arteriography as a standard and appear to have accuracy equivalent to the competing radionuclide procedures (Table 7-4) . In general, the sensitivity of thallium scintigraphy tends to be slightly higher than that of exercise echocardiography, whereas the specificity of exercise echocardiography typically has been higher than that of thallium. As with all other forms of cardiovascular stress, exercise echocardiography has distinct advantages and disadvantages. Even in experienced laboratories there may be a 5 percent failure rate due to suboptimal imaging and patients in whom adequate levels of cardiovascular stress have not been obtained will not have positive studies, even in the presence of coronary disease. The clinical utility and value of stress echocardiography has been specifically evaluated in female populations. In female populations it appears to be an effective clinical tool for diagnosis and prognosis, however with a slightly lower overall accuracy than seen in male patients.[265] [266]

In addition to the diagnosis of coronary disease, stress echocardiography has been used extensively for determining patient prognosis in general populations[267] [268] [269] [270] [270A] and after myocardial infarction[271] [272] [273] as well as in tracking results of percutaneous interventions.[274] It plays a major role in determining myocardial viability in suspected stunning or hibernation.[275] [276] [276A] [276B] [276C] [276D] [276E] [276F] Dobutamine stress echocardiography has seen substantial success in determining preoperative risk assessment in patients undergoing noncardiac surgery. Its accuracy for predicting cardiac events of myocardial infarction and death before major vascular surgery exceeds that of competing thallium scintigraphic techniques.[277]

MYOCARDIAL CONTRAST ECHOCARDIOGRAPHY.

This technique relies on use of newly developed contrast agents.[278] [279] [280] [280A] These agents, once injected into the circulation, perfuse the myocardium in a manner parallel to red blood cells. This technique should be considered investigational and still in evolution at this point, but it has shown tremendous promise for detection of coronary stenosis. Multiple technologies are under development for detection of contrast medium within the myocardium, no one of which has been uniformly accepted.

Technologies to detect contrast in the myocardium have included routine gray scale imaging, power Doppler imaging,[280B] second harmonic imaging, and pulse inversion imaging, and numerous others are being developed. It may also be necessary to compare perfused and nonperfused frames by using the ultrasound instrument itself to destroy contrast in the myocardium, thereby allowing creation of baseline frames immediately adjacent to perfused frames ((Figs. 7-110). Demonstration of myocardial perfusion with contrast echocardiography has

Figure 7-109 Exercise echocardiogram recorded in a patient with a disease of the right coronary artery. The two left panels were recorded at rest and the two right panels immediately after treadmill exercise; the top panels show diastole and the bottom panels show systole. In each panel the arrows note the location of the inferior wall endocardium at end diastole. At rest there is appropriate thickening and inward motion of the inferior wall that can be seen to move inward through the body of the arrows. Immediately after exercise the proximal inferior wall (lower two arrows) becomes frankly dyskinetic and the mid and diastole portion of the inferior wall is akinetic. Note that there is no incursion of the endocardium into the previously placed arrows.

also been suggested as a means of detecting myocardial viability.

DIRECT VISUALIZATION OF CORONARY ARTERIES.

Using high-frequency transducers, it is possible to directly visualize the proximal portions of the left main and right coronary arteries (Fig. 7-111) .[281] [282] [283] [284] This can be done to identify their takeoff and to exclude anomalous origin of a coronary artery. With scrupulous attention to detail one can visually characterize the wall of the left main and proximal left interior descending coronary artery and detect areas of atherosclerotic involvement and calcification. Detection of calcification within the proximal left anterior descending

Figure 7-110 Transthoracic two-dimensional echocardiogram recorded after intravenous injection of a perfluorocarbon-based contrast agent. A fill-destruction technique has been used in which the ventricular myocardium can be seen to be opacified by the contrast agent in the left panel. After sequential ultrasound pulses contrast medium is destroyed; the nonenhanced frame appears on the right. There is homogeneous opacification of the entire ventricular myocardium in this normal example.

coronary artery appears to be a potentially reliable marker that significant obstructive coronary artery disease is present. Proximal coronary artery aneurysms can also be detected in children with Kawasaki disease.[285] Either from the transesophageal or transthoracic approach it is also possible to place a Doppler sample volume in the coronary artery lumen and to quantify phasic flow in the coronary artery.[286] [287] It is also possible to use Doppler echocardiography to determine the velocity of flow in the coronary sinus. This can be done both under basal conditions and after vasodilation.

DISEASES OF THE AORTA (See Chap. 40.)

Transthoracic echocardiography visualizes the proximal 3 to 5 cm of the ascending aorta and portions of the descending thoracic aorta behind the left atrium from parasternal positions. In the majority of patients a substantial portion of the aortic arch can be visualized from the suprasternal transducer position. The sensitivity for detecting aortic disease is relatively poor from the transthoracic approach. If disease of the aorta is suspected, TEE is necessary. TEE provides a high-resolution view of the ascending aorta and descending thoracic aorta as far as the gastroesophageal junction but does not visualize the abdominal aorta. Additionally, there is a very limited area of the aortic arch that may be suboptimally viewed. In many centers, TEE has become the preferred and standard examination for evaluation of patients with suspected aortic disease.

AORTIC DISSECTION.

Acute aortic dissection is a life-threatening disease requiring emergent surgical intervention. TTE can be used for early screening and is valuable for detecting the presence of aortic dilation, secondary aortic insufficiency, and left ventricular function. Its accuracy for actual detection of the aortic dissection flap and determining its extent is not adequate as a stand-alone technique. TEE has proven to be a highly accurate and reliable technique for diagnosing and excluding aortic dissection, determining its extent, identification of communication points, and assessment of the severity of aortic insufficiency, and obviously determining complications such as rupture and adventitial hematoma. The accuracy for detection of acute aortic dissection is equivalent to that of CT and MRI (Table 7-5) .[288] [289] [290] [291] [292] [293] [294] [295] [296] [297] [298]

Aortic dissection is classified by several schemes, all of which are designed to distinguish dissection of ascending aorta from that confined to the descending thoracic aorta. A dissection flap appears as a linear echo within the lumen of the aorta (Fig. 7-112) . In patients with connective tissue disease and relatively nonatherosclerotic aortas, the intimal flap is frequently highly mobile. It may take a spiral course as it courses through the descending thoracic aorta. More chronic dissections appear as a linear echo dividing the aorta into two or more lumens. In this instance the intimal flap may appear more rigid and less mobile than in the acute setting. In acute dissection of the ascending aorta,

Figure 7-111 Transthoracic echocardiogram of the left coronary artery. The left main (LM), left anterior descending (LAD), and a proximal portion of the circumflex (CX) coronary artery are clearly visualized.

dilation of the ascending aorta is seen in virtually all instances. Other echocardiographic findings of acute aortic dissection include presence of pleural effusion and of

adventitial hematoma, which appears as a homogeneous echo-dense mass outside the wall of the aorta tracking along its course.

Specific cardiac features to be noted in aortic dissection include the presence or absence of pericardial effusion and of aortic insufficiency. Aortic insufficiency can be due either to annular dilation with abnormal coaptation, direct extension of the dissection into the annulus, disrupting the support for the aortic valve, or, less commonly, prolapse of a portion of the intimal flap through the aorta, resulting in a conduit for insufficiency.[298A]

AORTIC ANEURYSM.

Aneurysm of the ascending aorta, arch, and descending thoracic aorta can be diagnosed and characterized with TEE.[298] Characteristics of the aneurysm as fusiform or discrete and the extent of atherosclerotic involvement and secondary thrombus formation can all be determined. Because thoracic aneurysm without dissection is a chronic process requiring serial evaluation, most centers rely more heavily on CT or MRI for elective follow-up of chronic thoracic aortic aneurysms.

ATHEROSCLEROTIC DISEASE.

The transesophageal echocardiogram is an excellent tool for determining the extent and nature of atherosclerotic involvement of the thoracic aorta (Fig. 7-113) . Atherosclerotic disease can be characterized as focal or diffuse and further characterized as mild, moderate, and severe. Complex and mobile components likewise can be noted and have relevance for embolic phenomena.[299] [300] [300A] [300B] [300C]

The phenomenon of intramural hematoma has recently received much attention.[301] [302] Intramural hematoma occurs in the setting of underlying atherosclerotic disease and results in spontaneous rupture and lysis in the medial layers

TABLE 7-5 -- ACCURACY OF TRANSESOPHAGEAL ECHOCARDIOGRAPHY FOR DETECTION OF AORTIC DISSECTION

AUTHOR	YEAR	NO. OF PATIENTS	WITH DISSECTION	SENSITIVITY	SPECIFICITY
Erbel, et al.[289]	1989	164	82	81/82 (99%)	80/82 (98%)

Ballal, et al.[292]	1991	61	34	33/34 (97%)	27/27 (100%)
Nienaber, et al.[293]	1993	110	44	43/44 (98%)	20/26 (77%)

Figure 7-112 Transesophageal echocardiogram recorded in a patient with an acute type A dissection of the aorta. The top panel is a longitudinal view of the ascending aorta. Note the dilation of the proximal aorta and the thin linear echo present in both in the lumen of the aorta, a portion of which prolapses through the aortic valve into the left ventricular outflow tract (arrows). The white arrowheads denote the actual margins of the aortic annulus. The bottom panel is recorded in a view orthogonal to the upper panel and reveals the external diameter of the aorta (black arrowheads) as well as the open three leaflet aortic valve (small white arrows). Within the actual orifice of the aortic valve is a portion of the dissection tear (large white arrow). Abbreviations are as per previous figures.

of the aorta. The syndrome of acute intramural hemorrhage is virtually identical to acute dissection from the standpoint of clinical presentation. Intramural hemorrhage may be a focal process resulting in local breakdown in the medial layers with ulcer formation or can result in creation of a dissection plane through the media. In this instance, rather than seeing a thin intimal flap due to classic dissection a heavily diseased atherosclerotic aorta is seen with a dissection plane through the diseased medial tissue.

MARFAN SYNDROME AND DISEASE OF THE PROXIMAL AORTA.

Marfan syndrome is a heritable disorder of connective tissue that results in abnormalities in the proximal aorta. The underlying pathology is cystic medial necrosis, which results in characteristic dilation of the proximal aorta, most prominent in the sinuses of Valsalva. There is secondary effacement of the sinotubular junction and dilation of the ascending aorta. Because the predominant area of dilation is in the proximal aorta, TTE often suffices for screening in these patients (Fig. 7-114) . Complications of the aortic process in Marfan syndrome include progressive dilation with secondary aortic insufficiency and development of aortic dissection. Echocardiography has seen tremendous success in the serial evaluation of these individuals and in the timing of elective surgery.[303] [304]

SINUS OF VALSALVA ANEURYSM.

In addition to the characteristic symmetrical dilation seen in Marfan syndrome, aneurysms can arise in the sinus of Valsalva. These range from relatively small and discrete to large "windsock" aneurysms that protrude into the right ventricular outflow tract.[305] [306] On occasion, rupture occurs, leading to a continuous shunt from the aorta into the downstream chamber. The most common site for a sinus of Valsalva aneurysm to rupture is into the right atrium or the right ventricular outflow tract. In this instance, remnants of the aneurysm can be seen prolapsing into the right ventricular outflow tract and high velocity turbulent flow is noted in the downstream chamber. Because of the rupture, coarse fluttering of the right coronary cusp of the aortic valve may be noted.

CARDIAC MASSES (See Chap. 49.)

CARDIAC TUMORS.

Echocardiography is the primary screening tool for patients with known or suspected intracardiac tumors.[307] [308] Cardiac tumors can be divided into those that are primary to the heart and those that are secondary or metastatic. They can be further divided into benign and malignant types.

ATRIAL MYXOMA.

The most common benign primary tumor of the heart is the atrial myxoma. Approximately 75 percent of atrial myxomas are isolated, pedunculated tumors in the left atrium attached to the area of the foramen ovale by a stalk (Fig. 7-115) . Less common locations include the right atrium, either ventricle, or pulmonary vein or vena cava. The classic left atrial myxoma is a smooth, relatively homogeneously echo-dense mass with substantial mobility.[309] It moves into the orifice of the mitral valve in diastole and prolapses back into the left atrium in systole. Depending on its size, it may result in functional obstruction of the mitral valve, thereby mimicking mitral stenosis. Concurrent mitral regurgitation is not uncommon. In the presence of a typical appearance of a myxoma, the diagnosis is virtually certain from an echocardiographic standpoint and no further evaluation may be necessary. Because of the tendency to cause obstruction of the mitral valve, secondary pulmonary hypertension can occur. Additionally, emboli from the surface of the myxoma are not uncommon.

OTHER PRIMARY CARDIAC TUMORS.

Cardiac lipomas are benign primary cardiac tumors with a broad range of appearance. They are most common in the body of the left ventricle and occasionally may be present as pedunculated masses.[310] Although unlikely to embolize, they can be associated with superimposed thrombus, which can embolize. Echocardiography is useful for identification of the mass but is unable to precisely identify it as lipomatous tissue. MRI has substantially succeeded in tissue characterization of these masses.

PAPILLOMA.

Benign papillomas occasionally occur on valvular structures. These appear as homogeneous, usually spherical masses, typically less than 1 cm in diameter. They may appear on the mitral valve chordae and occasionally

Figure 7-113 Transesophageal echocardiograms recorded in three different patients, visualizing the descending thoracic aorta. The upper left panel is recorded in a normal, disease-free aorta. Notice the circular geometry and the lack of any thickening or irregularity in the wall of the aorta. The top right panel was recorded in a patient with a large descending thoracic aortic aneurysm measuring approximately 6 cm in its greatest dimension. Note the substantial atherosclerosis present as well as the vague, smokelike echoes in the lumen of the aorta representing stagnant blood. There is also a lucency posterior to the wall representing spontaneous intramural hemorrhage. The lower two panels were recorded in a patient with moderately severe atherosclerotic disease of the thoracic aorta. The panel on the left was recorded in the transverse view of the aorta. Note the irregular contour of the lumen, which is due to atherosclerotic involvement of the wall. The panel on the right was recorded at the same level of the aorta but in a longitudinal projection. The upper pointing arrows denote the outer wall of the aorta. Note the irregularity in the aortic lumen and the protruding atheroma (arrows).

Figure 7-114 Transthoracic echocardiogram in a patient with Marfan syndrome. Note the marked dilation of the sinuses of proximal aorta (arrow).

on the aortic valve. As with other cardiac tumors, they have been associated with emboli. The main differential diagnosis is between benign papilloma and vegetation.

CARDIAC MALIGNANCIES.

The majority of cardiac malignancies represent metastatic disease, most commonly from breast, esophagus, or lung. Diffuse malignancy, such as lymphoma, can also involve the heart either primarily or secondarily. Metastatic disease of the heart is virtually always associated with pericardial involvement as well. The appearance of metastatic disease in the heart is typically of mobile echo-dense masses attached to the endothelium (Fig. 7-116) , although isolated intramural masses and diffuse myocardial invasion have also been noted.[311] [312]

There are several primary malignant tumors of the heart, including angiosarcoma and rhabdomyoma. Rhabdomyoma is more common in children. Cardiac malignancies are relatively rare occurrences and can appear in virtually any chamber. There is a greater prevalence of sarcoma and rhabdomyoma in the right atrium (Fig. 7-117) and right ventricle and involving the veins or great vessels than the actual body of the heart in adults.

INTRACARDIAC THROMBUS.

Thrombi can occur in any chamber of the heart but are most common in the left ventricular apex (see Fig. 7-107) after myocardial infarction

Figure 7-115 Transthoracic *(top)* and transesophageal *(bottom)* echocardiogram recorded in a patient with an atrial myxoma. Note the vague echo-dense mass and the transthoracic echocardiogram that is more clearly defined in the transesophageal echo. Additionally, a thin stalk connecting the mass to the atrial septum is seen in the transesophageal echocardiogram.

or in the setting of cardiomyopathy and in the left atrium in the setting of mitral stenosis or atrial fibrillation. Ventricular thrombi have been discussed previously.

Atrial thrombi appear as echo-dense masses within the body of the left atrium but more commonly in the left atrial appendage. The left atrial appendage has a fine muscular ridgelike network that can be confused with small thrombi. Because thrombi occur in the presence of stasis, frequently spontaneous contrast with "smokelike" echoes is seen in the left atrium and left atrial appendage as well.

SPECIFIC CLINICAL UTILIZATION OF ECHOCARDIOGRAPHY

The previous discussion represents an outline of the diagnostic capabilities of echocardiography. There are several specific clinical situations in which echocardiography can be used and which should be understood by the clinician. Table 7-6 outlines the role of different echocardiographic modalities in clinical problem solving.

EVALUATION OF DYSPNEA AND CONGESTIVE HEART FAILURE.

Two-dimensional echocardiography is recommended as an initial part of the evaluation in patients with known or suspected congestive heart failure.[312A] Evaluation of ventricular function can be undertaken, and determination of both primary and secondary valvular abnormalities can likewise be accurately assessed. Doppler echocardiography can play a valuable role with respect to determining diastolic function and establishing the diagnosis of diastolic heart failure. Heart failure with normal systolic function but abnormal diastolic relaxation comprises 30 to 40 percent of patients presenting with congestive heart failure. Because the therapy of this is distinctly different from that of systolic dysfunction, establishing the appropriate etiology and diagnosis is essential. This can be effectively done with the combination of two-dimensional echocardiography and Doppler echocardiography.

CARDIAC SOURCE OF EMBOLUS.

It has become increasingly recognized that many neurological events and large artery occlusions are the result of embolization from the heart or other major vascular structures. Identifying which patients are most likely to have a cardiac source of embolus has been problematic, but, in general, any patient with abrupt occlusion of a major vessel or younger individual with a neurological event (typically younger than 45 years of age) should be suspected of having a potential cardiac etiology. Additionally, older individuals with neurological events but who do not have identifiable vascular disease require screening for a cardiac etiology. Several large-scale surveillance studies have demonstrated prevalence and range of abnormalities associated with neurological and embolic events.[313] [314] [315] One of the more common abnormalities to identify in this situation is a patent foramen ovale with or without a right-to-left shunt identified by contrast echocardiography (see Fig. 7-83) . TEE is often required for

Figure 7-116 Transesophageal echocardiogram recorded in a long-axis view of the left atrium and left ventricle in a patient with an intracardiac tumor. Note the approximate 1 cm diameter spherical mass attached to the posterior wall of the left ventricle by a thin stalk (arrow).

Figure 7-117 Apical four-chamber view *(top)* and transesophageal echocardiogram *(bottom)* in a patient with a large right atrial mass. In the top panel the mass can be seen arising from the area of the inferior vena cava and essentially filling the right atrium. A similar appearance is seen in the transesophageal echocardiogram *(bottom)* where the mass appears adjacent to the atrial septum. Abbreviations are as per previous figures.

complete evaluation because TTE is not sufficient to exclude left atrial thrombus or evaluate the thoracic aorta for atherosclerotic degree. A potential cardiac source of embolus will be identified in many patients with neurological and other events, but the identification of such a lesion does not necessarily prove cause and effect. The degree to which atherosclerotic disease of the aorta and patent foramen ovale are causative rather than coexistent with other etiologies often remains unproven. In a substantial number of patients, highly mobile strands and areas of fibrosis may be noted on either the aortic or mitral valve. The clinical implication of these anomalies is unknown.

ATRIAL FIBRILLATION.

Echocardiography plays a crucial role in the evaluation of patients with atrial fibrillation.[316] [317] [318] [319] [320] [320A] [320B] Patients with atrial fibrillation should be characterized as having underlying heart disease or having a structurally normal heart, in which case a diagnosis of lone atrial fibrillation can be made. Determination of the underlying cardiac anatomy is essential for decision-making regarding likelihood of conversion to and maintenance of sinus rhythm and for determining the embolic potential and hence the need for long-term anticoagulation. In general, patients with normal cardiac anatomy are unlikely to sustain an embolic event and highly likely to revert to sinus rhythm and have sinus rhythm maintained. Conversely, patients with cardiomyopathy and severe mitral stenosis are less likely to be maintained in sinus rhythm and have a higher likelihood of embolic events. Thus, these individuals are candidates for long-term anticoagulation. TEE has also been proposed as a management tool in determining the timing for elective cardioversion. Immediately after electrical cardioversion there is an increased likelihood of embolization. Embolization in this setting arises either from

Figure 7-118 Transesophageal echocardiogram recorded in a patient with a recent neurological event. In the top panel there is vague echo mass, which in real time has a swirling smokelike appearance (downward pointing arrow). At a slightly different transducer position, the actual apex of the left atrial appendage can be seen to contain a filling defect consistent with thrombus, noted between the two vertically oriented arrows. Abbreviations are as per previous figures.

TABLE 7-6 -- CLINICAL UTILITY OF ECHOCARDIOGRAPHY

	2D	DOPPLER	CFD	CONTINUOUS WAVE	TEE	STRESS
Pericardial disease	1	2	3	4	4	N/A

Dyspnea evaluation	1	1	1	1	4	1

1 = Indicated and essential; 2 = often required--may add, informative; 3 = necessary in select instances for specific question; 4 = rarely necessary;

2D = two-dimensional; CFD = color flow Doppler; TEE = transesophageal echocardiography; N/A = not available.

From Armstrong WF: Echocardiography. In Kelly's Textbook of Medicine. 4th ed. Philadelphia, Lippincott-Raven, 2000.

a preexisting thrombus or from atrial stunning with subsequent thrombus formation (Fig. 7-118) . A strategy of TEE to exclude left atrial thrombus, followed immediately by cardioversion, has been proposed as an efficient means of restoring sinus rhythm without requiring long-term pre-cardioversion anticoagulation. After cardioversion, atrial stunning occurs and the likelihood of new thrombus formation is actually transiently enhanced. For this reason, anticoagulation is clinically indicated in virtually all patients immediately after cardioversion.

PULMONARY EMBOLUS (See also Chap. 52) .

Patients with pulmonary embolus often present with atypical symptoms. In this instance, TEE and TTE can provide valuable clinical information.[321] [322] In a patient presenting with a combination of chest pain and dyspnea, with or without evidence of venous stasis, detection of right-sided heart dilation and dysfunction and/or elevation of pulmonary artery pressures can be valuable clues to the nature of the underlying process. Direct visualization of large pulmonary emboli is occasionally possible from either TTE but more usually TEE.[323] Additionally, by using either technique, embolus in transit can be detected as a highly mobile serpiginous mass, typically entrapped in the tricuspid valve apparatus and less commonly spanning a patent foramen ovale. Detection of typical serpiginous mass in the right atrium identifies a patient at substantial risk for further embolization and is a clinical situation requiring emergent therapy (Fig. 7-119) .

PULMONARY HYPERTENSION (See also Chap. 53) .

Pulmonary hypertension represents an elusive diagnosis. Clinically, pulmonary hypertension can occur either as a primary phenomenon or secondary to a variety of either cardiac or pulmonary processes. The majority of patients with established pulmonary hypertension have identifiable abnormalities on echocardiography, including variable degrees of right ventricular enlargement and hypertrophy ((Figs. 7-120). [324] [325] As noted earlier, pulmonary artery pressures can be estimated from the velocity of the tricuspid regurgitation jet (see Fig. 7-29) . In patients with only mild elevation of pulmonary pressure, exercise echocardiography to track pulmonary artery pressures with stress can also be performed and provides valuable information regarding the presence of occult, exercise-induced pulmonary hypertension. Doppler echocardiography can also be used to follow pulmonary artery pressures with therapy.

FETAL ECHOCARDIOGRAPHY.

Because cardiac ultrasonography carries no risk to the pregnant women or fetus and is fully noninvasive it can be used to make the antepartum diagnosis of congenital heart disease.[326] This should be undertaken only by pediatric echocardiographers with appropriate experience in the technique. Many major intracardiac abnormalities can be detected at the end of the first trimester, and the majority of physiologically significant abnormalities can be detected in utero in the second trimester. This technique has seen substantial use in identifying fetuses with congenital heart defects who may warrant urgent transfer to a neonatal intensive care unit or an emergent intervention for life-threatening cardiac problems immediately after birth.

EVALUATION AND MONITORING OF INVASIVE AND INTERVENTIONAL PROCEDURES.

Two-dimensional echocardiography, often using TEE, has seen substantial success as a means of monitoring invasive procedures. This includes direct online monitoring of pericardiocentesis[327] and assistance in localization and placement of catheters for electro

Figure 7-120 Transthoracic echocardiogram recorded in a parasternal long- and short-axis view in a patient with severe pulmonary hypertension. Note the dilation and hypertrophy of the right ventricle and the abnormal geometry of the left ventricle in which the ventricular septum is concave toward the right ventricle.

Figure 7-119 Transesophageal echocardiogram recorded in a patient with pulmonary embolus, found to have "thromboembolism in transit." The top panel is recorded at 0 degrees. The dilated right atrium and right ventricle are obvious. Three highly mobile components of a long serpiginous thrombus can be seen in the right atrium (arrows). The bottom panel is recorded at 106 degrees and visualizes the right atrium. The serpiginous nature of the thrombus can be appreciated, and it is noted to coil on itself in the cavity of the right atrium. Abbreviations are as per previous figures.

physiological ablation as well as online monitoring of endomyocardial biopsy specimens.[328] [329] [330] Additionally, TEE is an instrumental component of transcatheter closure of atrial septal defects in the catheterization laboratory[330A] and often used in other procedures where a transatrial approach is necessary for therapy, such as mitral balloon valvotomy.[331] [332] [333]

GUIDELINES
USE OF ECHOCARDIOGRAPHY

Thomas H. Lee

Guidelines for the use of echocardiography were published by an ACC/AHA task force in 1997.[1] These guidelines focus on transthoracic and transesophageal echocardiography (TTE and TEE, respectively), with Doppler analysis; they do not address newer technologies such as three-dimensional echocardiography, intravascular ultrasound, or contrast medium-enhanced echocardiography. In the absence of randomized trials that explictly test the impact of diagnostic tests on outcomes, these guidelines are based on expert consensus and observational studies. Additional recommendations for use of echocardiography for specific issues related to valvular heart disease were developed by a later ACC/AHA task force focusing on valvular heart disease.[2] These recommendations are summarized in the Guidelines following Chapter 46 . Recommendations for the use of echocardiography in patients with suspected endocarditis are also described in the Guidelines following Chapter 47 .

The guidelines provide recommendations regarding the appropriateness of use of echocardiography in various clinical settings, using the standard three-class system of ACC/AHA guidelines. The guidelines specify situations in which echocardiography is considered unlikely to contribute information that improves the management of patients. They also address recommendations about the frequency with which Doppler echocardiography should be repeated for some clinical issues. In general, the guidelines discourage routine use of echocardiography for patients whose initial echocardiograms show minimal or mild abnormalities, unless there is a change in clinical signs or symptoms.

MURMURS AND VALVULAR HEART DISEASE

Echocardiography is a critical tool for the assessment of patients with cardiac murmurs in the setting of cardiorespiratory symptoms and in patients with possible structural heart disease (Table 7-G-1) . However, the guidelines emphasize that echocardiography is not a substitute for a careful cardiovascular examination, and they specify that this test is not appropriate in patients with murmurs that an experienced observer identifies as functional or innocent. Characteristics of such murmurs as identified in the guidelines are a systolic murmur of short duration, grade 1 or 2 intensity at the left sternal border, a systolic ejection pattern, a normal S_2 , no other abnormal sounds or murmurs, no evidence of ventricular hypertrophy or dilatation, no thrills, and the absence of an increase in intensity with the Valsalva maneuver.

For patients with known or suspected valvular stenosis, echocardiography is an appropriate test for assessing severity of valvular stenosis and ventricular dysfunction. This test is appropriate for evaluation of changes in symptoms or signs, and also in asymptomatic patients with severe valvular stenosis or with left ventricular dysfunction or hypertrophy (see Table 7-G-1) . In contrast, the guidelines discourage routine use of echocardiography for serial re-evaluations of patients with mild aortic or mitral stenosis whose functional status and clinical examination are unchanged.

Doppler echocardiography is also the test of choice to evaluate valvular regurgitation and assess the need for surgical intervention.

TABLE 7-7-G-1 -- ACC/AHA GUIDELINES FOR USE OF ECHOCARDIOGRAPHY

Indication	Class I	Class IIa	Class IIb	Class III
Evaluation of heart murmurs	1. A murmur in a patient with cardiorespiratory symptoms 2. A murmur in an asymptomatic patient if the clinical features indicate at least a moderate probability that the murmur is reflective of structural heart disease	1. A murmur in an asymptomatic patient in whom there is a low probability of heart disease but in whom the diagnosis of heart disease cannot be reasonably excluded by the standard cardiovascular clinical evaluation		1. In an adult, an asymptomatic heart murmur that has been identified by an experienced observer as functional or innocent
Valvular stenosis	1. Diagnosis; assessment of hemodynamic severity 2. Assessment of LV and RV size, function, and/or hemodynamics 3. Reevaluation of patients with known valvular stenosis with changing symptoms or signs 4. Assessment of changes in hemodynamic severity and ventricular compensation in patients with known valvular stenosis during pregnancy 5. Reevaluation of asymptomatic patients with severe stenosis	1. Assessment of the hemodynamic significance of mild to moderate valvular stenosis by stress Doppler echocardiography 2. Reevaluation of patients with mild to moderate aortic stenosis with LV dysfunction or hypertrophy even without clinical symptoms	1. Reevaluation of patients with mild to moderate aortic valvular stenosis with stable signs and symptoms	1. Routine reevaluation of asymptomatic adult patients with mild aortic stenosis having stable physical signs and normal LV size and function 2. Routine reevaluation of asymptomatic patients with mild to moderate mitral stenosis and stable physical signs

Native valvular regurgitation	1. Diagnosis; assessment of hemodynamic severity 2. Initial assessment and reevaluation (when indicated) of LV and RV size, function, and/or hemodynamics 3. Reevaluation of patients with mild to moderate valvular changing symptoms 4. Reevaluation of asymptomatic patients with severe regurgitation 5. Assessment of changes in hemodynamic severity and ventricular compensation in patients with known valvular regurgitation during pregnancy 6. Reevaluation of patients with mild to moderate regurgitation with ventricular dilation without clinical symptoms 7. Assessment of the effects of medical therapy on the severity of regurgitation and ventricular compensation and function		1. Reevaluation of patients with mild to moderate mitral regurgitation without chamber dilation and without clinical symptoms 2. Reevaluation of patients with moderate aortic regurgitation without chamber dilation and without clinical symptoms	1. Routine reevaluation in asymptomatic patients with mild valvular regurgitation having stable physical signs and normal LV size and function
Mitral valve prolapse (MVP)	1. Diagnosis; assessment of hemodynamic severity, leaflet morphology, and/or ventricular compensation in patients with physical signs MVP	1. To exclude MVP in patients who have been diagnosed but without clinical evidence to support the diagnosis 2. To exclude MVP in patients with first-degree relatives with known myxomatous valve disease 3. Risk stratification in patients with physical signs of MVP or known MVP		1. Exclusion of MVP in patients with ill-defined symptoms in the absence of a constellation of clinical symptoms or physical findings suggestive of MVP or a positive family history 2. Routine repetition of echocardiography in patients with MVP with no or mild regurgitation and no changes in clinical signs or symptoms
Interventions for valvular heart disease and prosthetic valves	1. Assessment of the timing of valvular intervention based on ventricular compensation, function, and/or severity of primary and secondary lesions 2. Selection of alternative therapies for mitral valve disease (such as balloon valvuloplasty, operative valve repair, valve replacement)[*] 3. Use of echocardiography (especially transesophageal) in performing interventional techniques (e.g., balloon valvotomy) for valvular disease 4. Postinterventional baseline studies for valve function (early) and ventricular remodeling (late) 5. Reevaluation of patients with valve replacement with changing clinical signs and symptoms; suspected prosthetic dysfunction (stenosis, regurgitation) or thrombosis[*]	1. Routine reevaluation study after baseline studies of patients with valve replacements with mild to moderate ventricular dysfunction without changing clinical signs or symptoms	1. Routine reevaluation at the time of increased failure rate of a bioprosthesis without clinical evidence of prosthetic dysfunction	1. Routine reevaluation of patients with valve replacements without suspicion of valvular dysfunction and unchanged clinical signs and symptoms 2. Patients whose clinical status precludes therapeutic interventions
Patients with chest pain	1. Diagnosis of underlying cardiac disease in patients with chest pain and clinical evidence of valvular, pericardial, or primary myocardial disease 2. Evaluation of chest pain in patients with suspected acute myocardial ischemia, when baseline ECG is nondiagnostic and when study can be obtained during pain or soon after its abatement 3. Evaluation of chest pain in patients with suspected aortic dissection 4. Chest pain in patients with severe hemodynamic instability			1. Evaluation of chest pain for which a noncardiac etiology is apparent 2. Diagnosis of chest in a patient with ECG changes diagnostic of myocardial ischemia/infarction
Diagnosis of acute myocardial ischemic syndromes	1. Diagnosis of suspected acute ischemia or infarction not evident by standard means 2. Measurement of baseline LV function 3. Patients with inferior myocardial infarction and bedside evidence suggesting possible RV infarction 4. Assessment of mechanical complications and mural thrombus (TEE is indicated when TTE studies are not diagnostic.)	1. Identification of location/severity of disease in patients with ongoing ischemia		1. Diagnosis of acute myocardial infarction already evident by standard means
Risk assessment, prognosis, and assessment of therapy in acute myocardial ischemic syndromes	1. Assessment of infarct size and/or extent of jeopardized myocardium 2. In-hospital assessment of ventricular function when the results are used to guide therapy 3. In-hospital or early postdischarge assessment of the presence/extent of inducible ischemia whenever baseline abnormalities are expected to compromise ECG interpretation	1. In-hospital or early postdischarge assessment of the presence/extent of inducible ischemia in the absence of baseline abnormalities expected to compromise ECG interpretation 2. Assessment of myocardial viability when required to define potential efficacy of revascularization 3. Reevaluation of ventricular function during recovery when results are used to guide therapy 4. Assessment of ventricular function after revascularization	1. Assessment of long term prognosis (2 years after acute myocardial infarction)	1. Routine reevaluation in the absence of any change in clinical status

Diagnosis and prognosis of chronic ischemic heart disease	1. Diagnosis of myocardial ischemia in symptomatic individuals 2. Assessment of global ventricular function at rest 3. Assessment of myocardial viability (hibernating myocardium) for planning revascularization 4. Assessment of functional significance of coronary lesions (if not already known) in planning percutaneous transluminal coronary angioplasty	None	1. Diagnosis of myocardial ischemia in selected patients with an intermediate or high pretest likelihood of coronary artery disease 2. Assessment of an asymptomatic patient with positive results from a screening treadmill test 3. Assessment of a global ventricular function with exercise	1. Screening of asymptomatic persons with a low likelihood of coronary artery disease 2. Routine periodic reassessment of stable patients for whom no change in therapy is contemplated 3. Routine substitution for treadmill exercise testing in patients for whom ECG analysis is expected to suffice
Assessment of interventions in chronic ischemic heart disease	1. Assessment of LV function when needed to guide institution and modification of drug therapy in patients with known or suspected LV dysfunction 2. Assessment for restenosis after revascularization in patients with atypical recurrent symptoms	1. Assessment of restenosis after revascularization in patients with typical recurrent symptoms		1. Routine assessment of asymptomatic patients after revascularization
Patients with dyspnea, edema, or cardiomyopathy	1. Assessment of LV size and function in patients with suspected cardiomyopathy or clinical diagnosis of heart failure* 2. Edema with clinical signs of elevated central venous pressure when a potential cardiac etiology is suspected or when central venous pressure cannot be estimated with confidence and clinical suspicion of heart disease is high* 3. Dyspnea with clinical signs of heart disease 4. Patients with unexplained hypotension, especially in the intensive care unit* 5. Patients exposed to cardiotoxic agents, to determine the advisability of additional or increased dosages 6. Reevaluation of LV function in patients with established cardiomyopathy when there has been a documented change in clinical status to guide medical therapy	None	1. Reevaluation of patients with established cardiomyopathy when there is no change in clinical status 2. Reevaluation of patients with edema when a potential cardiac cause has already been demonstrated	1. Evaluation of LV ejection fraction in patients with recent (contrast or radionuclide) angiographic determination of ejection fraction 2. Routine reevaluation in clinically stable patients in whom no change is contemplated 3. In patients with edema, normal venous pressure, and no evidence of heart disease
Pericardial disease	1. Patients with suspected pericardial disease, including effusion, constriction, or effusive-constrictive process 2. Patients with suspected bleeding in the pericardial space (e.g., trauma, perforation) 3. Follow-up study to evaluate recurrence of effusion or to diagnose early constriction. Repeat studies may be goal directed to answer a specific clinical question. 4. Pericardial friction rub developing in acute myocardial infarction accompanied by symptoms such as persistent pain, hypotension, and nausea	1. Follow-up studies to detect early signs of tamponade in the presence of large or rapidly accumulating effusions. A goal-directed study may be appropriate. 2. Echocardiographic guidance and monitoring of pericardiocentesis	1. Postsurgical pericardial disease, including postpericardiotomy syndrome, with potential for hemodynamic impairment 2. In the presence of a strong clinical suspicion and nondiagnostic TTE, TEE assessment of pericardial thickness to support a diagnosis of constrictive pericarditis	1. Routine follow-up of small pericardial effusion in clinically stable patients 2. Follow-up studies in patients with cancer or other terminal illness for whom management would not be influenced by echocardiographic findings 3. Assessment of pericardial thickness in patients without clinical evidence of constrictive pericarditis 4. Pericardial friction rub in early uncomplicated myocardial infarction or early postoperative period after cardiac surgery
Patients with cardiac masses and tumors	1. Evaluation of patients with clinical syndromes and events suggesting an underlying cardiac mass 2. Evaluation of patients with underlying cardiac disease known to predispose to mass formation for whom a therapeutic decision regarding surgery or anticoagulation will depend on the results of echocardiography 3. Follow-up or surveillance studies after surgical removal of masses known to have a high likelihood of recurrence (i.e., myxoma) 4. Patients with known primary malignancies when echocardiographic surveillance for cardiac involvement is part of the disease staging process		1. Screening persons with disease states likely to result in mass formation but for whom no clinical evidence for the mass exists	1. Patients for whom the results of echocardiography will have no impact on diagnosis or clinical decision making
Suspected thoracic aortic disease	TEE: 1. Aortic dissection 2. Aortic aneurysm 3. Aortic rupture 4. Degenerative or traumatic aortic disease with clinical atheroembolism 5. Follow-up of aortic dissection especially after surgical repair when complication or progression is suspected TTE: 1. Aortic aneurysm (especially for aortic root aneurysm) 2. Aortic root dilation in Marfan or other connective tissue syndromes 3. Follow-up of aortic dissection, especially after surgical repair without suspicion of complication or progression 4. First-degree relative of a patient with Marfan syndrome or other connective tissue disorder			

Pulmonary disease	1. Suspected pulmonary hypertension 2. Pulmonary emboli and suspected clots in the right atrium or ventricle or main pulmonary artery branches * 3. For distinguishing cardiac vs. noncardiac etiology of dyspnea in patients in whom all clinical and laboratory clues are ambiguous* 4. Follow-up of pulmonary artery pressures in patients with pulmonary hypertension to evaluate response to treatment 5. Lung disease with clinical suspicion of cardiac involvement (suspected cor pulmonale)	1. Measurement of exercise pulmonary artery pressure 2. Patients being considered for lung transplantation or other surgical procedure for advanced lung disease *		1. Lung disease without any clinical suspicion of cardiac involvement 2. Reevaluation studies of RV function in patients with chronic obstructive lung disease without a change in clinical status
Hypertension	1. When assessment of resting LV function, hypertrophy, or concentric remodeling is important in clinical decision making 2. Detection and assessment of functional significance of concomitant coronary artery disease (stress echocardiography) 3. Follow-up assessment of LV size and function in patients with LV dysfunction when there has been a documented change in clinical status or to guide medical therapy	1. Identification of LV diastolic filling abnormalities 2. Assessment of LV hypertrophy in a patient with borderline hypertension without LV hypertrophy on ECG to guide decision making regarding initiation of therapy. A limited goal-directed echocardiogram may be indicated for this purpose	1. Risk stratification for prognosis by determination of LV performance	1. Reevaluation to guide antihypertensive therapy based on LV mass regression 2. Reevaluation in asymptomatic patients to assess LV function
Patients with neurological events or other vascular occlusive events	1. Patients of any age with abrupt occlusion of a major peripheral or visceral artery 2. Younger patients (typically < 45 years) with cerebrovascular events 3. Older patients (typically > 45 years) with neurological events without evidence of cerebrovascular disease or other obvious cause 4. Patients for whom a clinical therapeutic decision (e.g., anticoagulation) will depend on the results of echocardiography	1. Patients with suspicion of embolic disease and with cerebrovascular disease of questionable significance	1. Patients with a neurological event and intrinsic cerebrovascular disease of a nature sufficient to cause the clinical event	1. Patients for whom the results of echocardiography will not impact a decision to institute anticoagulant therapy or otherwise alter the approach to diagnosis or treatment
Patients with arrhythmias and palpitations	1. Arrhythmias with clinical suspicion of structural heart disease 2. Arrhythmia in a patient with a family history of a genetically transmitted cardiac lesion associated with arrhythmia such as tuberous sclerosis, rhabdomyoma, or hypertrophic cardiomyopathy 3. Evaluation of patients as a component of the work-up before electrophysiological ablative procedures	1. Arrhythmia requiring treatment 2. TEE guidance of transseptal catheterization and catheter placement during ablative procedures	1. Arrhythmias commonly associated with, but without clinical evidence of, heart disease 2. Evaluation of patients who have undergone radiofrequency ablation in the absence of complications. (In centers with established ablation programs, a postprocedural echocardiogram may not be necessary.)	1. Palpitation without corresponding arrhythmia or other cardiac signs or symptoms 2. Isolated premature ventricular contractions for which there is no clinical suspicion of heart disease
Before cardioversion	1. Evaluation of patient for whom a decision concerning cardioversion will be impacted by knowledge of prognostic factors (e.g., LV function, coexistent mitral valve disease) TEE only: 1. Patients requiring urgent (not emergent) cardioversion for whom extended precardioversion anticoagulation is not desirable* 2. Patients who have had prior cardioembolic events thought to be related to intraatrial thrombus* 3. Patients for whom anticoagulation is contraindicated and for whom a decision about cardioversion will be influenced by TEE results* 4. Patients for whom intraatrial thrombus has been demonstrated in previous TEE*	1. Patients with atrial fibrillation of <48 hours' duration and other heart disease (TEE only)	1. Patients with atrial fibrillation of <48 hours' duration and no other heart disease (TEE only) 2. Patients with mitral valve disease or hypertrophic cardiomyopathy who have been on long-term anticoagulation at therapeutic levels before cardioversion (TEE only) 3. Patients undergoing cardioversion from atrial flutter	1. Patients requiring emergent cardioversion 2. Patients who have been on long-term anticoagulation at therapeutic levels and who do not have mitral valve disease or hypertrophic cardiomyopathy before cardioversion 3. Precardioversion evaluation of patients who have undergone previous TEE and with no clinical suspicion of a significant interval change
Patient with syncope	1. Syncope in a patient with clinically suspected heart disease 2. Periexertional syncope	1. Syncope in a patient in a high-risk occupation (e.g., pilot)	1. Syncope of occult etiology with no findings of heart disease on history or physical examination	1. Recurrent syncope in a patient in whom previous echocardiographic or other testing demonstrated a cause of syncope 2. Syncope in a patient for whom there is no clinical suspicion of heart disease 3. Classic neurogenic syncope
Screen for the presence of cardiovascular disease	1. Patients with a family history of genetically transmitted cardiovascular disease 2. Potential donors for cardiac transplantation 3. Patients with phenotypic features of Marfan syndrome or related connective tissue diseases 4. Baseline and reevaluations of patients undergoing chemotherapy with cardiotoxic agents		1. Patients with systemic disease that may affect the heart	1. The general population 2. Competitive athletes without clinical evidence of heart disease
Critically ill	1. The hemodynamically unstable patient 2. Suspected aortic dissection (TEE)			1. The hemodynamically stable patient not expected to have cardiac disease 2. Reevaluation follow-up studies on hemodynamically stable patients

Critically injured	1. Serious blunt or penetrating chest trauma (suspected pericardial effusion or tamponade) 2. Mechanically ventilated multiple-trauma or chest trauma patient 3. Suspected preexisting valvular or myocardial disease in the trauma patient 4. The hemodynamically unstable multiple-injury patient without obvious chest trauma but with a mechanism of injury suggesting potential cardiac or aortic injury (deceleration or crush) 5. Widening of the mediastinum, post injury suspected aortic injury (TEE) 6. Potential catheter, guidewire, pacer electrode, or pericardiocentesis needle injury with or without signs of tamponade	1. Evaluation of hemodynamics in multiple-trauma or chest trauma patients with pulmonary artery catheter monitoring and data disparate with clinical situation 2. Follow-up study on victims of serious blunt or penetrating trauma		1. Suspected myocardial contusion in the hemodynamically stable patient with a normal ECG
Adult patient with congenital heart disease	1. Patients with clinically suspected congenital heart disease, as evidenced by signs and symptoms such as murmur, cyanosis, or unexplained arterial desaturation, and an abnormal ECG or radiograph suggesting congenital heart disease 2. Patients with known congenital heart disease on follow-up when there is a change in clinical findings 3. Patients with known congenital heart disease for whom there is uncertainty as to the original diagnosis or when the precise nature of the structural abnormalities or hemodynamics is unclear 4. Periodic echocardiograms in patients with known congenital heart lesions and for whom ventricular function and atrioventricular valve regurgitation must be followed (e.g., patients with a functionally single ventricle after Fontan procedure, transposition of the great vessels after Mustard procedure, L-transposition and ventricular inversion and palliative shunts) 5. Patients with known congenital heart disease for whom following pulmonary artery pressure is important (e.g., patients with moderate or ventricular septal defects, atrial septal defects, single ventricle ,or any of the above with an additional risk factor for pulmonary hypertension). 6. Periodic echocardiography in patients with surgically repaired (or palliated) congenital heart disease with the following: change in clinical condition or clinical suspicion of residual defects, LV or RV function that must be followed, or when there is a possibility of hemodynamic progression or a history of pulmonary hypertension 7. To direct interventional catheter valvotomy, radiofrequency ablation valvotomy interventions in the presence of complex cardiac anatomy		1. A follow-up Doppler echocardiographic study, annually or once every 2 years, in patients with known hemodynamically significant congenital heart disease without evident change in clinical condition	1. Multiple repeat Doppler echocardiography in patients with repaired patent ductus arteriosus, atrial septal defect, ventricular septal defect, coarctation of the aorta, or bicuspid aortic valve without change in clinical condition 2. Repeat Doppler echocardiography in patients with known hemodynamically insignificant congenital heart lesions (e.g., small atrial septal defect, small ventricular septal defect) without a change in clinical condition

LV = left ventricular; RV = right ventricular; ECG = electrocardiographic/electrocardiogram; TEE = transesophageal echocardiography; TTE = transthoracic echocardiography.

From Cheitlin MD, Alpert JS, Armstrong WF, et al: ACC/AHA guidelines for the clinical application of echocardiography: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Clinical Application of Echocardiography). *TEE may provide incremental value in addition to information obtained by TTE. The role of TEE in first-line examination awaits further study

Exercise or pharmacological stress echocardiogram.

Dobutamine stress echocardiogram.

Because left ventricular dysfunction is such a critical issue in the natural history of such patients, this test is appropriate in asymptomatic patients with severe regurgitation, as well as those with changes in symptoms or signs. The ACC/AHA task force considered routine use of echocardiography inappropriate for patients with mild valvular regurgitation, stable physical signs, and normal left ventricular size and function and was uncertain about its appropriateness in asymptomatic patients with moderate valvular regurgitation without chamber dilation.

The guidelines emphasize that the physical examination is the optimal method of diagnosing mitral valve prolapse, in part because of the substantial possibility of false-positive results with echocardiography. Specifically discouraged is use of echocardiography to exclude mitral valve prolapse in patients with ill-defined symptoms but no other clinical evidence for this condition and also routine repetition of echocardiography in patients with mitral valve prolapse with no or mild regurgitation and no changes in clinical signs or symptoms.

Echocardiography is strongly supported in virtually all patients with known or suspected infective endocarditis. ACC/AHA guidelines on use of this procedure in patients in this setting are described in the Guidelines in Chapter 47 (see Table 47-G-6).

The ACC/AHA task force was supportive of use of echocardiography before and after operative interventions for valvular disease, but it was uncertain about the ideal interval for repeat evaluation in patients without changing clinical signs or symptoms or evidence of prosthetic valve dysfunction. The guidelines discouraged routine echocardiography in patients whose overall clinical status precludes therapeutic interventions. For patients with suspected infective endocarditis involving prosthetic valves, the guidelines acknowledge the potential incremental value of TEE compared with TTE.

ACUTE CHEST PAIN

Many cardiac conditions that cause chest pain are associated with structural abnormalities that can be detected with echocardiography, and evidence for a useful role for echocardiography in the management of these patients has grown. The ACC/AHA guidelines supported use of echocardiography to help diagnose or exclude acute myocardial ischemia when the baseline electrocardiogram is nondiagnostic and when the study can be obtained promptly. Echocardiography was also endorsed as a test for suspected aortic dissection and in patients with severe hemodynamic instability. This test was not, however, considered appropriate for routine use for diagnostic purposes in patients with a high likelihood of myocardial ischemia or infarction.

ISCHEMIC HEART DISEASE

TTE and TEE are useful tools for detection of regional wall motion abnormalities, assessing left ventricular dysfunction, and evaluating structural complications of acute myocardial infarction (e.g., acute mitral regurgitation, free wall rupture, ventricular septal defect, or intracardiac thrombus formation). The ACC/AHA task force considered early echocardiography most useful in patients with a high clinical suspicion of acute myocardial infarction but a nondiagnostic electrocardiogram. Similarly, stress echocardiography was supported when the clinical history and electrocardiogram are not reliable sources on which to base a diagnosis.

The ACC/AHA task force was less certain but generally supportive of the use of echocardiography for assessment of the location and severity of disease in patients with ongoing ischemia, or for assessment of myocardial viability when patients were candidates for coronary revascularization (Class IIa). Routine use of echocardiography in the absence of change in clinical status or when the test was unlikely to change diagnosis or management was discouraged (Class III).

For patients with chronic ischemic heart disease, echocardiography is supported as a valuable test for assessing global left ventricular function. Echocardiography was also endorsed by the ACC/AHA guidelines as an adjunct to exercise or pharmacological stress studies for diagnosis of coronary disease and assessment of its severity. However, the ACC/AHA guidelines were not supportive of use of echocardiography to screen asymptomatic patients with a low likelihood of coronary disease, or for routine periodic assessments in patients for whom no change in therapy was contemplated. The guidelines explicitly state that echocardiography should not be routinely substituted "for treadmill exercise testing in patients for whom ECG analysis is expected to suffice" (see Table 7-G-1) .

CARDIOMYOPATHY AND ASSESSMENT OF LEFT VENTRICULAR FUNCTION

Echocardiography is the ideal first test for assessment of global and regional left ventricular function, and thus it is a preferred initial diagnostic test for patients with symptoms such as edema and dyspnea or with unexplained hypotension. TEE is recommended when TTE studies are not diagnostic. Echocardiography was also considered useful by the ACC/AHA task force for assessment of left ventricular hypertrophy, restrictive cardiomyopathy, and heart failure due to diastolic dysfunction. The guidelines discourage use of echocardiography for routine evaluation of clinically stable patients in whom no change in management is contemplated and in patients with edema but normal venous pressures and no evidence of heart disease.

PERICARDIAL DISEASE

Echocardiography remains the procedure of choice for detection of pericardial effusion, and it is considered an appropriate test for diagnosis of other pericardial disease. Use of echocardiography is discouraged when the results are unlikely to change management. The guidelines also note that pericardiac friction rubs are common in early acute myocardial infarction and the early postoperative period after cardiac surgery, so that echocardiography is not routinely necessary. Echocardiographic assessment of pericardial thickness to assess the diagnosis of constrictive pericarditis is not supported by these guidelines, which note that more accurate assessments can be made by computed tomography or magnetic resonance imaging.

CARDIAC MASSES AND TUMORS

Echocardiography is also the first-line test for detection of cardiac masses and tumors. Examples of such patients are those with one or more embolic peripheral or neurological events or those with hemodynamic or auscultatory findings suggesting intermittent obstruction to intracardiac flow. Other candidates include those with malignancies with a high incidence of cardiovascular involvement, such as hypernephroma, metastatic melanoma, or malignancies of intrathoracic organs. The appropriateness of echocardiography for screening asymptomatic patients for intracardiac masses is uncertain.

DISEASES OF THE GREAT VESSELS

TTE provides good visualization of the aortic root and the proximal pulmonary vasculature, and it is sometimes able to detect abnormalities such as an intimal flap in patients with aortic dissection. However, TEE is a far more sensitive tool for evaluation of most conditions affecting the great vessels. Therefore, TEE is the test of choice for diagnosis of aortic dissection or rupture (see Table 7-G-1) . Because TTE is a less invasive and expensive procedure than TEE, it is recommended for follow-up of patients after repair of aortic dissection who do not have suspicion of complications or progression and of first-degree relatives of patients with Marfan syndrome or other connective tissue disorders.

PULMONARY DISEASE

Primary pulmonary disease often compromises the quality of TTE, but echocardiography can be an appropriate test for evaluation of the right ventricle and right-sided heart pressures that may be abnormal in conditions including pulmonary hypertension and pulmonary emboli. The ACC/AHA guidelines considered echocardiography an appropriate strategy for distinguishing cardiac versus noncardiac dyspnea when other clinical data were not sufficient for diagnosis. In contrast, echocardiography was not considered appropriate for patients with lung disease without any suspicion of cardiac involvement or for reevaluation of right ventricular function in patients with chronic obstructive lung disease without any change in clinical status.

SYSTEMIC HYPERTENSION

The ACC/AHA guidelines support use of echocardiography in patients with hypertension when the assessment of left ventricular function or hypertrophy is likely to influence management. An example of appropriate use of echocardiography would be for a patient with mild hypertension for whom the presence of left ventricular hypertrophy might lead to initiation of drug therapy. The guidelines explicitly state that

not every patient with hypertension should have a left ventricular function assessment and discourage serial echocardiograms to assess changes in left ventricular mass as patients are treated.

NEUROLOGICAL DISEASE AND OTHER CARDIOEMBOLIC DISEASE

The ACC/AHA guidelines considered echocardiography an appropriate test for patients with embolic events affecting any major peripheral or visceral artery. Echocardiography was considered clearly appropriate for any patient with a cerebrovascular event in the absence of evidence of cerebrovascular disease or other obvious causes. The appropriateness of echocardiography in patients with a neurological event and intrinsic cerebrovascular disease was less clear (Class IIb). Echocardiography was considered inappropriate (Class III) when the results would not influence management, such as in a patient for whom anticoagulation was absolutely contraindicated.

ARRHYTHMIAS AND PALPITATIONS

The ACC/AHA guidelines recognized that echocardiography can be an appropriate test in patients with arrhythmias and other signs or symptoms suggestive of

structural heart disease. However, the guidelines discourage use of echocardiography in most patients with palpitations or isolated ventricular premature complexes if they do not have other evidence for structural or arrhythmic cardiac disease. The guidelines supported use of echocardiography as an adjunct to some advanced electrophysiological procedures.

For patients undergoing cardioversion of atrial fibrillation, the guidelines support use of TEE in several settings. For example, TEE was considered appropriate for detection of intraatrial thrombus in patients requiring urgent cardioversion when extended precardioversion anticoagulation is not desirable and in patients who have had prior cardioembolic events or other evidence of intraatrial thrombus. The ACC/AHA task force was uncertain but generally supportive of TEE for patients with atrial fibrillation of less than 48 hours' duration in the presence of other heart disease (Class IIa). The guidelines were less supportive (Class IIb) of TEE when patients had acute onset of atrial fibrillation in the absence of other heart disease. Because echocardiography findings were unlikely to change management, the ACC/AHA guidelines discourage use of this test in patients undergoing emergent cardioversion and in patients on long-term anticoagulation without mitral valve disease or hypertrophic cardiomyopathy.

The ACC/AHA guidelines discouraged routine use of echocardiography for evaluation of classic neurogenic syncope or for patients in whom there was no suspicion of cardiac disease. This test was considered appropriate for patients who had clinical evidence of cardiac disease or periexertional syncope, and the guidelines were somewhat supportive of use of echocardiography in patients with syncope who were in high risk professions, such as airline pilots (Class IIa).

SCREENING

Echocardiography was considered an appropriate strategy for screening for cardiac disease when it was likely to change management or outcomes. Examples of indications in which echocardiography was considered appropriate for screening included families with a history of genetically transmitted cardiovascular disease, potential donors for heart transplantation, and serial evaluation of patients receiving potentially cardiotoxic chemotherapy.

CRITICALLY ILL PATIENTS

Echocardiography is often useful for establishing the diagnosis in hemodynamically unstable, critically ill patients. The ACC/AHA expert panel considered TEE to be superior to transthoracic echocardiography for:

- Hemodynamically unstable patients on a ventilator
- Patients who were unable to be positioned for adequate TTE after major trauma or surgery.
- Suspected aortic dissection or aortic injury.

ADULT PATIENTS WITH CONGENITAL HEART DISEASE

Echocardiography is useful for diagnosis of congenital heart disease in adults, as well as serial follow-up of ventricular function, intracardiac and other shunts, and other manifestations of disease. The guidelines discourage overuse of serial echocardiography in patients without changes in clinical conditions, especially if they have lesions known to be hemodynamically insignificant, such as small atrial or ventricular septal defects.

Chapter 8 - Radiology of the Heart and Great Vessels

ROBERT M. STEINER

HISTORICAL PERSPECTIVE

Cardiac imaging is almost as old as radiology itself. Within 1 year of Roentgen's discovery, Francis H. Williams of Boston reported, "I found that the outline of the heart as seen...through the fluoroscope corresponds to the outline drawn on the skin with percussion as a guide." Williams was a true pioneer. He concluded that radiography was the best method for determining heart size based on a comparison of radiographic findings, digital percussion, and autopsy specimens in 546 patients.[1] [2]

During the decades that followed, dramatic developments occurred in cardiac imaging technology. These innovations were highlighted by kymography in the 1920s, angiocardiography in the early 1930s, and image intensification in 1952.[3] Since that time, a number of new modalities, including radioisotope scanning, echocardiography, computed tomography (CT), and magnetic resonance imaging (MRI), have revolutionized cardiac imaging. These new technologies permitted anatomically detailed examination of the heart and great vessels not possible with plain film techniques. In spite of these advances, the plain chest radiograph continues to provide unique and valuable information about the structure and function of the heart and thoracic vessels. The chest radiograph, used to screen patients upon entering the hospital or as part of a routine evaluation of cardiopulmonary and other disorders, presents an opportunity to identify subtle or overlooked cardiac pathology such as significant vascular calcification, chamber enlargement, and evidence of pulmonary arterial or venous hypertension. Adult-onset congenital heart disease, which may be overlooked clinically, can be identified by plain film chest radiography.[4]

In recent years, the bedside portable chest roentgenogram has gained special importance in the evaluation and monitoring of patients with cardiac disease in the intensive care unit (ICU), including postoperative cardiac patients and others with implanted cardiovascular devices.[5] [6] [7] [8] [9] [10] This chapter discusses the role of plain film chest radiology with an emphasis on cardiovascular anatomy and alterations of that anatomy in a variety of pathological disorders. Correlation with cross-sectional imaging is used to clarify important anatomical questions.

NORMAL CARDIAC ANATOMY

Plain Chest Radiography

The normal chest radiograph provides excellent contrast between the air-filled lung and the adjacent soft tissue and osseous structures. As a result, the pulmonary arteries and veins and the interlobar fissures are visualized in great detail. For this reason, the posteroanterior (PA) erect chest film remains the study of first choice for the evaluation of pulmonary parenchymal and vascular disease. On the other hand, the heart and other mediastinal structures appear as a featureless, opaque silhouette. Blood, myocardium, pericardium, coronary arteries and great vessels, valves, and mediastinal fat cannot be identified because they have similar radiographic attenuation characteristics, so there is little or no contrast available to differentiate these structures. However, the cardiac borders are clearly outlined, and deviation from the normal cardiac configuration does suggest disease. To take full advantage of the chest radiograph to study the cardiovascular system, it is necessary to interrogate the following structures: (1) the heart and its individual chambers; (2) the pulmonary veins and arteries, which reflect the physiological pressure and volume state of the cardiovascular system; (3) the mediastinum to evaluate the size and location of the aorta and major systemic veins; and (4) extracardiac abnormalities that may be associated with cardiac disease.[9] It is important to appreciate that an abnormal cardiac border may also be due to a nonvascular abnormality such as a pericardial cyst or tumor, a thymoma or lymphoma, and/or other solid or cystic masses that may alter the cardiac border.

Frontal View (Fig. 8-1)

In a well-positioned PA or frontal chest radiograph, the normal cardiac and other vascular structures are predictably outlined against the lung as a series of indentations and bulges along the right and left mediastinal borders.

THE LEFT MEDIASTINAL BORDER.

The left subclavian artery is the border-forming structure along the upper left portion of the mediastinum above the aortic arch. Although the left innominate vein is actually lateral to the left subclavian artery, it is adjacent to the anterior chest wall, and thus no contrast is available in the frontal view to identify the left innominate vein as a separate structure. The left subclavian artery, which extends from the clavicle to the aortic arch, usually forms a concave border with the lung. The left subclavian artery border will bulge laterally when blood flow through the vessel is increased, as in postductal coarctation of the aorta, or when the left subclavian artery is tortuous because of atherosclerosis or hypertension. A vertical or a smooth convex left supraaortic border is found in patients with persistent left superior vena cava (Fig. 8-2) .

THE AORTIC ARCH.

The normal aortic arch or "knob" forms a sharply marginated convex border immediately below the left subclavian artery. It is usually small in young patients, with a diameter of 2.0 ± 1.0 cm, and represents the left posterolateral portion of the aortic arch. The trachea is displaced slightly to the right at the level of the aortic

Figure 8-1 Frontal projection of the heart and great vessels. *A*, Left and right heart borders in the frontal projection. *B*, A line drawing in the frontal projection demonstrates the relationship of the cardiac valves, rings, and sulci to the mediastinal borders. *C*, Electron beam contrast-enhanced CT demonstrates cardiac anatomy relationships in cross section. A=ascending aorta; AZ=azygos vein; B=right and left bronchi; DA=descending aorta; LA=left atrial appendage; LV=left ventricle; PA=main pulmonary artery; RA=right atrium; RV=right ventricle; S=superior vena cava.

arch. When a right aortic arch is present, the trachea is displaced slightly to the left, a clear indication of that anomaly. A small bump or "nipple" measuring about 2 to 3 mm in diameter that represents the left superior intercostal vein can be seen along the aortic arch in 4 to 10 percent of individuals.[11] When enlarged, the left superior

intercostal vein has the same significance as a dilated azygos vein; i.e., enlargement is due to increased central venous pressure or increased blood flow caused by diversion of blood flow from other major venous structures, as may occur in superior vena cava syndrome, inferior vena cava obstruction, or deep mediastinal venous obstruction[11] (Fig. 8-3) . The vertical interface between the left lung and the normal descending aorta is clearly demonstrated in a well-penetrated PA chest radiograph. A left pleural effusion, atelectasis, pneumonia, or other causes of increased lung opacity adjacent to the descending aorta may obliterate this border. Focal obliteration of the descending aortic interface may also occur normally as a result of adjacent pulmonary arteries, veins, or mediastinal fat.[12]

The aortic arch is especially prominent on the frontal view in older individuals with pronounced aortic regurgitation, systemic hypertension, or atherosclerosis (Fig. 8-4) . It is wider and higher than the normal aortic arch and may even reach the level of the clavicle. The ascending aorta protrudes further to the right side than in normal patients, and the descending aorta assumes a tortuous or serpentine configuration. The brachiocephalic vessels also dilate and become tortuous. At times, a dilated right brachiocephalic artery may mimic the appearance of a substernal thyroid or other superior mediastinal mass and require CT or MRI for diagnosis. One in 1500 adult patients has a right-sided aortic arch that is usually associated with an aberrant left subclavian artery. When no aortic knob is visible on the left side and the trachea is displaced to the left, the presence of an aortic knob or arch on the right side of the mediastinum should suggest the diagnosis of right aortic arch[4] [13] (Fig. 8-5) .

The left mediastinal border immediately below the aortic arch is characterized by a variably sized indentation of the lung into the mediastinum. This indentation is termed the *aorticopulmonary window* (see Fig. 8-1) . It is bordered superiorly by the inferior margin of the aortic arch and inferiorly by the upper margin of the left pulmonary artery. This small space contains several important anatomical structures, including the left recurrent laryngeal nerve, the ligamentum or ductus arteriosus, and the ductus node. Enlargement of the ductus node or a ductus diverticulum may cause a convex bulge in the normally concave mediastinal reflection of the aorticopulmonary window. Encroachment on the recurrent laryngeal nerve within the aorticopulmonary window by a neoplasm, a ductus diverticulum, or an enlarged lymph node or by extrinsic pressure on the left recurrent laryngeal nerve from aortic dilation or a large left atrium can cause paralysis of the left vocal cord.

MAIN PULMONARY ARTERY (Fig. 8-6) .

The origin of the left main pulmonary artery is located immediately below the aorticopulmonary window and is border-forming with the left lung. It is identified as a small to moderate-sized, smoothly marginated arc at the level where the left pulmonary artery branches. Another indication of the location of the main pulmonary artery is the position of the left main stem bronchus. The left pulmonary artery arches over the left main stem bronchus, unlike the right pulmonary artery, which is located between the right upper lobe and right middle lobe bronchus. When enlarged, the normally slightly convex main pulmonary artery will form a prominent outward bulge. Enlargement of the main pulmonary artery is caused by increased flow, as in patients with anemia or a left-to-right shunt, by turbulent blood flow, as in pulmonary valvular stenosis, or by increased pressure related to Eisenmenger physiology or other causes of pulmonary hypertension. Finally, a large main pulmonary artery may be found in disorders of vascular wall collagen such as Marfan syndrome or "idiopathic pulmonary artery dilatation." On the other hand, the main pulmonary artery border may be flat or not seen at all in patients with transposition of the great vessels, truncus arteriosus, tetralogy of Fallot, or pulmonary atresia.[4]

THE LEFT ATRIAL BORDER (Fig. 8-7) .

The left atrial appendage or auricle lies immediately below the left main stem bronchus in the frontal projection. This structure normally forms a smooth and slightly concave segment of the left heart border. When the left atrial border is straightened or bulges laterally, atrial enlargement should be suspected. Nonvascular pathology may simulate enlargement of the left atrial appendage. For example, a pericardial fibroma or cyst, lymphoma, thymoma or other mediastinal or pleural neoplasms may appear to be a convexity of the left atrial border. Congenital absence of the pericardium also causes bulging of the left atrial appendage. An important sign of

left atrial enlargement in the frontal projection is elevation of the main stem bronchus so that the carinal angle is greater than the normal value of up to 75 degrees.

THE LEFT VENTRICULAR BORDER (see Fig. 8-1) .

The left ventricular border blends seamlessly with the left atrial border without a specific landmark to differentiate between the two chambers. The left ventricular border is mildly convex as it extends to the diaphragm. It may be rounded and the apex elevated if the left ventricle is hypertrophic as a result of aortic stenosis or cardiomyopathy (Fig. 8-8 *A*). When the left ventricle is enlarged because of dilatation, as may occur with aortic regurgitation or aneurysm, the apex is displaced downward and laterally. Much of the downward (Fig. 8-8 *B*) displacement of the apex may be obscured by the overlying left diaphragmatic dome or by extracardiac fat.

Figure 8-2 Persistent left superior vena cava (LSVC). *A*, Posteroanterior chest film in a man with a normally functioning intravenous cardiac pacemaker. The arrowhead indicates the pacemaker lead in the persistent LSVC. *B*, Left subclavian venogram illustrating the course of the LSVC: subclavian vein (single vertical arrow), the LSVC (two arrows), and the coronary sinus (three arrows).

When the left ventricle dilates because of volume overload as in mitral regurgitation, the dimensions of the chamber increase markedly and the heart assumes a globular appearance. The left ventricular border extends to the left and may reach the lateral rib convexities (see Fig. 8-7 *C*). As the left ventricle enlarges, the left atrial border is obscured. In such circumstances, the left anterior oblique (LAO) projection is helpful to separate the two chambers so that their relative sizes can be discerned. The ability to separate the left heart chambers assumes importance when the differential diagnosis lies between ischemic cardiomyopathy (in which case the left ventricle is larger than the left atrium) and mitral regurgitation (in which case the left atrium may be larger than the left ventricle).

THE RIGHT MEDIASTINAL BORDER (Fig. 8-9) .

The right atrial border forms a gentle convex interface with the adjacent

Figure 8-3 Left superior intercostal vein (LSIV). A small nipple or bulge is visible on the aortic knob. The LSIV normally measures 2 to 3 mm in diameter. Enlargement may be due to deep venous obstruction. *A*, Magnified posteroanterior projection in a young woman. LSIV is a beaklike bulge that extends to the left at the aortic knob (arrow). *B*, Contrast-enhanced CT shows the relationship of the left superior intercostal vein (V) to the aortic arch (A).

Figure 8-4 *A*, Aortic enlargement in a 63-year-old man with longstanding systemic hypertension and aortic regurgitation. Marked dilation and uncoiling of the arc and descending aorta can be noted. *B* and *C*, Aortic dissection in an 81-year-old woman along with marked dilation, calcification (arrows), and elongation of the arch and descending aorta. *D*, CT shows a descending aortic flap between the contrast-filled true lumen (Ao) and the thrombus-filled false lumen (FL). *E*, Sagittal reconstruction vividly demonstrates the multiple false and true lumina of the descending aorta (desc A). RPA=right pulmonary artery.

right middle lobe. In the frontal projection, the superior vena cava border above the right atrium is usually straight, and in a good inspiratory film it can be clearly separated from the right atrial convexity. The outline of the normal left atrium may be visible deep to the right atrial border as an additional convex shadow. The confluence of the right pulmonary veins is directed toward the midpoint of the left atrial border. The left atrium is clearly visualized within the right atrial shadow because of intrusion of lung between the posterior portion of the left atrium and the more anterior part of the right atrium (see Fig. 8-7 *D*). If the left atrium is markedly enlarged, the left atrial border may actually be lateral to the right atrium. The borders of the right and left atria can be differentiated because the inferior border of the right atrium blends with the inferior vena cava while the left atrial shadow crosses the midline toward the left side of the heart (see Fig. 8-7 *A*). The upper right atrial convexity blends superiorly with the superior vena cava, which forms a straight border with the adjacent lung as it continues toward the neck. The right atrial border is considered enlarged when it bulges more than 5.5 cm to the right of the midline.[14]

RIGHT VENTRICLE (Fig. 8-10) .

Unlike the right atrium, the right ventricle is not border-forming in the frontal projection and cannot be directly visualized. However, as the right ventricle dilates, the left ventricle is displaced posteriorly and to the left and the right atrium is displaced to the right, which causes widening of the cardiac shadow. In cardiac anomalies such as tetralogy of Fallot, the enlarged right ventricle displaces the left ventricle laterally and superiorly and thereby creates a high, round left ventricular border.[4]

THE ASCENDING AORTIC BORDER (see Fig. 8-8) .

The ascending aorta is superimposed on the superior vena cava and forms a convex border above the right atrium (see Fig. 8-1 *A*). The aortic valve and annulus and the coronary arteries are not visible on plain films unless they are calcified since they lie deep to the edge of the mediastinum and their x-ray attenuation characteristics are similar to those of the rest of the heart.

AZYGOS VEIN (see Fig. 8-1) .

The azygos vein is an elliptical structure at the right tracheobronchial angle. It ascends in the right paravertebral sulcus and arches forward over the right main stem bronchus to enter the back of the superior vena cava. The azygos vein and its left-sided equivalent, the hemiazygos vein, receive intercostal veins and act as an important collateral pathway when the deep mediastinal veins are obstructed.[11] [15] Normally measuring 0.7 to 1.0 cm across in the erect and 1.0 to 1.3 cm in the supine anteroposterior (AP) position, the azygos vein is a good

Figure 8-5 Right aortic arch. *A*, Right aortic arch (RAo) in a patient with truncus arteriosus I. *B*, Frontal view of the chest in an adult female. The barium column is displaced to the left by the right aortic arch. The bulge on the left is due to the patulous origin of the aberrant left subclavian artery (the diverticulum of Kommerall) (arrow). *C*, Aortography shows the right aortic arch and aberrant left subclavian artery, with a proximal bulge representing the diverticulum of Kommerall (arrowhead).

indicator of changing cardiovascular dynamics. It is enlarged in superior vena cava and inferior vena cava obstruction, in the absence of the intrahepatic portion of the inferior vena cava, in portal vein obstruction, and in both left- and right-sided cardiac failure. A change in diameter of the azygos vein will parallel changes in pulmonary venous pressure, which makes it a useful guide to the development of congestive heart failure on plain film radiographs. An azygos fissure can be found in 3 percent of the population. When a fissure is present, the azygos vein is displaced laterally and superiorly and will dilate under the same conditions as a normally positioned azygos vein.[16]

Lateral View (see Fig. 8-10)

Proper positioning of the patient in the lateral projection is critical for accurate identification of cardiac structures. The need for accurate positioning is exemplified by the right atrium. The normal right atrium is not border-forming in this projection, but if the patient is rotated backward, the right atrium will form part of the lower posterior cardiac border and simulate enlargement. The right ventricle is border-forming in the subxiphoid region and usually extends superiorly to a point about one-third the distance between the diaphragm and the suprasternal notch. As the right ventricle dilates, it encroaches further on the retrosternal space.[17] The relationship between the size of the right ventricle and the extent of retrosternal encroachment is affected by the patient's body habitus and lung volume. For example, in a patient with emphysema, right ventricular enlargement may coexist with an expanded retrosternal space. In a patient with a small AP diameter and/or pectus excavatum deformity, the retrosternal space may be obliterated despite the absence of right ventricular enlargement (Fig. 8-11 *A* and *B*). CT and MRI, as well as echocardiography, unlike the lateral chest film, portray relationships of the right ventricle to nearby structures with great accuracy and permit a clear analysis of right ventricular volume and function[17] [18] [19] [20] [21] (Fig. 8-11 *C*).

The anterior margin of the main pulmonary artery and the ascending aorta lie above the right ventricle; however, because of abundant mediastinal fat, neither structure is visualized clearly in the lateral view in a normal patient. In patients with severe emphysema, however, the increased lung volume permits the main pulmonary artery

Figure 8-6 The pulmonary artery contour. *A*, Normal pulmonary segment (arrow) in a 36-year-old woman with sickle cell anemia and moderate cardiomegaly. *B*, The pulmonary arteries are grossly enlarged in this patient with primary pulmonary hypertension (arrowheads). *C*, A posteroanterior radiograph shows engorged pulmonary arteries (white arrows) from a patient with AIDS and pulmonary arterial hypertension. *D*, Axial CT in the same patient shows a large main pulmonary artery (PA). Ao=ascending aorta, DA=descending aorta. *E*, The pulmonary artery contour is small in this 16-year-old with tetralogy of Fallot and pulmonary infundibular stenosis (arrowhead).

and the ascending aorta to be well outlined. The arch of the aorta is usually clearly outlined in normal patients, except where the superior vena cava crosses the aorta and where the brachiocephalic arteries enter the aorta. The inferior margin of the posterior aortic arch is often visible because of intrusion of lung into the aorticopulmonary window. The semilunar lucency of the aorticopulmonary window also outlines the superior margin of the left pulmonary artery. The descending aorta is not usually discernible in a normal individual because it lies adjacent to the spine and the posterior mediastinal fat. However, in patients with hyperaeration or those with a tortuous or calcified aorta, the descending aorta is better seen.

LEFT ATRIUM.

The normal *left atrium* forms a shallow convex bulge at the upper aspect of the posterior border of the heart on the lateral view. It may be easily identified because the posterior border of the left atrium lies immediately anterior to the pulmonary venous confluence (see Fig. 8-10) .

LEFT VENTRICLE.

The normal *left ventricle* forms a long convexity at the posteroinferior heart border just above the diaphragm. Enlargement of the left ventricle is suggested by use of the Hoffman-Rigler sign, a measurement determined by drawing a 2.0-cm vertical line upward along the inferior vena cava from the point where the posterior wall of the left ventricle and inferior vena cava cross in the lateral projection. At this point, a second line is drawn parallel to the vertebral bodies. The distance between the left ventricular border and the vertical line should not exceed 1.8 cm. If it does, left ventricular enlargement is suggested. Although this sign is helpful, it is far from accurate because poor positioning of the patient for a lateral chest film or backward displacement of the left ventricle because of right ventricular enlargement may adversely influence this measurement.[22]

ESOPHAGUS.

The *esophagus* lies immediately behind the left atrium and, when filled with contrast medium, can be used to locate the posterior border of the left atrial chamber. Normally, the left atrium does not displace the esophagus, but when the left atrium is enlarged, posterior displacement of the esophagus from the area of the left main stem bronchus to the level of the left ventricle will occur. The normal left ventricle does not usually displace the esophagus, but rather it overlaps or lies posterior and lateral to it. When both the left atrium and left ventricle are enlarged, the barium-filled esophagus may be pushed backward in one long curve (Fig. 8-12) . Sometimes, the left atrium enlarges without displacing the barium-filled esophagus because the esophagus may slide off the back of the left atrium to the left or right. When the aorta is tortuous and dilated or when scoliosis is present, the esophagus parallels the spinal curvature and cannot be used to evaluate left atrial size.

The Right Anterior Oblique Projection (Fig. 8-13)

Chest radiography in the right anterior oblique (RAO) projection is performed with the patient in a 45-degree oblique

Figure 8-7 Prominent left atrial contour. *A*, The left atrial appendage bulges laterally in this patient with multivalvular rheumatic heart disease (arrow). The double convex contour of enlarged right (curved arrow) and left (straight arrow) atria is visualized along the right atrial border (arrow). *B*, A 40-year-old woman with mitral stenosis, left atrial enlargement, and a double right-sided heart border (white arrow=right atrium; black arrow=left atrial border). The left main stem bronchus is elevated (black arrow). *C*, Giant left atrium. A wide convex bulge is seen in the area of the left atrial appendage (white arrow). The left atrium is grossly enlarged and is border-forming on the right side overlying the smaller right atrium. The inferior border of the left atrium (black arrow) extends back toward the midline. If this were the right atrial border instead, it would have blended imperceptibly with the right hemidiaphram and inferior vena cava. *D*, Enhanced CT demonstrates the anatomical relationship between the anterior of the right atrium (RA) and the posterior of the left atrium (LA). The indentation of lung and fat between the atria (arrow) permits separation of the right-sided borders of both atria as seen in the posteroanterior chest radiograph.

relationship to the film cassette (right shoulder toward the cassette). In this view, the ventricles are elongated; the long axes of the ventricles are in view and the atrioventricular groove is in profile. This position permits optimal visualization of a calcified mitral or tricuspid valve. The RAO view is used by angiographers to determine the presence of left atrial enlargement, a common feature in mitral stenosis or regurgitation. The aortic arch is foreshortened in the RAO projection, so the arch and proximal descending aorta are often superimposed and obscured. The anterior border of the heart in the RAO projection consists of the sinus portion of the right ventricle inferiorly and the right ventricular outflow tract and the main pulmonary artery superiorly.[17] The right-sided or posterior heart border is made up of the right atrium superiorly and the left atrium inferiorly.

The Left Anterior Oblique Projection (Fig. 8-14)

The LAO projection is performed with the patient in a 60-degree oblique relationship to the cassette. This view is useful for diagnosing the presence of left ventricular enlargement. Since the ventricular septum is in profile in this projection, septal defects and abnormalities of right and left ventricular function can be identified with angiography. In this projection, the aortic and pulmonary valves are in profile, so aortic valve calcifications can be clearly visualized and aortic or pulmonary stenosis and regurgitation can be assessed. The aortic arch is also in profile in the LAO projection, so that abnormalities of the arch, including dissection, contained rupture, aortitis, aneurysm, and coarctation, can be detected with aortography or by cross-sectional imaging.[23] [24] [25] [26] The anterior (right) heart border consists of the right atrium above and right ventricle below. Along the left posterior heart border, the left atrium is border-forming superiorly and the left ventricle is border-forming inferiorly. The LAO projection is superior to other projections for detecting right ventricular enlargement, which is usually characterized by an increase in the convexity of the anterior border of the cardiac silhouette. An enlarged right atrium may cause bulging of the right upper anterior border of the cardiac shadow and produce a typical shelflike configuration.

Cardiac Fluoroscopy

In the past, cardiac fluoroscopy was performed routinely to study cardiac motion and identify cardiac and other mediastinal calcifications. Today, it is seldom performed routinely but instead used to answer specific clinical questions.[27] Because fluoroscopy potentially poses a significant radiation risk to the patient, it should be used selectively, with careful beam collimation. Exposure time should be kept to a minimum, preferably for no more than 5 minutes. Perhaps the most important applications of fluoroscopy today are to identify pacemaker lead fractures; detect coronary artery, valvular, and neoplastic or pericardial calcifications; and evaluate prosthetic valve function in selected patients with older implanted valves.[28] [29] [30]

Cardiac fluoroscopy is usually performed with the patient in the upright position at 68 to 75 kVp to enhance contrast and reduce quantum mottle. The patient's position is determined by the structure to be studied. For example, if the presence or absence of aortic valve calcification is to be determined, positioning in the LAO projection is optimal. If mitral calcification is suspected, the RAO projection is most suitable. Coronary calcifications are best studied in the LAO and RAO projections. In the 60-degree LAO projection, the right coronary, left circumflex, and left main

Figure 8-8 Aortic valve disease. *A*, The left ventricular border is round and prominent as a result of left ventricular hypertrophy. The proximal ascending aorta is prominent because of poststenotic dilation (arrow) in this patient with aortic stenosis. *B*, Aortic regurgitation in a patient with Marfan syndrome. A prominent left ventricular border can be seen. The left ventricular chamber is dilated from regurgitant flow, and the ascending aorta (white arrows) is convex and enlarged (black arrows). *C*, Aortography in the left anterior oblique projection shows marked enlargement of the ascending aorta (Ao) with severe regurgitant flow in a patient with annuloaortic ectasia and Marfan syndrome. LV=left ventricle. *D*, Axial CT shows marked dilation of the ascending aorta (Ao) in a patient with Marfan syndrome.

coronary arteries are seen to advantage. In the lateral and RAO projections, left anterior descending artery calcifications are easily discernible.[30]

Although large deposits of calcium may be seen on the chest film, small calcifications are often obscured because of motion. On the other hand, motion is an advantage with fluoroscopy, and even small coronary artery calcifications are seen clearly as densely parallel tracks moving perpendicular to their long axes in a to-and-fro motion. The right main and circumflex coronary arteries move more vigorously than the anterior and posterior descending arteries do. Subepicardial fat represents an important landmark for the identification of vascular and valvular anatomy and is best seen with fluoroscopy. Fat surrounding the coronary arteries and within the atrioventricular groove is well visualized, so the location of the mitral and tricuspid valves, the coronary sinus, and the circumflex and right coronary arteries can be determined.

Fluoroscopy with videotape recording is useful to analyze the integrity of the radiopaque components of prosthetic valves. The results of fluoroscopic analysis of mechanical components of prosthetic valves compare favorably with echocardiography but do not yield useful information about the degree of valvular regurgitation as does Doppler echocardiography or MRI.[31]

MEASURING CARDIAC SIZE (Fig. 8-15)

Direct measurement of heart size by plain film radiographs has become practically obsolete inasmuch as more accurate analyses of cardiac chamber dimensions and volume are available with other methods. However, since an enlarged heart is abnormal, estimation of the cardiothoracic ratio remains a valuable yardstick to gain an impression of cardiac size and, in particular, serial changes in heart size coinciding with cardiac events. This assessment may be done subjectively by estimating whether a heart is normal in size, enlarged, or grossly enlarged on the basis of an average cardiothoracic ratio of 0.50.[32] [33] [34] Using more objective criteria, the cardiothoracic ratio may be expressed as the ratio between the maximum transverse diameter of the heart divided by the maximum width of the thorax. To obtain these measurements, a vertical line is drawn on the radiograph through the midpoint of the spine from the sternum to the diaphragm. The maximum transverse diameter of the heart is obtained by adding the widest distance of the right heart border from the midline and the left heart border to the midline. This value is then divided by the maximum transverse diameter of the thorax.[34] The normal range of the transverse diameter of the heart is 10 cm in a

Figure 8-9 *A*, Normal chest film with the right atrial (RA) contour indicated by white arrowheads. *B*, The RA border is enlarged and convex (white arrow), as is the entire cardiac silhouette. The pulmonary vasculature is normal in this mildly cyanotic male. A diagnosis of Ebstein anomaly was established by echocardiography. *(Courtesy of Dr. Ahmed Farag.)*

small, thin individual to 16.5 cm in a tall, heavy person. A measurement 10 percent beyond these values represents the upper limits of normal. A normal heart may appear large in the frontal projection because of a small AP diameter of the thorax caused by a pectus excavatum deformity or straight back. A large heart may appear smaller than it really is because of a downwardly displaced cardiac apex, for example, in patients with aortic regurgitation or in an elderly patient with a large AP diameter caused by severe dorsal kyphosis. The heart will be truly small in patients with Addison disease or anorexia nervosa as a result of the absence of brown fat. Because of cardiac magnification on AP films (including portable radiographs), visual correction must be made to avoid overdiagnosis of heart enlargement. A reduction in the calculation of heart size by 10 to 12.5 percent, depending on the anode-to-tube distance, will correct this discrepancy. For the most part, calculated cardiothoracic ratios are of historical or research interest. In practice, these calculations are seldom performed because they are time consuming and more accurate estimations of cardiac volume and size may be obtained with other imaging techniques.

THE PULMONARY VASCULATURE

The pulmonary vasculature is the most difficult portion of thoracic radiological anatomy to analyze because of its complexity and overlapping patterns of interstitial, arterial, and venous structures. However, the information elicited from accurate analysis of the pulmonary circulation is certainly as valuable as analysis of cardiac shape in arriving at a correct cardiac diagnosis.[9]

Because the pulmonary blood vessels are clearly visualized on the chest film, normal as well as increased, decreased, redistributed, or asymmetrical flow can be identified and correlated with other indicators of disease.

Normal Radiographic Anatomy (Fig. 8-16)

The main pulmonary artery bifurcates within the mediastinum. The left pulmonary artery then courses to the left and backward, and its borders are visible just above the middle of the left hilum. In the lateral projection, the left pulmonary artery passes over the left main stem bronchus and parallels the aortic arch. The right pulmonary artery follows a horizontal course within the mediastinum and forms a round or elliptical opacity anterior to the right main stem bronchus on the lateral view. The right pulmonary artery divides within the mediastinum proximal to the right hilum. The intrapulmonary branches parallel the bronchi, divide in an orderly manner, and gradually taper toward the periphery of the lung. The arteries and bronchi subtending the same pulmonary segment are of approximately the same diameter at any particular level, with a ratio of about 1.2:1.0. This relationship assumes importance when objective criteria are needed to support the impression of increased or redistributed blood flow.[35]

In the erect position, blood flow is greater to the lower lobes than to the upper lobes, partly because of the effects of gravity. Another factor affecting the normal distribution of pulmonary blood flow is the differential intraalveolar pressure between the upper lung zones (higher intraalveolar pressure) and the lower lung zones (lower intraalveolar pressure). In supine and prone chest films, blood flow appears equal in both the upper and lower lung zones, but actually, blood flow is greatest in the dependent position or posterior third of each lung in the supine position, and is best appreciated with axial CT images.

In normal individuals, the pulmonary arteries and veins in the outer third of the lung are too small to be seen clearly on chest x-rays. The central pulmonary veins can usually be distinguished from pulmonary arteries because they follow different pathways. Pulmonary veins course centrally in the interlobular septa and converge in the posterior aspect of the left atrium 2 to 3 cm below the hila. The pulmonary arteries radiate from the hila several centimeters above the pulmonary venous confluence. The veins of the upper lobes are usually lateral to or superimposed on their companion pulmonary arteries, and for the most part,

Figure 8-10 *A*, Lateral chest radiograph. *B*, Superimposed anatomical drawing of the cardiac chambers and great vessels. *C*, Computer-generated diagram of the lateral projection of the heart showing the position of the cardiac chambers, valve rings, and sulci.

the veins are larger than arteries and branch less frequently. In practice, because venous drainage and arterial supply to the upper lobes are so variable, it is often difficult to distinguish vein from artery. In a normal, erect individual, the vessels in the upper lung zone are smaller than vessels at the base of the lungs because important gravitational differences between the apex and lung base cause increased distribution of blood to the base of the lung.

Abnormal Pulmonary Blood Flow

INCREASED PULMONARY FLOW (Fig. 8-17) .

In normal individuals, the size of the pulmonary arteries is proportional to the volume of pulmonary blood flow, so if right-sided cardiac output is increased, the vessels will enlarge as long as the reserve of the pulmonary vascular bed (eight times normal flow) is not exceeded. When the reserve volume is overwhelmed or the reserve volume is reduced because of obliterative vascular disease, the size of the vessels will be related to both blood flow and blood pressure or to pressure alone. The pulmonary veins also enlarge as pulmonary arterial blood flow rises. Enlarged pulmonary branches are found in a variety of conditions, including left-to-right shunt, admixture lesions such as transposition of the great arteries, and conditions that produce an increase in cardiac output, such as chronic anemia, hyperthyroidism, arteriovenous fistula, and pregnancy.[36] As pulmonary artery flow increases, radiographs demonstrate enlarged pulmonary arteries, clearly seen to the edge of the lung. In a small left-to-right shunt, the increase may appear to be confined to the lower lobes, but in larger shunts, recruitment of the upper

Figure 8-11 *A*, A hyperinflated lung from emphysema reduces the extent of right ventricular encroachment on the retrosternal space. *B*, Severe pectus excavatum in a patient with a prolapsed mitral valve (arrow). The deformity exaggerates the extent of the retrosternal encroachment. *C*, Axial T1-weighted MRI shows the relationship of the anterior border of the right ventricle (RSV) to the anterior chest wall. RA=right atrium.

lobe vessels is seen as well, and differential flow between the upper and lower lobe vessels is lost. In left-to-right shunts smaller than 1.8:1, pulmonary vascular abnormalities may not be detected at all.

The size of the pulmonary vessels has been measured by determining the average transverse diameter of the right descending pulmonary artery immediately above the origin of the right middle lobe branch. The normal transverse diameter of this vessel is 10 to 15 mm in males and 9 to 14 mm in females. A variation of ±1.0 mm beyond these limits is considered abnormal.[37]

PULMONARY ARTERIAL HYPERTENSION (see Fig. 8-17) .

When the pulmonary vascular reserve is fully recruited by increased blood flow or reduced by endothelial cell injury and vasoconstriction, pulmonary arterial pressure rises.[38] The vascular engorgement that characterizes increased pressure is accompanied by vasospasm, peripheral vasoconstriction, and vessel wall thickening. Eventually, peripheral blood flow is decreased, and the outer third of the lungs becomes more lucent radiographically. The central elastic pulmonary arteries enlarge, including the main pulmonary artery, the right and left pulmonary arteries, and second-order branching vessels. Calcification of the main pulmonary artery and the proximal branch vessels may develop in longstanding and severe pulmonary arterial hypertension. Pericardial effusion and abnormal mosaic-like pulmo

Figure 8-12 Left atrial border in the lateral view. Discrete posterior displacement of the barium column because of left atrial enlargement can be seen in a patient with mitral stenosis.

nary parenchymal patterns have been described on CT.[38] [39] [40] Pulmonary arterial hypertension may be primary, particularly in women in the childbearing age group. It may also be secondary to a wide variety of cardiac and systemic disorders, including chronic recurrent pulmonary thromboembolic disease, chronic hypoxia, HIV-1 infection, collagen-vascular disease, drugs, sleep apnea syndrome, Eienmenger physiology, or pulmonary venous hypertension.[40] [41] [42] [43] [44]

PULMONARY VENOUS HYPERTENSION (Fig. 8-18) .

Left ventricular failure, mitral stenosis, venoocclusive disease, and other causes of vascular obstruction distal to the pulmonary arterial bed produce an increase in pulmonary venous pressure above the normal range of 8 to 12 mm Hg. When pressure rises to the level of 12 to 18 mm Hg, pulmonary blood flow is redirected into the upper lobes in the erect position and anteriorly in the supine position, so the normal difference in size between the smaller upper lobe and larger lower lobe vessels is

reversed.[35] [45] With further elevation of pulmonary venous pressure above 18 mm Hg, pulmonary interstitial edema occurs. With pressures above 25 mm Hg, alveolar flooding or edema is present.

Radiographically, cephalization or redistribution of pulmonary venous and arterial flow to the upper lobes is the earliest sign of pulmonary venous hypertension. A clue to the recognition of redistributed flow is the diameter of blood vessels at the first anterior interspace. Normally, vessels at that level do not measure more than 3 mm in diameter. If they are larger, increased or redirected flow should be considered. In practice, the chest radiograph is particularly useful in distinguishing significant elevations from mild elevations, but more precise grading of pulmonary venous pressure levels is usually futile.[45] Although the exact mechanism of vascular redistribution remains unresolved, one explanation has been proposed by several authors.[45] [46] With an increase in pulmonary venous pressure, fluid leaks from the pulmonary veins into the interlobular spaces, first in the lower lobes because of gravitational effects. Fluid accumulation in the interlobular spaces decreases pulmonary compliance and increases interstitial pressure. These two phenomena restrict flow to the lower lobes. Arterial spasm may also be a factor. Since these processes first develop in the lower lobes, redirection of blood flow to the upper lobes follows.

DECREASED PULMONARY BLOOD FLOW.

When blood flow is reduced, usually because of pulmonary outflow tract obstruction or an intracardiac right-to-left shunt, the pulmonary arteries and veins are reduced in size. The central vessels narrow and the peripheral vessels are not visible. Reduced pulmonary blood flow may be generalized, as in the tetralogy of Fallot, or may be regional as a result of pulmonary embolism, emphysema, tumor invasion, or vasculitis. When pulmonary perfusion is reduced, as in pulmonary atresia or chronic pulmonary thromboembolism, the bronchial and other collateral arterial vessels may be increased. Radiographically, bronchial vessels are tortuous, small, and nontapered, and because they emanate from the aorta, they do not radiate from the hilum. Otherwise normal but small pulmonary arteries and veins also contribute to pulmonary vascularity in lungs with significant bronchial circulation because pulmonary arteries and bronchial arteries interconnect and blood preferentially flows from the higher pressure systemic bronchial arteries to the lower pressure pulmonary arteries.[47]

ASYMMETRICAL PULMONARY BLOOD FLOW.

Asymmetrical pulmonary blood flow is caused by vessels in one lung being smaller than those in the other lung. A unilateral decrease or absence of pulmonary blood flow may occur in patients with pulmonary artery branch stenosis or atresia, hemitruncus, and tetralogy of Fallot with unilateral pulmonary artery branch narrowing. In addition, asymmetrical, increased flow may be found after creation of a Blalock-Taussig, Waterston, or Potts shunt. Sometimes, the differences in blood flow in congenital heart disease are caused by orientation of the pulmonary outflow tract. For example, in pulmonary valvular stenosis, the flow of blood through the stenotic valve may be directed toward the left pulmonary artery. In patent ductus arteriosus (PDA), preferential flow is often toward the left side because the ductus is oriented toward the origin of the left pulmonary artery in most patients.

Pulmonary Alveolar and Interstitial Edema (see Fig. 8-18)

In normal individuals, fluid continuously passes from the pulmonary veins into adjacent interlobular lymphatics, which return the fluid to the central mediastinal veins. If the lymphatic reserve is overcome by increased transudate as a result of elevated pulmonary venous pressure, the interlobular septa are thickened and become visible radiographically. Redistribution of blood flow to the upper lung zone, or "cephalization," will occur after reduction in compliance or vasoconstriction in the lower lobes roughly paralleling the increase in pulmonary venous pressure.[48] [49] [50] With a mean transmural arterial pressure of 18 to 25 mm Hg, interlobular septal lines, or Kerley B lines, are visible as thin horizontal lines present at both lung bases perpendicular to the lateral pleural surface on the frontal chest film.[51] Prominent interstitial linear opacities throughout the lung reflect additional thickened septal lines. Clear definition of the segmental and subsegmental vessels is lost, and subpleural effusions occur. If the origin of the pulmonary interstitial edema is related to the cardiovascular system, the heart may be normal or enlarged, depending on the chronicity of cardiac decompensation. Prominent interstitial lines may also occur in a wide variety of noncardiac diseases, including sarcoidosis, lymphatic spread of tumor, interstitial pneumonia, and asbestosis. When pulmonary interstitial edema is present without alveolar edema, the lungs may be clear to auscultation--a clue that the extravascular fluid is confined to the interstitium. With further increases in pulmonary venous pressure above 25 mm Hg, leakage of fluid into the pulmonary air spaces leads to alveolar edema. Small nodular areas of increased opacity representing fluid in scattered acini or primary lobules are visible,

Figure 8-13 Right anterior oblique (45-degree) projection. *A*, Chest radiograph. *(From Van Houten FX, Adams DF, Abrams HL: Radiology of valvular heart disease. B*, A computer-generated cardiac model demonstrates the valve rings, arterioventricular groove, and intercameral sulci.

followed by coalescence into larger confluent areas of opacity.[50]

Radiographically, pulmonary alveolar edema typically involves the inner two-thirds of the lung and produces a "butterfly" or "bat wing" appearance (see Fig. 8-18 *E*). An explanation for this pattern is that the outer third of the lung, aptly termed "the pulmonary cortex," has better aeration, better pumping effect during the respiratory cycle, better compliance, and more efficient lymphatic drainage than does the inner two-thirds of the lung. For these reasons, fluid concentrates preferentially in the central portion of the lung.[49] Distinguishing pulmonary edema caused by congestive heart failure from that caused by increased "capillary permeability" or "overhydration" is usually difficult. Recent studies have attempted to separate cardiovascular pulmonary edema from other forms of pulmonary edema by definable characteristics such as change in heart size, width of the pulmonary vascular pedicle, blood flow distribution, interstitial thickening, and regional distribution of pulmonary edema. In these studies, cardiovascular pulmonary edema is characteristically associated with a large heart, vascular redistribution, diffuse distribution of pulmonary edema fluid, a widened vascular pedicle, increased pulmonary blood volume, septal lines, and pleural effusions. Balanced blood flow distribution and perihilar pulmonary edema characterize overhydration pulmonary edema. In pulmonary edema caused by capillary permeability, there is no cardiac enlargement and little to no pleural effusion, the vascular pedicle is normal or reduced in size, no septal lines are found, and the pulmonary edema has a peripheral

Figure 8-14 Sixty-degree left anterior oblique projection. *A*, Plain chest radiograph. *B*, Superimposed line drawing in the same patient. *(From Van Houten FX, Adams DF, Abrams HL: Radiology of valvular heart disease. rather than central pattern.[52] Asymmetrical pulmonary edema is usually caused by underlying morphological changes in the lung parenchyma. Perhaps the most common etiology is emphysema in heavy cigarette smokers or in end-stage sarcoidosis or tuberculosis. Other causes of asymmetrical pulmonary edema include thromboembolism and therapeutic irradiation. Although the plain chest film is the basis for the radiographic diagnosis of the phases of cardiogenic pulmonary edema, the superior resolution of CT has led to a more precise description of the findings of both interstitial and alveolar edema. High-resolution CT will often yield additional insight into both the causes and the distribution of edema and the presence of other concurrent abnormalities. (See also Chap. 10.) [53] [54]

Figure 8-15 Measurement of the transverse cardiac diameter. *A*, A vertical reference line is drawn through the spinous processes of the vertebrae. The greatest distance from this line to the right and to the left margins of the cardiac shadow are then measured. The sum of the two measurements is the transverse cardiac diameter. *B*, The heart is unusually small in this young woman with anorexia nervosa and absence of brown fat.

CARDIAC CALCIFICATION

MYOCARDIAL CALCIFICATION (Fig. 8-19) .

Dystrophic calcification of the heart is usually caused by a large myocardial infarction and is reported to occur in 8 percent of infarcts more than 6 years old.[55] It has also been described in chronic renal disease and following cardiac trauma, particularly involving the anterior wall of the right ventricle.[56] Deposition of calcium in

myocardial tissue is related to the production of carbon dioxide in slowly metabolizing tissue. Consequently, the development of relative alkalinity and reduced solubility of calcium leads to soft tissue deposition.[55] Myocardial calcification occurs most frequently in true left ventricular aneurysms localized to the apical and anterolateral aspects of the left ventricular wall. The calcium deposits in left ventricular aneurysms are usually curvilinear and located within the periphery of the infarct or aneurysm and may occasionally be homogeneous when an entire infarcted area calcifies (Fig. 8-19 *A*). A false left ventricular aneurysm occurs when the chamber ruptures into the pericardium, where the blood is then contained by adhesions. False aneurysms usually occur along the posterolateral wall of the left ventricle.[9]

Calcification may also occur within the left atrium and left atrial appendage, usually in patients with rheumatic carditis, and is associated with mitral stenosis or regurgitation. Left atrial calcification is most often found in the endocardial or subendocardial layers of the heart muscle and is seen less often within an organized thrombus adherent to the chamber wall (Fig. 8-19 *B*). Left atrial calcification is usually thin walled and curvilinear and forms a shell around the circumference of the chamber or is confined to the left atrial appendage.[57] Although myocardial calcification can often be diagnosed on plain radiographs, MRI, CT, ultrasonography, and scintigraphy will augment the information derived from the plain film examination by demonstrating the extent of the aneurysm, estimate overall left ventricular function, and identify the presence of intercavitary thrombus.[57] [58] [59] [60] [61]

VALVULAR CALCIFICATION (see Figs. 8-19 C and D and 8-20).

Radiographically visible calcium within a cardiac valve suggests the presence of hemodynamically significant stenosis. In the mitral valve, calcification appears clumplike or linear, usually measuring about 2 to 4 cm in diameter, and is most often caused by rheumatic valvulitis. Isolated aortic valve calcification in patients younger than 40 years generally signifies marked aortic stenosis related to a bicuspid valve. In patients older than 65 years, aortic valve calcification can be due to "senile" sclerosis and degeneration of normal valve leaflets, or the calcification may be a manifestation of hemodynamically significant aortic stenosis.[62] [63]

The radiographic appearance of the calcification may help determine the origin of the valvular deformity. For example, a thick, irregular semilunar ring pattern with a central bar or knob is typical of a stenotic bicuspid valve and is found in 65 percent of patients with congenital aortic stenosis. The distinctive pattern of calcification of a bicuspid valve results from calcification of the valve raphe or dividing ridge and the line of insertion of the shallow conjoint leaflet and the convex unfused leaflet (see Fig. 8-19 *D*). The abundance of calcification in this entity is thought to be due to constant wear and tear from the abnormal injury-producing motion of the bicuspid valve leaflets. Occasionally, three-leaflet aortic valves will mimic bicuspid valves because of fusion of two of the three leaflets. In these patients, three sinuses of Valsalva are present.

Calcification of the pulmonary valve occurs occasionally in pulmonary valvular stenosis with gradients in excess of 80 mm Hg or in longstanding severe pulmonary hypertension. Calcification of the tricuspid valve is unusual and is caused most frequently by rheumatic disease.

ANNULAR CALCIFICATION (see Fig. 8-20).

Found in the valve rings or fibroskeleton of the heart, annular calcification is a degenerative process that occurs with aging. It is

Figure 8-16 Normal pulmonary blood flow. *A*, Detail of the normal chest radiograph shown in Figure 8-9 *A*. The lower lobe vessels (LLV) are two to three times larger in diameter than the upper lobe vessels (ULV) because of a combination of gravity and alveolar pressure differences. In a normal erect patient, the paired bronchus and vessel are approximately the same size. The arterial/bronchial ratio is helpful in analyzing alterations in pulmonary vasculature. *(Courtesy of Dr. Ahmed Farag.) B*, High-resolution CT shows the relationship of the bronchial and arterial branches lying within the secondary pulmonary lobule. The pulmonary veins follow a different course from the edge of the secondary lobule into the left atrium. *C*, Magnified view showing the relationship of the pulmonary arterial and venous branches entering the mediastinum to better advantage.

found most often in individuals older than 40 years and especially in women. Mitral annular calcification is seen radiographically as a wavy O-, J-, or C-shaped opacity. When calcification is limited to the posteromedial portion of the annulus near the base of the posterior leaflet, it usually has no effect on blood flow through the valve orifice, but when the calcification is more extensive, it may involve the valve leaflets themselves and cause limitation of motion leading to regurgitation. Aortic annular calcification may also extend into the ascending aorta and down into the interventricular septum. Atrial fibrillation, conduction abnormalities, endocarditis, and mitral valve incompetence are associated findings. Tricuspid annular calcification is rare and usually occurs in patients with longstanding pulmonary valvular stenosis, atrial septal defect (ASD), and/or right ventricular hypertension.

Several measurements have been suggested as a means of identifying the location of valvular calcification on plain films. A line drawn on the lateral chest film from the junction of the anterior chest wall and the diaphragm through the hilum to the lung apex will separate anterosuperior aortic calcification from posteroinferior mitral calcification. Another approach is to divide the heart on the lateral view into six sections; this technique will permit identification of the aortic valve in the upper row middle section and mitral calcification in the lower row posterior section.

CORONARY ARTERY CALCIFICATION (Fig. 8-21 ; see also Figs. 10-40 , 10-41 , and 10-42).

Calcium hydroxyapatite is deposited early in the formation of atherosclerotic plaque in coronary arteries. It is thought that calcification of a coronary artery is a regulated process similar to bone formation rather than passive precipitation of calcium crystals in damaged tissue.[64] [65] The presence of visible calcification can be used to monitor evolution of the atherosclerotic process. Coronary artery calcification can be detected by a number of imaging modalities, including plain radiography,

Figure 8-17 Increased pulmonary blood flow. *A*, This 41-year-old woman has an atrial septal defect, ostium primum type, with a pulmonary-to-systemic flow ratio of 5:1. Pulmonary hypertension is suggested because of disparity between the central and peripheral arterial branches. The right atrial border, the main pulmonary artery, and the upper and lower lobe vessels are enlarged and their branches are visible in the outer third of both lungs. *B*, Disparity between the large central and smaller peripheral vessels in a patient with ventricular septal defect and pulmonary arterial hypertension (Eisenmenger physiology). Arrows indicate peripheral pulmonary arteries. C=central pulmonary arteries. *C*, Lateral projection in the same patient as in *B*. Large pulmonary arteries are clearly seen on the lateral view. L=left pulmonary artery; R=right pulmonary artery. *D*, Severe longstanding pulmonary hypertension in a 64-year-old patient with an atrial septal defect and Eisenmenger physiology. The pulmonary arteries are calcified and aneurysmal. *E*, Severe longstanding pulmonary hypertension in a 30-year-old patient with an ostium secundum atrial septal defect. The pulmonary arteries are coiled and enlarged. *F*, A severe pectus excavatum deformity is often found in patients with congenital heart disease. S=posteriorly displaced sternum.

fluoroscopy, ultrafast CT, and ultrasonography.[65] [66] Of these modalities, ultrafast CT has been studied most intensively.[67]

The chest film is readily available and relatively inexpensive but has low sensitivity for the detection of coronary calcification when compared with fluoroscopy and CT.[67] Coronary artery calcifications are most often seen on the lateral chest x-ray, where a calcified left anterior descending artery is seen as a double line of calcification along the anterior border of the heart. In the PA projection, the main left coronary artery and its proximal branches may be visible just below the left main stem branches at the level of the left atrial appendage. Visualization of the coronary arteries by plain chest radiography is severely limited by superimposed structures, low contrast resolution, and motion when compared with other modalities.

While motion artifact degrades the image in a plain chest x-ray, motion is an advantage with fluoroscopy, and moving coronary artery calcifications are vividly seen and identifiable. A number of studies have compared the efficacy of fluoroscopy with coronary arteriography and exercise testing in the identification of significant coronary artery disease.[68] [69] As a result of these studies, a direct relationship between fluoroscopically identified coronary calcification and the frequency and severity of stenotic lesions was established. In one study of 360 patients undergoing coronary arteriography who also underwent cardiac fluoroscopy, 97 percent of those with calcified coronary arteries on fluoroscopy had significant (>75 percent occlusion) coronary artery stenosis of at least one major vessel on arteriography. Of those with significant coronary disease on arteriography, 56 percent had calcification at fluoroscopy.[69] Another study was performed in asymptomatic patients with type II hyperlipidemia who were younger than 55 years. Of those with both positive exercise tests and coronary calcification on fluoroscopy, 92 percent had angiographically determined coronary artery disease. Fluoroscopy had an 82 percent accuracy in the detection of significant coronary artery disease.[70] In yet a third study, 108 asymptomatic men underwent cardiac fluoroscopy and exercise testing; 81 percent of those with a positive exercise test had coronary calcifications, and 35 percent of these had a positive exercise test. Only 4 percent of men without calcified coronary arteries had a positive exercise test. Finally, in this same series, 92 percent had at least one stenosed coronary artery diagnosed by angiography.[71] The same authors showed that approximately 90 percent of patients with fluoroscopically detectable

coronary calcifications had significant coronary disease.[71]

Since exercise tests alone yield 10 to 20 percent positive results in asymptomatic middle-aged males without coronary artery disease, fluoroscopy was suggested as an effective additional screening test for the identification of patients with critical coronary artery disease.

Figure 8-18 *A*, Pulmonary blood flow redistribution. Enlargement of the upper lobe vessels is seen in a patient with ischemic cardiomyopathy and elevated pulmonary venous pressure. *B*, Pulmonary interstitial edema. The vessels are indistinct and enlarged, and peribronchial cuffing is present. *C*, Pulmonary alveolar edema in a patient with congestive cardiomyopathy. The central perihilar distribution of edema, termed "bat wing" edema, is typical of pulmonary alveolar edema caused by cardiovascular or fluid overload (uremic). *D*, Preferential right upper lobe distribution of pulmonary edema in a 65-year-old man with mitral regurgitation. *E*, Right pleural effusion and residual right upper and bilateral lower lobe edema in a patient with acute mitral regurgitation.

Fluoroscopy was most valuable for assessing atypical chest pain or for screening asymptomatic patients.

Although fluoroscopy can detect moderate to large calcifications, its ability to identify small calcifications is poor. For example, in a 1990 study, Agatston and colleagues found that only 52 percent of calcified deposits identified by CT were detected by fluoroscopy.[72] Other disadvantages of fluoroscopy are dependence on the skills of the fluoroscopist, the inability to objectively quantify the extent of calcification, and difficulty in diagnosis because of overlapping structures.[67]

Conventional CT.

Conventional CT is clearly superior to both plain film radiography and fluoroscopy for the detection of coronary calcification. In fact, approximately 50 percent more patients will be found to have calcified coronary arteries and critical coronary artery disease with CT than with fluoroscopy.[67] Recent studies with CT have emphasized its value as a screening procedure, but it also has important limitations that reduce its sensitivity,[60] [73] including slow scanning times, breathing misregistration, and volume averaging. Since CT is performed routinely for other disease indications, it is important to make note of coronary calcifications and their distribution on CT to alert the clinician to their presence and significance.

Spiral or Helical CT.

This technique is now commonly available in most radiology departments. The advantage of helical CT for the detection of coronary artery calcification is based on scan times as fast as 0.6 second with breath-holding technique. Calcific deposits are less blurred than on conventional CT, but small calcifications may still not be seen. Double-helical CT appears to be superior to single-helical CT for the identification of coronary artery calcifications because of thinner section capability and superior resolution.[74] [75] [76]

Electron Beam CT.

Electron beam or ultrafast CT (EBCT) uses an electron beam to traverse stationary tungsten targets to generate radiographic images. Three-millimeter, 100-millisecond axial slices triggered by the electrocardiogram at 80 percent of the RR interval to minimize cardiac motion are acquired during one or more breath-holds.[67] Because cardiac and respiratory motion are virtually eliminated, coronary arteries are readily identified and coronary artery wall calcification is detected. Small amounts of calcium can be detected with greater sensitivity than with either conventional or helical CT, in part because of the small pixel size (0.25 to 0.5 mm^2) possible with this technology. [65] [77] [78] [79] [80]

By using a calcium-scoring method based on an arbitrary Hounsfield number (CT values) of +130 H for calcium multiplied by the actual area of calcification, a total score is calculated. With this method, a number of investigators have demonstrated sensitivities of 85 to 100 percent for significant coronary artery stenosis.[76] [77] [78] [79] [80] [81] A recently published multicenter EBCT calcium-scoring study reviewed data from both coronary arteriography and EBCT studies. A high calcium score was very predictive in separating patients with and without cardiac events (Fig. 10-41) . Of a number of demographic variables and coronary arteriographic

Figure 8-19 Myocardial calcification. *A*, Left ventricular calcification. The thick mural calcification within the left ventricle is due to an aneurysm (arrows). *B*, A thin curvilinear calcification (arrow) is present in the superior and anterior wall of the left atrium in this patient with multivalvular rheumatic heart disease and atrial fibrillation. Prosthetic valves are seen in the aortic, tricuspid, and mitral areas. *C*, Aortic valve calcification. A fluoroscopic spot film shows that the aortic valve is densely calcified (the curved arrow indicates a calcified raphe in this patient with a biscuspid valve). *D*, Ultrafast CT demonstrates calcification of the aortic valve leaflets in a different patient with a congenital biscupid aortic valve (arrowheads). *(Courtesy of Stephanie Flicker, M.D.)*

findings, only the calcium score generated by EBCT appeared to significantly predict cardiac events.[82] However, the accumulated evidence leaves several questions unanswered concerning the efficacy of EBCT screening in asymptomatic patients and whether the calcium screening method addresses the problem of unstable or noncalcified atherosclerotic plaque.[67]

CALCIFICATION OF THE GREAT VESSELS(Fig. 8-22) .

Aortic calcification, particularly in the region of the arch, is almost ubiquitous in individuals older than 50 years. It is usually noted on chest radiographs as a thin curvilinear opacity near the lateral border of the arch. When the calcification is located deep to the aortic border, dissection may be present. Other causes of aortic calcification are syphilis (usually involving the ascending aorta), sinus of Valsalva aneurysm, calcified ductus arteriosus, and Takayasu arteritis[83] [84] The origin of the main pulmonary artery occasionally calcifies following right ventricular outflow tract surgery for total correction of tetralogy of Fallot. Calcification of the main pulmonary artery also occurs in severe longstanding pulmonary hypertension.[85]

TUMOR CALCIFICATION.

The most common primary tumor of the heart is myxoma, a polypoid gelatinous mass occurring most frequently in the left atrium. About 10 percent of myxomas calcify sufficiently to be seen radiographically.[86] [87] Calcification in cardiac tumors varies from a speckled pattern to a round clump of calcium mimicking mitral annular or valve calcification. Calcification may be visible on plain film or may be seen only with fluoroscopy or CT. With fluoroscopy or CT, a calcified atrial tumor may be seen to prolapse through the atrioventricular valve during diastole and cause obstructive symptoms. Echocardiography and cine-MRI will demonstrate prolapse of a noncalcified myxoma.[86] [88]

PERICARDIAL CALCIFICATION(Fig. 8-23; see also Chap. 50)

Pericardial calcification occurs most often in association with previous acute inflammation or blunt trauma.[89] The most common causes of pericardial inflammation, effusion, and later calcification are viral illness, especially Coxsackie or influenza A and B viral infection; granulomatous disease, including tuberculosis and histoplasmosis; hemopericardium following trauma; and autoimmune disease, including systemic lupus erythematosus and rheumatic heart disease.

Occasionally, pericardial tumors (among them, intrapericardial teratomas and cysts) calcify. Calcification is present in up to 50 percent of patients with constrictive pericarditis.[89] The presence of calcification helps distinguish pericardial constriction from restrictive cardiomyopathy that is not associated with pericardial calcification. On the other hand, extensive calcification may be present without the signs and symptoms of pericardial constriction. Pericardial and myocardial calcifications are frequently confused with each other. However, pericardial calcification can be distinguished from myocardial calcification by differences in distribution. Pericardial calcification is most abundant along the right atrial and ventricular borders and in the area of the atrioventricular groove. The pericardium adjacent to the left ventricle is usually free of calcification, probably because of its vigorous

Figure 8-20 *A*, Calcified aortic and mitral annulus in an elderly woman. The air in a large hiatal hernia permits excellent visualization of the mitral annulus (arrowheads) in the posteroanterior (PA) projection. *B*, In the lateral projection, calcification is present in both the aortic (white arrow) and mitral (black arrows) annuli. *C*, Aortic annular calcification (arrows) in an elderly patient without signs or symptoms of aortic stenosis. *D*, Mitral valve calcification in the PA projection. *E*, Mitral valve calcification in the lateral projection. Valve calcification (black arrows) lies below the line drawn from the left main bronchus to the anterior costophrenic sulcus, which localizes it to the mitral valve. The aortic valve in this projection lies more anteriorly and above the line (white arrows).

pulsations, and calcification rarely occurs along the left atrial border because of the absence of pericardium behind the left atrium. On the other hand, myocardial calcification is usually localized to the left ventricle and is rare in the right atrium or ventricle. Pericardial calcification is often obscured on a frontal chest film because of underexposure of the mediastinal structures. Overpenetrated films or fluoroscopic examination is helpful in localizing mediastinal calcification, including pericardial calcification, and CT may demonstrate calcium not visible on plain chest films.[89]

ACQUIRED HEART DISEASE

Diagnosis and assessment of the severity of acquired heart disease are assisted by a combination of imaging studies, including plain chest radiography. The chest film is particularly useful for assessing overall cardiac size and pulmonary vascularity. The plain chest radiograph also offers important clues to the enlargement of individual cardiac chambers through analysis of cardiac borders. Today, echocardiography, MRI, and other cross-sectional imaging techniques have largely replaced the plain film except for its role as a useful first examination in the work-up of a cardiac patient.[90] [91]

Valvular Heart Disease (Figs. 8-24 and 8-25; see also Chap. 46)

Aortic Stenosis

Isolated aortic stenosis is most frequently related to a congenital bicuspid aortic valve. Additional causes of left ventricular outflow tract narrowing resulting in left ventricular enlargement without valvular calcification are hypertrophic cardiomyopathy and supravalvular and subvalvular aortic stenoses.

The typical radiographic findings of mild to moderate aortic valvular stenosis include a normal-sized heart with rounding of the left ventricular border or an elongated cardiac silhouette with downward displacement of the cardiac apex because of concentric left ventricular hypertrophy[90] (see Fig. 8-8 *A*). A characteristic discrete bulge located on the right side of the ascending aorta just above the sinus of Valsalva is due to poststenotic dilatation and is best visualized in the LAO or PA projection. In pure aortic stenosis, the aortic arch and descending aorta remain normal in size and aortic valve calcification is frequent. Calcification increases with the severity of stenosis and the age of the

Figure 8-21 Coronary artery calcification. *A*, Lateral projection demonstrating the "tram track" pattern of coronary artery calcification involving the left anterior descending (arrowheads) and circumflex coronary (arrow) arteries. *B*, A coned-down magnification view in another patient shows a "tramtrack" calcification of the left anterior descending (LAD, arrow) artery. A calcified bicuspid valve inferior in position to the LAD artery is also present. *C*, Calcification of the LAD and the circumflex (Cx) arteries is clearly visualized on axial CT images.

patient, so by the age of 40 years, more than 90 percent of patients with aortic stenosis have visible aortic calcification. Aortic valvular calcification has also been associated with a peak systolic gradient at the aortic valve of greater than 30 mm Hg in 97 percent of patients.[9]

With severe aortic stenosis, the left atrium and ventricle will decompensate and enlarge.[92] The degree of enlargement of both chambers is correlated with the severity of aortic stenosis and with mitral regurgitation caused by left ventricular dilatation or by associated intrinsic mitral valve disease.

CONGENITAL AORTIC STENOSIS.

This type of stenosis may take two forms. The more common is a bicuspid valve with congenital commissural fusion and a central or eccentric orifice. The second form is a bicuspid valve or a tricuspid valve that is initially nonobstructive but undergoes commissural fusion with time. Turbulent blood flow traumatizes the valve and causes irregular nodular scarring of both leaflets, which subsequently undergo gradual fusion and calcification.[4] [91] With time, these valves may also become insufficient because of either incomplete closure of the deformed valve leaflets or infective endocarditis.[4]

DEGENERATIVE AND RHEUMATIC AORTIC VALVULAR STENOSIS.

These types of stenosis may be found in normally tricuspid aortic valves. On the chest film, linear or coarse calcifications may be found in the area of the aortic valve leaflets or annulus. In patients with rheumatic aortic stenosis, mitral calcifications are also frequently present.[93]

SUBAORTIC STENOSIS.

Both the obstructive and nonobstructive forms of hypertrophic cardiomyopathy (see Chap. 48) and membranous subaortic stenosis are characterized radiographically by left ventricular hypertrophy.[8] Although the plain film findings are suggestive, a specific diagnosis of hypertrophic cardiomyopathy can be best established with MRI, echocardiography, and/or radionuclide studies.[60] [94] [95] Since the aortic leaflets are not involved, blood flow is normal during ventricular systole, and as a result, the ascending aorta does not dilate and the aortic valve does not calcify. Left atrial enlargement, when present, is usually associated with mitral regurgitation.

Aortic Regurgitation (see Figs. 8-8 *B* and *C* and 8-24)

Aortic regurgitation may result from a stenotic bicuspid valve with incomplete closure caused by endocarditis or degeneration. Rheumatic valvulitis and infective endocarditis are other important primary causes. A secondary cause of aortic regurgitation is dilatation of the aortic annulus in diseases preferentially affecting the ascending aorta, such as

Figure 8-22 Aortic calcification. *A*, Posteroanterior projection. *B*, Lateral projection. An abundant thin line of calcification extends from the aortic root to the distal descending thoracic aorta in a young woman. Biopsy revealed Takayasu aortitis.

ankylosing spondylitis, annuloaortic ectasia, Marfan syndrome, Reiter syndrome and psoriatic arthritis.[96] [97] [98] Aortic regurgitation caused by rheumatic heart disease is commonly associated with mitral involvement alone or may involve all four cardiac valves. Aortic regurgitation may also be due to direct trauma or may accompany dissection of the ascending aorta.

In mild aortic regurgitation, the aorta is radiographically normal or mildly enlarged and the left ventricle remains normal in size. With moderate or severe regurgitation, increased dilatation of the left ventricle is seen, and the cardiothoracic ratio usually exceeds 0.55. The aorta is diffusely and often massively dilated, unlike aortic stenosis, where only the ascending aorta is involved (see Fig. 8-8 *C* and *D*). If the sinus portion of the ascending aorta is the only portion selectively dilated, Marfan syndrome (annuloaortic ectasia) is the most likely diagnosis. If the ascending aorta is also calcified, syphilis or, occasionally, Takayasu aortitis (see Chap. 40) is the likely diagnostic possibility. If the valve itself is calcified, aortic regurgitation secondary to a congenital bicuspid aortic valve or rheumatic disease should be considered. If the mitral valve is also regurgitant, the left atrium may be markedly enlarged visually and obscure the enlarged left ventricle. When aortic regurgitation occurs acutely as a result of infective endocarditis, trauma, or dissection, the left ventricle remains normal in size, but because end-diastolic pressure is dramatically increased,

pulmonary venous pressure rises and pulmonary interstitial and/or alveolar edema may be observed. Pulmonary arterial hypertension has been described in longstanding aortic regurgitation.[99] In chronic compensated aortic regurgitation, progressive volume overload occurs with left ventricular dilatation and an increase in overall cardiac size but with normal-appearing lungs.[97]

As is true of aortic stenosis, aortic regurgitation is best diagnosed by Doppler echocardiography or cine-MRI.[96] [100] In selected cases, especially those with calcified aortic valves, analysis of the plain chest radiograph will often establish the diagnosis or reveal specific findings that support the diagnosis of this abnormality.

Mitral Stenosis (see Fig. 8-25)

Rheumatic carditis is the most common cause of mitral stenosis. Isolated mitral valve involvement is most common, followed by a combination of mitral and aortic valve diseases. Left atrial myxoma and, rarely, congenital mitral stenosis, parachute mitral valve myxoma, and metastatic tumor are also causes of mitral valve obstruction. The early roentgenographic signs of mitral stenosis are often subtle and include mild left atrial enlargement with a discrete convex border in the area of the left atrial appendage on the PA projection. In most patients with mitral stenosis, the left ventricle or the pulmonary artery borders are normal in appearance.

With more severe mitral stenosis, the left atrium usually increases further in size; however, in any given patient, poor correlation is seen between the severity of mitral stenosis and the size of the left atrial chamber. The left atrial appendage can be disproportionately enlarged, but the shape of the appendage appears to bear no relationship to the presence or absence of thrombosis.[101] The left main stem bronchus may be displaced upward by the enlarged left atrium. The right atrium is displaced to the right, and pulmonary blood flow is redistributed to the upper lobes. The main pulmonary artery is enlarged, the left ventricle and aorta are usually normal or small, and the mitral valve is often calcified. In addition, calcification of the left atrial wall is most commonly found in the posterior wall and appendage and is often associated with atrial fibrillation. Patients have evidence of pulmonary interstitial edema, characterized by "hilar haze" or central vascular indistinctness, Kerley B lines or interlobular effusions at the lung bases, and subpleural stripes as pulmonary venous pressure rises to the range of 25 mm Hg.

Hemosiderosis resulting from recurrent small hemorrhages related to chronically elevated capillary pressure is often associated with chronic mitral stenosis. The radiographic appearance of hemosiderosis is that of interstitial or miliary lung disease, most prominent in the mid and lower lung zones. With chronic pulmonary interstitial edema, small punctate pulmonary opacities may be found that represent

Figure 8-23 Pericardial calcification. *A*, Posteroanterior projection. *B*, Lateral projection. Both show extensive calcification of the pericardium in the atrioventricular groove in a patient with a history of rheumatic heart disease. *C*, Axial CT at the level of the atrioventricular groove demonstrates extensive pericardial calcification (arrowheads). LA=left atrium, RA=right atrium.

small islands of bone within the alveoli and are visible as dense nodules on the chest radiograph.

Mitral Regurgitation (see Fig. 8-18 *D*)

Acute mitral regurgitation may be related to ruptured chordae tendineae, rupture of the papillary muscles, ischemic dysfunction, or infective endocarditis. While the heart may not be enlarged in acute mitral regurgitation, severe pulmonary edema is frequently present as a result of left-sided cardiac failure (see Fig. 8-18 *E*). Although pulmonary edema secondary to mitral regurgitation is usually symmetrical, selective right upper lobe pulmonary edema has been described in as many as 9 percent of patients with acute or chronic mitral regurgitation. It is probably due to selective retrograde flow from the mitral valve to the right upper lobe pulmonary veins.[102] [103]

Chronic mitral regurgitation may be secondary to rheumatic heart disease, mitral prolapse from myxomatous degeneration, infective endocarditis, ischemic cardiomyopathy, hypertrophic cardiomyopathy, extensive mitral annulus calcification, collagen disease, Marfan syndrome, and other causes.[92] In chronic mitral regurgitation, the left atrium as well as the left ventricular border appears enlarged radiographically and may be massive in size because of volume overload and increased pressure. When the left atrium is enlarged, it may extend toward the right side and will be observed as a double shadow along the right atrial border. In the LAO projection, the large atrium causes upward displacement of the left main stem bronchus. Coexistent pulmonary arterial hypertension or tricuspid regurgitation may cause dilatation of the right atrium and ventricle and enlargement of the pulmonary arteries.[96] MRI and echocardiography can demonstrate the abnormality of the valve apparatus and evaluate the amount of regurgitant flow.[100] [104] [105]

Ischemic Heart Disease

Many imaging modalities contribute to the diagnosis of ischemic heart disease, including coronary arteriography, radionuclide scintigraphy, echocardiography, CT, and MRI.[104] [105] [106] [107] In ischemic cardiomyopathy, the chest roentgenogram may be entirely normal, even in patients with advanced disease; however, left ventricular enlargement and/or

Figure 8-24 Aortic regurgitation with massive diffuse aortic dilation in a male with severe valvular regurgitation related to annuloaortic ectasia. *A*, Posteroanterior projection. *B*, Lateral projection.

Figure 8-25 Mitral stenosis. *A*, The left atrial border is prominently convex. The aorta is small in this 19-year-old patient with mitral stenosis (arrow). *B*, A subtle convex bulge can be noted at the level of the left atrial appendage (open arrow). A double atrial shadow is present on the right atrial border (black arrow), and the heart is not enlarged in this 54-year-old woman with mitral stenosis. *C*, Mitral stenosis with chronic interstitial pulmonary edema and small punctate opacities representing small islands of ossification within the alveoli. *D*, Mitral stenosis, right anterior oblique view. This posterior displacement of the barium column is related to the enlarged left atrium.

aneurysm is often present. After infarction of 25 percent or more of the left ventricular muscle mass, pulmonary edema may occur, even in patients with a normal-sized heart.[107] When congestive heart failure persists in spite of treatment, complications of myocardial infarction such as aneurysm, pseudoaneurysm, ventricular wall or papillary muscle rupture, and interventricular septal defect must be excluded.[9]

Complications of Myocardial Infarction (see Chap. 35)

An interventricular septal defect occurs in 0.5 to 1.0 percent of patients with recent septal infarction and is characterized by cardiomegaly, pulmonary edema, and poor myocardial contractility. On the plain film radiograph, the typical shunt pattern may not be appreciated because of pulmonary edema but can emerge months later if the patient survives. Such defects usually involve the muscular septum and occur within 7 to 12 days after myocardial infarction.

The radiographic picture of post-myocardial infarction syndrome (Dressler syndrome) is that of a heart enlarged because of pericardial effusion. Unilateral or, less often, bilateral pleural effusions are common, and lower lobe consolidation, particularly on the left side, occurs in less than 20 percent of patients. It generally occurs 2 to 6 weeks after myocardial infarction and is analogous to the postpericardiotomy syndrome.[97] [108]

Aneurysm of the left ventricle is an abnormal bulge or outpouching of the myocardial wall that develops in 12 to 15 percent of patients after myocardial infarction. It occurs most commonly at the cardiac apex or along the anterior free wall of the left ventricle. The chest film shows a localized bulge along the ventricular wall near the apex, with or without a thin rim of calcification. CT, MRI, and echocardiography will all demonstrate, with precision, areas of altered contractility often augmented by pharmaceutical challenge and contrast enhancement.[109] The differential diagnosis of left ventricular aneurysm includes other deformities of the left heart border

caused by pericardial cysts, mediastinal or pleural tumor, thymoma, and other mediastinal masses.

Cardiac rupture usually occurs in patients who have had an acute transmural infarction.[110] Most die immediately, but in a minority of patients the rupture is contained or enclosed by the surrounding extracardiac soft tissue and a pseudoaneurysm is formed. Radiographically, a paracardiac mass is present, with sharply marginated edges free of calcification. The mass is usually posterior on the lateral projection, unlike the more anterior position of a true aneurysm. A firm diagnosis is made by echocardiography, MRI, or contrast-enhanced CT. Coronary arteriography will show complete absence of vessels in the wall of the pseudoaneurysm, unlike a true aneurysm, which may have a rim of mural vessels.[108]

Papillary muscle rupture follows myocardial infarction in approximately 1 percent of patients. Plain film radiographic findings vary from a normal chest to gross cardiomegaly with left atrial and ventricular enlargement and pulmonary edema. Left ventriculography, MRI, or Doppler echocardiography will demonstrate the flail mitral valve leaflets and estimate the degree of mitral regurgitation.[102]

The Cardiomyopathies (see Chap. 48)

The term cardiomyopathy describes a spectrum of myocardial disorders of varying etiology and pathophysiology. They are classified as dilated or congestive, infiltrative, restrictive, hypertrophic, and ischemic.[9] [96]

In *congestive, dilated, and ischemic cardiomyopathy*, the left ventricular ejection fraction is reduced, often severely. Chest radiographs will exhibit a wide spectrum of findings from a normal heart to diffuse nonspecific enlargement that may resemble a large pericardial effusion. Echocardiography demonstrates decreased ventricular contraction and enlargement of the left atrium and ventricle. With time, the right atrium and ventricle also enlarge. Doppler echocardiography or MRI may reveal mitral or tricuspid regurgitation caused by dilatation of the valve annulus.[96] Left-sided and, later, biventricular failure occurs in most patients, an important predictive indicator of shortened survival time.

The radiographic appearance of *hypertrophic cardiomyopathy* is variable. Chest roentgenograms may demonstrate a normal heart or enlargement of the left ventricle, which can be focal or diffuse. If mitral regurgitation is present, the left atrium is also enlarged. Unlike aortic stenosis, no dilatation of the ascending aorta is present unless the patient has coincidental systemic hypertension or atherosclerotic uncoiling of the aorta. The diagnosis of hypertrophic cardiomyopathy is usually established by echocardiography or MRI, and cardiac catheterization with angiography is reserved for cases in which noninvasive techniques are technically inadequate, coronary disease is suspected, or surgery is contemplated. During systole, angiography demonstrates a narrow slitlike left ventricular chamber, marked wall thickening, and hyperdynamic contractions. CT and MRI are less invasive alternatives to angiography.[111]

Restrictive cardiomyopathy is characterized by marked myocardial rigidity with poor left ventricular diastolic relaxation. There are no consistent radiographic features of restrictive cardiomyopathy. The heart is normal in size or may be moderately or, more rarely, markedly enlarged. The left atrium may also be enlarged when mitral regurgitation is present. Pulmonary congestion occurs in most patients, and calcification of the right or left ventricular wall may develop.

POSTOPERATIVE AND CRITICAL CARE RADIOLOGY (Fig. 8-26)

With the continued growth of coronary artery bypass graft surgery and other cardiac surgical procedures during the last three decades, the postoperative supine portable chest roentgenogram has become one of the most frequently ordered examinations. In a typical tertiary care medical center, over 50 percent of inpatient chest roentgenograms are performed at the bedside, usually in the ICU. About one-third of these studies are of postsurgical cardiac patients. To interpret the postoperative chest film properly, special attention must be given to optimization of technique.

TECHNIQUES.

Appropriate film-screen combinations, as well as careful patient positioning, are needed to overcome the effects of low-capacity portable equipment producing low-kilovoltage technique and high amounts of scatter radiation and motion artifacts.[112] The use of laser beam-aligned antiscatter grids and featureless grids that require less precise alignment with the x-ray source are approaches to obtain higher quality portable chest films than are possible with nongrid systems.[113] Although conventional analog portable chest x-rays continue to be the "norm," digital images provide a variety of advantages and are becoming a popular replacement for film-screen chest radiographs as a radiation detector, image display modality, and archival medium.[114] At present, computed radiology with storage phosphor plates as the radiation detector and laser scanning of conventional film-screen radiographs are the most frequently

Figure 8-26 The early postoperative portable chest radiograph. *A*, Multiple catheters and tubes are present and must be identified and their position determined. A=intraaortic balloon catheter; E=endotracheal tube; N=nasogastric tube; S=Swan-Ganz catheter. *B*, The Swan-Ganz catheter is in the right pulmonary artery (arrowhead). The endotracheal tube lies 2 cm above the carina (arrow). It should be repositioned proximally to prevent selective bronchial placement. *C*, This 60-year-old man had a massive myocardial infarction. The intraaortic balloon catheter (IABP) is located above the top of the arch near the orifice of the left subclavian artery.

used methods for producing digital chest images.[115] One major advantage of storage phosphor plates is their sensitivity over a wide range of exposures as opposed to the much narrower exposure range of conventional x-ray film. This difference results in consistent image quality over a wider range of exposures than is possible with conventional film-screen systems.[116] This advantage is particularly important in bedside x-rays, where overexposure and underexposure are ubiquitous. Consistency of technique from film to film in the same patient helps increase diagnostic accuracy and reduces the need for repeat films.[117]

POSTOPERATIVE FILMS.

When preoperative and postoperative chest films are compared, the differences in vascularity, cardiac size, and degree of inspiration between preoperative erect PA and postoperative supine AP films must be taken into account. For example, an 11 percent increase in cardiac diameter, a 9 percent increase in the cardiothoracic ratio, and a 15 percent increase in mediastinal width have been described when an inspiratory PA film is compared with an inspiratory AP chest film. For this reason, many surgeons and radiologists recommend that a preoperative supine AP film be taken to guarantee the availability of a comparable film. Following cardiac surgery, a daily morning film exposed in the ICU is a typical scenario. A number of studies suggest that daily films in subsets of postoperative patients are justified, including patients with an endotracheal (ET) tube and those with a Swan-Ganz catheter or following placement of a pacing device or intraaortic balloon catheter[118] [119] [120] [121] (see Fig. 8-26) .

Most cardiac surgery is performed through an extrapleural median sternotomy with the use of cardiopulmonary bypass. Except for specific problems related to the patient's preexisting cardiac disorder or the specific surgical procedure, changes in the postoperative chest film are common to all cardiac surgical procedures. In the postoperative chest x-ray, a myriad of tubes, wires, catheters, and other devices are present in or overlie the postoperative chest,[119] [122] [123] including an ET tube, which should be positioned in the midtrachea 5 ± 2 cm above the carina to allow excursion with flexion and extension of the neck. If the ET tube is too close to the carina, flexion of the head or neck may force the distal end of the tube into the right or, less often, the left main stem bronchus and cause varying degrees of atelectasis of the opposite lung and barotrauma if assisted ventilation is used.[119] If the tube is too high, the patient may run the risk of aspiration, and dead space is increased.[123] [124] However, despite the opportunity that the bedside chest radiograph gives one to assess tube position, 12 to 15 percent of patients have significant malposition of the ET tube after cardiac surgery[118] [119] (see Fig. 8-26 *B*). A spherical endotracheal cuff seen in the postoperative x-ray indicates overinflation of the cuff, which may lead to tracheal injury.[122]

The central venous pressure monitor is ideally placed between the most proximal valve of the subclavian vein and the right atrium within the superior vena cava. When the distal tip is found in the right atrium, pressure measurements will remain accurate, but the risk of perforation of the thin-walled cardiac chamber is increased. In addition to malposition, compression or "pinch-off" of the catheter by the clavicle and first rib may produce narrowing or chinking of the catheter. Pinch-off is seen in 1 percent of catheter placements.[125] When pinch-off occurs, the catheter should be removed and replaced with a more rigid catheter, one that is oval rather than round in cross section.

Peripherally inserted central catheters (PICC lines) are frequently introduced after cardiac surgery. They are small-caliber tubes placed under sterile conditions. A

major advantage of PICC lines is that they may be left in place for long periods. A Swan-Ganz catheter is usually placed in either major pulmonary artery (ideally with the tip lying within a proximal pulmonary artery 2 to 3 cm distal to the bifurcation) to monitor pulmonary artery or pulmonary capillary wedge pressure and to obtain mixed venous blood samples (see Fig. 8-26 *A* and *B*). From that position, the tip can float distally to a wedged position, whereupon the balloon is inflated. If the catheter is too peripheral in position, the inflated balloon near the tip of the catheter may damage the pulmonary artery wall and produce a perforation leading to hemorrhage or pseudoaneurysm.

Anterior mediastinal drainage catheters are located in the parasternal area, and posterior mediastinal drainage catheters usually lie on the left side behind the heart. When circulatory assistance is needed, a sausage-shaped intraaortic counterpulsation balloon (IACB) may be positioned just below the level of the left subclavian artery within the proximal descending aorta. Placement of the IACB is critical to avoid occluding the subclavian or renal arteries (see Fig. 8-26 *A* and *C*). Pacemaker leads, prosthetic valves, and implantable cardioverter-defibrillators[126] require careful observation for lead or component malposition, pouch infection, or fracture.[127] A nasogastric tube is also usually present. It may be inadvertently placed in a bronchus and pass into the lung or even the pleura. If malposition of a nasogastric tube is unrecognized, aspiration of fluid may occur and cause a chemical pulmonary edema or pneumonia.

Early recognition of the normal and abnormal positions of the large number of catheters, wires, and tubes found on the postoperative chest radiograph requires rapid interpretation by a physician thoroughly familiar with both the appearance of the postoperative chest radiograph and the possible complications that may frequently occur.

The Early Postoperative Chest Radiograph (see Fig. 8-26) .

The first postoperative chest film usually demonstrates varying degrees of left and, to a lesser extent, right lower lobe atelectasis, mediastinal widening, pulmonary edema, and pleural effusion.[128] Unilateral or bilateral lower lobe atelectasis, usually accompanied by small pleural effusions, is the source of the lower lung zone opacities found in almost all cardiac surgery patients. Lower lobe opacities representing atelectases and pleural effusion usually appear within 8 hours after surgery and clear within 5 to 7 days. Pneumonia can occur as an early postoperative complication, but it is certainly unusual. The mechanisms for preferential left lower lobe atelectasis include paralysis of the phrenic nerve caused by cardioplegic solutions or crushed ice administered for myocardial preservation or retained secretions. Decreased diaphragmatic motion may persist for many weeks after surgery but eventually resolves in most patients. Other causes of postoperative left lower lobe atelectasis include dependent pooling of secretions, preferential suctioning of the right main stem bronchi, and compression from the cardiac insulation pad used during surgery.

Pleural Effusion.

Pleural effusion is manifested radiographically by blunting of the costophrenic angle, loss of sharpness of the diaphragmatic contour, and increased opacity behind the diaphragmatic dome. It may be difficult to identify in a postoperative supine film but is more easily identified on an erect bedside radiograph. A lateral bedside film may also help identify pleural effusion if necessary.[129] Postoperative pleural effusions are probably related to pericardial fluid that leaks into the pleural space through the surgically created pericardial window or to irritation of the pleura during surgery. Postpericardiotomy syndrome and congestive heart failure are sources of pleural effusion in some patients. Increasingly larger or persistent pleural effusions may be due to hemomediastinum, which occurs when blood escapes into the pleural space through a pleural tear. Large pleural effusions are more common after left internal mammary bypass surgery because the pleural space is entered during that procedure.

Patchy or occasionally diffuse *consolidation* in both lungs after cardiac surgery is usually caused by pulmonary edema. *Pulmonary edema* from increased capillary permeability or adult respiratory distress syndrome is common after cardiac surgery and is caused by release of vasoactive substances during cardiopulmonary bypass that affect capillary permeability. Pulmonary edema usually occurs within 2 days of surgery and is reversible with supportive therapy, including diuretics.[123] Postperfusion pulmonary edema occurs after cardiopulmonary bypass because of a marked increase in fluid in the extravascular space. The mechanism for postperfusion pulmonary edema is thought to be related to the contact of circulating blood with foreign surfaces during bypass.[123] Congestive heart failure following cardiac bypass surgery occurs in patients with poor cardiac output. Typically, vascular redistribution to the upper lobes, Kerley B lines, small bilateral pleural effusions, and the patchy opacities resulting from pulmonary edema are present.

Other early findings of cardiac surgery identified with the AP portable chest radiograph include sternal dehiscence, pneumothorax, pneumomediastinum, mediastinal hematoma, pneumopericardium, subcutaneous emphysema, and the findings of pulmonary embolism.[130] Rib fractures occur in 2 to 4 percent of patients and are usually identified by plain films. Their importance lies in the possible misdiagnosis of chest pain of another cause, such as angina or aortic dissection.

Pneumothorax is often difficult to identify in a supine patient. Unlike pneumothorax in the PA erect film, where the crisp opaque line of the visceral pleura located medial to the rib cage is diagnostic, in the supine position a pneumothorax appears as a poorly defined lucency overlying the lower lung zones.[123] Decubitus views are helpful in clearly defining the presence of a pleural air collection. Pneumomediastinum may occur when the mediastinum is entered during surgery. In most cases, the mediastinal air resolves spontaneously within several days. A radiolucency overlying the center of the sternum following median sternotomy is due to a small gap in the sternum and soft tissues at the surgical site; this finding occurs in approximately one-third of patients. No correlation between this thin radiolucency and sternal dehiscence has been proved.

MEDIASTINAL HEMORRHAGE.

Widening of the mediastinum because of hematoma is common after cardiac surgery but is seldom serious enough to require reoperation. In the typical postoperative patient, the mediastinum is widened by up to 35 percent in comparison with the preoperative PA chest film. Katzberg and associates found that if the mediastinum is widened more than 70 percent in comparison with the baseline radiograph, surgery is usually required to remove the hematoma.[131] However, considerable bleeding may be present without visible mediastinal widening, especially if the patient is receiving positive end-expiratory pressure support, which may compress the mediastinum. Moreover, some patients may have a wide mediastinum but are hemodynamically stable, have no significant bloody drainage, and do not require reoperation.

Both CT and echocardiography are helpful in establishing the diagnosis of intrapericardial hematoma. With echocardiography, the hematoma has an echo-free center and a refractile margin. CT, with and without contrast enhancement, is also useful to differentiate hematoma from other masses. On nonenhanced CT, the hematoma is denser than other soft tissues.

Enlargement of the cardiac silhouette during the early postoperative period may be due to cardiac failure with or without myocardial infarction or to a mediastinal or pericardial fluid collection. In some patients, pericardial tamponade occurs from bleeding of small arteries in the area of the sternal incision. Equalization of diastolic pressures and elevation of the pulmonary capillary wedge pressure without pulmonary redistribution or edema, together with diffuse enlargement of the cardiac silhouette, suggest pericardial tamponade. Although the chest roentgenogram may be suggestive of tamponade, both CT and echocardiography will clearly reveal the presence of pericardial fluid or thickening and tapered narrowing of both ventricles. CT is the imaging procedure of choice to detect an extrapericardial mediastinal fluid collection.

Late Complications of Cardiac Surgery

POSTPERICARDIOTOMY SYNDROME.

This common late complication of cardiac surgery is characterized by pleuritis, pericarditis, and fever. It is believed to be the result of an immune response to necrotic epicardial tissue. It generally occurs several weeks after surgery and is self-limited. Occasionally, cardiac tamponade or constrictive pericarditis occurs as a complication of the postpericardiotomy syndrome. Unilateral or bilateral pleural effusions may obscure portions of the cardiac silhouette, and small basilar pulmonary opacities are found radiographically. Echocardiography or CT will identify pleural or pericardial fluid collections. Other late postoperative complications of cardiac surgery include sternal osteomyelitis, especially after internal mammary artery surgery, dehiscence at the surgical site, mediastinitis, pneudoaneurysm of the ascending aorta, cardiac rupture, and dissection.[123] [132] [133]

PSEUDOANEURYSM OF THE THORACIC AORTA.

This rare but serious complication of cardiac surgery is associated with sternal osteomyelitis and mediastinitis following median sternotomy.[133] It may occur at the site of an aortic cannulation or vent, the aortic clamp line, or the saphenous graft-aortic anastomosis.[133] Cardiac pseudoaneurysms can also occur at sites where

full-thickness cardiac incisions were made. Although plain film radiographs will demonstrate a mass anterior to the heart or in the ascending aortic region, enhanced CT or MRI is diagnostic and should be performed before reoperation.[133]

AORTIC DISSECTION.

Although aortic dissection rarely occurs in patients who have undergone cardiac surgery, it should be considered in the differential diagnosis of mediastinal widening or a postoperative mediastinal mass. Although a dissection may appear immediately after surgery, it is more likely to occur weeks to months later. Transesophageal echocardiography in unstable patients, MRI, and contrast-enhanced CT are helpful to distinguish between dissection and hematoma, abscess, tumor, or prominent mediastinal fat.[134] [135]

Prosthetic Valve Surgery (see also Chap. 46)

The chest roentgenogram is helpful in monitoring patients for the potential complications of cardiac valve implantation. Identification of the site of a prosthetic valve is not as simple as identification of a calcified native cardiac valve because only an AP film may be available during the early postoperative period and prosthetic valves vary in position and often overlap each other. If the patient fails to improve clinically after valve replacement or if pulmonary edema occurs after a brief period of improvement, malfunction of the prosthetic valve may be the cause. Major malfunctions result from sewing ring dehiscence, tissue encroachment into the ring orifice, and infective endocarditis. The plain chest film may show enlargement of the adjacent cardiac chambers and/or pulmonary edema. Late calcification of the tissue components of a bioprothesis may be seen and is usually caused by tissue degeneration. Fracture and separation of radiopaque components and their distal migration have been described and may be identified by fluoroscopy or on radiographs of the chest and abdomen.[47] [55] However, these complications do not appear to be associated with currently implanted valves.[136]

Fluoroscopy will document prosthetic valve motion, the integrity of the mechanical components, and the presence of calcification. Reduced or absent excursion of the valve occluder suggests thrombus, tissue intrusion, or vegetation. Doppler echocardiography will document regurgitant blood flow proximal to the valve. Contrast-enhanced cine-EBCT and cine-MRI can identify and quantify valvular regurgitation.

Cardiac Transplantation (see also Chap. 20)

Most transplant candidates have a history of end-stage cardiac failure caused by ischemic cardiomyopathy. The heart is invariably enlarged, and vascular redistribution or edema is generally present. In orthotopic cardiac transplantation, the recipient heart is removed and the donor heart, with intact aorta and pulmonary arteries, is attached to a cuff of native left atrium containing the pulmonary veins. After transplant surgery, typical radiographic changes associated with median sternotomy are found, including a widened mediastinum, pleural effusion, left lower lobe consolidation, and atelectasis. Within 2 months of transplantation, the heart becomes smaller and reaches stability 6 months after surgery. Persistent cardiomegaly is most likely caused by pericardial effusion, which may result from cyclosporine therapy or placement of a small donor heart in a large pericardial sac.[137] After transplantation, the radiograph demonstrates a double density in the vicinity of the right atrial border because of the overlapping donor and recipient atria. MRI or CT can clearly depict postoperative transplantation anatomy, as well as the presence of pericardial effusion and lymphadenopathy.[138]

If graft rejection occurs, the heart enlarges, but pulmonary edema does not usually develop. Rejection is diagnosed by demonstration of lymphocytic infiltration and myocytic necrosis on endomyocardial biopsy.[139] MRI can demonstrate alterations in signal intensity caused by moderate and severe rejection.[140]

CONGENITAL HEART DISEASE IN THE ADULT (see also Chap. 44)

The plain film findings of adult congenital heart disease can be classified in a number of ways, such as classification based on the frequency of the disorder or a combination of the hallmarks of disease, such as the state of the pulmonary vasculature, related skeletal abnormalities, the position of the aortic arch and cardiac apex, cardiac size, and abdominal situs. Combining the radiographic findings with a history of the presence or absence of cyanosis, the time of onset of the cardiac murmur, and the clinical state of the patient should narrow the diagnostic choices.[36] [41] [142] Several of the more common congenital cardiovascular disorders found with some frequency in adults are discussed below.

Coarctation of the Aorta (Fig. 8-27)

Coarctation of the aorta is a common anomaly that accounts for 8 percent of congenital heart defects in children and about 6 percent of adult congenital heart disease. Of those who escape diagnosis in early childhood, 25 percent are dead by the age of 20 and almost 50 percent by the age of 30. The clinical findings are highly variable and range from left ventricular failure in infancy to systemic hypertension in otherwise asymptomatic adult patients, depending on the site and severity of the coarctation and the presence of associated abnormalities.[143] [144] The most common associated anomaly is a bicuspid aortic valve, which occurs in as many as 85 percent of patients with coarctation of the

Figure 8-27 Coarctation of the aorta. *A*, Displacement of the barium column to the right above and below the coarctation. *B*, Thoracic aortography. The luminal narrowing at the isthmus and enlargement of the left subclavian artery (LSCA) are characteristic of coarctation. It may be described as a "3" sign or "E" sign because of the precoarctation bulge of the LSCA, the coarctation itself, and postcoarctation aortic dilatation. Dilatation of the ascending aorta is due to a regurgitant bicuspid aortic valve. *C*, Sagittal T1-weighted MRI in the same patient shows the same findings as the aortogram but without contrast media, radiation, or catheterization.

aorta.[142] Other associated anomalies include ventricular septal defect, stenosis or atresia of the left subclavian artery, PDA, Turner syndrome PDA, and mitral valve prolapse.[145] [146]

The diagnosis of coarctation of the aorta can be established from the PA chest film alone in up to 92 percent of patients.[142] Widening of the left subclavian artery border is the most common finding, but the most useful radiographic sign is an abnormal contour of the aortic arch, which may appear as a double bulge above and below the usual site of the aortic knob. This pattern has been described as a "figure 3" sign. The upper arc of the "3" is the dilated arch proximal to the coarctation and/or a dilated left subclavian artery. The lower arc or bulge represents poststenotic dilatation of the aorta immediately below the coarctation. The indentation between the two bulges is the coarctation itself. When the esophagus is filled with barium, a reverse "3" or "E" sign is often seen and represents a mirror image of the areas of prestenotic and poststenotic dilatation. The "3" sign is variable in that the upper arc may be small and the lower arc large or vice versa. Superior mediastinal widening or sternal scalloping caused by large internal mammary collateral arteries is visible in some patients. A prominent left ventricular border often occurs with coarctation, particularly when a bicuspid aortic valve is associated with aortic stenosis.

Bilateral symmetrical rib notching, readily appreciated on the chest film, is diagnostic of aortic coarctation. It is due to obstructed blood flow at the narrowed aortic segment with collateral blood flow through the intercostal arteries. Rib notching is unusual in infancy, but becomes more frequent with increased age and is present in 75 percent of adults with coarctation. Rib notching occurs along the inferior margin of the third to the eighth ribs and is caused by pulsation of dilated intercostal arteries. The major pathways of collateral flow include (1) subclavian artery to the internal mammary artery to the intercostal arteries, (2) subclavian artery to the costovertebral trunk to the intercostal arteries, and (3) transverse cervical and suprascapular arteries to the intercostal arteries.

Cardiac catheterization and angiography are diagnostic and demonstrate both the site of the coarctation and associated anomalies, including aortic stenosis. However, MRI and echocardiography have largely replaced these procedures. Echocardiography, for example, clearly demonstrates the presence or absence of bicuspid aortic and mitral valve deformities. MRI will not only vividly portray the anatomy of the coarctation but will also demonstrate the bicuspid valve and the state of left ventricular function, as well as restenosis following angioplasty or surgical repair.[142] [147] [148] [149]

Left-to-Right Intracardiac Shunts

OSTIUM SECUNDUM ATRIAL SEPTAL DEFECT (Fig. 8-28) .

ASD, the most common left-to-right shunt diagnosed in adult life, accounts for over 40 percent of adult congenital heart defects.[150] [151] Although the chest radiograph may be normal in a patient with a small shunt, typically, the main pulmonary artery, the peripheral pulmonary branches, the right atrium, and the right ventricular borders are enlarged. Differentiation from other left-to-right shunts is often possible. Less pulmonary artery dilatation is usually seen in PDA than in ASD, and both PDA

and ventricular septal defect are associated with enlarged left-sided cardiac chambers (Fig. 8-29) . In adults older than 50 years, the radiographic findings of ASD are often atypical and may include left atrial enlargement, vascular cephalization, and pulmonary edema.[142] Echocardiography demonstrating right ventricular chamber dilatation and paradoxical anterior systolic motion of the interventricular septum is diagnostic of ASD. The size and the location of the ASD can often be visualized, as well as associated abnormalities such as mitral valve prolapse. Both CT and MRI can also demonstrate the defect of the atrial septum. However, a pitfall of MRI is the normally thin atrial septum at the fossa ovalis, which may not be visualized by MRI and thus simulate an ASD. For the diagnosis of ostium secundum ASD by MRI, at least two consecutive

Figure 8-28 Atrial septal defect. A 45-year-old woman with an ostium secundum defect has an enlarged pulmonary artery with prominence of the right atrial border. Enlargement of the right ventricle displaces the left heart border upward and to the left.

Figure 8-29 Patent ductus arteriosus in a patient with a cardiac pacemaker. An inverted "Y" calcification representing the ductus is present above an enlarged pulmonary artery (arrow).

anatomical sections showing the defect are necessary to establish the diagnosis with confidence.[152]

Pulmonary Valvular Stenosis (Fig. 8-30)

Valvular stenosis in adults is usually an isolated anomaly. Most patients are asymptomatic even with severe obstruction. Mild to moderate enlargement of the main pulmonary artery is present because of poststenotic dilatation resulting from the jet effect of blood flow through the narrowed pulmonary valve orifice. Since the jet is directed toward the left, the left pulmonary artery is often preferentially enlarged. Calcification of the pulmonary valve is rare in this condition. The differential diagnosis of pulmonary valvular stenosis includes primary and secondary pulmonary hypertension and idiopathic pulmonary artery dilatation.[141] [142]

Congenital Corrected Transposition of the Great Arteries (Fig. 8-31)

In this condition, ventricular inversion and transposition of the pulmonary artery and aorta result from formation of a left (*levo* or *l*) rather than a right (*dextro* or *d*) bulboventricular loop. Systemic venous flow is transmitted to the lungs by way of a right-sided anatomical left ventricle and the transposed pulmonary artery. Pulmonary venous flow traverses the left atrium and a left-sided anatomical right ventricle en route to the aorta. Radiographically, the ascending aorta is positioned to the left and forms a long continuous shadow along the left cardiac border from the ventricular apex to the aortic arch. The main pulmonary artery lies behind and to the right of the aorta and is not border-forming with the lung in the PA view. A left-to-right shunt may or may not be present, and left atrioventricular valve regurgitation and conduction abnormalities leading to heart block are fairly common. The heart is normal to enlarged, depending on the degree of atrioventricular valve regurgitation. Cross-sectional imaging supports the plain film diagnosis by showing an anterior left-sided aorta and a pulmonary artery lying behind and medial to the aorta.

Cyanotic Congenital Heart Disease in the Adult (see also Chap. 44)

TETRALOGY OF FALLOT.

This abnormality is the most common cyanotic congenital cardiac lesion in adults, as well as in children. Most adults with tetralogy of Fallot demonstrate mild to moderate pulmonary hypovascularity. Those with mild infundibular pulmonary stenosis have normal pulmonary blood flow. Small tortuous bronchial arteries are found in both lungs when severe pulmonary outflow tract stenosis or atresia is present. A right aortic arch is found in 25 percent of patients[153] (see Fig. 8-5) . The combination of a right aortic arch and cyanosis should always suggest the diagnosis of tetralogy of Fallot. Echocardiography often demonstrates a high and large ventricular septal defect, overriding of the ventricular septum by the aorta, and right ventricular hypertrophy. Both EBCT and MRI also demonstrate the septal defect and the large ascending aorta, as well a right aortic arch.[147] Plain films show a boot-shaped heart in some adult patients, but this finding is less common than in children because those who survive into adulthood are less likely to have severe right ventricular outflow tract stenosis (see Fig. 8-6 *E*).

EBSTEIN ANOMALY

(see Fig. 8-9 *B*). In Ebstein anomaly, the tricuspid valve is malformed and partially fused to the walls of the right ventricle. This combination results in downward displacement of the tricuspid orifice, and regurgitation ensues. A right-to-left shunt is present at the atrial level and causes cyanosis. The right heart chambers are enlarged, often markedly, as a manifestation of the tricuspid regurgitation. The typical radiographic findings are

Figure 8-30 Asymmetrical pulmonary blood flow in a 51-year-old man with pulmonary valvular stenosis. The left pulmonary artery is larger than the right because the jet of blood is directed to the left pulmonary artery (arrow).

Figure 8-31 Corrected transposition of the great vessels (ventricular inversion). *A*, Posteroanterior chest film. The unique appearance of the left-sided ascending aorta is diagnostic (arrow). *B*, Aortography also shows the left-sided aorta originating from a morphological right ventricle.

those of a large rounded or triangular heart with a narrow vascular pedicle.[147] The pulmonary vasculature is reduced, depending on the degree of right-to-left shunting. The greater the shunt, the more diminished the vascularity. Echocardiography shows the abnormal placement of the tricuspid valve with downward displacement of the septal and posterior leaflets. Tricuspid regurgitation can be evaluated by two-dimensional and Doppler echocardiography. MRI and CT also demonstrate the downward displacement of the valve and enlargement of the right atrium.[147]

THE PERICARDIUM (see also Chap. 50)

The incidence of pericardial disease in patients with cardiac disease parallels the frequency of cardiac surgery, multisystem inflammatory disease, thoracic irradiation, and the use of an array of therapeutic agents that affect the pericardium. The presence of pericardial disease is also increasingly being recognized because cross-sectional modalities such as echocardiography and CT portray pericardial disease with great accuracy.[154] [155] [156]

THE NORMAL PERICARDIUM.

The normal pericardium is frequently identified on lateral plain film projections of the chest as a thin linear opacity separating the anterior subxiphoid mediastinal fat from subepicardial fat. The pericardium may also be visualized in the frontal projection paralleling the left heart border. The extent of normal and abnormal pericardium is best appreciated with CT and MRI in most patients because of superior contrast resolution. With both CT and MRI, the anterior, lateral, and posterior portions of the pericardium are clearly separated from mediastinal fat, and subtle discontinuous areas of pericardial thickening and loculated effusions may be clearly seen. One disadvantage of MRI and CT is that while the pericardial recesses are clearly defined, they may on occasion mimic aortic dissection or mediastinal lymphadenopathy.

PERICARDIAL EFFUSION (Fig. 8-32) .

Pericardial effusion may be a transudate or exudate, may be hemorrhagic, gaseous, or chylous, and may be caused by a wide variety of disorders. When fluid accumulates in the pericardial space, the cardiac silhouette assumes a flasklike, triangular, or globular silhouette. The normal indentations and prominences along both the left and right heart borders are effaced, so the shape of the cardiac silhouette becomes smooth and featureless. Since the pericardium extends up to the pulmonary bifurcation, when a large pericardial effusion is present, the hilar structures are draped and obscured by the distended pericardial cavity. This radiographic appearance

should help distinguish a large pericardial effusion from massive cardiomegaly, which will not obscure the hilar vessels.

In the lateral chest radiograph in a patient with pericardial effusion, the retrosternal space is typically narrowed or obliterated by the expanding cardiac silhouette. Normally, the low-density subepicardial fat merges imperceptibly with the mediastinal fat since the two fat planes are separated by only the 2-mm-thick stripe of the pericardium. When pericardial effusion is present, the subepicardial fat is displaced posteriorly by the higher density fluid, which may be visible as a wide opaque vertical band between the anterior border of the heart and the mediastinum. This "epicardial fat pad sign" is best visualized on the lateral projection and is highly specific for pericardial effusion (Fig. 8-32 *B* and *C*).

ECHOCARDIOGRAPHY (see also Fig. 7-94) .

Echocardiography is the most efficient method for the detection of simple pericardial effusion and/or thickening. A major advantage of echocardiography is that the ultrasound apparatus can be transported to the bedside to examine critically ill patients. The technique is noninvasive and is diagnostically sensitive to fluid-filled structures. When the pericardial fluid volume is small, it appears as an elliptical hypoechoic region behind the left ventricle. When the effusion is large, the pericardial hypoechoic zone expands to surround the right ventricular apex. In some cases, echocardiography may fail to identify pericardial fluid when constriction, neoplasm, or hemorrhage is present.[154] [157] If echocardiography is inconclusive, CT can be helpful in detecting pericardial thickening, diffuse or loculated effusion, calcification, and adjacent mediastinal and pulmonary disease, as well as neoplasm[154] (see Fig. 8-32 *E*). The nature of the fluid may be identified by analysis of CT density numbers. For example, higher CT density values are seen in hemopericardium than in serous effusions. Chylous pericardial effusions may have a lower attenuation value than normal pericardial fluid.[158]

MRI (see also Fig. 10-17) .

MRI can clearly detect pericardial effusion. On T1-weighted images, the pericardial cavity is shown as a dark signal void because of motion of fluid in the pericardial sac. On the other hand, the pericardial effusion is bright on a gradient-echo sequence. Pericardial fibrosis is characterized by a medium-intensity signal on T1-weighted or dark signal on T2-weighted images. Intrapericardial masses, cysts, and diffuse thickening are well demonstrated with MRI. Furthermore, MRI can clearly define pericardial recesses, mediastinal fat, and other anatomical landmarks that may present pitfalls for the echocardiographer.[159]

PERICARDIAL CONSTRICTION.

Pericardial constriction may complicate viral or tuberculous pericarditis, hemopericardium,

Figure 8-32 Pericardial effusion. *A*, The heart assumes a globular shape after development of a pericardial effusion. The normal indentations along the heart borders are effaced, so the cardiac silhouette is smooth and featureless. *B*, The subepicardial radiolucent fat stripe is derived from the subxiphoid fat anterior to a thin, higher density stripe of pericardial fluid (arrowhead). *C*, The pericardial stripe (arrowheads) is wider than in *B* because of a small pericardial effusion. *D*, A large pericardial effusion is present (arrows). *E*, Contrast-enhanced CT shows a large band of nonenhanced water density surrounding the heart that represents pericardial effusion.

pericarditis associated with radiation, and postpericardiotomy syndrome. In patients with chronic pericardial constriction, the overall heart size is large when the pericardium is thickened to 2 cm or more; otherwise, the cardiac silhouette remains normal or small. The right atrial border is flattened, and pulmonary vascular redistribution may be observed.

Small to large pleural effusions are found in 60 percent of patients with pericardial constriction, and enlargement of the azygos vein and left atrium occurs in 20 percent. Pericardial calcification is best appreciated along the anterior and inferior cardiac borders or in the atrioventricular groove. While it is important to appreciate that the presence of pericardial calcification indicates chronic pericarditis, it does not in itself establish a diagnosis of pericardial constriction.

Pericardial constriction is often confused with restrictive cardiomyopathy, and MRI and CT are particularly helpful in differentiating between these entities (see Fig. 10-45) . The pericardium in patients with restrictive cardiomyopathy is normal in thickness, and no calcification is present. In addition, diffuse limitation of global cardiac excursion in systole and diastole is present, together with myocardial thickening in hearts with restrictive cardiomyopathy.[157]

CONGENITAL ABSENCE OF THE PERICARDIUM.

This abnormality may be partial or complete. Complete absence is less common than partial absence and is usually left sided.[160] Partial absence most frequently occurs along the upper border of the pericardium on either side. If the left-sided defect is small, herniation of the left atrial appendage and/or the pulmonary trunk may occur. On the frontal chest film, herniation through a pericardial defect may resemble the appearance of pulmonary stenosis, mitral stenosis, or a mediastinal tumor. When the left pericardium is completely absent, the aortic knob remains in its usual position, but the remainder of the cardiac silhouette shifts to the left and rotates toward the right so that the right ventricle may become border-forming and the pulmonary artery and left atrial appendage are prominent.[160]

In patients with absence of the left pericardium, a plain film shows the lung interposed between the medial border of the pulmonary artery and the thoracic aorta and outlining the pulmonary artery on both its medial and lateral sides, and aerated lung may be visible between the heart and the diaphragm. CT and MRI demonstrate to best advantage absence of the left anterior pericardium between the ascending aorta and the main pulmonary artery. Displacement of the main pulmonary artery laterally and anteriorly is often a clue to the diagnosis.

PERICARDIAL CYST.

A pericardial cyst generally appears as a smooth convex bulge along the middle or lower right heart border near the cardiophrenic sulcus. However, 20 percent of pericardial cysts lie along the left heart border, sometimes mimicking a prominent left atrial appendage or left ventricular aneurysm.[161] Occasionally, pericardial recess cysts are manifested as a soft tissue mass along the right superior mediastinal border in the area of the superior vena cava[161] (Fig. 8-33) . Pericardial cysts rarely calcify and do not communicate with the pericardial space. Their clinical importance lies in the need to differentiate pericardial cysts from other masses with a similar appearance, such as thymoma, lymphoma, and postoperative hematoma. Pericardial cysts are best diagnosed by echocardiography, CT, or MRI as smoothly marginated, fluid-filled structures adjacent to the right heart border.[58] [59] [60] [61]

Figure 8-33 Pericardial recess cyst. *A*, Posteroanterior chest film showing a mediastinal bulge along the right paratracheal line. *B*, MRI in the sagittal plane shows the cyst as a homogeneous medium-intensity structure behind the superior vena cava.

BARRY L. ZARET

Myocardial Perfusion Imaging

The regional distribution of coronary myocardial perfusion can be visualized with radiopharmaceuticals that accumulate proportional to regional myocardial blood flow. The first scintigraphic images of myocardial perfusion were acquired in 1964 by Carr and colleagues with cesium-131.[1] Exercise-induced myocardial ischemia was initially visualized with potassium-43 in 1973 by Zaret and coworkers.[2] Thallium-201 (^{201} Tl), a potassium analog, became available in 1974 and has since has been used successfully for over 25 years. In the early 1990s, new technetium-99m (^{99m} Tc)-labeled compounds with better imaging characteristics and novel biological properties were introduced for visualization of myocardial perfusion. [3] Any of these imaging agents can be used to visualize the *relative* distribution of myocardial blood flow. *Absolute* quantification of myocardial blood flow is not yet feasible with single-photon-emitting radioisotopes but can be achieved with positron-emission tomography (PET). State-of-the-art myocardial perfusion imaging with ^{99m} Tc-labeled agents is acquired with electrocardiographically (ECG) synchronized gating and thus provides information on both myocardial perfusion and function.

The clinically most important application of myocardial perfusion imaging is in conjunction with stress testing for evaluation of ischemic heart disease. Numerous investigators have shown the diagnostic usefulness of exercise myocardial perfusion imaging with either ^{201} Tl or the ^{99m} Tc-labeled imaging agents. Agreement between the results of stress myocardial perfusion imaging and findings on contrast coronary angiography is generally good. More importantly, there is ample evidence that findings on stress myocardial perfusion images reflect the hemodynamic and functional significance of coronary artery stenoses and thus provide important prognostic information. Finally, the information derived from radionuclide myocardial perfusion imaging has independent and incremental value over that derived by other diagnostic methods.

In 1999, approximately 5 million stress myocardial perfusion studies were performed in the United States alone. Sixty-five percent of these studies were performed in conjunction with physical exercise and 35 percent after pharmacological vasodilation. Seventy-five percent of the stress images were acquired with ^{99m} Tc-labeled compounds and 25 percent with ^{201} Tl. Single-photon emission computed tomography (SPECT) was the predominant imaging technique used in over 90 percent of studies. In 1999, planar imaging was rarely used as the primary imaging modality in state-of-art nuclear cardiology laboratories.

RADIOPHARMACEUTICALS

^{99m} Tc-LABELED COMPOUNDS.

A number of ^{99m} Tc-labeled compounds have been developed for myocardial imaging (Table 9-1) . Presently, ^{99m} Tc-sestamibi and ^{99m} Tc-tetrofosmin are widely used.[3] The ^{99m} Tc label of these agents emits gamma rays at 140 keV and has a physical half-life of 6 hours. Because of the slow body clearance, the biological half-life of sestamibi and tetrofosmin is approximately the same as the physical half-life. The whole-body absorbed radiation dose for these agents is approximately 0.02 rad/mCi. The target organ is the gallbladder, which receives approximately 0.18 rad/mCi.

Because of more favorable dosimetry of the ^{99m} Tc-labeled compounds than ^{201} Tl, up to 30 mCi can be administered per day (see Imaging Protocols). The initial myocardial distribution of ^{99m} Tc-labeled agents is proportional to the regional distribution of myocardial blood flow. After injection, the radiopharmaceutical also accumulates rapidly in the liver and is subsequently cleared into the biliary tract. The net myocardial extraction fraction of ^{99m} Tc-sestamibi is 41 percent and that of ^{99m} Tc-tetrofosmin is 30 percent, which is substantially less efficient than that of ^{201} Tl (see below).[4] Both agents enter the myocyte by passive diffusion and bind stably to intracellular membranes. Because of intracellular retention and additional subsequent myocardial uptake during recirculation, the *absolute net retention* of

TABLE 9-1 -- COMPARATIVE CHARACTERISTICS OF VARIOUS MYOCARDIAL PERFUSION IMAGING AGENTS

CHARACTERISTIC	THALLIUM-201	TECHNETIUM Tc 99m SESTAMIBITECHNETIUM Tc 99m TETROFOSMIN
Energy emission (keV)	69-83 (x-rays) 135, 165, 167 (gamma rays)	140

^{99m} Tc-labeled agents several minutes after administration is approximately comparable to that of ^{201} Tl.

Myocardial Kinetics of ^{99m} Tc-Labeled Agents.

During the first 3 hours after injection, approximately 30 percent of a ^{99m} Tc-labeled myocardial perfusion imaging agent is cleared from the heart (Figs. 9-1 and 9-2) . Although redistribution of sestamibi in ischemic defects has been demonstrated in experimental animals[5] and in selected patients, the degree of redistribution in humans is minimal and does not have clinical significance. Since myocardial distribution of ^{99m} Tc-labeled agents remains relatively fixed over time, the distribution of myocardial blood flow *at the time of injection* is "frozen" over time and can be imaged for several hours. In addition, two separate injections are required to evaluate myocardial uptake at rest and during exercise.

THALLIUM-201.

^{201} Tl is cyclotron produced and emits mercury x-rays at 69 to 83 keV (88 percent) and gamma rays at 135, 165, and 167 keV (12 percent). Its physical half-life is 74 hours; however, its biological half-life is approximately 58 hours (see Table 9-1) . The estimated absorbed radiation dose to the whole body is 0.21 rad/mCi. The target organs are the testes (3.1 rad/mCi), the thyroid (2.3 rad/mCi), and the intestines and kidney, which receive 1.5 rad/mCi. Because of the relatively long half-life of ^{201} Tl, only a relatively small amount of radioactivity can be administered. For planar imaging, usually 2 to 2.5 mCi is administered, whereas for tomographic imaging, 3.0 to 4.5 mCi is given. The 60 percent net myocardial extraction fraction of ^{201} Tl is relatively high.[4] The initial myocardial accumulation of ^{201} Tl is proportional to myocardial blood flow. Once ^{201} Tl has entered the myocyte, continuous exchange of ^{201} Tl takes place across the cell membrane. This

Figure 9-1 ^{99m} Tc-sestamibi organ time activity curves after injection at rest and after exercise in five normal volunteers (mean + SD). The data are normalized at cardiac activity 5 minutes after injection. For clarity, standard deviations are only shown at 5, 60, 120, and 180 minutes. ^{99m} Tc-hexamibi is obsolete nomenclature for ^{99m} Tc-sestamibi. *(From Wackers FJTh, Berman DS, Maddahi J, et al: Technetium-99m hexakis 2-methoxyisobutyl isonitrile: Human biodistribution dosimetry, safety and preliminary comparison to thallium-201 for myocardial perfusion imaging. J Nucl Med 30:301, 1989. Reprinted with permission from the Society of Nuclear Medicine.)*

Figure 9-2 Planar myocardial perfusion images with ^{99m} Tc-sestamibi. Images of a normal volunteer after exercise were taken with a large-field-of-view camera. Both the right (RV) and left (LV) ventricles are well visualized. The imaging agent initially accumulated in the liver and cleared into the gallbladder (G). After 30 minutes no significant liver accumulation is seen. *(From Wackers FJTh, Berman DS, Maddahi J, et al: Technetium-99m hexakis 2-methoxyisobutyl isonitrile: Human biodistribution dosimetry, safety and preliminary comparison to thallium-201 for myocardial perfusion imaging. J Nucl Med 30:301, 1989. Reprinted with permission from the Society of Nuclear Medicine.)*

process involves the Na+, K+-ATPase pump. The intrinsic half-life of ^{201} Tl within the myocardial cell is approximately 85 minutes. However, because of continued cellular reaccumulation of ^{201} Tl, the effective half-life of ^{201} Tl in the heart is 7.5 hours. A unique aspect of ^{201} Tl studies is that images obtained *early* and *late* after injection provide different pathophysiological information:

1. Images immediately after injection reflect the flow-dependent initial distribution and thus regional myocardial blood flow.
2. Images taken after a delay of 2 to 24 hours reflect the distribution of the potassium pool and hence myocardial viability.

Myocardial Kinetics of ^{201} Tl.

After injection during peak exercise, ^{201} Tl accumulates rapidly in myocardium supplied by normal coronary arteries and subsequently clears slowly (Fig. 9-3) . In normal patients, washout at 2 hours after injection is approximately 30 percent, and at 4 hours, 35 percent. The rate of ^{201} Tl washout is related to the peak exercise heart rate, exercise duration, and ^{201} Tl blood level. The kinetics of ^{201} Tl in *ischemic myocardium* is variable.[6] When a significant coronary artery stenosis is present, the initial uptake of ^{201} Tl during exercise is lower than in normal myocardium. Subsequently, the washout of ^{201} Tl from ischemic tissue is lower than normal, and accumulation of ^{201} Tl may even occur over time. Thus, an ischemic perfusion defect normalizes, or "fills in," over time. Initial uptake of ^{201} Tl in infarcted or scarred myocardium is considerably lower than in normal myocardium. On planar images, ^{201} Tl clearance from an infarct parallels that of normal myocardium, which is very likely explained by overlap of normal myocardium on planar images.

Technical Considerations

The American Society of Nuclear Cardiology has published standards for the acquisition of nuclear cardiology studies. For a detailed description of the technical and practical aspects of imaging, we refer to these publications.[7]

COMPUTER ACQUISITION.

Radionuclide images are always acquired on computer and stored on computer disk or magnetic tape for data processing. For SPECT myocardial perfusion imaging, a 64 × 64 matrix is commonly used, whereas for planar imaging, acquisition with a 128 × 128 matrix is preferred. Many SPECT studies are acquired with ECG gating. The computer acquires imaging data synchronized with the ECG R wave. The R-R interval is usually divided into eight or sixteen frames.

IMAGING PROTOCOLS.

With the introduction of ^{99m} Tc-labeled agents and new insight in ^{201} Tl biokinetics, several standardized imaging protocols have been developed. Figure 9-4 provides a schematic representation of the most frequently used imaging protocols at the time of this writing. More detailed discussion of variations of standard imaging protocols can be found elsewhere.[8]

For imaging with ^{99m} *Tc-labeled perfusion imaging agents* (Fig. 9-4 *A* to *C*) two separate injections are given: one during exercise and a second at rest. The injections can be administered either on 1 day or on 2 days. With ^{99m} Tc-sestamibi, imaging is started approximately *15 minutes after*

Figure 9-3 Thallium-201 time-activity curves after exercise in normal myocardium (1); transiently ischemic myocardium without visual defect (2); transiently ischemic myocardium with a visible defect (3); and old myocardial infarction (4). Normal myocardium (1) shows a gradual decrease in ^{201} Tl activity over time. After transient ischemia, ^{201} Tl clearance is slower than normal (2), or ^{201} Tl uptake may increase (3) in the myocardium over time. An old infarct area (4) without exercise-induced myocardial ischemia shows a gradual decrease in ^{201} Tl activity over time, similar to that in normal

myocardium. The images show an example of a septal defect that gradually fills in over time, except at the apex, where an old scar is present (4).

Figure 9-4 Schematic representation of preferred myocardial perfusion imaging protocols using either ^{201} Tl, ^{99m} Tc-sestamibi (2-day and same-day imaging protocol), or dual isotope imaging (see the text).

injection during exercise and 60 minutes after injection at rest. Since ^{99m} Tc-tetrofosmin clears relatively fast from the liver after injection at rest, rest imaging with this compound can be started earlier than with ^{99m} Tc-sestamibi (approximately *15 minutes after injection*).

^{201} Tl STRESS IMAGING.

For stress imaging (Fig 9-4 *A*), one single dose (3.0 to 4.5 mCi) of ^{201} Tl is injected at peak exercise. Initial stress imaging should be started *within 5 minutes* of the injection. Delayed or redistribution imaging is performed *2 to 4 hours later* (the timing of delayed imaging should be standardized in each laboratory). For complete assessment of viable myocardium, a second injection of ^{201} Tl is administered at rest in selected patients. The repeat rest injection can be given either following redistribution imaging, following imaging, or on a different day (see viability).

DUAL-ISOTOPE IMAGING.

Dual-isotope imaging (Fig. 9-4 *D*) is a "hybrid" imaging protocol designed to overcome the disadvantage of a relatively lengthy imaging protocol involving two injections of sestamibi.[9] In the dual-isotope protocol, a rest injection of ^{201} Tl (3.5 mCi) is given first, followed by rest ^{201} Tl imaging. The patient is then stressed and injected with 25 to 30 mCi of sestamibi at peak stress, followed after 15 minutes by sestamibi imaging. This imaging protocol can be completed in 1.5 to 2 hours.

PATIENT IMAGING TECHNIQUES

PLANAR IMAGING.

Although SPECT imaging is at present the predominant imaging technique used in clinical nuclear cardiology, the technical basis for good-quality SPECT imaging remains the ability to perform good-quality planar imaging. Moreover, in many countries outside the United States, planar imaging is still commonly performed. To acquire optimal planar myocardial perfusion images, some basic requirements should be met.[10] The most frequent reasons for suboptimal-quality planar images are (1) insufficient count density within the heart, (2) inconsistent *patient positioning and repositioning,* (3) the use of *too large a zoom factor,* and (4) inadequate display of images.

ADEQUATE COUNT DENSITY.

Planar images should have a count of at least 600,000 in the field of view. However, when extracardiac activity is present, e.g., in the lungs or subdiaphragmatic organs, the count density in the field of view does not reflect the count density in the heart. Longer imaging time is needed to obtain adequate counts from the heart. Therefore, it is recommended that images be acquired for a certain *preset time.* For planar ^{201} Tl imaging, 8- to 10-minute acquisitions per view usually result in adequate count density imaging. With ^{99m} Tc-labeled imaging agents, adequate count density is readily achieved since 10 to 30 mC is administered. With the latter agents, a count of 1.5 to 2 million per field of view can be obtained with 5-minute acquisitions per view.

PATIENT POSITIONING.

Planar Imaging is routinely performed in three views. The *left anterior oblique* (LAO) view is usually obtained with the patient lying supine. An optimal LAO is the projection that best shows separation of the right and left ventricular cavity with the septum straight and vertical. This angulation should be used as a reference angle for the other views. The *anterior view* is obtained with the patient lying supine, 45 degrees to the right of the LAO view. For the *left lateral view,* the patient should be turned on the *right side,* with the camera head in the same position as for the anterior view. The detector head should be angled in such a way that it is as close as possible to the patient's chest wall.

PLANAR IMAGE DISPLAY.

The *display* of planar myocardial perfusion images is of importance for reproducible and consistent interpretation. Planar images should be displayed in a "white-on-black" linear gray scale (see Figs. 9-1 and 9-2) . On these images the heart is white (radioactivity). Color display of *planar* images is discouraged because of exaggeration of nonsignificant differences in radiotracer uptake. The linear gray scale should be normalized to the "hottest pixel" within the heart (Fig. 9-5) . In this manner, the full gray scale is used in representation of the heart, a feature particularly important for display of images acquired with ^{99m} Tc-labeled agents, which may have

Figure 9-5 Normalization of exercise/rest ^{99m} Tc-sestamibi images. Intense subdiaphragmatic activity (arrow) may cause problems with adequate display of the image of the heart. Radionuclide images are usually normalized to the "hottest" area in the field of view. On exercise sestamibi images, the heart is the "hottest" organ. However, on the rest image the gastrointestinal tract is "the hottest" area (arrow). Consequently, when the rest image is normalized to subdiaphragmatic activity, the heart is only faintly visualized (*top*). By using ^{99m} Tc-labeled myocardial perfusion imaging agents, images should be normalized to the heart, as shown in the *bottom panel,* and produce adequate visualization of the heart. *(From Wackers FJTh: Myocardial perfusion imaging. In Sandler MP, Coleman RE, Wackers FJTh, et al: Diagnostic Nuclear Medicine. 3rd ed. Baltimore, Williams & Wilkins, 1995.)*

substantial extracardiac radiotracer accumulation. Exercise and rest/delayed images should be displayed side by side for comparison.

TOMOGRAPHIC (SPECT) IMAGING.

Careful attention to technical details is essential for good-quality SPECT imaging. Energy settings are the same as for planar imaging. During cardiac SPECT imaging, the gamma camera rotates in a circular orbit around the patient. The camera acquires a multitude of planar projection images in a stop-and-shoot or continuous acquisition mode. With ^{99m} Tc-labeled agents, the time for each stop is approximately 25 seconds for a high-dose (20 to 30 mCi) study and 30 seconds for a low-dose (10 mCi) study. For imaging with ^{201} Tl, the duration of each stop is extended to 40 seconds. Extensive recommendations for optimal-quality SPECT imaging can be found in guidelines published by the American Society of Nuclear Cardiology.[7]

The basic principle of tomographic reconstruction involves the acquisition of multiple planar projection images around an object and reconstruction of the three-dimensional object by "filtered backprojection."[11] With ^{99m} Tc-labeled radiotracers and multiheaded gamma cameras, images are usually acquired over a 360- or 180-degree arc. For ^{201} Tl SPECT imaging, 180-degree anterior image acquisition is preferred. After backprojection, filtering techniques are used to correct for reconstruction artifacts, suppress noise, and enhance image quality. Tomographic slices are generated perpendicular to the anatomical axis of the heart rather than the anatomical axis of the body.

PATIENT POSITIONING

Patient positioning and patient preparation are extremely important for optimal SPECT imaging. Patient motion is a common cause of artifacts on SPECT imaging. Motion may involve movement of the upper half of the patient's body but may also result from a change in position of the heart within the chest. Immediately after exercise, the heart may be in a vertical position because of deeper breathing. While the patient recovers from exercise, the heart may move into a horizontal position. This phenomenon of "upward creep" can cause artifactual inferior wall defects on reconstructed slices and was a problem with ^{201} Tl SPECT since imaging was started

as soon as possible after termination of exercise. Artifacts caused by upward creep can be avoided by delaying the start of SPECT imaging for approximately 10 minutes. This delay allows for the acquisition of one *planar* image immediately after exercise, which is useful for evaluation of increased lung uptake. Since SPECT imaging with ^{99m} Tc-labeled agents is not started before 15 minutes after exercise, upward creep is not usually an issue when using these radiotracers.

ADEQUATE COUNT DENSITY.

Adequate count density is a frequently ignored aspect of tomographic perfusion imaging. Poor count density on reconstructed and filtered SPECT images should be suspected when the distribution of radiopharmaceutical appears to occur in multiple "patches" of apparent higher and lower activity, a pattern that does not match the usual anatomy of coronary artery disease.

SPECT ORBIT.

Many cameras provide a choice of various acquisition orbits. The camera may rotate around the patient in a perfect *circle* or may follow the *body contour* of the patient. A body-contour orbit may cause artifacts because of varying gamma camera resolution with varying distance of the detector head from the target organ. These artifacts are characteristic and consist of small 180-degree diametrical defects on the short-axis slices. High-resolution collimation reduces the effect of varying spatial resolution and resulting artifacts. A circular orbit is preferred for cardiac SPECT imaging.

SPECT IMAGE DISPLAY.

Display of reconstructed SPECT slices has been standardized (Fig. 9-6) .[12] [13] Images are preferably displayed on computer screen in "white on black" with a linear gray scale (Fig. 9-7) . In many laboratories, color display is used as well. However, color tends to exaggerate subtle differences in myocardial radiotracer uptake, so images should be interpreted with caution. Three sets of tomographic slices are reconstructed: short-axis slices, horizontal long-axis slices, and vertical long-axis slices. The exercise and rest (or delayed) images are displayed side by side to facilitate comparison. Because of the multitude of images, it is useful to "condense" all information into one color-coded polar map, or "bull's-eye," image (see Figs. 9-13 *B* and 9-14*B*). For the interpretation of ECG-gated SPECT images, selected slices are displayed in color on computer screen and played as an endless-loop movie. The change in color intensity during the cardiac cycle correlates with regional myocardial thickening.[14]

Normal Planar Myocardial Perfusion Images

In planar imaging, perfusion is visualized as the projection of myocardial radioactivity on a plane parallel to the crystal surface of the gamma camera (see Figs. 9-2 and 9-5) . The "left ventricular cavity" as it appears on planar images is in part an optical illusion.[10] The "horseshoe" appearance of the left ventricle on planar images is a result of attenuation of radiation from the distant myocardial wall by the ventricular blood pool and the relatively greater myocardial mass of the walls perpendicular to the plane of view. The "facing" myocardial wall contains relatively less radiopharmaceutical, which creates the illusion of visualization of the ventricular cavity.

Because of overprojection of myocardial regions in one plane, it is necessary to obtain multiple planar images from different angles to visualize all segments of left ventricular myocardium. The anatomy and standardized nomenclature

Figure 9-6 Standardized display of single-photon emission computed tomographic myocardial perfusion images. The short-axis slices are displayed with the right ventricle to the left and the left ventricle to the right. The short-axis slices are displayed as a horizontal row of images, starting with the apical slice on the left and the basal slices on the right. The vertical long-axis slices are cut from the septum toward the lateral wall and display the septal slices on the left and the lateral slices on the right. The horizontal long-axis slices are cut from the inferior wall toward the anterior wall and display the inferior wall slices on the left and the anterior wall slices on the right. *(From the Cardiovascular Imaging Committee, American College of Cardiology; the Committee on Advanced Cardiac Imaging and Technology, Council of Clinical Cardiology, American Heart Association; and the Board of Directors, Cardiovascular Council Society of Nuclear Medicine: ACC/AHA/SNM Policy Statement: Standardization of cardiac tomographic imaging. J Nucl Cardiol 1:117, 1994.)*

of the heart as projected on various planar views and the various coronary artery territories are shown in Figure 9-8 .[13]

NORMAL VARIATIONS OF PLANAR MYOCARDIAL PERFUSION IMAGES.

There are several variations in the pattern of normal radiotracer uptake on planar images with which an interpreter should be familiar.[10]

Apex.

Decreased tracer activity at the apex of the left ventricle is normal. In patients with a vertical position of the heart, this feature may be prominent. A typical apical variant appears as a narrow slit or cleft-like area aligned with the long axis of the left ventricle.

Aortic Valve Plane.

On the LAO view, the membranous septum and aortic valve plane are projected at the open end of the horseshoe, which at times may appear to be causing a high septal defect. This variation may be seen prominently in patients with a horizontal position of the heart.

Mitral Valve Plane.

The mitral valve plane is seen as the open end of the horseshoe in all three views.

ARTIFACTS ON PLANAR IMAGES

INFERIOR ATTENUATION.

Attenuation of the inferior left ventricular wall is a common artifact on myocardial perfusion images and occurs in approximately 25 percent of patients.[10] Recognition of this artifact is relevant for an understanding of SPECT imaging. When a patient is imaged in the supine position, planar left lateral images may appear to reveal inferior wall defects. These defects are artifactual and caused by attenuation of inferior wall activity by the left hemidiaphragm. When the patient is turned on the right side, the defect is no longer present (Fig. 9-9) . This disappearance of the defect can be explained by a change in position of the heart and the left hemidiaphragm. By moving to the right side, the heart shifts to a vertical position and the left hemidiaphragm moves caudally, thereby resulting in less attenuation of the inferoposterior wall. Since patients are usually in the supine position for SPECT imaging, inferior attenuation artifacts are common.

OBESITY/LARGE BREASTS.

Attenuation artifacts in obese patients or patients with large pendulous breasts may render planar images almost uninterpretable. These artifactual defects on different planar views are often multiple and occur in a pattern that is inconsistent with known coronary artery territories. Superimposition of breast tissue over the heart may also result in linear areas of relatively increased activity, which is believed to be caused by small-angle scatter from the breast tissue fold. Breast artifacts are the most frequent cause of false-positive planar images. The use of breast markers is an important aid in correctly interpreting planar images (Fig. 9-10) .[10]

Normal SPECT Myocardial Perfusion Images

SPECT images are reconstructed as multiple slices oriented along the anatomical axis of the left ventricle. For interpretation of short-axis slices, it is convenient to divide the slices into three groups: apical slices, midventricular slices, and basal slices. To avoid apical artifacts from tangential cuts, only apical slices that clearly show the ventricular cavity should by analyzed. When interpreting basal slices, slices showing the membranous septum are excluded.

The standardized nomenclature, segmentation, and coronary territories are shown in Figure 9-11 .

NORMAL VARIATIONS OF SPECT MYOCARDIAL PERFUSION IMAGES.

A useful practical rule of thumb for interpreting a SPECT study is that a perfusion defect should be clearly seen on at least three consecutive slices to be considered a true abnormality. The *vertical long-axis* slices and the *horizontal long-axis* slices contain the same information shown on the short-axis slices. However, the apex and base of the heart can be analyzed in these long-axis slices without partial volume artifacts. Only slices that clearly show the left ventricular cavity should be analyzed. Slightly less inferoseptal uptake can be noted in male patients as a normal variant (see Fig. 9-7) . In females, radiotracer distribution is usually more homogeneous. The basal short-axis slices generally show a septal defect, which is a normal finding and represents the membranous portion of the septum.

ARTIFACTS ON SPECT IMAGES

MOTION ARTIFACTS.

Motion artifacts and how to avoid them have been discussed above (Patient Positioning). Most gamma camera computer systems have motion correction software. Nevertheless, it is better to prevent movement by the patient during imaging than to correct for it later.

ATTENUATION ARTIFACTS.

Attenuation artifacts are the most common source of error in SPECT imaging. The supine position may cause inferior wall defects because of attenuation by the left hemidiaphragm (see Fig. 9-9) . To avoid such artifacts, alternative patient positioning has been proposed. For instance, the patient can be imaged prone (lying on the stomach), turned on the right side, or sitting in an upright position. We recommend repeat imaging in the prone position when inferior attenuation is suspected. Attenuation by breast tissue can cause artifacts on SPECT imaging as well. However, rarely do they render SPECT images uninterpretable as may happen with planar imaging, possibly because SPECT images are acquired and reconstructed from numerous positions rather than from one single planar projection. Nevertheless, it is important to be aware of the potential presence of artifacts *before* starting interpretation. Careful inspection of the *cinegraphic display of unprocessed projection images* on the computer screen may help anticipate potential attenuation problems. The breast can often be recognized as a "shadow" moving over the heart in certain projections and may therefore cause attenuation artifacts.

All commercial vendors of nuclear imaging equipment are presently developing attenuation correction software. Although the progress is promising, at the time of this writing no attenuation correction system has as yet earned full clinical acceptance.[15] The development of software that accurately corrects for nonuniform attenuation over a wide range of clinical conditions is the single most important challenge that computer scientists face in the field of nuclear cardiology.[16]

QUALITY CONTROL.

Quality control should be performed systematically as a part of *every* interpretation of a SPECT study and should involve the following: (1) The cinegraphic display of all planar projection images should be inspected to assess motion of the patient or the heart and the presence of a breast shadow. (2) Adequate count density should be checked, e.g., a count of *at least 100* within the "hottest" pixel of the heart in one of the unprocessed anterior projection

Figure 9-7 Single-photon emission computed tomographic (SPECT) ^{99m} Tc-sestamibi myocardial images after exercise and at rest in a normal subject showing normal variations of radiopharmaceutical distribution. On the midventricular short-axis slices (*A*) the inferior septal areas (small arrows) have slightly less activity than seen in the lateral wall, which is a normal variation. The hottest area is in the lateral wall. On the basal slices (*B*), an apparent septal defect is present (large arrow) in the membranous portion of the septum. This "septal defect" and normal variation are also seen in the horizontal long-axis slices (*C*), where the septum is shorter (arrow) than the lateral wall. Vertical long-axis slices are shown in *D. (From Wackers FJTh: Artifacts in planar and SPECT myocardial perfusion imaging. Am J Card Imaging 6:42, 1992.)*

images. (3) The presence of diaphragmatic attenuation of the inferoposterior wall should be assessed by comparing a planar left lateral "supine" view with a planar left lateral "right side down" decubitus view (see Fig. 9-9) . When attenuation of the inferior wall is suspected, imaging should be repeated immediately in the prone position. (4) Regional wall motion and thickening should be assessed on cinegraphic display of ECG-gated SPECT images in regions with perfusion defects. A fixed perfusion defect with normal regional wall motion on gated SPECT is very likely an attenuation artifact.

Image Interpretation

Myocardial perfusion images are interpreted qualitatively by visual analysis, often aided by computer quantification. Image interpretation can be described as follows (Fig. 9-12) :

NORMAL.

Homogeneous uptake of the radiopharmaceutical throughout the myocardium is considered normal.

DEFECT.

A defect is a localized myocardial area with relatively less radiotracer uptake than normal. Defects may vary in intensity from slightly reduced activity to almost absent activity.

REVERSIBLE DEFECT.

A defect present on the initial stress images and no longer present or present to a lesser degree on resting or delayed images is a reversible defect. This pattern indicates myocardial ischemia. Improvement over time on ^{201} Tl imaging is referred to as "redistribution." It is not appropriate to use this terminology for ^{99m} Tc-labeled agents.

FIXED DEFECT.

A defect that is unchanged and present on both exercise and rest (delayed) images is a fixed defect. This pattern generally indicates infarction and scar tissue. However, in some patients with fixed ^{201} Tl defects on 2- to 4-hour delayed imaging, improved uptake can be noted on 24-hour redistribution imaging or after a new resting injection (see below).[17] Similarly, a fixed defect with ^{99m} Tc-labeled agents (which involves injection at rest) may at times underestimate myocardial viability.

REVERSE REDISTRIBUTION.

This pattern occurs mainly with ^{201} Tl imaging. However, a "reverse defect" is observed occasionally with ^{99m} Tc-labeled agents. The initial stress images are either normal or show a defect, whereas the delayed or rest images show a new defect or a more severe defect. This pattern is frequently observed in patients with

Figure 9-8 *Top,* Anatomy of the heart as projected on planar views. *Bottom,* Coronary artery territories on three planar views. The shaded area indicates the facing myocardium overlying the left

ventricular cavity. *(From Wackers FJTh: Artifacts in planar and SPECT myocardial perfusion imaging. Am J Card Imaging 6:42, 1992.)*

infarction who are undergoing thrombolytic therapy or percutaneous coronary angioplasty. The phenomenon is thought to be caused by initial *excess* of tracer uptake in a reperfused area with a mixture of scar tissue and viable myocytes. Initial accumulation is followed by rapid clearance from scar tissue. Although the significance of this finding is controversial, it does *not* represent evidence of exercise-induced ischemia. With PET using fluorine-18-labeled fluorodeoxyglucose (FDG), the presence of residual viable myocardium has been demonstrated within areas with reverse redistribution.[18]

RADIOTRACER LUNG UPTAKE.

Normally, no or very little radiotracer is noted in the lung fields on postexercise images. Increased lung uptake can be quantified as a lung/heart ratio (normal, <0.5 for ^{201} Tl, <0.45 for ^{99m} Tc-sestamibi). This abnormal image pattern indicates stress-induced left ventricular dysfunction and severe coronary artery disease,[19] [20] [21] a powerful predictor of adverse outcome.

TRANSIENT LEFT VENTRICULAR DILATION.

Occasionally, the left ventricle can be noted to be larger following exercise than on the rest or delayed image. This pattern of transient dilation probably indicates exercise-induced left ventricular dysfunction. It has been suggested that rather than a true increase in volume of the left ventricle, this image pattern is caused by decreased subendocardial radiotracer uptake and, consequently, apparent thinning of the myocardium on the stress image.

RIGHT VENTRICULAR VISUALIZATION.

Usually, the right

Figure 9-9 Artifactual inferior defect resulting from diaphragmatic attenuation. *Top,* ^{99m} Tc-sestamibi short-axis images acquired in the supine position. A mild inferior myocardial perfusion defect (arrow) is present. Because of a clinically low likelihood of coronary artery disease, imaging was repeated in the prone position (*bottom*). The prone images are normal. The artifactual defect is caused by diaphragmatic attenuation. On the right side are two planar left lateral (LL) images obtained with the patients supine and in a right-sided decubitus position (decub). The planar supine image shows again a posterior wall defect (arrow) caused by diaphragmatic attenuation, whereas the decubitus images are normal. The acquisition of two planar LL images is a simple quality assurance measure that can be performed in every patient.

Figure 9-10 Planar^{201} Tl left anterior oblique (LAO) and anterior (ANT) images in a woman with large breasts (LAO1, ANT1 = exercise images; LAO2, ANT2 = delayed images). The breasts are marked with radioactive line markers (m) in the images on the right. On the LAO exercise images (*top*), a definite attenuation artifact is present (arrow). At delayed imaging, the breast contour is lower and is visualized as a linear area (arrow) with increased activity caused by "small-angle scatter." The exercise anterior view (*bottom*) is normal because the breast did not cover the heart. However, at delayed imaging, the contour of the breast is across the heart and is causing an attenuation artifact (arrow). This example demonstrates how breast attenuation artifacts can vary in the same view with different breast positions. Note that on the delayed LAO image, unequal attenuation mimics an image with increased lung uptake of ^{201} Tl. *(From Wackers FJTh: Artifacts in planar and SPECT myocardial perfusion imaging. Am J Card Imaging 6:42, 1992.)*

Figure 9-11 Left ventricular anatomy and coronary artery territories on single-photon emission computed tomographic slices taken from a 17-segment model. *(Modified from Port SC (ed): Imaging Guidelines for Nuclear Cardiology Procedures, Part 2. J Nucl Cardiol 6:649, 1999.)*

Figure 9-12 Schematic representation of the interpretation of myocardial perfusion images. Shaded areas indicate myocardial perfusion defects.

ventricle is only faintly visualized on rest or stress SPECT myocardial perfusion images. Right ventricular myocardial mass and blood flow are approximately 50 percent less than that of the left ventricle. Marked visualization of the right ventricle at rest is abnormal and in most cases indicates right ventricular hypertrophy. Markedly increased right ventricular uptake on exercise SPECT images is an abnormal pattern that has been associated with severe coronary artery disease.[22]

GLOBAL AND REGIONAL CONTRACTION ON ECG-GATED IMAGES.

The ECG-gated image should be analyzed in color display. Regional myocardial wall thickening can be appreciated as a regional increase in the brightness of color. Wall thickening can be scored subjectively as normal, hypokinetic, or absent.

Visual and Quantitative Image Analysis

Myocardial perfusion images are relatively difficult to interpret. As with visual interpretation of any image data, considerable intraobserver and interobserver variability in subjective interpretation is noted, even among experienced readers.[23] Reproducibility of interpretation is related to a number of factors: (1) the overall quality of raw data, (2) image display quality, (3) the degree of abnormality, (4) the degree of change between exercise and rest images, and (5) familiarity with normal variations.

SCORING OF SPECT IMAGES

SEMIQUANTITATIVE.

Myocardial perfusion defects may vary in extent and severity. The extent of a defect can be expressed as the number of segments involved with the use of a scheme as shown in Figure 9-11 . Although computer quantification of defect size is preferred, a semiquantitative scoring system using a 5-point score for each segment is well established. For each segment, the severity of reduced radiotracer uptake can be scored subjectively as follows: 0 = normal, 1 = mildly reduced or equivocal, 2 = moderately reduced, 3 = severely reduced, and 4 = absent uptake. From this scoring system a "summed stress score," a "summed rest score," and a "summed reversibility score" can be derived.[24] A summed stress score less than 4 is considered normal, 4 to 8 is mildly abnormal, 8 to 13 is moderately abnormal, and more than 13 is severely abnormal.

QUANTIFICATION OF SPECT IMAGES.

Computer quantification of myocardial perfusion images provides an important means of improving the consistency of image interpretation and decreasing reader variability.[23] Several approaches to image quantification have been described. The output of computer quantification generally consists of

Figure 9-13 Exercise-rest single-photon emission computed tomographic (SPECT) myocardial perfusion imaging with ^{99m} Tc-sestamibi in a normal subject. *A,* Horizontal long-axis, short-axis, and vertical long-axis slices. A normal distribution of ^{99m} Tc-sestamibi is noted. *B,* Exercise and rest polar maps (bull's-eye display) of the tomographic slices in *A.* On both the exercise and rest polar map, the distribution of radiopharmaceutical is approximately homogeneous. Color scale: White represents the area with highest activity; yellow, orange, red, violet, blue, and black indicate gradually decreasing count activity. The coronary artery territories of the left anterior descending coronary artery (LAD), left circumflex coronary artery (LCX), and the right coronary artery (RCA) are indicated. *C,* Circumferential count profiles. The relative activity of sestamibi on the exercise images is displayed as a white line. The relative activity of sestamibi on the rest images is displayed as a black line. The

lower limit of normal sestamibi distribution is indicated as the thin white line. Relative radiotracer activity in the anterior (Ant) septum (Sep) and inferior (Inf) and lateral (Lat) wall is shown in representative basal, midventricular, and apical short-axis slices. In this normal subject the relative distribution of sestamibi is above the lower limit of normal distribution, which indicates absence of perfusion defects and thus normal images. *D,* electrocardiographic (ECG)-gated exercise myocardial perfusion images of the same patient. End-diastolic and end-systolic frames of the short-axis slices (SA), horizontal long-axis slices (HLA), and vertical long-axis slices (VLA) are shown. The color coding is the same as in *B.* Comparison of the end-diastolic and end-systolic frames allows assessment of regional wall motion and regional wall thickening. In this normal subject, wall motion and thickening are homogeneous: The color in the anterior wall, septum, and lateral wall change from yellow to white; in the inferior wall the color changes from orange to yellow. The relatively lesser activity in the inferior wall is caused by diaphragmatic attenuation. *Continued. E,* The left ventricular ejection fraction (LVEF) can be computed from the ECG-gated SPECT slices.

Figure 9-14 *Continued. C,* Circumferential profiles analysis. The relative distribution of radiopharmaceutical is displayed for representative apical, midventricular, and basal short-axis slices. The yellow line represents the exercise study, the orange line represents the rest study, and the thin white line represents the lower limit of normal distribution. The apical slice (*top left*) shows no significant improvement on the resting study. In contrast, septal defect reversibility is demonstrated in the midventricular slice (*top right*) and the basal slice (*bottom left*). The apical defect (*bottom right*) is fixed. Total exercise myocardial perfusion defect size is quantified as 38 percent of the total left ventricle. The rest defect is 24 percent. Defect reversibility is 37 percent. *D,* Electrocardiographic (ECG)-gated exercise SPECT images. End-diastolic and end-systolic frames are shown for the short-axis slices (SA), horizontal long-axis slices (HLA), and vertical long-axis slices (VLA). On the end-diastolic frames an extensive anteroapical and septal myocardial perfusion defect is present. Analysis of wall motion shows absence of thickening in the anteroapical segment on the vertical long-axis and horizontal long-axis slices. On the short-axis slice and horizontal long-axis slice, in spite of the presence of an exercise-induced anteroseptal myocardial perfusion defect, thickening (change from orange and blue to yellow) of the anteroseptal segment can be appreciated. *Continued. E,* The left ventricular ejection fraction (LVEF) is computed from the ECG-gated SPECT images as 40 percent.

the following: (1) graphic or polar map display of the relative myocardial distribution of radiotracer, (2) quantitative comparison of relative radiotracer distribution with a normal reference data base, and (3) quantitative comparison of stress defect size with rest (delayed) defect size and quantification of defect reversibility.

Polar Maps (Bull's-Eye Display).

In SPECT imaging, a multitude of reconstructed images are available for analysis. A typical SPECT study consists of approximately 32 paired (stress and rest) images in short-axis, vertical long-axis, and horizontal long-axis slices (Fig. 9-13 *A* and 9-14 *A*). Computer quantification is usually performed on reconstructed short-axis slices. The most widely used and commercially available approach is that of a polar map, or bull's-eye, display (Fig. 9-13 *B* and 9-14 *B*) The purpose of a polar map is to generate one single image that encompasses the relative radiopharmaceutical distribution in the entire heart. Relative radiopharmaceutical uptake on short-axis images is compressed to color-coded concentric rings, with the apical slice in the center and the basal slices on the periphery of the polar map. It is important to understand that a polar map is *not a true image,* but a simplified color-coded derivative of analog images. The bull's-eye image can be compared with a normal reference polar map. A normal data base is not usually derived from patients with normal coronary arteries, but rather from subjects with a low (<3 percent) likelihood of coronary artery disease. Considerable variation exists with regard to the generation of SPECT normal data bases. In some software packages, the lower limit is a uniform mean -2 SD. In other approaches, different criteria are applied for each coronary artery territory. Gender-specific data bases have also been recommended.

Areas with a significant myocardial perfusion defect (i.e., relative count distribution below the lower limit of normal) can be highlighted on a polar map as a "blackout area" (Fig. 9-14 *B*). By comparing stress and rest polar maps and image subtraction, the amount of defect reversibility can be visualized and quantified.[25] Although several commercially available software packages exist for the generation of polar maps, manufacturers often do not supply a normal data base. Consequently, in many laboratories, SPECT polar maps are interpreted visually without a normal reference file and without quantification.

Circumferential Profiles.

An alternative approach to the polar map display for quantification of SPECT images is the use of circumferential profiles (Figs. 9-13 *C* and 9-14 *C*). Multiple circumferential profiles are generated over each of the short-axis slices and compared with those of a normal reference data base.[26] In a normal image, all data points of circumferential profiles are above the lower limit of normal (see Fig. 9-13 *C*). In a patient with a myocardial perfusion defect (Fig. 9-14 *C*), the count profile is below the lower limit of normal in the areas corresponding to a visually perceived defect. With circumferential profiles, a defect can be quantified as an integral, i.e., the area below the lower limit of a normal curve proportional to the total potentially visualized normal myocardium.

The total size of a myocardial perfusion defect can be expressed as a percentage of the entire left ventricle. The computed defect size is adjusted for slice thickness and varying diameter of each short-axis slice from base to apex. This approach provides quantification of total exercise defect size, rest defect size, and percent defect reversibility.[26]

Regardless of the quantitative approach used, the advantage of computer quantification is in providing a *graphic display of the relative distribution of radiopharmaceutical uptake in the myocardium and the degree of perfusion abnormality in comparison to a normal reference data base.*

Clinical Use of Quantification of Myocardial Perfusion Imaging

Computer quantification of myocardial perfusion images enhances the overall accuracy of detection of coronary artery disease and also enhances the reproducibility of interpretation.[23] However, quantification should be used astutely. In general, from the standpoint of diagnostic interpretation, quantification should confirm impressions derived from visual analysis of images.[27] If the quantitative information appears to be discordant, one should inspect the images again. Frequently, one may recognize that the quantification was correct. However, sometimes artifacts may cause abnormal quantitative results. The process of integrating visual and quantitative information can be referred to as "quantitative analysis with visual overread." It is important to realize that artifacts, such as those caused by attenuation from the overlying soft tissue or diaphragm or resulting from patient motion, often have an unpredictable effect on the appearance of reconstructed slices. Although a normal data base, to a certain extent, incorporates normal variations, computer quantification per se should not be expected to be able to distinguish between true perfusion defects and artifacts.

For reasons to be discussed later, it is important that reports to referring physicians describe image abnormalities

TABLE 9-2 -- COMPARATIVE CHARACTERIZATION OF ABNORMAL SPECT RESULTS

CHARACTERISTIC	DEFECT SIZE

in terms of "*small, moderate, and large and high or low risk.*" Table 9-2 shows a comparative categorization of myocardial perfusion abnormalities by semiquantitive scoring or computer quantification.[9]

ECG-Gated Myocardial Perfusion Imaging

The high photon flux of ^{99m} Tc-labeled compounds makes it feasible to acquire myocardial perfusion images in an ECG-gated mode.[7] ECG-gated myocardial perfusion images can be displayed as an endless-loop cine on the computer screen. ECG-gated SPECT images allow for assessment of global left ventricular ejection fraction (LVEF) (Figs. 9-13 *E* and 9-14 *E*), regional wall motion, and regional wall thickening.[28] [29] [30] [31] Regardless of whether the injection of radiopharmaceutical was performed during peak stress or at rest, since the *acquisition* is performed at rest, ECG-gated SPECT images reveal *resting* global function and wall motion and *resting* wall thickening in areas with exercise-induced myocardial perfusion defects. Regional wall thickening on ECG-gated SPECT images can be quantified as "percent wall thickening" in comparison to end-diastole.[30] [31] Commercially available and validated software packages exist for the automatic calculation of resting global LVEF, left ventricular volume, and regional wall thickening from ECG-gated SPECT slices.[28] [29] When eight frames are acquired during the R-R cycle, one should anticipate a slight underestimation of LVEF by approximately 4 percent. In general, LVEF from gated SPECT agrees well with resting LVEF determined by other modalities. Quality assurance is important. LVEF from gated SPECT can be less accurate, even invalidated, by an irregular heart rate, low count density, intense extracardiac radiotracer uptake adjacent to the left ventricle, and small size of the left ventricle.

Combined interpretation of perfusion and function on ECG-gated images substantially increases the confidence of interpretation. Taillefer and associates reported that interpretation of stress *and* rest end-diastolic slices rather than summed ungated slices may enhance the overall sensitivity of detecting mild coronary artery disease.[32] ECG-gated images are also useful for the recognition of artifactual defects caused by attenuation (breast and diaphragm) and thus adds to quality control of SPECT imaging. ECG-gated SPECT imaging is presently considered the state of the art of radionuclide myocardial perfusion imaging.[33]

CLINICAL APPLICATIONS OF MYOCARDIAL PERFUSION IMAGING

Acute Coronary Syndromes

Acute Myocardial Infarction (see also Chap. 35)

DETECTION.

Myocardial perfusion imaging with either ^{201} Tl or ^{99m} Tc-labeled compounds is a very sensitive and reliable means for the early detection of acute myocardial infarction (Fig. 9-15) . The timing of imaging after the onset of acute chest pain is relevant to the results of imaging. Images obtained during the first 6 hours after the onset of myocardial infarction show without exception perfusion abnormalities at the anatomical location of infarction. However, as the time interval after the onset of chest pain increases, some patients may have normal perfusion images. Serial imaging in patients with acute myocardial infarction has revealed that in some patients the size of a myocardial perfusion defect may decrease over time. These observations, initially made in 1976 with ^{201} Tl, are now better understood. Endogenous thrombolysis occurs in approximately 20 percent of patients with acute infarction, which may explain the observed spontaneous improvement in myocardial perfusion images over time. The location and size of myocardial perfusion defects in acute myocardial infarction correlate well with postmortem findings.

THROMBOLYTIC THERAPY.

During the early hours of acute myocardial infarction, serial myocardial perfusion imaging with ^{99m} Tc-labeled compounds can be used to visualize the effectiveness of thrombolytic therapy. Because of the lack of significant redistribution, ^{99m} Tc-labeled compounds can be injected *before* the initiation of thrombolytic therapy, and imaging of myocardial perfusion can be performed later.[34] [35] [35A] [36] [37] Gibbons and coworkers,[34] Wackers and colleagues,[35] and others[36] [37] showed that successful thrombolysis of an infarcted artery can be predicted by a decrease in the size of myocardial perfusion defects on serial ^{99m} Tc-sestamibi imaging (Fig. 9-16) . This imaging modality allows for noninvasive assessment of the area at risk and the amount of salvaged myocardium.

Gibbons and coworkers conducted a series of important clinical studies with ^{99m} Tc-sestamibi in patients with acute infarction that provided unique new insight in the pathophysiology of human acute myocardial infarction. Their experience can be summarized as follows. The myocardial area at risk varies greatly in individual patients,[34] [35] [35A] with little correlation between the extent of the area at risk as demonstrated by sestamibi imaging and the anatomical site of occlusion of the infarcted artery, i.e., distal or proximal.[38] The area at risk in acute anterior myocardial infarction is usually larger than that in acute inferior infarction. Infarct size as measured by sestamibi at hospital discharge is predictive of subsequent remodeling.[39] Patients with collateral coronary circulation to the infarcted artery have a smaller ultimate infarct size than do patients without collateral vessels.[40] [41] A decrease in myocardial perfusion defect size between images obtained before and after thrombolytic therapy reliably predicts subsequent improvement in left ventricular regional wall motion.[42] Serial myocardial perfusion imaging has further shown that in many patients (approximately 40 percent), myocardial perfusion defect size continues to decrease during the days after administration

Figure 9-15 *Top,* Typical singlephoton emission computed tomographic (SPECT) ^{99m} Tc-sestamibi images of acute myocardial infarction in short-axis (SA), horizontal long-axis (HLA), and vertical long-axis (VLA) slices. From top to bottom are shown anterior (ANT), anteroseptal (SEP), lateral (LAT), and inferior (INF) infarctions. Defects are indicated by arrows. *(From Wackers FJTh: Myocardial perfusion imaging. In Sandler MP, Coleman RE, Wackers FJTh (eds): Diagnostic Nuclear Medicine. Baltimore, Williams & Wilkins, 1995.)Bottom,* Quantification of infarct size on SPECT myocardial perfusion images. ^{99m} Tc-sestamibi images in a patient with anteroseptal myocardial infarction are shown. The images on the *left* show horizontal long-axis, short-axis, and vertical long-axis slices. An anterior apical myocardial perfusion defect (arrow) is present. On the *right* is the circumferential profile count distribution. The thin line represents the lower limit of normal distribution of sestamibi. The white data points represent the patient's circumferential profile. The circumferential profile is below the lower limit of normal in the anteroseptal and lateral areas. The defect is quantified as 30 percent of the total left ventricle.

of thrombolytic therapy.[34] [43] Marcassa and colleagues observed the same phenomenon of continued decreasing resting defect size in stable patients late (7 months) after anterior wall infarction.[44] The pathophysiological basis of this phenomenon remains unclear. Ito and coworkers demonstrated delayed recovery from microvascular damage after acute infarction,[45] which could be a potential explanation for late improvement in defect size.

Serial myocardial perfusion imaging with ^{99m} Tc-labeled myocardial perfusion imaging agents should be viewed as a useful clinical research tool to assess the efficacy of reperfusion strategies in acute myocardial infarction.[46] [47] Patients serve as their own controls, and fewer patients are needed to achieve statistical power in a clinical trial.

EARLY RISK STRATIFICATION.

An inverse relationship exists between the size of a resting myocardial perfusion defect and global LVEF. Not surprisingly, the size of the resting myocardial perfusion defect after acute myocardial infarction correlates with the patient's prognosis. As early as 1980, Silverman and associates showed with planar imaging that patients with large resting myocardial perfusion defects had a significantly poorer prognosis and survival than did patients with small myocardial perfusion defects. This outcome appeared to be independent of other clinical parameters. Similar prognostic value of resting SPECT myocardial perfusion defect size was confirmed by Cerqueira and colleagues after thrombolytic therapy for acute infarction[48] (see Fig. 9-22) . Certain resting image patterns indicate a poor outcome after acute infarction. Visualization of the right ventricle at rest[49] and increased lung uptake of ^{201} Tl at rest in patients with recent infarction [50] are indicators of an unfavorable course after acute myocardial infarction. These image patterns reflect impaired left ventricular function.

Brown and associates demonstrated the value of ^{201} Tl and ^{99m} Tc-sestamibi dipyridamole myocardial perfusion imaging for *early* (days 2 to 4) *risk stratification* of patients with recent acute myocardial infarction.[51] Early vasodilation myocardial perfusion imaging was safe and predicted in-hospital and late cardiac events (cardiac death and recurrent infarction) better than did submaximal exercise imaging at hospital discharge. The ability to perform early risk stratification after infarction with nuclear imaging is of clinical importance. Management decisions regarding discharge or intervention can be made on day 2 after acute infarction rather than on days 5 to 7 at the time of predischarge stress testing with the conventional approach. Such earlier risk stratification may result in the prevention of in-hospital

Figure 9-16 Planar myocardial perfusion imaging with ^{99m} Tc-sestamibi before and after thrombolytic therapy in a patient with an acute anteroseptal myocardial infarct. ^{99m} Tc-sestamibi was injected

immediately before initiation of thrombolytic therapy and imaging performed 2 hour later. Because of the lack of significant redistribution of ^{99m} Tc-sestamibi, the distribution of myocardial blood flow at the time of injection is "frozen" in time. The images before thrombolytic therapy show an anteroseptal myocardial perfusion defect (arrows) that was quantified as 53 percent. The patient was reinjected with ^{99m} Tc-sestamibi when thrombolytic therapy was completed. These images show improved perfusion of the anteroseptal segments, indicative of successful reperfusion of the infarct artery. The size of the perfusion defect after thrombolytic therapy was 35 percent. Therefore, 33 percent of myocardium was salvaged by thrombolytic therapy in this patient. *(From Wackers FJTh, Gibbons RJ, Verani MS, et al: Serial quantitative planar technetium-99m-isonitrile imaging in acute myocardial infarction: Efficacy for noninvasive assessment of thrombolytic therapy. J Am Coll Cardiol 14:861, 1989. Reprinted with permission from the American College of Cardiology.)*

events and will definitely result in shorter in-hospital length of stay. The potential economic impact of this approach still needs to be evaluated.

Unstable Angina (see also Chap. 36)

Patients with unstable angina but without prior myocardial infarction may have abnormal resting myocardial perfusion images. Such resting myocardial perfusion defects are demonstrable not only when the radiopharmaceutical is injected *during* chest pain but also for considerable time *after* the angina has subsided.[52] Resting ^{201} Tl defects in patients with unstable angina are invariably reversible and indicate transient hypoperfusion of viable myocardium. ^{99m} Tc-labeled myocardial perfusion imaging agents that do not redistribute have a particular advantage in patients with unstable angina. The lack of redistribution makes it possible to inject the radiotracer during pain and acquire images at a later time when the patient is pain free and stable. Bilodeau and coworkers studied patients with unstable angina by ^{99m} Tc-sestamibi SPECT imaging.[52] Patients with abnormal ECGs during pain had larger myocardial perfusion defects than did those who did not have abnormal ECGs. The observations with myocardial perfusion imaging in patients with unstable angina imply that impaired regional myocardial blood flow persists longer than can be judged from the clinical status or ECG. Patients with reversible resting myocardial perfusion defects usually have severe multivessel coronary artery disease. Resting myocardial perfusion imaging during pain was more sensitive and more specific for the presence of significant coronary artery disease than the resting ECG was.[52]

Resting imaging in patients with recurrent chest pain after infarction or with unstable angina is useful for objectively demonstrating the presence of transient myocardial hypoperfusion and viable myocardium. This information can be very helpful when myocardial revascularization is considered. In patients with unstable angina who have been stabilized, subsequent exercise myocardial perfusion defect size reliably predicts the extent of coronary artery disease.

Old Myocardial Infarction

Myocardial perfusion imaging with either ^{201} Tl or the ^{99m} Tc-labeled compounds does not differentiate between acute myocardial infarction, acute ischemia, or scar. Nevertheless, a substantial number of patients with presumably old myocardial infarction may have normal or near-normal perfusion images. Frequently, however, prior myocardial infarction can be recognized only as "thinner" myocardial segments, particularly in patients with old inferior wall myocardial infarcts. SPECT imaging may be more sensitive than planar imaging for the detection of such small myocardial scars.

Myocardial Perfusion Imaging in Emergency Departments and Chest Pain Centers

Since acute myocardial ischemia can be visualized almost instantaneously with ^{201} Tl or ^{99m} Tc-labeled compounds, resting radionuclide myocardial perfusion imaging is increasingly used as a means to triage patients with acute chest pain in emergency departments and chest pain centers.[53] Of the millions of patients who visit emergency departments yearly with complaints of acute chest pain, many have normal or nondiagnostic ECGs. Approximately half of these patients had previously been admitted to a hospital to "rule out acute myocardial infarction." In only a small proportion of these patients (15 to 20 percent) could an acute coronary syndrome be confirmed. In the majority of patients, the chest discomfort was apparently not caused by acute myocardial ischemia and hospitalization was unnecessary.

Wackers and colleagues demonstrated in 1979 the potential value of resting myocardial perfusion imaging in patients with acute chest pain in the emergency room. The presently available ^{99m} Tc-labeled compounds are better suited than ^{201} Tl for acute imaging of patients with chest pain. These compounds can be readily reconstituted when a patient arrives with chest pain. Moreover, the lack of redistribution of these agents provides greater flexibility with regard to the timing of imaging. SPECT imaging also provides useful information relative to the coronary vascular territory involved and, by using ECG gating, allows for assessment of regional and global left ventricular function. Several investigators[53] have shown that acute rest SPECT imaging in the emergency department has high sensitivity for the early detection of acute myocardial infarction. In a total of 1581 patients the sensitivity for acute infarction was 95 percent.[53] Resting myocardial perfusion images are abnormal at a time when enzymes in many patients have not yet risen to diagnostic levels.[54] Furthermore, the negative

predictive value of resting imaging was better than 99 percent. Thus, patients with acute chest pain, a nondiagnostic ECG, and *normal rest* SPECT images have less than a 1 percent chance of having an ongoing acute infarction. The rare patient with acute infarction who was undetected by rest SPECT imaging invariably had small and uncomplicated infarcts.[53] On the other hand, patients with *abnormal* SPECT images had an increased risk of coronary events during hospitalization (death, acute infarction, or revascularization).[53] Patients with normal acute myocardial perfusion images in general had a favorable outcome.[53] Stowers and coauthors reported that acute resting SPECT could be used as a cost-effective means to manage patients with acute chest pain and nondiagnostic ECG.[55] When compared with conventional management, a SPECT imaging-guided approach resulted in fewer cardiac catheterizations and substantial cost savings.

Once acute myocardial infarction has been ruled out in a chest pain center, the evaluation protocol is completed with risk stratification by stress testing. Although most patients can be evaluated with exercise ECG, a substantial number of patients are not able to perform an adequate level of physical exercise. In these patients, pharmacological vasodilation in conjunction with radionuclide myocardial perfusion imaging is performed. Discriminative use of either resting or stress radionuclide imaging has an important place in the efficient triaging of patients in chest pain centers.

Chronic Coronary Artery Disease (see also Chap. 37)

Stress Testing

In patients with chronic stable coronary artery disease who are capable of physical exercise, myocardial perfusion imaging is used in conjunction with exercise testing. Physical exercise can be performed either on a treadmill, which is most popular in the United States, or on an upright bicycle, which is frequently used in Europe and other countries. Physical exercise has the advantage of providing additional useful clinical and physiological parameters, such as duration of exercise, total workload, maximum heart rate, exercise-induced symptoms, ECG changes, and blood pressure response. However, a substantial number of patients referred for evaluation cannot physically exercise because of orthopedic, neurological, or peripheral vascular problems. In the latter group of patients, pharmacological vasodilatation with dipyridamole or adenosine or pharmacological stress with dobutamine provides useful alternative approaches.

The basic principle of the application of various modes of stress in conjunction with radionuclide myocardial perfusion imaging is used to create *heterogeneity of myocardial blood flow* between vascular territories supplied by normal coronary arteries and that supplied by an artery with significant obstructive coronary artery stenosis (Fig. 9-17) . Heterogeneity in regional myocardial blood flow can be visualized with radionuclide myocardial perfusion agents and is a requirement for abnormal images. However, regional heterogenity does not necessarily imply myocardial ischemia.

PHYSICAL EXERCISE.

Several standardized treadmill exercise protocols exist (see also Chap. 6) . The most widely used protocol was designed by Bruce. Nonimaging endpoints are reproduction of the patient's symptoms, exhaustion, hypotension or a decrease in systolic blood pressure of 20 mm Hg or more, ventricular arrhythmias, or severe ST segment depression on ECG. An intravenous line should be in place in a large antecubital vein for injection of the radiopharmaceutical agent. When the end point of exercise

Figure 9-17 Schematic representation of the principle underlying rest/stress myocardial perfusion imaging. *Top,* Two branches of a coronary artery are schematically shown; the left branch is normal whereas the right branch has a significant stenosis. *Middle,* Myocardial perfusion images of the territories supplied by the two branches. *Bottom,* Schematic representation of coronary blood flow in the branches at rest and during stress. At rest, myocardial blood flow is similar in both coronary artery branches. When a myocardial perfusion imaging agent is injected at rest, myocardial uptake is homogeneous (normal image). During stress, coronary blood flow increases 2.0 to 2.5 times in the normal branch, but not to the same extent in the stenosed branch, thereby resulting in heterogeneous distribution of blood flow. This heterogeneity in blood flow can be visualized with ^{201} Tl or ^{99m} Tc-sestamibi as an area with relatively decreased radiotracer uptake (myocardial perfusion defect). *(From Wackers FJTh: Exercise myocardial perfusion imaging. J Nucl Med 35:726, 1994. Reprinted with permission from the Society of Nuclear Medicine.)*

is reached, the radiopharmaceutical is injected rapidly through the intravenous line, followed by flushing with saline. The patient is then encouraged to exercise for

another 1 to 2 minutes at the same level of exercise. This continuation of exercise after injection of the radiotracer is crucial for diagnostic stress imaging. It is important to maintain the heart rate and thus myocardial blood flow at the peak exercise level to allow for accumulation of the radiotracer during a "steady ischemic state." If the patient is unable to continue exercising at the same level, the speed and grade of the treadmill can be decreased to a lower level.

For bicycle exercise, a similar graded exercise protocol is used. Usually, the patient starts at 25 kpm, and resistance is increased every 3 minutes until an exercise endpoint is reached.

The purpose of exercise is to increase cardiac metabolic demand and to test the ability of the coronary circulation to meet these demands with an appropriate increase in myocardial blood flow. Consequently, myocardial ischemia is frequently provoked with physical exercise.

PHARMACOLOGICAL VASODILATION.

Patients with orthopedic, neurological, or peripheral vascular problems are incapable of exercising adequately on a treadmill or bicycle. These patients can be evaluated for the presence of significant coronary artery disease by the use of pharmacological vasodilatation in combination with radionuclide myocardial perfusion imaging. Furthermore, patients taking

beta-blocking medication who are unable to increase their heart rate adequately by physical exercise have been studied successfully with pharmacological coronary vasodilation. In addition, patients with complete left bundle branch block or ventricular pacemakers are preferably studied with vasodilators to avoid artifactual perfusion defects.

Intravenous infusion of dipyridamole blocks the cellular reabsorption of adenosine and thus increases the concentrations of adenosine, an endogenous vasodilator that activates specific receptors. Coronary blood flow is autoregulated by adenosine to meet myocardial metabolic demands.[56] In patients without coronary artery disease, dipyridamole or adenosine infusion creates vasodilatation and increases coronary blood flow three to five times above baseline levels. In patients with significant coronary artery disease, the resistance vessels distal to a stenosis are already dilated, often maximally, to maintain normal resting flow. In these patients, infusion of dipyridamole or adenosine does not cause further significant vasodilation in the diseased vascular bed. However, in the adjacent myocardium supplied by normal coronary arteries, a substantial increase in myocardial blood flow occurs. In this manner, *heterogeneity in regional myocardial blood flow is created:* Territories supplied by diseased arteries are relatively hypoperfused in comparison to normal regions (see Fig 9-19) . Pharmacological vasodilation by dipyridamole or adenosine infusion does not usually provoke myocardial ischemia. Xanthine derivatives and caffeine block adenosine receptors. Consequently, patients should not be taking these medications and should not drink any caffeine-containing beverages (including caffeine-free drinks and chocolate) the night before testing to avoid false-negative images.[57]

DIPYRIDAMOLE INFUSION PROTOCOL.

Dipyridamole is infused over a 4-minute period (0.142 mg/kg/min)[56] by using an infusion pump or by injection slowly by hand. Approximately 4 minutes after completion of the infusion, the maximal vasodilatory effect is achieved. At this time the radiotracer is injected intravenously. The maximum vasolidatory effect is usually associated with a modest increase in heart rate (10 beats/min) and a slight decrease (10 mm Hg) in systolic blood pressure. In some laboratories, dipyridamole infusion is combined with low-level exercise *after* the completion of dipyridamole infusion. This combination appears to decrease the incidence of side effects in about 50 percent of patients during infusion of dipyridamole. Approximately 20 percent of patients may have ECG changes, and 10 percent may experience angina, although the most frequent complaints consist of headache, flushing, and nausea (Table 9-3) .[58] [61] Ischemia may be caused by "coronary steal." In this situation, the marked increase in blood flow in the *normal* myocardial zones "steals" blood away via collaterals from the vascular bed supplied by significantly diseased coronary arteries. This and other undesirable side effects can usually be reversed quickly by blocking adenosine receptor sites with intravenous aminophylline.

ADENOSINE INFUSION.

Clinical experience with direct intravenous infusion of adenosine (maximum of 140 mug/kg/min) has been comparable to that reported for dipyridamole.[61] [62] Adenosine should be administered only with an infusion pump. It appears that the coronary vasodilatory effect of adenosine is more potent and more consistent than that of dipyridamole. However, side effects are more common and occur in about 75 percent of patients (see Table 9-3) . Approximately 50 percent of patients may have chest pain, and many have headache, nausea, and flushing. The severity of side effects can be limited by simultaneous low-level exercise. In contrast to dipyridamole, the

exercise has to be done *during* the infusion of adenosine, which makes it somewhat complicated but still possible. Atrioventricular (AV) conduction abnormalities (second- and third-degree AV block) are not infrequently seen in patients receiving an adenosine infusion, a matter of some concern. However, because of the short half-life (30 seconds) of adenosine, side effects can be reversed almost instantaneously by terminating the infusion of adenosine. Samuels and colleagues observed that adenosine SPECT imaging was well tolerated by patients with moderate to severe aortic valvular stenosis who were evaluated for coexisting coronary artery disease.[63]

DOBUTAMINE STRESS.

For patients with contraindications to dipyridamole or adenosine infusion, such as those with bronchospastic pulmonary disease, or for patients who are taking xanthine derivatives or who have consumed caffeine, dobutamine infusion offers an alternative diagnostic approach.[60] [64] Dobutamine increases myocardial oxygen demand by increasing myocardial contractility, heart rate, and blood pressure. The increase in coronary blood flow is comparable to that during physical exercise (twofold to threefold) but less than that with adenosine or dipyridamole. Nevertheless, dobutamine infusion should not be considered equivalent to physical exercise. Useful clinical information such as duration of exercise, exercise capacity, and reproduction of symptoms is not obtained. The increase in heart rate is usually lower than that with exercise. Thus, dobutamine pharmacological stress should be considered a last resort in patients who cannot exercise rather than a substitute for exercise.

Dobutamine Infusion Protocol.

Infusion of dobutamine is started

with a low dose of 5 mug/kg/min. The dose is increased each 3 minutes if tolerated, to a maximal dose of 40 mug/kg/min. The radiopharmaceutical is injected during infusion of the maximum dose and the infusion continued for 2 to 3 minutes. Table 9-3 shows the incidence of side effects during dobutamine infusion. [60] A similar infusion protocol is used for dobutamine stress echocardiography. In a review of 2942 patients who had dobutamine-atropine stress echocardiography, 9 patients (0.3 percent) had serious cardiac side effects, including 2 nonfatal infarctions, 2 instances of ventricular fibrillation, 2 instances of sustained ventricular tachycardia, 2 patients with severe hypotension, and 1 patient with prolonged severe myocardial ischemia.[65]

Clinical Results of Exercise Testing and Myocardial Perfusion Imaging (see also Chap. 13)

Over the last 25 years the clinical usefulness of stress myocardial perfusion imaging has been well established. During the 1980s, most data in the literature were based on planar ^{201} Tl imaging. Since the early 1990s, numerous reports have confirmed that similar results are obtained with SPECT imaging and with the use of ^{99m} Tc-labeled agents. Presently, ECG gating is an integral part of SPECT myocardial perfusion imaging. Thus, state-of-the-art stress SPECT imaging provides information not only on myocardial perfusion but also on resting left ventricular function.[33]

The introduction of computer processing and quantification of myocardial perfusion images improved the overall detection of coronary artery disease substantially. For instance, the detection of single-vessel disease with ^{201} Tl improved from 55 percent by visual analysis to 84 percent by quantitative analysis (Table 9-4) . Almost all patients with double- or triple-vessel coronary artery disease were detected by quantitative myocardial perfusion imaging[66] [67] [68] [69] [70] (see Table 9-4) .

In 1994, the American Medical Association commissioned a Diagnostic and Therapeutic Technology Assessment (DATTA) review of SPECT myocardial perfusion imaging.[71] This extensive review of the literature revealed sensitivities for planar imaging ranging from 67 to 96 percent and sensitivities for SPECT imaging ranging from 83 to 98 percent. The range of specificities for planar imaging varied from 40 to 100 percent and from 53 to 100 percent for SPECT imaging. The report did not address the potential contribution of image quantification on improvement in diagnostic accuracy. Representative results of qualitative and quantitative SPECT imaging for the detection of coronary artery disease with available radiopharmaceuticals are shown in Table 9-5 . [72] [73] [74] [75] [76] [77] [78] [79] [80] [81] [82] [83]

The ability to accurately predict coronary disease in specific individual vessels was consistently suboptimal by planar imaging and reflected an inherent limitation of the planar imaging modality. With SPECT imaging, detection of coronary artery disease in individual vessels, in particular, the left circumflex coronary artery, has significantly improved.[73] Consequently, SPECT stress myocardial perfusion imaging is particularly useful to assess patients with known coronary artery disease in whom decisions regarding revascularization are to be made.

VALUE OF ^{99m} Tc-LABELED RADIOPHARMACEUTICALS.

Since the introduction of ^{99m} Tc-sestamibi and ^{99m} Tc-tetrofosmin, many thousands of patients have been evaluated with these agents. Several comparative studies have shown

Figure 9-18 Simultaneous assessment of myocardial perfusion and function. ^{99m} Tc-sestamibi imaging in acute myocardial infarction allows assessment of both function and perfusion. In this patient with a large anteroseptal infarction, resting injection of sestamibi was used for first-pass radionuclide angiography (*left*). The end-diastolic and systolic frames are shown. The global left ventricular ejection fraction was severely depressed at 0.33. On the *right* are resting single-photon emission computed tomographic sestamibi images in short-axis and vertical and horizontal long-axis slices. A large anteroseptal myocardial perfusion defect is present (arrows).

that detection of coronary artery disease with both agents is comparable to that with ^{201} Tl.[3] [84] [85] The relative high dose of ^{99m} Tc administered makes it feasible not only to acquire images in ECG-gated mode but also to perform first-pass radionuclide angiocardiography in combination with myocardial perfusion imaging[28] [79] (Fig. 9-18) . Combined analysis of "still" slices and perfusion wall motion images further improves the accuracy and confidence of interpretation. The clinical importance of acquiring both resting and peak exercise LVEF is discussed elsewhere in this chapter.

The sensitivity and specificity of using pharmacological vasodilation with various myocardial perfusion imaging agents to detect coronary artery disease reportedly resemble those obtained with physical exercise.[86] [87] [88] [89]

REFERRAL BIAS.

As mentioned above, the reported specificity of stress SPECT myocardial perfusion imaging is relatively low, from 53 to 100 percent. This lack of specificity has been partially explained by "referral bias"; that is, since stress myocardial imaging has become accepted in the clinical practice of cardiology, patients with normal stress radionuclide images are no longer referred for cardiac catheterization. Thus, the occasional patient who has normal coronary arteries on angiography is almost always referred because of abnormal stress myocardial perfusion images. The true specificity of stress SPECT imaging can therefore no longer be assessed in patients undergoing coronary angiography because of this referral bias. Specificity should, however, be tested in patients with a low likelihood of coronary artery disease. In such patients, the "normalcy rate" is determined. The normalcy rate of planar imaging with ^{201} Tl was generally over 95 percent. With SPECT imaging, the normalcy rate ranges from 85 percent for ^{201} Tl to 95 to 100 percent for ^{99m} Tc-labeled agents.

NONUNIFORM ATTENUATION.

Although referral bias may be a partial explanation for the less than desirable specificity of SPECT imaging, nonuniform attenuation is a likely culprit as well. In contrast to planar imaging, breast artifacts are not a major cause of suboptimal specificity of SPECT imaging. Of all the projection images acquired, only a few may be sufficiently affected by breast attenuation to create false-positive defects. A mild defect in the anterior wall can be suspected to be a breast artifact if the defect is fixed and wall motion on gated SPECT is normal. The most serious problem on SPECT imaging is that of attenuation of the inferior wall, which occurs frequently because patients are imaged in the supine position. An experienced interpreter is always alert to the possibility of inferior artifacts. Although a number of "tricks" can be used to recognize inferior wall attenuation, such as prone imaging, gated SPECT, and right-side decubitus left lateral images, at best these techniques may lessen or heighten suspicion. Patients with inferior attenuation artifacts may also have right coronary artery disease and vice versa. Only adequately validated attenuation correction devices and software will solve this dilemma and improve the specificity of SPECT imaging. As mentioned above, at the time of this writing, no commercially available attenuation correction system has as yet passed full clinical testing in a wide range of clinical conditions.[15] [16]

STRESS MYOCARDIAL PERFUSION IMAGING AND PROGNOSIS.

Detection of coronary artery disease is only one aspect of the clinical value of stress myocardial perfusion imaging.[89A] A more important feature is the ability to predict prognosis and identify high- and low-risk patients. The first critical finding on myocardial perfusion images is the presence or absence of defect reversibility, i.e., ischemia. Patients with evidence of transient ischemia on stress myocardial perfusion images have been shown to have a higher incidence of future cardiac events than do patients with fixed scars. In patients with suspected or known chronic coronary artery disease, semiquantitative and quantitative assessment of the number or extent of myocardial perfusion defects, the magnitude of defect reversibility, and poststress LVEF are predictive of cardiac events during follow-up[90] [91] [92] [93] [94] (Fig. 9-19) . Vanzetto and colleagues showed in 1137 patients that the incremental prognostic value of ^{201} Tl exercise SPECT was maintained over a period of 6 years[91] (Fig. 9-20) .

Evidence of transient left ventricular dysfunction during stress (i.e., transient postexercise dilatation and/or increased radiotracer lung uptake) constitutes an important additional scintigraphic marker of adverse outcome.[92] Similarly, increased right ventricular uptake on stress images is another image pattern that indicates severe coronary artery disease. It has been proposed that this increased uptake may be due to acute right ventricular strain and/or right ventricular/left ventricular perfusion imbalance.[22]

DETECTION OF HIGH-RISK CORONARY ARTERY DISEASE.

The greater the functional severity of coronary artery disease, the more abnormal exercise myocardial perfusion images are likely to be. Most patients (approximately 95 percent) with left main coronary disease have abnormal stress myocardial perfusion images. However, the expected typical left main pattern, i.e., defects in the anteroseptal and posterolateral walls, is found in only a minority (approximately 14 percent) of patients with left main coronary artery disease. The majority (approximately 75 percent) of patients nevertheless have multiple perfusion defects and, frequently, abnormally increased lung uptake of ^{201} Tl.

Although most patients with triple-vessel disease have abnormal stress images, only approximately 60 percent have multiple defects in two or more vascular regions. Disease in the left circumflex coronary artery is better detected with SPECT imaging than with planar imaging.[73]

Myocardial perfusion images of a high-risk patient (Fig. 9-21) can be characterized by *one or more* of the following image features: (1) multiple reversible defects in two or more coronary artery territories, (2) quantitatively large

Figure 9-19 Prognostic importance of the size and type of myocardial perfusion abnormality. The data are from 816 patients with stable coronary artery disease enrolled in the Multicenter Study on Silent Myocardial Ischemia (MSSMI). The patients had 26 months' follow-up. All patients had quantitative planar ^{201} Tl stress imaging. The graph relates the size of exercise defects, defect reversibility, and number of abnormal segments to the cardiac death rate during follow-up. The highest cardiac death rate occurred in patients with the most abnormal images. In particular, patients with the greatest defect reversibility had the highest cardiac death rate. *(Modified from Bodenheimer MM, Wackers FJTh, Schwartz RG, et al: Prognostic significance of a fixed thallium defect one to six months after onset of acute myocardial infarction or unstable angina. Am J Cardiol 74:1196, 1994.)*

myocardial perfusion defects,[90] [91] (3) increased pulmonary radiotracer uptake after exercise,[19] [20] [21] (4) transient dilatation of the left ventricle immediately after exercise,[92] (5) depressed resting LVEF on either gated SPECT[93] or first-pass angiography, and (6) increased right ventricular uptake on stress images.[22] This high-risk pattern is highly specific (approximately 95 percent) for multivessel coronary artery disease; however, the sensitivity is only about 70 percent. Therefore, in the absence of the above-mentioned scintigraphic characteristics, multivessel disease cannot be ruled out.

PREDISCHARGE STRESS TESTING AFTER ACUTE INFARCTION (see also Chap. 35) .

Gibson and associates were the first to demonstrate the importance of quantitative planar ^{201} Tl stress imaging at the time of discharge in patients with uncomplicated myocardial infarction. Patients without ischemia at hospital discharge had only a 6 percent cardiac event rate (death, recurrent infarction, or unstable angina), whereas patients who had high-risk findings on predischarge ^{201} Tl stress images (multiple defects in more than one vascular region, abnormal washout, or increased lung uptake) had a 51 percent cardiac event rate. Numerous other investigators have since reported a similar prognostic value of stress myocardial perfusion imaging after myocardial infarction with the use of either physical or pharmacological stress.[95] [96] [97] [98] [99] [100] Brown and colleagues observed that patients with recurrent chest pain

after myocardial infarction frequently had ischemia within the infarct region (75 percent of patients), whereas only 25 percent of patients had ischemia at a distance: Patients with evidence of reversibility had a substantially poorer prognosis and higher incidence of revascularization procedures than did patients who did not have demonstrable defect reversibility. Dipyridamole and adenosine myocardial perfusion imaging can be used for very early risk stratification during the first days after the acute event (see Acute Myocardial Infarction above) or at the time of discharge from the hospital. Mahmarian and coworkers demonstrated that at discharge, the absolute extent of stress-induced myocardial ischemia and the resting LVEF were multivariate predictors of future cardiac events[97] (Fig. 9-22) . In the Veterans Affairs Non-Q-Wave Infarction Strategies in Hospital (VANQWISH) trial,[100] invasive management (routine angiography) was compared with conservative management (noninvasive testing) in stable survivors of non-Q-wave acute infarctions. Patients in the conservative limb (who had radionuclide stress myocardial perfusion imaging) had significantly less coronary angiography (96 vs. 48 percent) but a higher revascularization rate (42 vs. 68 percent). Importantly, overall infarct-free survival was comparable in both groups. Thus, stress myocardial perfusion imaging at the time of discharge effectively identified high- and low-risk patients.

STRESS MYOCARDIAL PERFUSION IMAGING AFTER THROMBOLYTIC THERAPY.

Early reports on stress testing in patients who had thrombolytic therapy for acute infarction suggested decreased sensitivity of stress myocardial perfusion imaging for predicting multivessel coronary artery disease and cardiac events.[101] [102] It now appears that this observation can be explained on the basis of unintentional bias in patient selection. In the early 1990s, patients who were eligible for thrombolytic therapy constituted a patient cohort at relatively low risk. These patients were generally younger and had fewer prior myocardial infarctions, fewer non-Q-wave infarctions, and less multivessel coronary artery disease than did patients with acute infarction

Figure 9-20 Kaplan-Meier cardiac survival curves according to the number of abnormal segments on ^{201}Tl single-photon emission computed tomography ([201] Tl SPECT). = normal ^{201}Tl SPECT;
= presence of one to two abnormal segments;

Study in 1,137 patients with 6 year follow-up. Circulation 100:1521, 1999. By permission of the American Heart Association, Inc.)*

Figure 9-21 ^{99m}Tc sestamibi single-photon emission computed tomographic images of a high-risk patient. The "raw" planar projection image obtained 15 minutes after termination of stress (*top*) shows increased bilateral lung uptake. The left ventricle is enlarged and dilated. On the resting image the left ventricle is still enlarged but lung uptake is normal. On the reconstructed short-axis slices (*bottom*), the left ventricle is enlarged and shows multiple (anterior and inferior wall) fixed defects. These images are consistent with transient left ventricular dysfunction during stress.

in the prethrombolytic era. Because of the favorable outcome and low mortality in these patients, one would predict, based on bayesian principles, diminished predictive value for stress myocardial perfusion imaging. Dakik and associates recently evaluated the prognostic value of predischarge quantitative ^{201}Tl SPECT in 71 patients who had thrombolytic therapy for acute infarction.[103] They observed that ^{201}Tl SPECT imaging, particularly when combined with assessment of LVEF, continued to provide important incremental and long-term (36 months) prognostic information over other clinical variables, including angiography.

PROGNOSTIC SIGNIFICANCE OF NORMAL STRESS PERFUSION IMAGES.

Normal planar or SPECT stress myocardial perfusion images, even when coronary artery stenosis is angiographically documented, indicate a favorable prognosis with a low subsequent cardiac event rate.[104] [105] [106] Patients with quantitatively normal myocardial perfusion images have a yearly nonfatal myocardial infarction rate of 0.5 to 1 percent per year and a mortality rate of 0 to 0.5 percent per year[107] [108] [109] [110] (Table 9-6) . *The "warranty" for normal stress myocardial perfusion images is believed to expire after 1.5 to 2 years.*[111]

These data on abnormal and normal stress myocardial perfusion images indicate that the extent of myocardial perfusion defects, or the lack thereof, provides significant physiological and prognostic information that surpasses the anatomical information obtained from coronary angiograms. The prognostic predictive value of stress myocardial perfusion imaging is independent of the imaging technique applied (planar or SPECT) or the radiopharmaceutical used ([201] Tl or ^{99m}Tc-labeled agents).

Independent Incremental Value of Stress Myocardial Perfusion Imaging (see also Chap. 13)

In clinical practice, diagnostic tests are generally used in conjunction with each other. The clinician usually has other clinical and diagnostic information available. Evidence for the prognostic value of stress myocardial perfusion imaging as outlined above is compelling. However, if similar information can be derived from other less costly and readily available tests, it may not be cost-effective to perform radionuclide myocardial perfusion imaging. The incremental prognostic value of various diagnostic data obtained in succession (clinical data, exercise ECG, stress ^{201}Tl-myocardial perfusion imaging, and coronary angiography) was first assessed by Pollock and coworkers.[112] The combination of clinical and exercise ^{201}Tl variables provided greater prognostic information than did the combination of clinical and angiographic data alone. Iskandrian and coworkers[113] and others[24] [114] [115] [116] [117] [118] observed similar independent and incremental prognostic information from SPECT stress imaging, even when cardiac catheterization data are available (Fig. 9-23) .

Pursuing the same goal of defining the incremental prognostic value of noninvasive testing, Hachamovitch and colleagues performed a series of large data bank analyses that further clarified the role of stress myocardial perfusion imaging.[106] [116] [117] [118] [119] Patients can be categorized into low, intermediate, and high risk for coronary artery disease on the basis of clinical, historical, and exercise information. In each clinical

Figure 9-22 Cox regression model displaying 1-year risk for a cardiac event after acute myocardial infarction according to rest left ventricular (LV) ejection fraction and total LV ischemia on adenosine ^{201}Tl single-photon emission computed tomography at hospital discharge. Patient risk for cardiac death (triangles) or nonfatal infarction (solid circles) increases as total ischemia increases and the resting LV ejection fraction decreases. Diagonal lines represent separate clusters of image variables signifying increasing risk for cardiac events, i.e., 10 to 75 percent. Patients with no events are represented by open circles. *(Modified from Mahmarian JJ, Mahmarian AC, Marks GF, et al: Role of adenosine thallium-201 tomography for defining long-term risk in patients after acute myocardial infarction. J Am Coll Cardiol 25:1333, 1995.)*

risk category, radionuclide imaging can further enhance risk stratification with respect to the occurrence of future cardiac events (Fig. 9-24) . As stated above, in all clinical subgroups, normal perfusion studies were associated with an exceedingly low yearly event rate (<1 percent).

However, the cost for detecting one hard event (death or myocardial infarction) by noninvasive testing varied in each group and was extremely high in the group with low pretest risk ($253,307 per event for the low-risk population vs. $59,096 per event for the high-risk population). It follows that systematic testing is only cost-effective in the group of patients with intermediate and high risk. Hachamovitch demonstrated that incremental value and enhanced risk stratification can be achieved in both men and women and in young and elderly patients.[120]

Several investigators have proposed a strategy of hierarchical testing.[121] [122] [123] Patients with low pretest risk generally do not need testing. Patients with intermediate to high risk for coronary artery disease (and who have a normal resting ECG) should first have an exercise ECG. If the result of exercise ECG is normal, the patient is at low risk and perfusion imaging will not provide additional new information. If the exercise ECG is abnormal and/or the posttest risk is intermediate, stress SPECT imaging is appropriate for further evaluation. In a multicenter data base study, Shaw and coworkers analyzed the cost of two diagnostic approaches in patients referred for the evaluation of chest

Figure 9-23 Independent and incremental prognostic power of clinical, exercise, catheterization, and quantitative ^{201}Tl single-photon emission computed tomographic (SPECT) variables. Data shown represent the global chi-square statistics of various clinical and diagnostic variables. SPECT imaging provides independent and incremental information to identify high-risk patients. Note that angiography (cath) has less incremental value over clinical variables than ^{201}Tl SPECT imaging does. *(From Iskandrian AS, Chae SC, Heo J, et al: Independent and incremental prognostic value of exercise single-photon emission computed tomographic (SPECT) thallium imaging in coronary artery disease. J Am Coll Cardiol 22:665, 1993. Reprinted with permission from the American College of*

Cardiology.)

pain. [124] One group of 5826 patients first underwent stress SPECT imaging, followed by cardiac catheterization if SPECT images were abnormal, whereas the other group of 5423 patients was directly referred for cardiac catheterization. They found no differences in short- or long-term outcome. However, the total diagnostic cost and the long-term follow-up cost were 30 to 41 percent lower when SPECT imaging was performed as the first step of the evaluation (Fig. 9-25) . Similar cost savings for the noninvasive diagnostic strategy in comparison to the primary invasive diagnostic strategy were reported in the Economics Myocardial Perfusion Imaging in Europe (EMPIRE) Study.[125]

Hachamovitch and associates showed in an observational study of 5183 patients that a significant association existed between the degree of abnormality on stress SPECT imaging and the occurrence of death or myocardial infarction[106] (Fig. 9-26) . However, in patients with mildly abnormal SPECT images, differential risk was noted. These patients were at a low risk for cardiac death (0.8 percent per year), but intermediate risk for myocardial infarction (2.7 percent per year), which suggests that patients with mildly abnormal myocardial perfusion images are best treated with aggressive risk factor modification. Reports to referring physicians should therefore reflect *the degree of abnormality* observed on stress SPECT images. Bateman and colleagues [126] and Nallamothu and associates[127] showed that categorizing patients in reports as "high" or "low" risk is an effective way to direct appropriate patients for coronary angiography and avoid unnecessary cardiac catheterization. Sharir and coworkers showed that the poststress

Figure 9-24 Incremental prognostic value obtained by stress myocardial perfusion imaging over and beyond risk stratification in a low-, intermediate-, and high-risk group on the basis of clinical, historical, and exercise information. In each postexercise electrocardiographic risk category, the result of stress myocardial perfusion imaging, i.e., normal, mild, and moderate-severe (MOD-SEV), provides enhanced risk stratification for cardiac events (death and myocardial infarction). *(Modified from Hachamovitch R, Berman DS, Kiat H, et al: Exercise myocardial perfusion SPECT in patients without known coronary artery disease: Incremental prognostic value and impact on subsequent patient management. Circulation 93:905, 1996.)*

LVEF derived from gated SPECT has significant additional incremental value over myocardial perfusion in predicting cardiac death[93] (Fig. 9-27) .

DETECTION OF CORONARY ARTERY DISEASE IN WOMEN (see also Chap. 58) .

Exercise ECG has been reported to be less accurate in women than in men for the detection of coronary artery disease. This variability can be explained in part by differences in disease prevalence in men and women.[128] Moreover, women more often have an abnormal baseline ECG, which affects accuracy of interpretation of exercise ECGs. Although breast attenuation artifacts may make the interpretation of stress myocardial perfusion images in women more difficult, Desmarais and colleagues demonstrated that experienced interpreters usually recognize artifacts and can avoid false-positive interpretations.[129]

Several investigators have examined the performance of stress myocardial perfusion imaging in women. Although women in general achieve lower exercise workload, the detection of significant coronary artery disease by radionuclide stress perfusion imaging is similar to that in men.[117] [130] [131] [132] [133] [134] Moreover, Chae and coworkers and others showed that low- and high-risk patients are identified without gender differences.[121] [131] [132] [133] [134] [135] Hachamovitch and associates demonstrated that risk stratification by myocardial perfusion imaging was effective in both men and women.[117] In fact, radionuclide stress myocardial perfusion imaging had superior discrimination for high risk in women than men. Irrespective of gender, the long-term outcome for vascular surgery patients could be predicted by dipyridamole ^{201} Tl imaging.[135] The multicenter "Women's Ischemic Syndrome Evaluation" (WISE) Study is ongoing. This study, which incorporates noninvasive stress testing, may further clarify the role of nuclear cardiology studies in women.[136]

Syndrome X (typical exertional angina pectoris, positive ECG response to exercise, and angiographically normal coronary

Figure 9-26 Cardiac event rate as a function of the degree of stress myocardial perfusion abnormalities. The event rate increases as stress single-photon emission computed tomographic images are more abnormal. However, patients with mildly abnormal images have a low risk for cardiac death, but intermediate risk for myocardial infarction (MI). *(From Hachamovitch R, Berman DS, Shaw LJ, et al: Incremental prognostic value of myocardial perfusion single photon emission computed tomography for the prediction of cardiac death. Circulation 97:535, 1998. By permission of the American Heart Association, Inc.)*

arteries) occurs predominantly in postmenopausal women.[137] These patients, who have a favorable prognosis, generally have normal myocardial perfusion images, although in an occasional patient myocardial perfusion abnormalities have been noted.

DETECTION OF CORONARY ARTERY DISEASE IN DIABETIC PATIENTS (see also Chap. 63) .

Patients with diabetes

Figure 9-27 Cardiac death rate as a function of the degree of stress myocardial perfusion abnormality and poststress left ventricular ejection fraction (EF) by gated single-photon emission computed tomography. Assessment of resting EF in each category provides significant incremental value in predicting cardiac death. Patients with a normal EF have a low cardiac death rate even in the presence of severe perfusion abnormalities. The number of patients in each category is indicated below each column. Abn = abnormal; Mod = moderate. *(From Sharir T, Germano G, Kavanagh PB, et al: Incremental prognostic value of post-stress left ventricular ejection fraction and volume by gated myocardial perfusion single photon emission computed tomography. Circulation 100:1035, 1999. By permission of the American Heart Association, Inc.)*

mellitus have an increased risk of coronary artery disease.[138] Moreover, when compared with the nondiabetic population, they have an increased risk for ischemic death, myocardial infarction, and congestive heart failure. Myocardial ischemia is frequently asymptomatic and silent in patients with diabetes. It is not uncommon that an asymptomatic patient with diabetes is referred for stress testing as part of the preoperative evaluation and found to have markedly abnormal myocardial perfusion

images. Clearly significant coronary artery disease is detected late in many diabetic patients. Thus far, the value of radionuclide myocardial perfusion imaging has been evaluated only in diabetic patients with *known or suspected* coronary artery disease. As shown in other subgroup analyses, stress perfusion imaging also has important incremental prognostic value in patients with diabetes.[117] However, for any given degree of myocardial perfusion abnormality, the outcome in a diabetic patient was two to three times poorer than in a nondiabetic patient.[139]

The American Diabetes Association published a consensus statement with guidelines for stress testing in diabetic patients without known coronary artery disease.[140] However, these recommendations were based on the clinical judgment of a panel of experts rather than published evidence. Myocardial perfusion imaging can play an important role in the timely detection of coronary artery disease. Observational data are needed in the large cohort of asymptomatic patients with diabetes, as well as characterization of those at highest risk for asymptomatic coronary artery disease.

MYOCARDIAL PERFUSION IMAGING IN PATIENTS WITH LEFT BUNDLE BRANCH BLOCK.

In patients with complete left bundle branch block, the conduction abnormality precludes the use of conventional ECG criteria for the diagnosis of infarction or exercise-induced ischemia. It was expected that myocardial uptake of perfusion imaging agents would be unaffected by the ECG abnormality.[141] Indeed, in patients with left bundle branch block without prior myocardial infarction, *resting* myocardial perfusion images are generally normal. However, the septum is frequently thin, and in older patients the left ventricle is often dilated.

A number of investigators have reported exercise-induced myocardial perfusion defects in anteroapical and anteroseptal areas in patients with complete left bundle branch block and angiographically normal coronary arteries.[142] In some patients, partial or complete reversibility of these defects has been observed. Hirzel and colleagues proposed,

on the basis of experimental animal data with right ventricular pacing, that diminished septal myocardial blood flow during an abnormal sequence of electrical ventricular depolarization caused septal defects. We compared regional myocardial uptake of ^{201} Tl during rapid atrial pacing (normal conduction) with that during rapid right ventricular pacing (left bundle branch block). No significant quantitative difference was observed in regional ^{201} Tl uptake. Thus, it appears that the altered sequence of ventricular depolarization *itself* is not a principal cause for myocardial perfusion defects in left bundle branch block.

We noted a relationship between the presence of exercise-induced myocardial perfusion defects in left bundle branch block and the degree of *left ventricular dilatation* at rest. Patients with left bundle branch block often have clinically unexpected cardiomyopathy with ventricular dilation and a depressed LVEF. Thus, altered geometry with a partial volume effect may be another plausible explanation for the observed defects. Regardless of the cause of abnormal perfusion images in patients with left bundle branch block, patients with abnormal images have a poorer prognosis than do those with normal images.[143] Similar stress-induced false-positive myocardial perfusion abnormalities have been noted in patients with right ventricular pacemakers and paced rhythm during exercise.[144] The use of pharmacological vasodilation with dipyridamole has been shown to reduce the incidence of artifactual perfusion defects in left bundle branch block.[145] It is recommended that patients with left bundle branch block by ECG be evaluated with dipyridamole or adenosine rather than with physical exercise to avoid false-positive results.

MYOCARDIAL PERFUSION IMAGING FOR PREOPERATIVE SCREENING (see also Chap. 60) .

An important clinical application of myocardial perfusion imaging involves the preoperative evaluation of patients undergoing noncardiac surgery. Such perfusion imaging has had its most meaningful application in the study of patients prior to revascularization surgery involving the descending aorta and the lower extremities. This group of patients has a strong likelihood of the coexistence of coronary artery disease. Boucher and colleagues were the first to show that evidence of ischemia on dipyridamole ^{201} Tl imaging was predictive of subsequent perioperative cardiac events.[146] Preoperative risk assessment has been extended to patients scheduled to undergo major noncardiac surgery.[147] Eagle and coworkers demonstrated that on the basis of simple clinical assessment, patients with high risk of coronary disease and those with very low risk of coronary disease did not require noninvasive testing for appropriate risk stratification.[148] However, the majority of patients consisted of an intermediate clinical risk group and were categorized quite effectively by perfusion studies. The American College of Cardiology/American Heart Association Joint Task Force published guidelines for preoperative risk assessment.[149] Leppo and Dahlberg suggested a shortcut approach based on these guidelines (Table 9-7) for deciding whether a patient needs preoperative testing.[150] If two of the factors listed are present, the guidelines suggest noninvasive testing. In addition to assessing short-term risk, vasodilator myocardial perfusion imaging is also of value in predicting long-term outcome, beyond the perioperative period.[151] [152]

MYOCARDIAL PERFUSION IMAGING BEFORE AND AFTER REVASCULARIZATION.

A main purpose for performing stress myocardial perfusion imaging is not only to detect significant coronary artery disease but also to aid in patient management decisions. Patients with markedly abnormal and high-risk stress myocardial perfusion images will usually be considered candidates for coronary revascularization, either by coronary bypass surgery or by percutaneous transluminal coronary angioplasty and stenting. Myocardial perfusion imaging is not routinely performed after coronary bypass surgery and is only indicated when symptoms recur. Since many patients have nonspecific ST-T segment changes on the baseline ECG after surgery, myocardial perfusion imaging is preferred over exercise ECG to evaluate these patients.[24] [153] Tomographic localization of perfusion abnormalities allows a determination of whether clinical ischemia is likely to be caused by coronary graft closure or by newly developed disease in other coronary arteries. Alazraki and associates monitored 336 patients randomized to

TABLE 9-7 -- SHORTCUT TO NONINVASIVE TESTING IN PREOPERATIVE PATIENTS

Intermediate clinical predictors are present, i.e., Canadian class 1 or 2 angina, prior myocardial infarct based on history or pathological Q waves, compensated or prior CHF, or diabetes
Poor functional capacity, i.e., less than 4 METS
High-risk surgical procedure, i.e., semiemergency major operations; aortic or peripheral vascular repair; prolonged surgical procedures with large fluid shifts and/or blood loss
If two or three factors are present, noninvasive testing is appropriate.
From Leppo JA, Dahlberg ST: The question: To test or not to test in preoperative cardiac risk evaluation. J Nucl Cardiol 5:332, 1998.

coronary bypass graft surgery or coronary angioplasty in the Emory Angioplasty Versus Surgery Trial (EAST) with quantitative ^{201} Tl SPECT imaging.[154] At 1 year after revascularization, stress-induced ischemia occurred more frequently after angioplasty than after surgery (46 vs. 27 percent, $p < 0.001$). Quantitative ^{201} Tl SPECT imaging effectively stratified patients according to the occurrence of subsequent cardiac events at a 3-year follow-up.

Coronary Angioplasty.

Stress myocardial perfusion imaging may be particularly useful after coronary angioplasty in patients with multivessel coronary artery disease. Often, the most severe stenosis in one vessel was dilated and questions remain whether the stenoses in other vessels are of significance. With SPECT imaging, a specified vascular territory can be evaluated readily. The optimal timing of imaging after angioplasty is unclear. Some investigators reported a high incidence of false-positive myocardial perfusion abnormalities early after angioplasty, presumably because of delayed return of coronary flow reserve within the territory of the dilated artery. However, such is not the general experience. Most patients have normal myocardial perfusion images within the first week after successful angioplasty. At approximately 4 weeks after coronary angioplasty, good correlation has been demonstrated between stress-induced myocardial perfusion abnormalities and the presence or absence of restenosis, independent of clinical symptoms.[155] In our own laboratory, we perform ECG treadmill stress testing shortly after angioplasty to assess functional status and exercise-induced symptoms. Stress myocardial perfusion imaging is performed in patients in whom symptoms suggestive of restenosis develop or at 6 months in those who are asymptomatic. SPECT imaging allows one to determine whether clinical ischemia is caused by restenosis at the site of angioplasty and stenting[155A] or by progression of disease in other coronary arteries.

ASSESSMENT OF MYOCARDIAL VIABILITY (see also Chaps. 13 and 37) .

For patients with angina, known coronary artery disease, previous infarction(s), and left ventricular dysfunction, a reliable method for assessing the presence, extent, and location of viable myocardium is of considerable clinical importance. It is well established that global or regional ischemic left ventricular dysfunction is not always

an irreversible condition. Approximately 25 to 40 percent of patients have the potential for improvement in function after adequate revascularization. Extensive research has been conducted to establish the relative value of myocardial perfusion imaging with ^{201} Tl[7] [156] [157] [158] [159] and ^{99m} Tc-labeled tracers[160] [161] [162] [163] for predicting myocardial viability. Initially, ^{18} F-FDG regional uptake on positron imaging was used as a reference standard for myocardial viability.[164] [165] Unfortunately, in many later publications only improvement in regional dysfunction on dobutamine echocardiography has been equated with viability.[166] [167] This practice ignores the clinical importance of relieving ischemia in myocardial segments that are unlikely to have improved function after revascularization because of nontransmural

Figure 9-28 [201] Tl-labeled images after exercise (stress), 2.5-hour delayed imaging, and 24-hour delayed imaging and after reinjection of ^{201} Tl at rest. This patient has an apparently fixed defect (arrow) at 2.5-hour delayed imaging. However, on 24-hour redistribution imaging, filling-in of the defect can be appreciated. After reinjection of ^{201} Tl at rest, further normalization of the image can be appreciated. *(From Kayden DS, Sigal S, Soufer R, et al: Thallium-201 for assessment of myocardial viability: Quantitative comparison of 24 hour redistribution imaging with imaging after reinjection at rest. J Am Coll Cardiol 18:1480, 1991. Reprinted with permission from the American College of Cardiology.)*

scarring. [168] Myocardial metabolic activity on positron ^{18} F-FDG imaging is a more appropriate benchmark for viability. [165] [169]

Two important practical issues need to be addressed when evaluating patients with presumed ischemic dysfunction: (1) assessment of the relative regional myocardial uptake of ^{201} Tl (often after rest reinjection [Fig. 9-28]), ^{99m} Tc-sestamibi, or ^{99m} Tc-tetrofosmin [170] (often after rest administration of nitroglycerin[171] [172]). When the resting uptake of radiotracer is greater than 50 percent of normal, one can expect recovery of function after revascularization.[165] [169] (2) Assessment of the presence of demonstrable ischemia (i.e., partially reversible defect) in a myocardial segment with decreased uptake, even if the resting uptake is less than 50 percent.[173]

Bax and colleagues performed a pooled analysis of the various available techniques to predict functional recovery after surgical revascularization by reviewing 37 studies performed between 1980 and 1997.[174] They concluded that the sensitivity for predicting recovery of function was high (86 to 91 percent) for all methodologies analyzed (^{201} Tl rest-redistribution, ^{201} Tl stress-redistribution-reinjection, rest ^{99m} Tc sestamibi, low-dose dobutamine echocardiography, and ^{18} F-FDG PET). However, specificity varied considerably: lowest for ^{201} Tl stress-rest-reinjection (47 percent) and highest for dobutamine echocardiography. These studies were limited since myocardial viability was defined as improvement in regional function on echocardiography. Amanullah and associates observed that contractile reserve on dobutamine echocardiography was more frequently present in segments with normal ^{201} Tl uptake, reversible ^{201} Tl defects, or mild to moderate fixed ^{201} Tl defects than in segments with severely fixed defects.[175] Perrone-Filardi and coworkers showed that the level of resting ^{201} Tl uptake was strongly correlated with the frequency of functional improvement after surgery, consistent with the concept that myocardial viability is a continuum from full-thickness viability without scar to full-thickness scar without viable cells.[176] Patients with larger areas of myocardial viability have improved short- and long-term outcomes when compared with patients with lesser amounts of viable myocardium, which justifies efforts to assess myocardial viability.[177] However, patients with a low myocardial viability index and presumably, less or no improvement in ventricular function also have better survival rates after revascularization than when similar patients are treated medically. Samady and colleagues showed that failure to improve global left ventricular function after bypass surgery was not associated with a worse outcome than seen in patients who had improved function.[178] Thus, the reported lower specificity of myocardial perfusion imaging for detection of viability may be deceptive because of the use of an inappropriate benchmark.

The experience with ^{201} Tl single-photon imaging for assessment of myocardial viability is extensive. At the time of this writing, resting-4 hour redistribution ^{201} Tl imaging is the preferred protocol for myocardial viability evaluation (see also Chaps. 10 and 13) .

Selection of Patients for Myocardial Perfusion Stress Imaging

Although the sensitivity and specificity of myocardial perfusion imaging for detection of coronary artery disease is better than that of ECG stress testing, false-negative and false-positive results occur. According to Bayes theorem, the clinical utility of test results relates not only to the sensitivity and specificity of a test but also to the prevalence of disease in the population under study.[179] For instance, quantitative ^{99m} Tc-sestamibi stress imaging has a reported sensitivity of approximately 90 percent and a specificity of approximately 80 percent. A positive result obtained in a population with a very low prevalence of coronary disease (e.g., less than 3 percent) will have a predictive value of only 13 percent since a relatively large absolute number of false-positives as compared with expected true-positive results can be anticipated. However, in a patient population with a high prevalence of coronary disease, e.g., 90 percent, a positive result has a predictive value of 99 percent. In this setting, relative to the true-positive results, only a few false-positive results are obtained. On the other hand, in a population with a high prevalence of disease, a relatively large number of false-negative results are also obtained, and the predictive value of a negative test for absence of coronary disease is only 51 percent. Thus, in a population with a low prevalence of coronary disease (such as young asymptomatic subjects or patients in a chest pain center), a positive test is of little predictive value, whereas in a population with a high prevalence of coronary artery disease (50- to 60-year-old men with typical angina pectoris), a negative test is of little practical diagnostic value. The difference between the pretest probability of disease (determined by the patient's age, symptoms, and stress ECG) and posttest probability (determined by the results of myocardial perfusion stress imaging) indicates the practical value of the test. Stress myocardial perfusion imaging has optimal discriminative value in a patient population with a pretest probability of coronary artery disease ranging from about 40 to 70 percent. This population includes patients with atypical chest pain,

asymptomatic patients with major risk factors, and asymptomatic patients with a positive stress ECG.

When a stress test is ordered for diagnostic purposes, the baseline ECG should be considered. In patients with normal baseline ECGs, the ST-T segment response to maximal exercise is of diagnostic value. We and others observed that patients with a normal ST segment response to maximal exercise, almost without exception, also had normal exercise myocardial perfusion images.[121] [123] Thus, myocardial perfusion imaging *did not provide additional new information.* However, of patients with positive or equivocal exercise ECGs, a substantial number of patients had normal exercise myocardial perfusion images. Thus, in certain patient populations it may be cost-effective to perform exercise ECG as a first test in patients with normal baseline ECGs and repeat the exercise test with added myocardial perfusion imaging only in patients with abnormal exercise ECGs. However, Nallamothu and coworkers showed that in patients with an intermediate to high likelihood of coronary artery disease and normal baseline ECG, SPECT is superior to the ECG response in detecting coronary artery disease.[122]

Stress Myocardial Perfusion Imaging in Non-Coronary Artery Disease

Stress myocardial perfusion imaging has been used in a number of clinical conditions that may be characterized by symptoms of chest pain but angiographically normal epicardial arteries. In a number of these patients, abnormal and "false positive" ^{201} Tl images have been observed. Zeiher and colleagues[180] and others[181] [182] demonstrated abnormal coronary flow reserve in selected patients with such "false-positive" ^{201} Tl images. Cannon and associates found that these patients also had abnormal global and regional systolic and diastolic function.[182] It would appear that at least some of the so-called false-positive ^{201} Tl images in patients with angiographically normal coronary arteries may in fact reveal true abnormalities in endothelial function.

Unique Value of Radionuclide Myocardial Perfusion Imaging in Comparison to Other Diagnostic Modalities

When compared with other diagnostic modalities radionuclide myocardial perfusion imaging has certain distinct characteristics (see also Chap. 13) . (1) An extensive literature has demonstrated that radionuclide myocardial perfusion imaging provides information regarding the pathophysiological significance of disease that surpasses anatomical information. (2) Radionuclide myocardial perfusion imaging provides information that has independent and incremental prognostic value over other clinical and diagnostic information, including the contrast coronary angiogram. (3) Radionuclide myocardial perfusion images are digital count-based images that can be quantified readily. (4) Quantitative radionuclide myocardial perfusion imaging has been shown to be highly reproducible. (5) Diagnostic-quality radionuclide myocardial perfusion images can be acquired in almost all patients, regardless of body habitus or patient cooperation.

Myocardial Infarct Imaging

From the early days of nuclear cardiology, myocardial infarction was visualized either as a "cold spot" (perfusion defect) or as a "hot spot." Cold spot imaging has been extensively discussed above. When a radiopharmaceutical localizes specifically in an area of recent infarction, the infarct is visualized as a "hot spot." The advantage of hot spot imaging is that it is generally easier to image the presence of a tracer than its absence. The clinical usefulness of infarct imaging still requires clear definition. The diagnosis of acute myocardial infarction in the majority of patients can be readily made on the basis of simple and inexpensive tests such as the ECG and cardiac enzyme analysis.

^{99m} Tc-Sn-PYROPHOSPHATE.

The first clinically useful hot spot imaging of acute infarction was performed with ^{99m} Tc-Sn-pyrophosphate. This imaging agent was very sensitive for detecting acute myocardial infarction from 24 hours to 5 days after the onset of chest pain.[183] The intensity and pattern of ^{99m} Tc-Sn-pyrophosphate uptake were found to be of prognostic significance. At the present time, ^{99m} Tc-pyrophosphate infarct imaging is mainly of historical interest and is performed infrequently in most laboratories.

In occasional patients suspected of having sustained an acute infarction 2 to 3 days prior to hospital admission, ^{99m} Tc-pyrophosphate imaging may be useful to establish the diagnosis at a time when plasma enzymes levels have returned to normal. SPECT imaging appears to be more sensitive than planar imaging. At the present time, cardiac troponins can be used for the same purpose, although the anatomical site is an extent of infarction and cannot be assessed by using these biochemical markers of myocardial injury.

^{99m} Tc-pyrophosphate is occasionally used to detect cardiac amyloid. For this purpose, ^{99m} Tc-pyrophosphate is a relatively specific, but not very sensitive imaging agent.[184]

INDIUM-111-LABELED ANTIMYOSIN.

The ^{111} In-labeled murine monoclonal antimyosin binds selectively to irreversibly damaged myocytes. Imaging should be performed 24 hours after injection of the radiopharmaceutical to allow clearance of ^{111} In from the blood. Typical ^{111} In-antimyosin images of an acute infarct demonstrate discrete uptake in the myocardium. In addition, substantial liver and spleen uptake may be seen. Clinical studies have shown that ^{111} In-labeled antimyosin is highly specific (100 percent) and sensitive (92 percent) for the detection of acute myocardial necrosis.[185] In addition to positive images in patients with acute myocardial infarction, uptake of ^{111} In-antimyosin has been noted in patients with unstable angina. The intensity and extent of ^{111} In-antimyosin accumulation were of prognostic significance both in patients with acute infarction and in those with unstable angina. Patients with extensive antimyosin uptake, i.e., greater than 50 percent of the myocardium, had a four to nine times increased risk for future cardiac events, i.e., cardiac death and nonfatal myocardial infarction, than did patients with less or no uptake. The positive uptake seen in patients with unstable angina probably represents small clinically undetectable focal areas of necrosis.

In addition to imaging acute myocardial infarction, ^{111} In-antimyosin imaging may have a role in cardiac transplant patients for the detection of cardiac rejection.[186] Furthermore, in patients with active myocarditis, diffuse ^{111} In-antimyosin uptake has been observed.[187] More patients (55 percent) had abnormal ^{111} In-antimyosin images than abnormal endomyocardial biopsies (22 percent). Nearly all patients with abnormal myocardial biopsy findings had abnormal ^{111} In-antimyosin images. More than half of the patients with positive antimyosin images showed improvement in left ventricular function over time, whereas only 18 percent of patients with normal scans improved. This clinical course was independent of the biopsy results. These observations suggest that imaging with ^{111} In-antimyosin provides independent important clinical information in myocarditis. Further studies are needed to define the usefulness of ^{111} In-antimyosin imaging in acute ischemic syndromes and other cardiac diseases associated with cellular necrosis.

Only limited experience exists with ^{99m} *Tc-labeled antimyosin.* [188] The initial clinical results were comparable to those with the ^{111} In label. If this formulation became commercially available, antimyosin imaging might be used more widely for clinical purposes.

^{99m} Tc-GLUCARATE.

^{99m} Tc-glucarate, a glucose analog, accumulates rapidly and specifically in very recent infarctions. This agent is not yet commercially available. In contrast to antimyosin imaging, glucarate imaging can be performed within 30 minutes of injection. Mariani and colleagues demonstrated a time dependence for positive images.[189] Only patients who were imaged within 9 hours of the onset of chest pain had positive images. If these results can be confirmed, ^{99m} Tc-glucarate imaging could be a very useful imaging agent in selected patients in chest pain centers.

Assessment of Cardiac Performance

Cardiac performance can be assessed with radionuclide techniques by either of two generic approaches. The first involves analysis of the first transit of a radionuclide bolus through the central circulation (first-pass radionuclide angiocardiogram [FPRNA]). The second, more widely applied method involves analysis following equilibrium intravascular labeling, which allows repeat imaging over several hours (equilibrium radionuclide angiocardiogram [ERNA]).

Variations of each technique involve assessment of the right and left ventricles, diastolic as well as systolic function, regional or global performance, ventricular volume, and adaptations for longer-term or ambulatory monitoring. Although the radionuclide approach for the evaluation of ventricular function has been challenged by echocardiography, these techniques still play a role in the quantitative assessment of cardiac performance. These specific approaches and their clinical implications and applications are discussed below.

EQUILIBRIUM RADIONUCLIDE ANGIOCARDIOGRAPHY

The concept of using a physiological signal such as the ECG to "gate," or physiologically control, the otherwise static imaging of the cardiac blood pool was initially proposed in 1971.[190] The ERNA uses ECG events to define the temporal relationship between the acquisition of nuclear data and the volumetric components of the cardiac cycle. Sampling is performed repetitively over several hundred heartbeats with physiological segregation of nuclear data according to occurrence within the cardiac cycle (Fig. 9-29) . Data are accumulated until the radioactivity count density is sufficient for statistically meaningful analysis. The ECG provides a reasonably sensitive and easily defined physiological signal with which to link the static imaging technique. Data are quantified and displayed in an endless-loop cinegraphic format for additional qualitative visual interpretation and analysis.

TECHNICAL CONSIDERATIONS.

Because analysis involves the summation of several hundred cardiac cycles, a number of factors must be considered for the study to be deemed adequate. First, the patient must be able to remain relatively still beneath the detector during the period of data acquisition. In general, studies should be obtained with multiple views for interpretation to be complete, including the standard anterior and LAO views, as well as left lateral and/or left posterior oblique views (Fig. 9-30) .

The need for multiple views is inherent in this form of imaging because overlying radioactivity in multiple cardiac and noncardiac structures can obscure a given ventricular region in any one view. In addition, specific abnormalities in regional left ventricular performance, such as ventricular aneurysms or akinesis of the posterobasal segment, may be appreciated only on lateral or posterior oblique views. It is also assumed that cardiac performance remains relatively stable during the entire period of acquisition. Such stability is obviously not the case in the presence of substantial arrhythmia such as atrial fibrillation or frequent premature beats. The presence of major arrhythmia must be accounted for in interpretation: otherwise, the potential exists for substantially underestimating ventricular performance. Some currently available programs routinely exclude premature beats. Finally, the radionuclide label must also remain stable during the period of analysis, and the interval of data acquisition (framing interval) must be sufficiently short to allow adequate temporal resolution for definition of both systolic and diastolic performance parameters.

PERFORMANCE.

Equilibrium blood pool labeling is achieved by using ^{99m}Tc. The intravascular label is affixed to the patient's own red blood cells by using an in vitro or modified in vitro technique. Unlabeled stannous pyrophosphate is used to facilitate this reaction. The labeling techniques are now well standardized and quality control can be ensured.[191] Following a single labeling procedure, serial studies can be readily obtained for periods ranging from 4 to 6 hours. If necessary, additional labeling can be achieved and the duration of observation extended.

Conventional Anger scintillation cameras are used for these studies. Data are analyzed by computer, generally with some operator interaction. Analysis may be obtained in either the "frame" or "list" mode.[191] Radionuclide data are collected and segregated temporally. In the frame mode, which is used most frequently, the R-R interval of the ECG is divided into 20- to 50-millisecond portions, depending on the patient's intrinsic heart rate and the conditions of the study, i.e., rest or exercise. If one is interested in defining diastolic filling events, a relatively short framing interval is required. The process generally requires 3 to 10 minutes for completion of each view. Following data acquisition, data from the several hundred individual beats are summed, processed, and displayed as a single "representative cardiac cycle."

Data from the LAO view are also used for qualitative analysis of

Figure 9-29 Diagrammatic representation of the technique for equilibrium radionuclide angiocardiography. Each cardiac cycle is divided into 28 equal segments. For each heartbeat, data are accumulated and then stored in a separate file. To the right, these data for the 28 portions of the cycle are displayed as a single summed ventricular volume curve. The numbers 1 to 28 refer to the temporal sequence within the cardiac cycle. *(From Zaret BL, Berger HJ: Nuclear cardiology. In Hurst JW (ed): The Heart, Arteries and Veins. 7th ed: New York, McGraw-Hill, 1990, p 1899. Copyright © by McGraw-Hill, Inc. Used by permission of McGraw-Hill Book Company.)*

Figure 9-30 Planar and single-photon emission computed tomographic (SPECT) equilibrium radionuclide angiocardiography at rest in a patient with a basal inferior aneurysm after infarction. *Top,* Planar images in the left anterior oblique (LAO), anterior (ANT), and left lateral (LLAT) views. The basal inferior aneurysm is best appreciated in the LLAT view (arrow). *Bottom,* SPECT images of the same patient. Short-axis (SA), vertical long-axis (VLA), and horizontal long-axis (HLA) slices are shown. The basal inferior aneurysm is appreciated on multiple reconstructed slices (arrows). A schematic drawing of the anatomy is shown on the right.

Figure 9-31 Ventricular volume curve derived from an equilibrium radionuclide angiocardiographic study. The raw data have been smoothed with a Fourier filter technique to four harmonics. Note the discrimination of the period of rapid diastolic filling, as well as the atrial contribution to diastolic filling.

global left ventricular function. In this view, overlap of the two ventricles is minimal. In a count-based approach, LVEF and other indices of filling and ejection, are

calculated from the left ventricular radioactivity preset at various points throughout the cardiac cycle (Fig. 9-31) . Measurements obtained in this manner correlate well with other defined standards, such as contrast-enhanced left ventricular angiography.

BACKGROUND ACTIVITY.

Because radioactivity is present within the entire intravascular space. It is necessary to correct for the contribution of activity in adjacent intravascular structures to the overall measured left ventricular radioactivity. Major contributions to this "background" come from the lungs and left atrium. Because the left atrium is posterior to the left ventricle in the LAO view. Its background contribution is substantially attenuated by the more anterior left ventricular blood pool. Semiautomated methods are now routine for determining regions of interest, as well as background zones. With the equilibrium technique, a variable region of interest is used for determining the left ventricular blood pool for each frame of the cardiac cycle. This adaptation is necessary because using a so-called fixed or single region of interest throughout the cardiac cycle introduces error and results in underestimation of the ejection fraction.

INTERPRETATION.

Interpretation of ERNA requires both visual and quantitative analysis. The approximate 45-degree LAO view provides data for quantitative count-based assessment of left ventricular function. In the equilibrium study, quantitative analysis of right ventricular function is difficult because of contamination from overlying anterior right atrial activity. For this reason, right ventricular function is best evaluated by first-pass techniques. The degree of left anterior obliquity must be individualized with consideration of specific patient anatomy and cardiac orientation within the thorax. The degree of obliquity is determined in a manner providing optimal separation of the right and left ventricles ("best septal view"). This relatively straightforward approach can be used by a technologist without physician interaction. The LAO view also provides qualitative information concerning contraction of the septal, inferoapical, and lateral walls. The anterior view provides data concerning regional motion of the anterior and apical segments. The left lateral or left posterior oblique views provide optimal qualitative information concerning contraction of the inferior wall and posterobasal segment.

Ventricular aneurysm can be assessed best in the lateral views as well. Analysis of only the anterior and LAO views may give the false impression of an enlarged, diffusely hypokinetic ventricle, when in fact, additional obscured zones of normally contracting myocardium are present. In addition to a purely visual assessment, a point scoring system can be used for assessing regional function. Each segment is generally graded on a 5-point scale, with specific numerical grades assigned for dyskinesis, akinesis, mild and severe hypokinesis, and normal function.

An advantage of labeling the entire intravascular blood pool involves visualization of all cardiac and vascular structures. Such visual assessment can provide information concerning relative cardiac chamber size and the relative adequacy of contraction of each chamber. In addition, the size, orientation, and pathology of the great vessels can be defined. The relative thickness of the interventricular septum can be appreciated, as can the presence of filling defects representing intracardiac masses such as left atrial myxoma or intraventricular thrombus.

The ERNA can easily be combined with additional physiological stress testing or provocation, which may be in the form of either physiological stress such as exercise, pharmacological stress with positive ionotropic agents such as dobutamine or isoproterenol, or psychological stress.[192] Because equilibrium labeling is stable for the short term, studies can be repeated and can therefore provide multiple stress and control measurements.

VENTRICULAR VOLUMES.

Ventricular volume can also be determined by count-based methods. Because radioactivity at equilibrium is directly proportional to volume, it is straightforward to establish a relationship between volume of a chamber and counts emanating from a region of interest representing that chamber in the two-dimensional display. The study also requires a blood sample to serve as a calibration standard. In addition, radiation attenuation must be accounted for. Attenuation measurement represents the major source of error of the technique. However, volumes measured in this manner correlate well with other analyses. Because the analysis is count based, data are independent of the constraints and errors associated with fitting a deformed left ventricle to a geometrically ideal shape. Count-based approaches are now available to measure volume that do not involve attenuation correction. This innovative new approach substantially simplifies current volumetric analysis.

The ability to measure ventricular volume is quite important because volumetric changes may be critical for analysis of patients with heart failure and severely depressed systolic function. In such individuals, therapeutic benefit may be documented by a reduction in ventricular size while the ejection fraction does not change. Measurement of volume is also key to understanding the process of ventricular remodeling.

QUANTIFICATION OF REGIONAL FUNCTION.

The equilibrium technique has been adapted for quantitative measurement of regional left ventricular function. In the LAO view, measurement is best done by using a regional ejection fraction technique.[193] This technique is based on the same principles used for measuring the global ejection fraction. However, when regional function is assessed, the left ventricular blood pool is divided into several discrete regions with well-established anatomical correlates. The best approach involves division of the left ventricular blood pool into five regions of equal size (Fig. 9-32) . These regions are the upper and lower septal regions and the inferoapical, inferolateral, and posterolateral regions. An upper zone involving the valve planes is excluded.

PHASE ANALYSIS OF CONTRACTION.

Regional function can also be assessed from phase analysis based on the onset, timing, and extent of contraction. The phase and amplitude images can also be used for specific localization of bypass tracts in Wolff-Parkinson-White syndrome, as well as for definition of the site of sustained ventricular ectopy or tachycardia.[194]

OTHER CIRCULATORY BEDS.

With the same study in which an ERNA is obtained, it is also possible to gather quantitative data concerning circulatory beds other than the heart. Since counts are proportional to volume, a relative change in counts provides information concerning alterations in the volume of various capacitance beds. This approach has been used to assess the effects of exercise and drugs.[195] [196]

Ambulatory Monitoring

Further application of the technique of equilibrium angiocardiography relates to the use of miniaturized equipment suitable for monitoring patients during routine activities. An instrument called the VEST allows for monitoring over several hours following blood pool labeling.[197] It again uses the basic principles of ERNA. The device is worn by patients, so they are fully ambulatory. Radionuclide and ECG data are stored on tape in a manner comparable to use of the Holter monitor for arrhythmia detection. Off-line analysis

Figure 9-32 A typical regional ejection fraction display obtained from a left anterior oblique equilibrium study. The left ventricle is divided into five sectors. An upper sector involving the valve planes is excluded. These sectors, from upper left to upper right counterclockwise, involve the upper septum, lower septum, apex, and inferolateral and posterolateral segments. In this particular study, regional ejection fraction is decreased in the upper and lower septum, as well as the apex, with maintained contraction of the two lateral segments.

provides trended data concerning ventricular function (Fig. 9-33) . This instrumentation has been validated and standardized in several laboratories and is ready for broader clinical application. A second-generation device with significant technical improvement has recently become available. Initial studies suggest a potential major role for this device in the assessment of silent myocardial ischemia and mental stress.[197] [198]

SPECT Studies

The equilibrium radionuclide technique may also be suitable for application to SPECT studies. At present, work in this area is still relatively early and experimental.[199] This approach may assist in better defining ventricular aneurysms (see Fig. 9-30) . However, tomographic studies may provide optimal radionuclide three-dimensional

assessment of global and regional function.[200]

FIRST-PASS RADIONUCLIDE ANGIOCARDIOGRAPHY

FPRNA was the first radionuclide technique applied to the study of cardiac physiology. The initial reports of Blumgart and Weiss appeared in 1927.[201] However, it was not until the early 1970s that the clinical and investigative impact of the measurement was appreciated.[202] The first-pass approach remains a viable alternative to equilibrium studies. At present, it is performed less frequently than ERNA. However, with the recent availability and use of technetium-labeled myocardial perfusion agents, (see p. 273), the first-pass technique may take on new significance because ventricular function can be assessed by first-pass methods at the time of injection of the perfusion agent before subsequent static perfusion imaging.

TECHNICAL CONSIDERATIONS

The FPRNA technique involves sampling for only seconds during initial transit of the bolus through the central circulation. The high-frequency components of this radioactive passage are recorded and analyzed quantitatively. It is assumed that mixing of the indicator with blood is sufficient that changes in count rates are proportional to volumetric changes. During the initial passage, temporal and anatomical separation of radioactivity within each ventricle should be observed. Therefore, it is possible to analyze right and left ventricular function independently during this brief transit. Regional function can also be assessed from the generated outlines of ventricular silhouettes.

THE SCINTILLATION CAMERA.

In contrast to the equilibrium study, the choice of scintillation camera for the first-pass study is critical. Instrumentation must be used that provides high sensitivity with respect to count rate acquisition. If system linearity is lacking and there are major dead time losses, the data will be inaccurate. For this reason the multicrystal scintillation camera was initially developed. This instrument has since been replaced by second- and third-generation digital cameras that are suitable for rapid acquisition of the high count rate data necessary for first-pass studies.

Several technical issues are relevant to the performance of first-pass studies. First, the injection technique must be impeccable; it is necessary to have a compact radionuclide bolus without streaming. Injections can be made from either the jugular or the antecubital venous systems. Injections at more peripheral sites are not suitable. The presence of major arrhythmia during the evaluation invalidates the data. Because analysis is based on at most 8 to 10 cardiac cycles, the presence of rhythmic irregularity or premature beats negates the validity of the study.

RADIOPHARMACEUTICALS.

^{99m} Tc-labeled radiopharmaceuticals are used for first-pass studies; for the most part, in the past technetium pertechnetate or technetium complexed to either diethylenetriaminepentaacetic acid (DTPA) or sulfur colloid was used. Thus, based on the clearance of individual tracers, multiple injections can be made during a single study. Again, with the advent of technetium-labeled

Figure 9-33 Trended data obtained with the VEST in a patient in whom postmyocardial infarction ischemia is developing. Data for ejection fraction are shown in the *upper panel* and data for relative end-diastolic volume and end-systolic volume are shown in the *lower panel.* Continuous data are shown for a 25-minute period. The times of onset and relief of angina are indicated. The fall in ejection fraction precedes the clinical occurrence of angina. This fall is associated predominantly with a rise in end-systolic volume, with minimal change in end-diastolic volume. *(From Kayden DS, Wackers FJ, Zaret BL: Silent left ventricular dysfunction during routine activity after thrombolytic therapy for acute myocardial infarction. J Am Coll Cardiol 15:1500, 1990. Reprinted with permission of the American College of Cardiology.)*

perfusion agents. It is now also possible to use these perfusion agents for several purposes, including first-pass functional evaluation. In the past, attempts were made to develop additional radiopharmaceuticals suitable for first-pass techniques. However, these short-lived generator systems have been purely investigational and have been used for the most part only in individual laboratories with a specific research interest in their use.

PROCESSING OF FIRST-PASS STUDIES.

The first-pass study is computer processed in frame mode (Fig. 9-34) . Regions of interest are selected over either the right or left ventricle; generally, a fixed region of interest is used. Activity is analyzed only when the initial bolus passes through the specific chamber of interest. This temporal segregation of radioactivity compensates for the potential problem of overlapping regions of interest. Background corrections are necessary, and a variety of approaches have been described. The same approach used for the equilibrium study can be applied to the first-pass technique. In such a manner, global and regional left ventricular performance can be assessed. The first-pass technique is the radionuclide modality of choice for assessing *right* ventricular function.[201] This technique can be carried out in concert with left ventricular analysis as part of a total first-pass evaluation.

GATED FIRST-PASS TECHNIQUE.

Alternatively, a gated first-pass technique can be used at the time of tracer injection for a subsequent equilibrium study. With this latter technique, first-pass data are acquired synchronously with the ECG. They are stored temporally, and several beats are subsequently summed to form a representative cardiac cycle obtained during the right-heart phase. This particular approach provides higher count rate data than could be obtained with simple bolus injection and conventional Anger camera acquisition. The data from this study can also be viewed in an endless-loop cinegraphic format. Unlike the case for the left ventricle, poor contrast-enhanced angiographic standards are available for comparison with right ventricular radionuclide data. For this reason, normal values for the right ventricular ejection fraction have been established independently and the technique standardized. The right ventricular ejection fraction is a highly afterload-dependent measure. The finding of abnormal right ventricular ejection in the absence of intrinsic right ventricular disease is excellent evidence of acquired pulmonary hypertension.[203]

Shunt Studies

The first-pass study can also be used to detect and quantify intracardiac shunts.[204] With this particular approach, a region of interest is selected over the lung field. A pulmonary time-activity curve from the region is analyzed. Normally, a sharp rise and subsequent falloff of radioactivity are observed when the bolus enters and leaves the pulmonary vasculature. A second, lower amplitude peak occurs as a result of normal recirculation of the bolus. In the presence of a significant left-to-right shunt, persistent activity remains

Figure 9-34 Radionuclide time-activity curves obtained from a right ventricular (RV) and left ventricular (LV) region of interest during a first-pass radionuclide angiocardiogram. Each peak plus valley represents a single cardiac cycle. Data from this study are summed to provide RV and LV ejection fractions. *(From Zaret BL, Berger HJ: Nuclear cardiology. In Hurst JW (ed): The Heart, Arteries and Veins. 7th ed. New York, McGraw-Hill, 1990, p 1899. Copyright © by McGraw-Hill, Inc. Used by permission of McGraw-Hill Book Company.)*

in the lungs and washout is relatively slow. Techniques have been developed for applying this approach to quantification of the degree of shunting. The degree of shunting correlates extremely well with oximetry measures of left-to-right shunting. From right-to-left shunting, qualitative assessment demonstrating early appearance of activity in the aorta is often sufficient. Quantitative approaches also exist for defining the degree of right-to-left shunts. At present, this approach has largely been supplanted by Doppler echocardiographic techniques.

Comparison of First-Pass and Equilibrium Techniques

Both the ERNA and FPRNA techniques have advantages and limitations. In addition, any one laboratory should perform the study with which it is most familiar and for which its equipment is optimal. The ERNA has several distinct advantages: (1) Multiple studies can be performed following a single radionuclide injection; (2) regional assessment can be done in as many views as are relevant for analysis: (3) sequential and serial data can be obtained during a variety of control, physiological, and/or pharmacological states; (4) the statistical reliability of high-count rate equilibrium studies is superior to that of the first-pass technique; (5) the entire cardiovascular blood pool may be viewed at equilibrium; and (6) the equilibrium study is less prone to invalidation because of transient arrhythmia than is the first-pass study. On the

other hand, additional activity from adjacent or overlying tissue can hinder optimal visualization of a specific ventricular segment in the ERNA. Evaluation of right ventricular performance, as well as shunt detection, is better achieved with the first-pass than the equilibrium technique. While the equipment necessary for performing first-pass studies is more complex, as already stated, first-pass techniques will probably achieve resurgent popularity when combined with perfusion studies involving technetium-labeled agents.

CLINICAL ASSESSMENT OF CARDIAC PERFORMANCE

Diastolic Function (see also Chap. 15)

This function of the ventricles can be evaluated from either an equilibrium or first-pass study, although the former has been more frequently used. A number of indices have been described for assessing diastolic function. The most widely used are the peak filling rate and the time to the peak filling rate. Filling fraction has also been recently studied.[205] High temporal resolution is necessary for performing these studies. Equilibrium studies have often been obtained in list mode so that ectopic or irregular beats can be eliminated from analysis. It is crucial that there be high temporal resolution and reliability of the diastolic filling phase if accurate data are to be obtained. Fourier filtering techniques, in conjunction with polynomial mathematical algorithms, have been applied to volume curves obtained by frame mode equilibrium studies of lower temporal resolution in a manner that provides accurate data.

Assessment of diastolic function has achieved importance with clinical recognition of the entity of congestive heart failure associated with normal systolic and abnormal diastolic function (see Chap. 15) . This complication has been most commonly observed in left ventricular hypertrophy and coronary artery disease, as well as in restrictive cardiomyopathies. Abnormal peak filling rates have been noted in a majority of patients with coronary disease, even in the presence of normal systolic function. Improvement

in filling parameters has been noted following successful coronary angioplasty or after the institution of antianginal therapy. Abnormal diastolic function has been estimated to occur in as many as 30 to 40 percent of patients hospitalized with congestive heart failure.[206]

Follow-up of these patients has indicated substantial cardiovascular morbidity and mortality that is not dissimilar to that of individuals manifesting systolic dysfunction alone.[207] Treatment with verapamil has been shown to improve objective and clinical parameters of heart failure as well as left ventricular filling in such patients.[208] Measurement of diastolic function is an important dimension in the assessment of ventricular performance in patients with heart failure. However, it must be noted that parameters of diastolic filling are age dependent. Abnormal filling proportional to age is noted in the absence of disease.[209]

RESTING VENTRICULAR PERFORMANCE.

Measurement of right and left ventricular performance at rest is clearly of value in the evaluation of patients with congestive heart failure. In the simplest assessment, this particular study can be used to distinguish cardiac from pulmonary or other noncardiac causes of the symptom complex. Resting function is valuable for assessing preoperative surgical risk. The cause of heart failure may be inferred from involvement of the right and/or the left ventricle, as well as the presence of diffuse left ventricular dysfunction as opposed to regional dysfunction.[191] Systolic versus diastolic heart failure may be differentiated by this study. Relative chamber size may also provide important insight concerning the occurrence of concomitant or primary valvular disease.

Coronary Artery Disease

Perhaps the widest clinical and investigative application of resting radionuclide ventricular function studies has been for the assessment of patients with myocardial infarction. Several reports have documented the importance of prognostic stratification on the basis of global ventricular function as measured by the ejection fraction. The ejection fraction, certainly in the prethrombolytic era, was a key factor in defining prognosis.[210] [211] [212] In the thrombolytic era, the ejection fraction at rest remains an important prognostic index; however, for any level of ejection fraction, mortality is substantially lower than noted in the prethrombolytic period [211] (Fig. 9-35) . The Coronary Artery Surgery Study (CASS) has also shown the importance of prognostic stratification based on the ejection fraction in patients with multivessel disease when survival was compared in patients assigned to surgical as opposed to medical therapy.[213] In patients who have survived out-of-hospital cardiac arrest, the single best prognostic factor has also been the degree of impairment in global function as measured by the ejection fraction.

In addition, the finding of a postinfarction functional left ventricular aneurysm carries further prognostic significance. In one study involving patients with an anterior wall infarction, the finding of aneurysm formation, as defined by nuclear data, provided relevant prognostic information not available from the ejection fraction alone.[214] In the setting of acute infarction, radionuclide studies at rest are also of major value in distinguishing a true aneurysm from a pseudoaneurysm and in distinguishing right from left ventricular infarction.

EXERCISE STUDIES.

Ventricular performance during exercise can be assessed with either equilibrium or first-pass techniques. In general, exercise may be performed in the supine, semisupine, or nearly upright position. A normal exercise response is generally defined by an increment of at least 5 percent (in absolute terms) in the global ejection fraction of both the right and left ventricles. In patients with coronary artery disease, abnormal ventricular reserve is manifested by failure of such augmentation. The finding of a major fall (>5 percent) in the ejection fraction from

Figure 9-35 Relationship of the ejection fraction at rest to cardiac mortality in the Thrombolysis in Myocardial Infarction (TIMI) Phase II study (*black circles*) and Multicenter Postinfarction Research Group Study (MPRG) (*open circles*). Note the comparable shape of both mortality curves and the significantly lower mortality associated with lower ejection fraction levels noted in the TIMI II study. *(From Zaret BL, Wackers FJ, Terrin ML, et al: Value of radionuclide rest and exercise left ventricular ejection fraction to assess survival of patients following thrombolytic therapy for acute myocardial infarction: Results of the Thrombolysis in Myocardial Infarction (TIMI) Phase II study. J Am Coll Cardiol 26:73, 1995. Reprinted with permission from the American College of Cardiology.)*

rest to exercise carries with it a poor prognosis. Lee and colleagues have defined the prognostic impact of exercise ejection fraction data.[215] They noted that the exercise ejection fraction itself as an absolute number provides the most relevant prognostic information. The ventricular response to exercise in patients with abnormal resting function may have greater prognostic significance than the extent of coronary disease.[216]

SILENT MYOCARDIAL ISCHEMIA (See also Chap. 37) .

The prognosis associated with ischemia appears to not be affected by the presence or absence of a concomitant pain syndrome.[217] Because it is recognized that radionuclide exercise studies generally add to the sensitivity and specificity of the exercise ECG, it is not surprising that the study of left ventricular function during rest and exercise provides additional information concerning the prognosis in silent ischemia.[218] The ability to detect silent myocardial ischemia during routine activities (as opposed to exercise in the laboratory) is of additional importance. It is within this context that ambulatory ventricular function monitoring has achieved prominence (see Fig. 9-33) . Transient abnormalities in global left ventricular function during routine activity frequently occur silently.

Silent ventricular dysfunction is also relatively common under conditions of mental stress. This phenomenon has been demonstrated in studies using the gamma camera or nuclear probe during several forms of induced mental stress.[191] [198] Regional wall motion abnormalities were readily demonstrated during mental stress in patients with coronary artery disease, with or without an associated abnormal global ejection fraction response. These responses occurred in the absence of major increments in heart rate, which suggests that altered myocardial oxygen supply is the major mechanism. The independent prognostic significance of mental stress-induced ventricular dysfunction has been demonstrated.[219] The major factor involved in triggering an abnormal response appears to be a change in peripheral vascular resistance. In addition, specific patterns of cerebral activation are associated with an abnormal response.[305]

Congestive Heart Failure (see also Chap. 17)

Analysis of left ventricular function is cardinal for the assessment of patients with known or presumed congestive

heart failure. Radionuclide studies provide systolic and diastolic data of relevance. The finding of diastolic dysfunction as the primary pathophysiological abnormality may necessitate the use of a different therapeutic regimen than when systolic dysfunction alone is noted. The radionuclide study can also provide insight into the presence of valvular problems complicating or mimicking heart failure. Serial radionuclide studies provide a basis for monitoring the effects of therapy. In the presence of unexplained congestive heart failure, the demonstration of intact right ventricular function with abnormal left ventricular function speaks against primary cardiomyopathy as a cause. Generally, the most likely culprits in such a circumstance are coronary artery disease (ischemic cardiomyopathy), hypertensive heart disease, or aortic valvular disease. However, it should be noted that the converse is not necessarily true; secondary pulmonary hypertension and, with this, secondary right ventricular dysfunction may develop in patients with advanced left ventricular dysfunction.

DOXORUBICIN CARDIOTOXICITY (see also Chap. 69) .

A major role for serial radionuclide left ventricular function studies involves the monitoring of patients with neoplastic disease for drug-induced cardiotoxicity. Doxorubicin, a commonly used antineoplastic agent, may be associated with the development of a severe cardiomyopathy that is often both irreversible and ultimately fatal. Radionuclide ventriculography has become established as a means of detecting presymptomatic cardiotoxicity.[220] [221]

Guidelines for patient management with doxorubicin based on resting ejection fraction data have been developed. Retrospective analysis noted marked differences in outcome between individuals who were managed with adherence to the radionuclide guidelines and those who were not. Recent reevaluation of these guidelines has once again demonstrated their utility and clinical relevance.[222]

It appears that the resting ejection fraction provides an optimal means of assessing patients receiving cardiotoxic medication. The addition of exercise stress does not appear to add significantly to this prognostic assessment.

Valvular Heart Disease (see also Chap. 46) .

Rest and exercise ventricular performance studies have been used in the study of valvular heart disease. It has been suggested that left ventricular responses during exercise are of value in patients with aortic and mitral regurgitation with respect to defining the indications for valve replacement, even in the asymptomatic state.[223] At the present time, this general approach is not popular. Resting studies of ventricular performance clearly play a role in the assessment of patients with suspected or known valvular disease in whom surgery is being contemplated. In the context of the mitral regurgitation, such an evaluation may be particularly relevant clinically with respect to the definition of operability.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (see also Chap. 54) .

Patients with chronic obstructive pulmonary disease were studied intensively when radionuclide techniques for assessing the right ventricle were developed initially.[203] It is recognized that the right ventricle is an extremely afterload-dependent structure. The presence of an abnormal right ventricular ejection fraction in such patients strongly suggests the presence of significant pulmonary hypertension. Abnormalities in right ventricular performance can also be related to the degree of ventilatory and physiological impairment. Right ventricular performance, as measured by the ejection fraction, is responsive to agents that both augment inotropic performance and serve as pulmonary vasodilators.[224]

Positron-Emission Tomography

PET, long viewed as primarily a research imaging modality, is emerging as a clinically important technique. The uniqueness of PET imaging lies in its ability to image and quantify metabolic processes, receptor occupancy, and blood flow. The main advantages of positron imaging are the ability to label and thus image biologically active compounds and drugs, the higher energy of the positron signal (allowing enhanced count statistics), and the ability to correct for body attenuation, thereby increasing specificity. A major result of these advantages is the ability to derive absolute quantitative measurements with the appropriate kinetic model.

Technical Considerations

Positron-emitting radionuclides are characterized by excess positive charge. This unstable structure results in the emission of a positron (antielectron) from the nucleus, thereby converting a proton to a neutron. The positron travels a few millimeters in tissue; when it encounters an electron, annihilation ensues and results in the release of a photon pair with a characteristic energy of 511 keV. These photon gamma rays travel in opposite directions, 180 degrees apart. Thus, detectors that are placed on opposite sides of a positron decay event should detect each photon emitted at nearly the same time (coincidence). Because the travel of these photon pairs is always 180 degrees apart, when two detectors sense gamma rays coincidentally, the PET camera circuitry records that radioactive decay has occurred somewhere along the line that connects these two detectors. Unlike the collimators used in SPECT imaging, this form of "electronic" collimation, referred to as coincidence detection, increases the sensitivity of the camera and allows more accurate correction for attenuation effects.

While PET images are tomographic, like SPECT, PET cameras are designed to optimize the detection of high-energy photons (511 keV) and coincident events. PET imaging uses arrays of small stationary crystals/detectors (several thousand detectors are in most cameras) arranged in rings that allow photons to be detected in coincidence. In this manner, multiple tomographic slices are obtained simultaneously in a field of view that can range from 10 to 16 cm.

For most PET systems, attenuation is measured before any radioisotope is injected into the patient by using an external source of radiation, often in the form of a rotating line source. As the source rotates about the patient, PET detectors on the opposite side of the patient measure how much radiation reaches the detector. In this manner, a measurement of the degree of attenuation can be stored, and a correction factor can then be applied to every subsequent emission scan. This technique necessitates that the patient remain in one position during the entire PET study but results in very accurate correction for the effects of attenuation.

PROCEDURES

Current cardiac PET imaging protocols generally follow a prescribed imaging sequence. First, since the field of view of many cameras is relatively small, procedures must ensure that the heart is within the camera's field of view, which can be done by using data from limited transmission scans or by using very small doses of perfusion tracer sufficient to localize the heart. Whenever possible, the patient is positioned with arms above the head since any movement of the arms, if they are within the camera's range, may result in inaccurate attenuation correction. After the patient is made comfortable, a 10- to 30-minute attenuation (transmission) scan is acquired with an external source of radiation. The positron-emitting radionuclide is then injected. The specific imaging protocol depends on the radiotracer used. Allowance must be made for individual variation in the time needed for accumulation and subsequent acquisition of each radiopharmaceutical. For example, metabolic imaging with ^{18} F-FDG requires the injection of 5 to 10 mCi, and 30 to 40 minutes must elapse before FDG image acquisition is initiated. Perfusion tracers, however, do not require such a prolonged period to allow for radiotracer uptake. As noted previously, it is important that the patient not move during the entire study to ensure accurate attenuation correction.

RADIOPHARMACEUTICALS

Positron emitters are unique in several respects. First, the radioisotopes used are naturally occurring, small-atomic weight atoms (carbon [C], nitrogen [N], and oxygen [O]) that are the predominant constituents of organic compounds. Therefore, positron-emitting

isotopes of carbon, nitrogen, and oxygen may replace stable counterparts in the synthesis of metabolic substrate, receptor ligands, drugs, and other biologically active compounds without disrupting biochemical properties or activity. ^{18} F is also a suitable substitute for naturally occurring hydrogen because of its strong carbon-fluorine bond and stearic effect similar to that of hydrogen. Secondly, positron-emitting tracers generally have shorter physical half-lives than most single-photon emitters. This

property allows for repeat injections as a means of observing rapidly changing events over time. Table 9-8 summarizes the PET radioisotopes, half-lives, and synthesized radiopharmaceuticals suitable for use in cardiovascular medicine.

Clinical Indications

The primary clinical indications for PET studies are for the identification of myocardial viability in patients with established coronary artery disease and regional or global left ventricular dysfunction[225] [226] and for the noninvasive diagnosis of coronary artery disease. In selected patients, the enhanced accuracy of this technique may be clinically important.

Assessment of Myocardial Viability (see also Chap. 37)

As discussed above, accurate assessment of the presence and extent of viable, yet poorly contractile myocardium and its discrimination from purely infarcted tissue are of potential clinical importance. A number of diagnostic techniques are available for assessing myocardial viability. Approaches to viability assessment using radionuclide techniques involve the assessment of myocardial perfusion, cell membrane integrity, or myocardial metabolism. For institutions without PET facilities, myocardial viability is generally assessed with resting ^{201} Tl imaging. Assessment of myocardial viability with ^{99m} Tc-sestamibi is still under active investigation, and results are variable with regard to the assessment of viability.[227] [228] PET imaging is generally regarded as the noninvasive "gold standard" in decisions regarding viability. Identification of viable myocardium with PET is usually based on assessment of metabolism, although certain parameters of perfusion have been shown to be indicators of preserved viability as well. ^{18} F-FDG, a marker of glucose utilization, is the most commonly used metabolic radiotracer. Other metabolic tracers include ^{11} C-acetate and ^{11} C-palmitate as markers of oxidative metabolism.

^{18} F-FLUORODEOXYGLUCOSE.

Metabolism as assessed with FDG traces exogenous glucose uptake. When FDG is exchanged across the cellular membrane in proportion to glucose exchange, it competes for the enzyme hexokinase. The phosphorylated glucose analog FDG 6-phosphate, unlike the native glucose 6 phosphate, is a poor substrate for glycolysis, glycogen synthesis, or the fructose-pentose shunt. It is also relatively impermeable to cell membranes since the enzyme that catalyzes the reverse reaction, glucose-6-phosphatase, is absent or only present in negligible quantities. Therefore, the tracer becomes trapped in the myocardium and its persistent activity reflects regional rates of exogenous glucose uptake and preserved utilization.[229] Viability assessment with FDG is based on the principle that viable myocardium is metabolically active and that ischemic myocardium may in fact have enhanced glucose uptake. Experimental studies have demonstrated that glucose utilization is augmented in segments that are hypoperfused and ischemic but nevertheless viable. During ischemia, energy production is shifted from the oxidation of free fatty acids to that of glucose, and glucose may contribute up to 70 percent of the total energy production. Enhancement of myocardial glucose uptake also occurs in the postprandial state, where insulin levels increase. Clinical assessment of viability with FDG is generally performed in a controlled postprandial state, i.e., after the ingestion of a known quantity of glucose, to promote uniformity of FDG uptake. Since FDG uptake may be abnormally low or abnormally high, it is necessary to have a reference by which to compare its uptake on standard imaging. Thus, assessment of myocardial viability by PET imaging involves a comparison of regional myocardial perfusion with regional glucose utilization. Myocardial perfusion can be visualized and quantified with flow tracers such as ^{82} Rb, ^{13} N-ammonia, and ^{15} O-water.

The most common PET viability studies are usually performed at rest, with an initial assessment of resting perfusion followed by an assessment of FDG uptake. Since ^{18} F has a relatively long half-life of about 2 hours, imaging does not require an on-site cyclotron. The choice of perfusion tracer may be dictated by the presence or absence of a cyclotron (^{82} Rb is generator produced, whereas ^{13} N-ammonia and ^{15} O-water require an on-site cyclotron). As noted above, subjects are usually given 50 gm of oral glucose just prior to beginning the study to facilitate uniform myocardial FDG uptake. Diabetic patients require glucose monitoring and may need a combination of glucose and/or insulin administration to stimulate myocyte glucose uptake. Initial resting perfusion images are obtained following the intravenous injection of a flow tracer. Then, 5 to 15 mCi of FDG is injected and metabolic images obtained 30 to 50 minutes after injection. Perfusion and FDG images can be analyzed by visual and quantitative activity profile analysis similar to that used in SPECT image processing. Three basic patterns of

Figure 9-36 Three positron-emission tomographic scintigraphic presentations. On each panel, perfusion is represented by NH_3 and glucose metabolism by flourodeoxyglucose (FDG). The *left panel* shows normal homogeneous uptake of NH_3 and FDG. In the *middle panel,* the arrows point to markedly reduced blood flow with preserved glucose uptake in a patient with myocardial viability in an area of an old anterior wall myocardial infarction. On the *right,* the arrows point to concordant reduction in blood flow and FDG in a patient with remote inferior wall myocardial infarction. (Reprinted by permission from Zaret BL, Wackers FJTh: Nuclear cardiology (I). N Engl J Med 329:775, 1993.)

comparative blood flow and distribution of metabolic activity are demonstrable (Fig.9-36). First, there may a match between flow and metabolic activity with homogeneous myocardial distribution of each tracer (normal). Second, regional blood flow may be decreased while glucose utilization in the same area is normal or increased relative to normally perfused myocardium or to the region with reduced blood flow. This pattern of blood flow--metabolism mismatch is the PET scintigraphic signature of myocardial viability in the presence of ventricular dysfunction. Third, regional myocardial blood flow and glucose utilization may be concordantly decreased. This pattern is the marker of myocardial scar and irreversible damage, although mild to moderate degrees of matched defects imply an admixture of viable and scarred myocardium.

CORRELATIONS WITH CLINICAL OUTCOME.

Clinical investigations have consistently demonstrated that preserved viability by PET is associated with improvement in regional wall motion after revascularization, particularly in regions demonstrating flow-metabolism mismatch (diminished flow, increased glucose uptake).[165] [230] These studies indicate positive and negative predictive accuracies in the 80 to 90 percent range. One of the initial studies that suggested the feasibility of this approach was by Tillisch and colleagues, who evaluated 17 patients with abnormal resting wall motion.[164] Eighty-five percent of myocardial segments that showed preserved glucose uptake in regions of abnormal wall motion improved following bypass surgery. In contrast, 92 percent of segments with depressed glucose uptake in regions with abnormal wall motion did not improve following revascularization. An alternative approach using postexercise FDG PET imaging was used by Marwick and colleagues to determine the spectrum of metabolic responses of hibernating myocardium, as well as predict improvement in exercise capacity after revascularization.[230] Taken together, these studies reinforce the concept that metabolic imaging with PET is a useful tool to predict the reversal of preoperative wall motion abnormalities after successful revascularization.

LIMITATIONS OF FDG IMAGING.

Several limitations of FDG imaging should be mentioned. First, approximately 10 percent of patients with diabetes mellitus will have unreadable studies as a result of inadequate radiotracer uptake. In such patients, an insulin clamp procedure, while technically demanding, may improve the study. In the majority of patients with diabetes, image quality will be good without performing an insulin clamp, and the diagnostic accuracy of the procedure is similar to that in nondiabetics.[231] Second, FDG imaging early (within 1 week) after myocardial infarction is inaccurate, possibly because of the inflammatory response soon after infarction. Finally, although the strength of PET lies in its potential for accurate quantitation of metabolic processes, quantification of regional myocardial glucose uptake with FDG has not been shown to enhance the accuracy of viability assessment over semiquantitative and/or visual assessment.[232] This limitation may in part relate to the fact that differences in FDG uptake versus endogenous glucose uptake may not be accounted for in current techniques.

Studies addressing the ability of modified SPECT camera systems to accept keV photons, specifically, ^{18} F-FDG, have been performed.[233] [234] [235] Such imaging can be accomplished with SPECT technology by using high-energy collimators (single-photon imaging of PET tracers) or with SPECT cameras that have special coincidence circuitry (hybrid PET-SPECT systems). In general, the resolution of SPECT with high-energy collimation is poor, although probably sufficient for clinical cardiac studies. While coincidence detection with hybrid PET-SPECT systems in the practice of nuclear oncology has shown promise, such systems have not been used for cardiac imaging and will probably not be used for this purpose until accurate methods for attenuation correction can be developed. At present, initial studies suggest that FDG SPECT imaging may be a clinically useful and cost-effective means for the metabolic assessment of left ventricular myocardial viability.

Figure 9-37 Static^{11} C-acetate images in a patient within 1 week of an anterior wall myocardial infarction are shown above. The white arrows point to a marked decrease in ^{11} C-acetate in the anteroapical region. Serial data acquisition over time revealed a marked decrease in ^{11} C-acetate washout in these regions.

Other PET Tracers of Myocardial Metabolism

^{11} C-ACETATE.

Dynamic PET studies of ^{11} C-acetate kinetics provide a noninvasive measurement of regional myocardial oxygen consumption. Unlike FDG PET imaging, the utility of acetate imaging is dependent on accurate quantification of dynamic studies. Also, the short half-life of ^{11} C (20 minutes) necessitates a cyclotron on-site. Therefore, this approach is technically demanding and limited to selected centers. Clearance of ^{11} C-acetate from the myocardium is biexponential. The decay constant of the initial component of the clearance curve is linearly related to myocardial oxygen consumption, and thus analysis of ^{11} C kinetics is thought to accurately reflect myocardial oxygen consumption and thus mitochondrial oxidative flux in human subjects.[236] Furthermore, since initial uptake of acetate is proportional to myocardial blood flow, it may be used to assess perfusion with the same tracer injection.

Despite its complex imaging requirements, the available data on acetate imaging for viability assessment are promising and highlight potential advantages over FDG. Gropler and colleagues quantified myocardial oxidative metabolism by analysis of the rate of myocardial clearance of acetate in 35 patients with ischemic myocardial dysfunction who were undergoing coronary revascularization. Glucose metabolism was assessed preoperatively by analysis of FDG uptake. The predictive value for recovery of regional function was comparable for both techniques, with a trend toward improved accuracy with acetate.[237] The complementary role of ^{11} C-acetate in PET myocardial viability imaging may be its ability to distinguish viable from nonviable myocardium early after acute infarction (Fig. 9-37). In this setting, where myocardial stunning may be predominant, an index of overall oxidative metabolism may be more accurate than FDG.[229] Additionally, because acetate kinetics is not influenced by diabetes, it may be more useful than FDG imaging in diabetic patients with chronic coronary artery disease. Finally, acetate imaging combined with low-dose dobutamine infusion may be more accurate than assessment of oxidative metabolism at rest alone, possibly reflecting the fact that intact "oxidative reserve" may be a useful marker of viability. [238]

^{11} C-PALMITATE.

[11] C-palmitate is a positron-emitting radiopharmaceutical that has been used to characterize fatty acid metabolism experimentally and clinically.[239] Impaired mitochondrial function as a result of ischemia is characterized by slower palmitate clearance and presumably reflects decreased fatty acid oxidation. There is controversy, however, regarding how palmitate kinetics is affected by ischemia, the arterial content of nonesterified fatty acids, and the hormonal milieu. These confounding observations and the observation of increased backdiffusion of altered tracer in myocardial ischemia have limited the usefulness of ^{11} C-palmitate in the evaluation of myocardial ischemia.[240] Currently, this agent is rarely used in PET studies.

PET Perfusion Tracers for Myocardial Viability

The concept that myocardial perfusion tracers alone may be useful in the assessment of myocardial viability rests on several principles. The first principle is that myocardial perfusion and viability are linked and are not independent of each other. In particular, it is understood that myocardial viability is not maintained below a certain threshold of perfusion. Second, as for SPECT perfusion tracers, certain PET perfusion tracers have dual properties, with kinetics that reflects not only perfusion but also cell membrane integrity, a potential marker of viability. Finally, emerging evidence suggests that intact coronary flow reserve may also serve as a useful marker of viability.

PET TRACERS OF MYOCARDIAL PERFUSION.

Myocardial positron-emitting perfusion tracers include ^{82} Rb, ^{13} N-ammonia, ^{15} O-water, and ^{62} Cu-pyruvaldehyde-bis-(*N*-4-methylthiosemicarbazone (PTSM). ^{15} O-water is freely diffusable,[241]

whereas uptake and retention of the other tracers are dependent on both perfusion and cell membrane integrity. ^{82} Rb and ^{62} Cu-PTSM are generator produced and thus do not require a cyclotron. Both agents result in good-quality images for visual and circumferential analysis, although only ^{82} Rb is currently approved by the FDA for this indication. Rubidium is a potassium analog that like thallium, requires the sodium-potassium pump for uptake.[242] Its first-pass extraction is 65 percent.[243] ^{13} N-ammonia is perhaps the most versatile perfusion tracer in that it yields excellent images for visual and circumferential analysis, as well as being quantifiable for analysis of absolute myocardial blood flow and flow reserve. Ammonia has a first-pass extraction rate of 80 percent, and its extraction is in part energy dependent. Finally, ^{15} O-water is an excellent perfusion tracer in theory since its extraction is independent of the metabolic state and its uptake is linear across a wide spectrum of flow values.[244] The requirement for complex analysis to differentiate myocardium from the blood pool and surrounding tissues, however, makes its use more technically challenging.

PARAMETERS OF MYOCARDIAL PERFUSION FOR VIABILITY ASSESSMENT

As noted above, PET perfusion tracers may be used to assess absolute blood flow, flow reserve, or cell membrane integrity. Each of these parmeters has been studied as a potential marker of myocyte viability. Using PET measurements of absolute myocardial blood flow, clinical studies indicate that myocardial regions with blood flow less than 0.25 ml/gm/min are almost always nonviable.[245] [246] Similarly, recent studies have suggested that relative ^{13} N-ammonia activity of less than 40 percent of maximal uptake is associated with nonviable myocardium.[247] [248] While these studies suggest that a certain threshold of flow exists below which viability is not maintained, considerable overlap is seen in values between viable and nonviable segments in most studies. Also, it is not clear whether the various perfusion tracers exhibit differences in accuracy and whether absolute quantitation of flow is necessary.

More recently, experimental studies have suggested that preserved coronary flow reserve may be a marker of intact myocardial viability.[249] Preliminary clinical studies have likewise demonstrated an association between flow reserve and viability. Marzullo and colleagues compared rest/stress ammonia PET with FDG PET in patients with chronic coronary artery disease and showed that intact coronary flow reserve was associated with preserved metabolic activity on FDG imaging.[250] Similarly, preserved flow reserve has been demonstrated with radiolabeled microspheres even in regions with critical stenosis and left ventricular dysfunction.[251] These data, while preliminary, suggest that intact coronary flow reserve may be an accurate marker of myocardial viability.

Techniques are also available that relate aspects of perfusion tracer kinetics to myocardial viability.[82] Rb is analogous to thallium with regard to uptake and trapping characteristics. Experimental studies indicate that its retention in particular is dependent on intact myocyte viability. Gould and colleagues, who used a background-corrected ratio of early versus late rubidium uptake, demonstrated the feasibility of using assessment of rubidium retention as a marker of viable myocardium. Subsequently, this technique has been shown to correlate well with FDG imaging.[252] Similar preliminary studies have examined how ^{13} N-ammonia kinetics relates to myocardial viability. These studies suggest that measurement of the volume of distribution[253] or late ammonia uptake[254] may enhance viability detection in comparison to perfusion kinetics alone. Therefore, with the development of appropriate analytical methods, it may be feasible to assess both myocardial perfusion and viability with a single injection of a "perfusion" tracer.

PERFUSABLE TISSUE INDEX

The water-perfusable tissue index bases assessment of myocardial viability on the principle that normal or viable myocardium, and not scar, exchanges water rapidly.[255] The technique uses an assessment of the fractional volume of distribution of ^{15} O-water and an estimate of extravascular tissue density derived from from data transmission and ^{15} O-water blood pool images. Preliminary data suggest that measurement of the perfusable tissue index is an accurate predictor of functional recovery both after reperfusion for acute myocardial infarction and after revascularization for chronic coronary artery disease.[255] [256] This technique remains technically demanding and is thus limited to a few academic centers.

PET Imaging for Myocardial Viability in Risk Stratification

Prognostic stratification of patients with coronary artery disease and left ventricular dysfunction has been addressed with metabolic PET imaging. These data are particularly important inasmuch as the preponderance of the literature has used improvement in left ventricular function as a clinical endpoint. Four reports have addressed this issue by performing PET studies of myocardial viability[257] [258] [259] [260] (Table 9-9) . In each of these studies, patients were characterized as FDG viable or nonviable and then according to treatment with medical therapy or revascularization. Despite methodological differences among studies, the results have been consistent. The mortality rate was significantly lower in patients with a PET mismatch pattern who were revascularized, whereas such patients had very high mortality if medically managed. In contrast, patients with primarily matched perfusion-metabolism defects showed no major differences in outcome whether medically or surgically managed. Thus, these data suggest that intact myocardial viability, in particular, the pattern of flow-metabolism mismatch, is associated with a poor prognosis unless

revascularized.

In a related study by Tamaki and colleagues, the prognostic importance of increased FDG uptake was demonstrated in 158 patients with myocardial infarction who were referred for FDG PET and stress ^{201} Tl imaging.[261] Eighty-four patients were monitored for a mean interval of 23 months. This study confirmed that an increase in FDG uptake was the best predictor of future cardiac events when compared with clinical, angiographic, and radionuclide variables. An increase in FDG uptake was also predictive even when a stress ^{201} Tl scan did not show redistribution.

Finally, recent studies suggest that viability assessment with PET may have a significant clinical impact on decisions concerning management in patients with coronary artery disease. In particular, PET imaging may identify a subset of patients with severe ischemic cardiomyopathy who in the presence of a preponderance of viable myocardium may benefit from coronary revascularization rather than transplantation.[257] [262] In one study, one quarter of patients with severe ischemic cardiomyopathy had evidence of viable myocardium in at least five regions.[263] Additional studies are warranted to determine the optimum utilization of PET viability imaging in such patients.

TABLE 9-9 -- POSITRON IMAGING PATTERNS AND MORTALITY IN CORONARY ARTERY DISEASE AND LEFT VENTRICULAR DYSFUNCTION

STUDY	NUMBER OF PATIENTS	VIABLE		NONVIABLE	
		Medical	Revascularization	Medical	Revascularization
Eitzman et al.[257]	83	6/18	1/26	2/24	0/14
DiCarli et al.[258]	93	7/17	3/26	3/33	1/17
Lee et al.[259]	137	10/21	4/49	2/40	2/19

Mortality		41%	8%	7%	6%

Comparison of PET FDG with SPECT Techniques

[201] Tl SPECT.

[201] Tl SPECT is widely used as a means of assessing myocardial viability in centers without access to PET. As previously discussed, modifications to standard stress-redistribution ^{201} Tl imaging have been made to optimize detection of myocardial viability. Early studies showed a consistent underestimation of viability with stress-redistribution ^{201} Tl imaging comparison to FDG PET. Acquisition of late (24-hour) redistribution ^{201} Tl images improves accuracy, but viability is still underestimated in comparison to FDG PET.[264] Two protocols have subsequently proved to be quite accurate for viability assessment: stress-redistribution-reinjection and rest-redistribution imaging.

Several studies have directly compared thallium reinjection and PET FDG imaging in the same patients.[165] [264] [265] [266] Overall, these studies suggest that concordance between these techniques is in the range of 80 percent. A study by Bonow and Dilsizian highlighted the importance of ^{201} Tl defect quantitation to achieve optimal accuracy in comparison to PET. Specifically, the best correlation between FDG was observed in the severest ^{201} Tl defects on reinjection imaging.[165] [266]

Although ^{201} Tl imaging appears to be a clinically acceptable substitute for FDG PET, several issues remain unresolved. First, while the concordance of ^{201} Tl imaging is around 80 percent in most series, the potential underestimation of viability even in 10 to 20 percent of patients may not be acceptable in all clinical situations, particularly in patients with very poor left ventricular function. Second, the accuracy of thallium imaging is not likely to improve much further until reliable methods to correct for photon attenuation are developed for SPECT. Third, it is not clear whether gated SPECT imaging will improve the accuracy of viability detection.

^{99m} Tc-SESTAMIBI SPECT.

Studies comparing FDG and ^{99m} Tc-sestamibi SPECT in the assessment of myocardial viability in patients with chronic coronary artery disease have yielded mixed results. Even when quantitative SPECT imaging is used, significant underestimation of myocardial viability has been demonstrated in many studies.[267] [268] [269] [270] [271] In the study by Sawada and colleagues, for example, FDG evidence of viability was present in 47 percent of segments with severe sestamibi defects. Other studies have suggested potential factors that may explain this underestimation. One study revealed that a major portion of the discordance was contributed by the inferior wall myocardial segments, which suggests that inferior wall attenuation may contribute significantly to the underestimation of viability by ^{99m} Tc-sestamibi.[269] [270] Another study compared the two techniques in patients with varying degrees of left ventricular dysfunction and revealed that concordance was worse in patients with severe left ventricular dysfunction than in those with mild to moderate dysfunction.[271] [272] In particular, ^{99m} Tc-sestamibi SPECT identified only 42 percent of regions with PET flow-metabolism mismatch as viable, which highlights the potential influence of left ventricular dysfunction and/or regional hypoperfusion on the accuracy of sestamibi imaging for viability assessment.[272] Several methods have been proposed to enhance the detection of viable myocardium with ^{99m} Tc-sestamibi, including attenuation correction, administration of nitrates prior to resting imaging, and acquisition of delayed sestamibi images. The degree to which these methods will improve the accuracy of sestamibi imaging in comparison to PET is unclear.

Diagnosis of Coronary Artery Disease

Similar to SPECT imaging, stress-rest PET perfusion imaging may be used for the diagnosis of coronary artery disease and/or the assessment of disease severity in patients with known coronary artery disease. The clinical application of PET in this regard is very similar to that for SPECT; i.e., stress and rest images are obtained with radiotracers that track myocardial perfusion. Although absolute quantification of myocardial perfusion and flow reserve is possible, routine clinical studies for the diagnosis or assessment of coronary artery disease are usually performed with semiquantitative approaches, also similar to SPECT. As noted previously, attenuation correction is always performed with PET imaging, and count statistics are higher than for SPECT. As such, it is theoretically possible to detect smaller and milder defects with PET. Since the patient is required to maintain one position throughout the PET study, however, PET imaging is restricted to the use of pharmacological stressors.

A number of clinical studies have demonstrated that stress-rest PET perfusion imaging has a sensitivity and specificity for the diagnosis of coronary artery disease[75] [273] [274] [275] [276] [277] [278] that generally exceed 90 percent. PET perfusion imaging detects coronary artery disease with similar accuracy in asymptomatic as well as symptomatic subjects,[275] and it is equal to or better than arteriography for monitoring changes in stenosis severity.[243]

While the accuracy of PET perfusion imaging for routine diagnostic imaging is unequivocal, the incremental value of PET over SPECT remains controversial. Certainly, patients likely to have significant attenuation artifacts would be expected to benefit from PET, but this group probably does not represent the majority of patients. Initial studies comparing rest-dipyridamole rubidium PET with ^{201} Tl SPECT demonstrated a significantly higher accuracy of PET for the diagnosis of coronary artery disease.[75] [278] One study suggested improvement in both sensitivity and specificity,[75] while others suggested that the primary benefit of PET over thallium SPECT was increased specificity.[278] Methodological concerns, such as timing of PET versus SPECT acquisitions in relation to stress, and potential referral bias make these studies inconclusive. Studies using ^{13} N-ammonia as the perfusion tracer have likewise demonstrated excellent diagnostic accuracy for the detection of coronary artery disease, but direct comparisons to SPECT imaging are lacking.[275] A major question that remains unresolved is whether the application of quantitative techniques, such as measurement of absolute myocardial blood flow and/or coronary flow reserve (see below), will add incremental diagnostic information to qualitative PET imaging.

Special Applications of PET and Future Directions

The true potential of cardiac PET is its ability to label organic compounds and accurately quantitate radiotracer uptake, thereby allowing assessment of absolute myocardial and brain blood flow, coronary flow reserve, cardiac and brain receptor density, and other potential in vivo markers of cardiac and/or vascular physiology. Cardiac PET has added much to our understanding of a variety of cardiac disorders and will continue to do so with the future development of quantitative techniques. Selected areas in which quantitative cardiac PET may contribute relevant clinical information will be presented.

Coronary Blood Flow and Flow Reserve

The anatomical delineation of coronary artery luminal narrowing by coronary angiography may not accurately reflect the functional significance of coronary artery

disease.[279] With stress-rest dynamic PET perfusion imaging, measurements of absolute myocardial blood flow and flow reserve can be determined. The term "flow reserve" is meaningful to the extent that absolute measurement before and after pharmacological intervention is measured. Absolute flow reserve, that is, the difference between stress and rest flow, reflects the cumulative effects of physiological factors such as vasomotor tone, workload, hypertrophy, and coronary stenosis. Relative flow reserve, that is, the ratio of stress to

rest flow, reflects more specifically coronary stenosis independent of these other physiological variables and is thus comparable (with regard to mechanism) to reversible/nonreversible SPECT flow tracers for the assessment of coronary artery disease. In general, stress perfusion imaging is performed after vasodilator hyperemia with either dipyridamole or adenosine. Delineation of absolute myocardial blood flow and determination of flow reserves with PET are powerful noninvasive techniques by which to assess the effects of coronary and other cardiovascular diseases on cardiac physiology.

The contribution of absolute flow measurements with cardiac PET can be demonstrated by several examples. Studies have demonstrated the feasibility of delineating absolute myocardial blood flow in normal individuals[280] and have examined the effects of aging on flow reserve.[281] [282] PET myocardial perfusion imaging using either ^{83} Rb, ^{13} N-ammonia, or ^{15} O-labeled water has identified abnormal perfusion reserve in patients with coronary artery disease.[75] [273] [278] [283] [284] [285] [286] More recently, the performance of quantitative flow measurements for the diagnosis of varying degrees of epicardial coronary stenosis was assessed with dynamic ^{13} N-ammonia PET.[287] Diagnostic accuracy and the sensitivity of coronary flow reserve for the detection of epicardial stenosis greater than 50 percent were high, and specificity was moderately high. Additionally, flow reserve in regions with anatomically normal coronaries in patients with coronary artery disease was lower than that in normal individuals, thus suggesting early functional abnormalities in vascular reactivity. Abnormalities in coronary flow reserve have also been demonstrated in young patients with insulin-dependent diabetes mellitus despite normal exercise echocardiography and tests of autonomic function,[288] in patients with hypertrophic cardiomyopathy, and in a subset of patients with chest pain and angiographically normal coronary arteries. Taken together, these studies highlight the potential for quantitative perfusion imaging in the assessment of a variety of cardiac disorders.

NONINVASIVE ASSESSMENT OF LIPID LOWERING AND CORONARY PLAQUE REGRESSION

Considerable evidence supports the benefits of aggressive cholesterol lowering in the primary and secondary prevention of coronary events.[289] [290] [291] [292] Initial studies suggest that cardiac PET imaging may be used to assess the effect of therapy on myocardial perfusion in such patients. Longitudinal noninvasive assessment with dipyridamole PET has demonstrated a decrease in the size and severity of perfusion abnormalities in patients with successful vigorous cholesterol lowering during a 90-day intensive cholesterol-lowering treatment plan.[293] These same patients had a final control period without administration of lipid-lowering regimens; repeat rest-dipyridamole PET showed significant increases (worsening) in the size and severity of perfusion abnormalities. PET perfusion imaging has also been used to monitor long-term risk factor modification in patients with established coronary artery disease.[294] In a study of 35 patients, those randomized to risk factor modification that included a very low fat diet, regular exercise, and stress management showed improvement in PET perfusion parameters both during stress and at rest when compared with patients randomized to the usual care. The pathophysiological mechanisms that may account for improved perfusion defects over such a short period of cholesterol lowering are probably not explained by anatomical regression of atherosclerosis but may be more consistent with restoration of endothelium-dependent vasodilatation by a reduction and/or pharmacological manipulation of serum lipids.[295] This concept is supported by observations that coronary flow reserve measured with cardiac PET is abnormal in young patients with familial hypercholesterolemia and is inversely associated with the total serum cholesterol concentration.[296] Similar studies using SPECT imaging to assess the efficacy of lipid-lowering medical therapy are ongoing. These provocative observations provide a basis for future studies with larger populations that would address absolute serial changes in perfusion.

NEUROCARDIAC PET IMAGING

Neurocardiac PET imaging refers to the use of PET to assess either cardiac innervation with specific neuronal radiotracers or central nervous system activation as it relates to the expression of cardiac disease (e.g., chest pain, mental stress-induced ischemia). PET studies of cardiac innervation may include assessment of sympathetic and parasympathetic interactions, neural regulation of the coronary circulation, adrenergic mechanisms in the genesis of arrhythmias, cardiac reflexes, and sympathetic innervation in the failing heart. Visualization of the cardiac sympathetic nervous system has also been performed with ^{11} C-hydroxyephedrine (^{11} C-HED), an analog of norepinephrine. Comparative studies were performed in six normal volunteers and five cardiac transplant patients, the latter representing a model of global cardiac denervation. The normal volunteers showed homogeneous uptake of ^{11} C-HED and ^{82} Rb. However, the transplant patients, while demonstrating normal blood flow with ^{82} Rb, had markedly reduced uptake of ^{11} C-HED. Subsequently, abnormalities in innervation were associated with abnormalities in coronary blood flow, thus indicating a link between cardiac sympathetic innervation and myocardial blood flow responses.[297] Recently, it has been demonstrated that patients with diabetes exhibit distal dysinnervation with proximal hyperinnervation, potentially indicative of electrical instability in susceptible individuals.[298] These abnormalities have also been associated with abnormalities in myocardial perfusion.[299] Other cardiac neuronal agents that image presynaptic and postsynaptic sympathetic and parasympathetic nerves are under investigation.[300] Furthermore, true postganglionic receptor imaging may be possible with the ongoing development of muscarinic and beta receptor ligands. Assessment of adrenergic receptor density in the myocardium may be of increasing importance in the future. Given the neurohormonal contribution to conditions such as congestive heart failure,[301] acute myocardial infarction,[302] long QT syndrome, [303] and sudden death,[304] PET may play an important role in identifying, stratifying, and monitoring therapy in these patients.

Studies examining the role of the central nervous system in the expression of cardiac disease have focused on two areas: the pathophysiology of mental stress-induced ischemia and silent versus symptomatic demand-induced ischemia. A recent study used PET to measure brain activation during arithmetic mental stress along with simultaneous cardiac echocardiographic monitoring in patients with coronary artery disease and normal subjects. Patients with coronary artery disease had hyperactivation in brain regions that mediate emotion and memory. In addition, the subset of patients with coronary artery disease who became ischemic showed depression of the right hemispheric regions. Furthermore, these mental stress-induced ischemic patients showed bilateral deactivation in the anterior cingulate in the absence of angina. The anterior cingulate has been associated with pain perception. Deactivation of this region may provide insight into the silent nature of mental stress-induced ischemia.[305] Similarly, the absence of angina secondary to demand (dobutamine)-induced ischemia has been investigated. Rosen and colleagues studied two groups of patients with coronary artery disease, one with dobutamine-induced myocardial ischemia *with* angina and the other *without* angina.[306] Patients underwent brain PET imaging at baseline and during dobutamine stress. In both groups of patients, activation of the thalamus occurred during myocardial ischemia, which implies that peripheral nerve dysfunction cannot fully explain differences in pain perception. Subtle differences between groups were noted in cortical activation, possibly indicative of a significant role for central processing of afferent stimuli in the ultimate perception of ischemic pain. The quantification of regional opiate receptors with tracers such as ^{11} C-diprenorphine may deliver important additional insight into silent myocardial ischemia and the central nervous system modulation of specific cardiovascular manifestations.[307]

Future of Clinical Cardiovascular PET Imaging

In institutions in which PET and SPECT are both available, established referral patterns suggest that PET is used in situations where conventional modalities render equivocal results (for example, attenuation artifacts on SPECT imaging or questions about the presence of viable myocardium). The higher spatial resolution and attenuation correction may justify direct PET referrals when the pretest likelihood of coronary artery disease is low (see also Chap. 13) .[308] Socioeconomic changes have influenced institutions with PET capability to offer PET imaging at a cost competitive with that of SPECT and conventional nuclear cardiology studies. In institutions where SPECT and PET are both available, for reasons stated above, PET viability studies are frequently a final resort for making difficult clinical decisions in high-risk coronary artery disease patients after conventional myocardial perfusion imaging, echocardiography, and coronary angiography have been performed.[228] [258] [309] [310] In the future, cardiac PET may be more widely used if the cost of PET studies declines and regional distribution of PET radiopharmaceuticals or generator-produced radiopharmaceuticals becomes available. These trends are already in place in some locales and may play an important role in the future use of PET in clinical cardiology. Patterson and

colleagues addressed the economic aspects of a multimodality approach to the diagnosis of coronary artery disease with a comparison of stress PET, SPECT, coronary angiography, and stress ECG.[310] Their analysis suggested that stress PET is the most economical, with lowest cost per use in patients with a less than 70 percent pretest likelihood of coronary artery disease. Two future diagnostic indications may provide an expanded role of PET in clinical cardiology: absolute quantification of regional myocardial blood flow and assessment of adrenergic neuronal integrity.

Special Imaging Techniques

Fatty Acid Imaging

Sixty-eight percent of the adenosine triphosphate (ATP) that is produced within the myocardium under aerobic conditions is derived from fatty acid oxidation. Consequently, for a number of years, efforts have been under way to base imaging of the myocardium on radiolabeled fatty acid uptake to assess myocardial metabolism and viability. The first major efforts involved PET with ^{11}C-palmitate. Because of the rapid turnover of this compound, imaging was difficult and has for the most part been abandoned.

Current efforts focus on radioactive iodine (^{123}I)-labeled fatty acids for imaging purposes.[311] These efforts have achieved the widest use in Japan, as well as in Europe. To date, relatively limited studies have been performed in the United States. Two major types of radiolabeled fatty acids are suitable for imaging. ^{123}I-labeled straight-chain compounds undergo rapid beta oxidation and are then released from the myocardium. Consequently, their turnover rate is relatively rapid. For this reason, compounds of this class are best used for assessing the kinetics of fatty acid washout rather being used to provide static imaging data of the more conventional type iodophenyl pentadecaenoic acid (IPPA).[312] [313] [314] [315] Investigators have demonstrated imaging at rest with associated kinetic evaluation to be of value for assessing viability and functional recovery after revascularization. However, again it must be noted that the rapid washout will present difficulties with respect to high-quality SPECT imaging because of low count statistics.

The second category involves the modified branched-chain fatty acids, which because of the chemical manipulation of their structure, are metabolically trapped within the myocardium. These compounds provide excellent image quality. However, uptake probably does not reflect beta oxidation. Rather, uptake is based on fatty acid accumulation and the turnover rate of the lipid pool. The compound representing this class is BMIPP, which is 15(*p*-iodophenyl)-3*R,S*-methylpentadecanoic acid. BMIPP is currently the most widely used fatty acid imaging agent. A number of studies have demonstrated disparity between the uptake of a perfusion agent such as thallium or sestamibi and BMIPP, an indication that this tracer is providing information concerning metabolism that is independent of perfusion.[316] [317] [318] [319] [320] BMIPP remains within the myocardium for a protracted period. Only 25 percent is cleared at 2 hours. Sixty-five to 68 percent of the activity remains within the myocyte triglyceride pool. Abnormalities have been seen for a protracted period after an ischemic event, particularly in vasospastic angina, which suggests that delayed imaging with BMIPP may provide a "memory image" of a previously occurring ischemic event that has protracted metabolic consequences. Particularly in Japan, significant work has been done with the use of BMIPP in the setting of coronary artery disease, as well as cardiomyopathy.

Neurotransmitter Imaging

The mammalian heart contains dense adrenergic innervation. On the basis of norepinephrine regional concentrations, a gradient of adrenergic innervation is seen from the atria to the base of the heart, as well as from the base to the apex of both ventricles. In contrast to sympathetic activation, parasympathetic innervation is most evident in the atria, with much less uptake in the ventricular myocardium.

[123] I-metaiodobenzylguanidine (MIBG) has been used most widely to evaluate and image sympathetic innervation patterns.[321] This compound was initially developed for the diagnosis of pheochromocytoma and first used in studies of the human heart in the 1980s. The radiopharmaceutical is an analog of guanethidine and has uptake mechanisms similar to that of norepinephrine at sympathetic nerve terminals. It is transported into cells by uptake 1 and is stored in vesicles but not catabolized. The compound has little pharmacological action. Its uptake within the myocardium correlates with concentrations of norepinephrine in tissue. A problem with MIBG is that it has additional nonspecific uptake (uptake 2) by nonneuronal tissue. Clearance of MIBG from normal human heart is slow (5 to 12 percent in 3 to 4 hours). This rate is consistent with norepinephrine turnover. A significant number of clinical studies using MIBG imaging have been reported in the literature.

Perhaps the most relevant clinical application of myocardial MIBG imaging relates to the study of congestive heart failure.[322] [323] It is well recognized that the adrenergic nervous system plays a major role in the pathophysiology of heart failure, which is also associated with increased plasma norepinephrine levels, reduced cardiac stores of norepinephrine, and desensitization of beta receptors. It is also well recognized that elevated plasma norepinephrine levels have been associated with an unfavorable prognosis in heart failure patients. A number of studies have now demonstrated that an abnormal decrement in cardiac MIBG activity is associated with poor outcome in heart failure. In these studies, myocardial MIBG uptake is expressed as a heart/mediastinal ratio. A ratio of less than 1.2 has been associated with poor prognosis, independent of the ejection fraction.[324] It is likely that MIBG imaging could provide important insight into the heart failure population, both with ischemic and nonischemic cardiomyopathies.

Abnormal uptake has also been noted in patients with diabetes mellitis. This observation is consistent with altered autonomic innervation in diabetics and could provide at least one explanation for the frequent finding of silent myocardial ischemic in diabetics with coronary disease.[325] Likewise, decreased uptake has been noted following cardiac transplantation.[326] A level of reinnervation is often noted several years after successful transplantation.

In acute myocardial infarction a mismatch has often been noted between perfusion imaging patterns and MIBG patterns, with larger defects noted on MIBG imaging.[327] This finding is consistent with local denervation associated with the ischemic insult. A level of reinnervation has been noted several months after the infarction.

A role for MIBG has also been suggested in certain cardiac arrhythmias. In patients with arrhythmogenic right ventricular cardiomyopathy, abnormal findings on MIBG imaging have frequently been noted in the presence of normal thallium imaging.[328] Additional abnormalities have been noted in patients with prolonged QT syndrome.[329]

The general area of neurotransmitter imaging holds significant potential for studies in patients with cardiac disease. While its major application appears to be in the heart failure population, additional studies in patients with coronary disease, diabetes, and cardiac arrhythmias seem warranted.

Myocardial Imaging with Hypoxia Markers

Imaging of myocardial hypoxia is of significant interest in that such imaging could offer a new approach to the assessment of myocardial ischemia and viability. In addition, an imaging marker for myocardial hypoxia could prove of value in noninvasively defining a regional stimulus for angiogenesis. A good deal of work in this area has derived from tumor imaging. However, major applications have

been made to the study of myocardial hypoxia.[330] [331] Imaging is based on use of a radiolabeled compound that incorporates the nitroimidazole moiety. Recent studies have involved ^{99m}Tc-labeled nitroimidazoles. Two technetiumlabeled compounds have been studied. One represents a class of technetium (V) oxopropylene-amneoxime (PnAO) complexes that is called (BMS-181321).[332] Another recently studied compound is derived from removal of the 2-nitroimidazole moiety from a nitroimidazole-containing ligand. This compound is 4,9-diaza-3,3,10,10-tetramethyldodecan-2,11-dione (^{99m}Tc-HL91).[333] [334]

The nitroimidazoles are believed to diffuse passively across the cell membrane. Once in the cytoplasm of the myocardial cell, nitroreduction occurs with formation of an

$R\text{-}NO_2$ radical ion, which is an oxygen-independent step. In the presence of normoxia, the radical interacts with oxygen to yield superoxide and noncharged nitroimidazole. The free radical anion formation is then reversed in the presence of oxygen. The noncharged compound diffuses back out of the cell. Under hypoxic conditions, the radical anion is reduced further and yields a nitroso compound. The reduced metabolites of the nitroimidazole have lower permeability and are retained within the hypoxic cell. The additionally formed hydroxylamines also bind to intracellular macromolecules and are trapped within the cell. As a result, areas of hypoxia are visualized as zones of increased radionuclide uptake. These agents have been tested in pilot experiments both in isolated heart preparations and in canine models of experimental ischemia.[335] [336] [337] Agents also appear to have a threshold level of hypoxemia below which retention will be demonstrated.[338] Issues relating to the target-background ratio and uptake in adjacent organs may at this time limit clinical applicability with the first-generation compounds. However, this new class of compounds presents potential excitement for studying ischemia, regional hypoxia, and angiogenesis.

Molecular Imaging

As nuclear cardiology moves forward into new areas, fundamental advances continue to be made with respect to applying the principles of molecular and cellular biology to myocardial and vascular nuclear imaging. The development of such approaches will ultimately have meaning in assessing diagnosis and prognosis in coronary artery disease, as well as in various forms of myocardial disease and heart failure. Issues relating to the presence of significant atherosclerosis in its earliest phases, vulnerability of arterial plaque, myocardial necrosis, apoptosis, receptor affinity, upregulation and downregulation of receptors, monitoring of endogenous gene expression, and modalities for assessing the efficacy of gene therapy should all be readily achieved in the next era of modern nuclear cardiology techniques. [339]

Vascular Imaging

A significant challenge to nuclear cardiology and to the field of cardiology in general involves the ability to image the components of the vascular wall. In so doing one should be able to define the two extremes of the pathological process: (1) atherosclerosis at its earliest stages, when recognition of the problem could lead to aggressive intervention prior to major cardiovascular events, and (2) plaque vulnerability prior to the development of thrombosis and total occlusion. The issue of imaging the vascular wall will require major innovation with respect to both new radiopharmaceuticals and new instrumentation. In general, it is anticipated that one will be defining areas of interest involving enhanced radiopharmaceutical uptake, which will allow specific issues relating to target size, target-to-background ratio, and system resolution to be appropriately modulated such that reasonable results can be obtained with external imaging. Alternatively, because of the small size and geometry of the lesion, it may become necessary to develop intravascular probes or imaging devices, akin to intravascular ultrasound, to evaluate this emerging area of interest.[340] [340A] This requirement would be particularly true for defining plaque vulnerability.

A number of different targets have already been studied as prototypes for imaging the vascular wall. Initial targets have focused on proliferating smooth muscle cells, macrophages, and lipid pools. One of the newer approaches involves using a radiolabeled murine monoclonal antibody (Z2D3) generated against homogenized human atherosclerotic plaque; the antibody appears to be specific for antigenic components of proliferating smooth muscle cells. To date, the nature of the actual antigen(s) has not been defined biochemically. In the rabbit aorta atherosclerosis model, Narula and associates demonstrated increased uptake of the radiolabeled antibody, which could be imaged in vivo by using relatively simple planar imaging techniques[341] (Fig. 9-38) . The significant increase in uptake was also readily noted on ex vivo imaging and macro-autoradiography. This work has since been extended by Carrio and colleagues, who demonstrated that the radiolabeled antibody could also be used to image atherosclerotic plaque in human carotid arteries[342] (Fig. 9-39) . These investigators used both planar and SPECT techniques in patients who were about to undergo carotid endarterectomy procedures. This study is the first to demonstrate the feasibility of targeting atherosclerotic lesions with a specific radiolabeled antibody against a significant component of the vascular wall.

Figure 9-38 Left lateral oblique scintillation camera images of rabbits injected with ^{111} In-labeled conventional Z2D3 (*A*) and nonspecific antibody (*B*) for visualization of experimental lesions in the atherosclerotic aortic of a rabbit 48 hours after injection. Focal accumulation of Z2D3 is seen (solid arrows) between the vertebral activity (open arrow) and the kidney activity (bottom K). No localization is noted with the nonspecific antibody (open arrow). The in vivo localization of Z2D3 for the animal in figure *A* is seen in the ex vivo image (*C*). The nonspecific antibody does not show localization in the ex vivo image (*D*). *(From Narula J, Petrov A, Bianchi C, et al: Noninvasive localization of experimental atherosclerotic lesions with mouse/human chimeric Z2D3 F(ab)$_2$ specific for the proliferating smooth muscle cells of human atheroma: Imaging with conventional and negative charge-modified antibody fragments. Circulation 92:474, 1995. By permission of the American Heart Association, Inc.)*

Figure 9-39 Scintigraphy with ^{111} In-labeled Z2D3 antibody before carotid endarterectomy. The planar images demonstrate a diffuse increase in antibody uptake in the affected left carotid artery (*A*) as compared with a normal study (*B*). The walls of the arteries are indicated with the arrows. The carotid angiogram revealed 80 percent stenosis of the left carotid artery. *(From Carrio I, Pieri PL, Narula J, et al: Noninvasive localization of human atherosclerotic lesions with indium 111-labeled monoclonal Z2D3 antibody specific for proliferating smooth muscle cells. J Nucl Cardiol 5:551, 1998.)*

Elmaleh and associates applied the concept that ATP and its analogs are significant inducers of aortic medial smooth muscle cell proliferation in cell culture to the development of an imaging approach to the vessel wall.[343] It was hypothesized that ^{99m} Tc-labeled diadenosine polyphosphate could be used for the noninvasive imaging of active atherosclerotic lesions. This radiopharmaceutical was then tested in the same rabbit aortic atherosclerosis model used by Narula and coworkers for the study of Z2D3. The authors noted significant uptake of the technetium-labeled diadenosine tetrophosphate in vivo as well as ex vivo.

Additional vascular imaging studies have used the principle that endothelin receptors are present on the surface of smooth muscle cells.[344] Since the atherosclerosis is characterized by proliferation and migration of smooth muscle cells, it was believed that imaging with radiolabeled endothelin derivatives could play a role in vascular imaging. A ^{99m} Tc-labeled endothelin analog has been developed and tested in the rabbit atherosclerosis model. Imaging of the atherosclerotic aorta has been demonstrated in vivo and confirmed by tissue counting and ex vivo imaging. Additionally, the degree of uptake of the radiolabeled endothelin derivative correlated directly with the number of smooth muscle cells present in the vascular wall, but it did not correlate with either the amount of macrophages present or the area of maximal plaque thickness.

Atherosclerotic plaque contains large amounts of lipid and cholesterol. Consequently, the lipid pool would also represent an appropriate imaging target. Initial attempts designed to capitalize on this strategy were not successful. However, recently, Tsimikas and coworkers demonstrated the feasibility of this approach and used a radiolabeled monoclonal antibody against oxidized low-density lipoprotein cholesterol as a means of imaging atherosclerotic lesions.[345] In vivo scintigraphy demonstrated significant uptake in the rabbit aorta. In addition, histological and histochemical studies demonstrated uptake predominately in lipid-laden legions of the rabbit aorta; uptake was also greatest in areas with abundant foam cells and in the lipid-rich necrotic core areas of lesions. Such an approach, after appropriate development and calibration, might also provide a means for directly assessing the efficacy of aggressive lipid-lowering therapy on specific atherosclerotic lesions.

Other appropriate targets for vascular imaging obviously include the endothelium, macrophages or monocyte products or attractants, and antigens specific for neovascularization and angiogenesis.[346] With respect to the endothelium, antibodies against adhesion molecules have already been studied with in vitro systems and should ultimately be applicable to nuclear imaging strategies.[347] Nonimaging probe studies with FDG have demonstrated increased uptake at the site of active atherosclerotic lesions, presumably caused by enhanced metabolic activity of the macrophages present in the lesion.[348] Magnetic resonance imaging in experimental tumor angiogenesis has demonstrated that $alpha_V$ $beta_3$ activity can be imaged as an index of angiogenesis in experimental tumors.[349] A similar conceptual approach using nuclear imaging strategies could be readily adapted to the study of angiogenesis.

Apoptosis

Recently, it has been demonstrated that it is possible to image the process of programmed cell death, apoptosis,

Figure 9-40 Imaging cardiac allograft rejection with radiolabeled annexin V. Representative images of an abdominal cardiac ACI rat isograft and a PVG allograft in ACI host rats 5 days after transplantation are shown. Rats were imaged after injection of technetium-99m and annexin V. Locations of the transplanted hearts are marked by arrows. Intense uptake of annexin V was observed in the cardiac allograft animal (right) versus the lack of visualization of the syngeneic cardiac isograft (left). *(From Blankenberg FG, Katsikis PD, Tait JF, et al: In vivo detection and imaging of phosphatidyl-serine expression during programmed cell death. Proc Natl Acad Sci U S A 95:6349, 1998.)*

with nuclear imaging techniques. Blankenberg and coworkers reported imaging apoptosis based on the principle that annexin V, an endogenous human protein with a high affinity for membrane-bound phosphatidyl serine, can be used in vitro to detect apoptosis before other changes are noted.[350] ^{99m} Tc-labeled annexin V was used to image apoptosis in a number of experimental models in vivo, including

Figure 9-41 Positron-emission tomographic (PET) imaging for detecting the location, magnitude, and persistence of HSV1-tk reporter gene expression. Adenoviral-mediated delivery of the HSV1-tk reporter gene followed by subsequent ^{18} F-fluoroganciclovir ([F-18]FGCV) PET reporter probe trapping is used. Transcription and translation of HSV1-tk lead to the production of HSV1-tk enzyme, which can phosphorylate and thereby trap [F-18]FGCV. *(From Gambhir SS, Barrio JR, Herschman HR, Phelps ME: Imaging gene expression: Principles and assays. J Nucl Cardiol 6:219, 1999.)*

Figure 9-42 Transverse sections through the myocardium of a 300-gm rat injected with 2 mCi of fluorine-18 imaged with a micro-positron-emission tomographic scanner. Imaging time was 30 minutes and reconstructed resolution is 1.8 mm. Notice the clear definition of myocardium from the blood pool. *(From Weber DA, Ivanovic M: Ultra-high-resolution imaging of small animals: Implications for preclinical and research studies. J Nucl Cardiol 6:332, 1999.)*

rejecting cardiac allografts in the rat (Fig. 9-40) . Histological correlation of the presence of apoptosis in regions with increased annexin V uptake was noted. This new technique presents significant opportunities to use concepts of modern cell biology for imaging important pathophysiological processes. By studying both apoptosis and conventional necrosis in myocardium associated with heart failure, insight into potential new therapy can probably be achieved.

Imaging Gene Expression

One of the most exciting new directions in nuclear imaging involves the ability to directly visualize gene expression.[351] This new area of nuclear imaging has enormous potential. As yet, the technology has not been applied to direct study of the heart. However, the principles developed are readily applicable to any organ. Two general approaches have been used. One involves using reporter gene/reporter probe systems to image the expression of endogenous or exogenous genes. The second involves the use of antisense oligodeoxynucleotides that are radionuclide labeled and targeted to a specific mRNA of a particular gene radiolabeled antisense oligodeoxynucleotide (RASON). Both techniques are still in early phases of study, and both have been applied to in vivo imaging in small animals (mice and rats). One such system using PET involves the herpes simplex virus type I thymidine kinase gene (HSV-1tk) and ^{18} F-ganciclovir (Fig. 9-41) . In this setting, thymidine kinase serves as the reporter gene, which is introduced with any other gene used in a therapeutic manner, and ^{18} F-ganciclovir serves as the reporter probe, which will allow imaging.[352] This imaging probe serves as a substrate for thymidine kinase, which phosphorylates the imaging probe and thereby results in intracellular trapping of the fluorinated marker and consequently the ability to detect the location, magnitude, and persistence of reporter gene expression with PET imaging. Preliminary results are extremely exciting and offer a genetic approach applicable to both PET and ultimately to conventional SPECT technology. While initial studies have focused on exogenous genes, subsequent studies will also involve the imaging of endogenous gene expression.

Many such studies involve mice, in which direct gene manipulation is routine. Consequently, the availability of high-resolution instruments capable of imaging small animals is mandatory. Systems to meet this need have already been designed and developed for both PET and SPECT technologies[353] (Fig. 9-42) . Micro-PET and micro-SPECT systems will shortly be available for widespread use and will probably have a major impact on fundamental scientific and pharmacological approaches that extend far beyond the scope of cardiology.

Instrumentation

Acquisition and display of a nuclear image are dependent on the detection of radiation emitted from the patient after administration of a radionuclide. In radionuclide cardiac imaging, the radionuclides are either extracted by myocardium or remain in the cardiac blood pool. Several components are required to acquire gamma rays and produce an image, including a scintillation device such as the sodium iodide crystal, which absorbs the gamma rays and generates photons that are converted to an electrical signal by photomultiplier tubes. The electric signal is then amplified and accelerated such that the energy of the gamma ray initially absorbed by the crystal is directly proportional to the height of the generated electrical pulse. Different radionuclides emit at different energies, which allows discrimination between photons from the target and scatter.

Scintillation (Gamma) Camera

The acquisition of nuclear cardiology images is performed with a scintillation camera interfaced with a computer. Radionuclide images are the result of gamma rays passing through several principal camera components: a collimator (for single-photon imaging), a large sodium iodide crystal, and a hexagonal array of photomultiplier tubes.[354] The gamma camera provides an image of the location and intensity of a radiopharmaceutical in the heart. The image is the result of interaction between gamma rays and the camera crystal, which converts part of this energy into light (scintillation). The photomultiplier tubes translate these scintillations into voltage pulses, which are measured as an electrical signal that defines the position at which gamma rays

---

and the crystal interact. Such localization is accomplished by electronic circuits that compute *x* and *y* coordinates of crystal interaction and display this interaction in a two-dimensional matrix anatomically analogous to the site of occurrence within the patient. A multichannel analyzer (pulse height analyzer) defines the appropriate energy of the event; thus, low-energy (Compton) scatter events are not accepted. Most cameras have the capability of selecting more than one energy window, potentially allowing simultaneous dual-energy acquisition (a single isotope with more than one gamma emission or two isotopes with different gamma emissions). A crucial part of quality control involves periodic "balancing" of the photomultiplier tubes to ensure uniformity of the amplification and resultant image.

Characteristics that influence overall performance of the gamma camera are spatial resolution, sensitivity, maximum count rate, and field of view. Spatial resolution is the ability of the camera to differentiate two sources of activity in space. It is measured in terms of "full width at half maximum" (FWHM) and expression of the amount of blur. Typical gamma camera resolution is 4 to 5 mm without collimation and 6 to 10 mm with collimation. Sensitivity refers to the ability of the camera to detect incident photons. Intrinsic sensitivity reflects the sensitivity of the gamma camera itself and is dependent on crystal structure, crystal thickness, and the energy of the incident photons. Extrinsic sensitivity reflects the sensitivity of the system with a collimator and is much lower than intrinsic sensitivity. Crystals of most gamma cameras are composed of 1/4- to 5/8-inch-thick NaI. Cameras specifically designed to image high-energy photons (e.g., ^{18}F) may have thicker crystals at a minor loss of spatial resolution. The maximum count rate refers to the camera's ability to record counts over time. Most general-purpose gamma cameras have maximum count rates in the range of 300,000 counts per second, and multicrystal cameras have significantly higher count rate capabilities.

COLLIMATION

For single-photon imaging, collimation is important for appropriate localization of the radioactive event in space and serves as the primary means to reject scatter. A collimator is composed of lead channels designed in either a parallel, convergent, or diverging manner. Gamma rays must pass through the collimator before reaching the crystal. The purpose of the collimator is to approximate the origin of the photon emission within the patient to an analogous location within the crystal. Parallel-hole collimators are of either the high-resolution or high-sensitivity variety. A high-resolution collimator permits better spatial resolution (the ability of the detector source to discriminate between neighboring sources of activity and visually resolve various components within the field of view), but with a loss of count sensitivity (the number of counts acquired per unit time). Alternatively, a high-sensitivity collimator maximizes count sensitivity at the expense of spatial resolution. A compromise between the two types of collimators is the low-energy all-purpose or general all-purpose collimator, which is intermediate with respect to sensitivity and resolution. The thickness of the crystal and the type of collimation determine the sensitivity of a gamma camera. The type of collimation used for a particular study is based on these simple concepts. For instance, a parallel-hole high-sensitivity collimator would be appropriate for rapidly acquired studies such as first-pass blood pool studies.

COMPUTING

The computer is a principal component of all nuclear imaging systems. These data processing systems are interfaced with the gamma camera. The routine use of computers makes radionuclide imaging intrinsically quantitative. The computers have software containing algorithms for quantification of both static and dynamic digital images. The principal hardware components of the computer include an analog-digital converter, central processing unit, image memory, mass storage, an array processor, and a display monitor. The scintigraphic matrix is generally 64 × 64 or 128 × 128 pixels (picture elements).

Single-Photon Emission Computed Tomography (SPECT)

SPECT acquisition is the most widely used imaging technique in cardiovascular nuclear medicine imaging. Planar images, however, are still routinely used for equilibrium gated blood pool imaging. With SPECT, a series of planar images are obtained over a 180- to 360-degree arc around the patient's thorax.[11] Transaxial images are re-created by using a technique called filtered backprojection, although iterative reconstruction, which may be better suited to nuclear imaging, is currently being developed. These transaxial images are reconstructed into short-axis and horizontal and vertical long-axis orientations relative to the anatomical axis of the heart. The overall result is an improvement in anatomical contrast up to five to eight times that of a planar image, but at the expense of some decrease in spatial resolution. SPECT imaging requires diligent attention to detail with regard to the parameters set for acquisition and more stringent quality control measures. The most important parameters for SPECT imaging are the number of views obtained, the number of counts, and pixel size. Also, it should be emphasized that patient movement during the scan will significantly degrade the image.

Although the first SPECT camera systems used single heads, i.e., one gamma camera, most systems sold today have multiple (two or three) heads. The addition of more heads increases sensitivity and decreases imaging time. Some dual-headed camera systems also have movable heads that allow a configuration either 90 or 180 degrees apart. Cardiac SPECT acquisitions can be obtained over 180- or 360-degree orbits and with circular or noncircular orbits. The relative merits of each of these approaches remain a subject of study.

TECHNICAL ADVANCES

GATED SPECT.

Gated SPECT imaging is now routinely performed in many laboratories and allows for simultaneous measurement of both left ventricular perfusion and function. Using the same principle as for equilibrium gated blood pool imaging, SPECT acquisition is gated to the ECG, and the cardiac cycle is sampled over 8 to 16 frames. It is crucial that the patient be in a regular rhythm during the acquisition of a gated SPECT study. Arrhythmias have a serious degrading effect and make assessment of left

ventricular function unreliable. Images are then displayed in a cinegraphic mode to allow visual analysis of ventricular wall motion, and methods have been developed to determine LVEF from these digital images.[28] [29] [30] Gated studies are preferably performed with ^{99m}Tc-based perfusion tracers because the high photon flux ensures good-quality images.

ATTENUATION CORRECTION.

One of the major limitations of SPECT imaging in clinical practice is suboptimal specificity, which is probably caused by attenuation artifacts from the breast or diaphragm. Attenuation artifacts are often recognized by their characteristic[355] [356] appearance and location, but such methods are subjective and may not reliably distinguish artifactual defects from real defects. Normal data bases for circumferential profile analysis and gated SPECT imaging have been used to enhance specificity. Ideally, however, unique nonuniform attentuation masks are computed to correct for attenuation in each individual patient. A variety of investigational methods using fixed and moving line sources, various collimator configurations, and reconstruction algorithms have been developed for measurement and correction for attenuation. Clinical results, however, remain mixed, and the methodology requires further development.

Scattered photons are perhaps the major source of degraded image quality.[192] Accurate scatter correction would signify a major improvement in radionuclide image quality. Methods are under development to correct for scatter by using techniques such as convolution subtraction (from emission data) and transmission-based approaches. Recently, a combined attenuation and scatter correction transmission-based method was evaluated in a multicenter trial of patients with and without coronary artery disease.[15] Although normalcy rates improved with attenuation/scatter correction, overall receiver operator characteristic curves were no different, and the ability to detect multivessel disease was reduced.

QUANTIFICATION.

Quantification of SPECT myocardial perfusion images is generally performed by assessing the count in a given region relative to the maximum count in the image. Short-axis slices are generally used, and counts are sampled over evenly spaced angles. The maximum or mean count values then can be plotted against the angle at which they were encountered, and circumferential profiles can be generated.[26] This approach has several advantages. First, the profiles can be used as a more quantitative confirmation of what is seen by visual analysis alone. Second, profiles can be created for normal populations and can then serve as normal data bases. Third, the profiles can be used to assess both the severity and size of a perfusion defect in quantitative terms. Fourth, use of such quantitative analysis in concert with normal data bases reduces interobserver variability and thus improves the consistency of test performance. A variety of programs have been developed that are based on these circumferential profile-based concepts. Some programs display selected short-axis slices and graphs of profiles, while others display polar maps ("bull's-eye" images) for an overall overview of perfusion in a single image.[25]

TELEMED/NETWORK.

Advances in network-based telemedicine initiatives will probably develop into a useful tool for the nuclear medicine community. Applications of such technology include improvement in access to diagnostic imaging services in remote areas,

facilitation of consultation with expert readers, and development of an almost unlimited data base for teaching cases.

MICROIMAGING.

Small animals are often used for initial experimental studies in areas such as vascular biology, genetics, biochemistry, and metabolism. The development of imaging systems tailored specifically for small animals (e.g., mice, rats) may open new possibilities in the research of novel imaging applications. Recently, a PET scanner dedicated to the imaging of small animals has been developed.[357] This system uses lutetium oxyorthosilicate crystals arranged in a 17.2-cm diameter ring. The usable resolution for this system is in the range of 2 to 2.5 mm with typical filtered backprojection and a potential resolution of 1.2 mm with newer reconstruction algorithms.[358]

IMAGING OF POSITRON-EMITTING RADIOISOTOPES WITH SPECT SYSTEMS.

Primarily driven by the clinical impact of FDG imaging in the area of oncology, considerable interest has been expressed in developing techniques to image FDG with modified SPECT cameras. Initial studies have relied on the use of high-energy collimators and increased shielding of detector heads. Although the spatial resolution of such a system is poor, this approach has been shown to be feasible for myocardial viability assessment.[359] Recently, extensive research and development have been devoted to dual-purpose camera systems that can function as SPECT cameras but also have coincidence detection capability and thus function as "part-time" PET cameras. These systems tend to have resolution approaching that of dedicated PET systems, albeit with substantially reduced sensitivity. Methods for attenuation correction are not yet fully developed for these dual systems.

GUIDELINES
CARDIAC RADIONUCLIDE IMAGING

Thomas H. Lee

Guidelines for the use of cardiac radionuclide imaging have been difficult to develop and apply for several reasons. As is true for most diagnostic tests, there have been no randomized trials comparing outcomes for patients who did and did not undergo nuclear cardiology tests; nor have there been large trials comparing these tests with competing technologies. Furthermore, there has been rapid evolution in radionuclide imaging technologies, in which both the number and the complexity of choices for clinicians have increased.

An American College of Cardiology/American Heart Association (ACC/AHA) task force issued guidelines for use of cardiovascular nuclear imaging tests in 1995.[1] These guidelines are relatively old in comparison with other ACC/AHA guidelines, but the themes of the ACC/AHA guidelines for nuclear imaging have not been contradicted by subsequent guidelines. As with most ACC/AHA guidelines, this task force designated some indications for cardiac radionuclide imaging as generally appropriate (Class I) and generally inappropriate (Class III). Equivocal indications for nuclear cardiology tests are divided into two groups: Class IIa (weight of evidence in favor of usefulness) and Class IIb (can be helpful but are not well established by evidence).

Acute Myocardial Infarction

The ACC/AHA guidelines indicate that nuclear cardiology tests have a limited role in the diagnosis of acute myocardial infarction and should be used only when the history, electrocardiogram, and chemistry test results are less reliable. Technetium-99m pyrophosphate scanning was considered potentially useful (Class IIa) for patients who presented more than 24 hours and less than 7 days after the onset of symptoms, and radionuclide angiography can be used to support the diagnosis of right ventricular infarction by demonstrating a reduced right ventricular ejection fraction and right ventricular asynergy. However, nuclear tests were considered inappropriate for routine use for diagnosis.

For evaluation of prognosis *after* acute myocardial infarction, stress myocardial perfusion imaging was considered appropriate (Class I) to assess whether further myocardium is in jeopardy (Table 9-G-1) . The method used to provoke ischemia can be physical exercise or pharmacological, although these guidelines noted that the safety of dipyridamole and adenosine testing that is performed 2 to 3 days after admission "remains to be established." The guidelines do not address settings in which radionuclide imaging would be preferred over standard exercise electrocardiography. However, as described in guidelines to Chapters 6 , 35 , and 36 , other, more recent guidelines from ACC/AHA task forces have concluded that exercise electrocardiography should be the first-line test for patients who can exercise and whose electrocardiograms lend themselves to interpretation with stress testing.

Radionuclide angiography was considered useful for assessment of ventricular function after acute myocardial infarction and also can help detect aneurysms and mechanical complications such as an infarct-related ventricular septal defect. However, the ACC/AHA guidelines imply that for assessment of mechanical complications, nuclear cardiology testing is a second-choice technology that should be used when echocardiography is not available or definitive.

Unstable Angina

The ACC/AHA task force identified two principal issues for which radionuclide imaging techniques are potentially useful in patients with unstable angina: assessment of myocardial viability and prediction of future cardiac events in patients whose angina is successfully stabilized with medical therapy. Therefore, the two indications that were considered clearly appropriate (Class I) were use of stress myocardial perfusion imaging to detect ischemia and use of radionuclide angiography to assess baseline left ventricular function. Myocardial perfusion imaging was also considered potentially useful (Class IIa) for patients with ongoing ischemia who undergo imaging at rest. The use of rest myocardial perfusion imaging was considered less definitive (Class IIb) in patients in whom the diagnosis of myocardial ischemia was unreliable after consideration of routinely available clinical data.

Chronic Ischemic Heart Disease

The ACC/AHA guidelines considered exercise or pharmacological myocardial perfusion imaging to be appropriate (Class I) for identification of the extent and severity of ischemia and localization of ischemia in patients with chronic ischemic heart disease. The guidelines considered thallium-201 and technetium-99m to be sufficiently similar to be used interchangeably in this patient population. Review of data on the three most commonly used agents in pharmacological perfusion imaging (dipyridamole, adenosine, and dobutamine) led the ACC/AHA writing committee to conclude that their diagnostic performances were in the same range as exercise testing.

Asymptomatic Patients

The ACC/AHA guidelines did *not* consider cardiac radionuclide imaging an appropriate routine test for diagnosis of coronary artery disease

TABLE 9-9-G-1 -- ACC/AHA GUIDELINES FOR USE OF EXERCISE OR PHARMACOLOGICAL MYOCARDIAL PERFUSION IMAGING

Class I (Appropriate)

1. Prognostic stratification after acute myocardial infarction.
2. Identification of ischemia in patients with unstable angina.
3. Identification of extent and severity of ischemia in symptomatic patients and selected patients with asymptomatic myocardial ischemia.
4. Planning PTCA--identifying lesions causing myocardial ischemia if not otherwise known.
5. Risk stratification for selected patients before noncardiac surgery.
6. Assessment for restenosis after PTCA for symptomatic patients.
7. Assessment of ischemia in symptomatic patients after CABG.
8. Assessment of selected asymptomatic patients after PTCA of CABG, such as patients with an abnormal electrocardiographic response to exercise or those with rest electrocardiographic changes precluding identification of ischemia during exercise.

Class IIa

1. Identification of severity/extent of disease in patients whose angina is satisfactorily stabilized with medical therapy.
2. Diagnosis of anomalies of coronary circulation in adults with congenital heart disease.
3. Detection and assessment of functional significance of concomitant coronary artery disease in patients with valvular heart disease.

Class IIb

1. Assessment of drug therapy upon myocardial perfusion.
2. Assessment of coronary arteriopathy after cardiac transplantation.

Class III (Inappropriate)

1. Screening of asymptomatic patients with low likelihood of ischemic heart disease.

ACC/AHA = American College of Cardiology/American Heart Association; CABG = coronary artery bypass graft; PTCA = percutaneous transluminal coronary angiography.

From Guidelines for Clinical Use of Cardiac Radionuclide Imaging. A Report of the American College of Cardiology/American Heart Association Task Force on Assessment of Cardiovascular Procedures (Committee on Nuclear Imaging). J Am Coll Cardiol 25:521-547, 1995.

in patients who are not symptomatic. However, a stress radionuclide test (either perfusion imaging or radionuclide angiography) can be useful for determining the need for coronary angiography for asymptomatic patients with positive exercise electrocardiography tests. The use of a stress radionuclide test can also be valuable in asymptomatic patients with known coronary artery disease to determine the presence and severity of inducible ischemia.

Before Noncardiac Surgery

Several studies have demonstrated that abnormal dipyridamole- or adenosine-thallium-201 scintigraphy identifies patients at increased risk for cardiovascular complications associated with noncardiac surgery (see Chap. 61) . Most of these investigations have focused on vascular surgical procedures, but some data indicate that these tests can also be expected to help stratify patients according to risk associated with other types of major operations. However, because the overall risk involved in elective noncardiac surgery is low, the positive predictive value of abnormal tests is only between 15 percent and 30 percent. Therefore, the ACC/AHA guidelines concluded that noninvasive testing is not needed in most patients undergoing nonvascular surgery because their cardiac risk is low.

Before and After Revascularization Interventions

Myocardial perfusion imaging can be useful in planning percutaneous coronary interventions (PCI) procedures by providing insight into the functional impact of single or multiple coronary artery stenoses. This type of imaging can also be used after PCI to assess whether restenosis has occurred and for patients who become symptomatic after coronary artery bypass graft (CABG) surgery, to determine whether grafts may have occluded. However, the ACC/AHA guidelines on nuclear imaging did *not* endorse routine testing for patients who are asymptomatic after PCI or CABG because of the lack of data that outcomes are improved with this approach. These conclusions are consistent with more recent guidelines from the ACC/AHA on exercise testing.[2]

Myocarditis and Cardiomyopathies

With the exception of assessment of ventricular function with radionuclide angiography, there were no indications for the use of nuclear cardiology tests in patients with myocarditis and cardiomyopathies that were considered clearly appropriate (Class I) by the ACC/AHA task force. Thallium-201 scintigraphy was believed to be potentially useful (Class IIa) for the purpose of differentiating ischemic and dilated cardiomyopathy and assessment of myocardial ischemia in patients with hypertrophic cardiomyopathy. Other indications for testing in patients with myocarditis or cardiomyopathies, such as gallium-67 imaging to demonstrate myocardial inflammation, were considered possibly useful but unproven (Class IIb).

Other Conditions

Echocardiography is the imaging technology of choice for patients with congenital heart disease, but first-pass radionuclide angiography and lung perfusion scanning can be used to detect, localize, and quantitate shunts. For patients who have undergone cardiac transplantation, the use of radionuclide tests to detect rejection or coronary arteriopathy is not well established (Class IIb). Similarly, cardiac nuclear tests are not directly useful for assessment of patients with valvular heart disease, except for assessment of left ventricular function.

Chapter 10 - Newer Cardiac Imaging Modalities: Magnetic Resonance Imaging and Computed Tomography

CHARLES B. HIGGINS

MAGNETIC RESONANCE IMAGING OF THE HEART

Magnetic resonance imaging (MRI) has several important attributes that make it intrinsically advantageous for cardiovascular diagnosis. First, a high natural contrast exists between the blood pool and the cardiovascular structures because of the lack of signal from flowing blood with the spin-echo MRI technique or the bright signal from blood with the gradient-echo (cine MRI) technique. When the spin-echo technique is used, blood appears black on images; therefore, internal structures of the heart can be visualized within the signal void of the cardiac chambers. With the use of the gradient-echo technique, the blood pool appears white and has substantially higher signal than the myocardium, again providing good edge definition of the endocardial margin. Consequently, contrast medium is not required for discrimination of the blood pool, making MRI an entirely noninvasive imaging technique. Second, a wide range of soft tissue contrast provides the potential for the characterization of myocardial tissue. This contrast among tissues depends on proton (hydrogen nuclei) density, magnetic relaxation times of the protons, and magnetic susceptibility effects. Myocardial tissue characterization is improved with the use of MR contrast media. Third, imaging can be done in any plane, including those parallel and perpendicular to the major axis of the ventricles. Fourth, blood flow can be measured in any cardiac chamber or blood vessel using velocity encoded MR.

MAGNETIC RESONANCE GLOSSARY

Brief descriptions of the MRI process, general imaging techniques, and specific imaging techniques for the heart are given here, along with some useful terminology for MRI. A more detailed description of the principles underlying MRI is available elsewhere.[1]

ECHO-PLANAR IMAGING (EPI).

A method for obtaining MR images in 30 to 50 milliseconds. Multiple lines of the image matrix are acquired after the initiating radiofrequency (RF) pulse. In EPI, a very rapid series of echoes is generated by rapidly switching a strong phase-encoding gradient in the presence of a weaker read gradient. Data for all points in the image matrix can be obtained with a single pulse repetition (single PR). Image quality is increased by acquiring every second (or third or fourth) line of the image matrix with each initiating RF pulse. This sequence is called interleaved EPI.

FREE INDUCTION DECAY (FID).

The signal produced by the release of energy absorbed by the nuclei from a previously applied RF pulse. The FID is the signal analyzed in MRI and spectroscopy. The signal obtained with FID is related to field inhomogeneities.

GRADIENT-ECHO IMAGING SEQUENCE.

A method by which images are acquired more rapidly than with spin-echo imaging by substantially reducing the repetition time (TR). The technique uses a flip angle of 90 degrees or less and a short TR. This reduction is achieved by switching the read gradient to focus the signal rather than by a time-consuming refocusing RF pulse. Contrast on these images is very different from that for spin-echo images. A major difference is that blood flow produces a strong signal and appears bright.

HYDROGEN DENSITY (SPIN DENSITY, PROTON DENSITY).

Density of protons at a site in a sample that is resonating as part of the MR process. From the point of view of quantum mechanics, these are the protons making transitions from high-energy states to lower-energy ones and vice versa, when energy just equal to the difference between these two states is applied.

MAGNETIC MOMENT.

Intensity and direction of the net magnetic field of spinning nuclei. In a magnetic field, nuclei align to produce a net magnetic moment parallel to the field.

MAGNETIC RESONANCE IMAGING (MRI).

Spatial two- or three-dimensional map of nuclei resonating at a characteristic frequency when placed in a magnetic field and subjected to intermittently applied RF pulses.

MAGNETIC RESONANCE SIGNAL.

During relaxation after cessation of an RF pulse, energy absorbed from this pulse is released and provides an RF signal.

MAGNETIC RESONANCE SPECTROSCOPY.

Spectrum of resonant frequencies of a specific nucleus contained within a sample. This spectrum results from the chemical shift of a nucleus caused by the influence of the local chemical environment. Consequently, the resonant frequency of phosphorus in the inorganic state is slightly different from its frequency in creatine phosphate. MR spectroscopy detects and maps these chemical shifts of a nucleus.

MULTINUCLEAR MRI.

Imaging using nuclei other than hydrogen, such as sodium-23 and phosphorus-31.

PROTON MRI.

Imaging dependent on the concentration and relaxation time of hydrogen nuclei.

PROTON SPECTROSCOPY.

Spectrum of resonant frequencies of hydrogen nuclei (protons) in relation to the chemical environment. Proton spectroscopy can define chemical peaks representative of substances such as fats, water, lactic acid, choline, and carnitine.

PARAMAGNETIC SUBSTANCES.

Substances that alter the natural relaxation times of nuclei undergoing the MR process. These are usually molecules with unpaired electrons that reduce the relaxation times of resonating nuclei. These substances are being used and developed as contrast media for MRI.

RELAXATION.

Return of nuclei to the original state of alignment with a magnetic field after having been tilted by an RF pulse.

RELAXATION TIMES.

Relaxation of nuclei undergoing the MR process has two components, called T1 and T2 relaxation times. These relaxation times are time constants, measured as the magnetization vector processes into alignment with the magnetic field after perturbation by an RF pulse.

RESONANT FREQUENCY.

Each nucleus that is sensitive to the MR process must be tilted in the magnetic field by a specific frequency (resonant frequency) to induce resonance. When this frequency is applied, the nucleus is rotated away from its equilibrium alignment with the magnetic field. When the RF pulse ceases, the nucleus realigns with the magnetic field through a process of magnetic relaxation.

SEGMENTED CINE GRADIENT-ECHO IMAGING.

Multiple image lines are obtained during a phase of a cardiac cycle using a gradient-echo sequence. It is done to permit a cine gradient-echo acquisition during breath holding.

SPIN-ECHO IMAGING SEQUENCE.

Images are produced by sampling the signal after an initial 90-degree RF pulse, followed by one or more 180-degree pulses. The 180-degree pulse refocuses spins and thereby enhances the signal from them. A signal is sampled some time after the 180-degree pulse. The signal is usually lost from the flowing blood, producing low signal from the blood pool.

SURFACE COILS.

RF receiver coils placed upon the surface of the subject or upon an organ of interest to detect the MR signal. These coils increase the efficiency and signal strength for both MRI and spectroscopy.

T1 RELAXATION TIME.

Also called spin-lattice or longitudinal relaxation time. T1 relaxation is a measure of the exponential rate of growth of the magnetization vector along the direction of the external magnetic field after the nuclei have been tilted (flipped) by an RF pulse. T1 values vary with the magnetic field strength.

T1-WEIGHTED IMAGE.

Image in which the intensity of image voxels depends greatly on the T1 relaxation time of tissues. For the spin-echo technique, this is done with a short TR and echo delay time (TE). T1 weighting is done by setting TR
T1 of tissue and TE
T2 of tissue.

T2 RELAXATION TIME.

Also called spin-spin or transverse relaxation time. Immediately after cessation of a 90-degree RF pulse, the nuclei process in phase, resulting in a magnetization vector in the transverse plane. There is gradual dephasing of nuclei, leading to cancellation of the magnetization vector in the transverse plane.

T2-WEIGHTED IMAGE.

Image in which the intensity of image voxels depends heavily on the T2 relaxation time of tissues. For the spin-echo technique, this is done with a long TR and TE. T2 weighting is accomplished by setting TR
T1 of tissue and TE
T2 of tissue.

TE.

Echo delay time. Time between the initiation of a pulse sequence (90-degree pulse) and the sampling of the spin-echo signal. For the spin-echo sequence, this sampling is done after the 180-degree pulse. For example, the first spin-echo signal is sampled at a time that is twice the duration between the initial 90-degree pulse and the 180-degree refocusing pulse.

TR.

Pulse repetition time. The interval between sets of RF pulses that are used to acquire the necessary lines of the image matrix. For the standard spin-echo and gradient-echo sequence one line is acquired for each TR. With fast sequences, multiple lines of the image matrix are acquired within each TR.

TECHNICAL ASPECTS

Atomic nuclei with a net charge have a magnetic moment. A net charge exists when a nucleus contains unpaired (an odd number) protons, neutrons, or both. The hydrogen nucleus contains only a proton; it is positively charged and has a strong magnetic moment. The magnetic properties of nuclei are expressed when they are placed in an external magnetic field. When protons or other nuclei with magnetic moment lie within a magnetic field and are then exposed to electromagnetic radiation

(RF waves), energy is absorbed and subsequently emitted. This absorption and release of energy causes resonance-nuclear MR. The RF necessary to induce resonance has to be proportional to the local magnetic field (H_L) and a constant (magnetogyric ratio [g]) related to the specific nucleus involved. The relationship between frequency (f) and magnetic field is expressed by the following equation:
$f=gH_L /2pi$

When nuclei at equilibrium in a magnetic field are irradiated at the resonant frequency, they attain a higher energy state. When they return to equilibrium, they emit energy at the same frequency if the magnetic field remains constant. If the magnetic field changes between the time of excitation and emission, then the emission occurs at a frequency corresponding to the new field strength as expressed by this equation. The physics and techniques of MRI are discussed in greater detail elsewhere.[1]

Localization of Magnetic Resonance Signal

Magnetic resonance imaging depends on the reception of the emitted RF signal from resonating nuclei and on the capability of locating these nuclei in space. Location of the resonating nuclei can be achieved by spatially varying the field strength in a known manner. Because resonance frequency of a nucleus at a specific site is related to local field strength, the emitted frequency characterizes the spatial location of the nucleus when a magnetic gradient exists in one or more planes.

Selection of a transverse section for imaging is done by applying a magnetic gradient along the Z axis (long axis of the body). In such a gradient, each transverse plane (XY plane) has a specific and different resonant frequency. If the body is irradiated with a 90-degree RF pulse consisting of a narrow range of frequencies corresponding to the resonance frequency of a single plane, only the nuclei in that plane resonate *selective irradiation* and the image plane is delineated.

Once a plane is excited by selective irradiation, spatial localization is attained in that plane by another gradient oriented parallel to that plane. After the selective 90-degree RF pulse is applied, a magnetic field gradient is produced in the X or Y direction. Nuclei at the stronger end of the field gradient resonate at a higher frequency than those at the weaker end of the gradient. This provides spatial localization within the selected plane.

MAGNETIC RESONANCE SIGNAL INTENSITY

The magnetic signal from a sample undergoing MRI is detected by an RF receiver coil. The intensity of the signal at foci in the imaging plane depends on the concentration of resonating nuclei at the site and the magnetic relaxation times of the nuclei. The relaxation times are measures of the interaction of the resonating protons with the static magnetic field and the intermittently applied RF pulses.

The net magnetic moment of nuclei at any site can be expressed as a vector with length (intensity) and direction. At equilibrium, the vector points along the main static magnetic field. The vector can be tipped 90 degrees by the application of an RF pulse. The component of the net magnetic moment that points along the main magnetic field is called *longitudinal magnetization.* The component at 90 degrees to the main field is the *transverse magnetization.* The component at 90 degrees to the main field is fully aligned with the magnetic field (equilibrium); the vector varies continuously between longitudinal and transverse magnetization and gradually approaches full longitudinal magnetization.

MAGNETIC RELAXATION TIMES

After the application of a 90-degree RF pulse, net magnetization is rotated from the longitudinal direction (ZY plane) into the transverse direction (XY plane). At this instant, transverse magnetization is maximum

and longitudinal magnetization is zero. Immediately after this, longitudinal magnetization recovers toward its equilibrium value. This exponential growth has a time constant called *T1*. Likewise, after the 90-degree pulse, transverse magnetization exponentially decays; the time constant is called *T2*. In tissues, T2 is much shorter than T1. These relaxation times are related to several characteristics of tissues, including temperature. Tissues have different relaxation times, and these differences contribute to contrast among tissues during imaging. Contrast between two tissues can be accentuated by sampling signal at an instant when the difference between the relaxation times of the two tissues is maximal. Another term, T2*, is the effective T2 relaxation time, which is much more rapid due to movement of spins in static gradient fields. This value is greatly influenced by spatial inhomogeneity of the magnetic field and substances including contrast media, which induce local macroscopic and microscopic susceptibility variations in tissue.

IMAGING, TR, AND TE.

The MR image is produced by applying the sets of RF pulses many times over several minutes; generally, 128 to 512 pulse sequences are used. The time between application of sets of RF pulses is called the *repetition time* (TR). Depending on the technique employed for imaging, each set consists of one or more RF pulses. The time between the initial pulse in a sequence and the instant when a signal is acquired from the sample is called the *echo delay time* (TE). It is possible to alter the pulse sequences in such a way that differences in T1 and T2 relaxation times among the tissues can be accentuated to produce contrast among these tissues. This is referred to as *T1* or *T2 weighting of the images.* T1-weighted images have short TR and TE intervals, whereas T2-weighted images have long TR and TE intervals when using the spin-echo technique. T1 and T2 weighting for new fast-imaging techniques is achieved to some extent by variations in the flip angles induced in the nuclei by the initial RF pulses.

EFFECTS OF MOVING BLOOD.

During an imaging sequence, the motion of nuclei through the region that is being imaged greatly influences signal intensity. Although the influence of blood flow on MR images is complex, motion of the excited nuclei causes either a loss or an increase of signal intensity, depending on the RF pulse sequence employed. For the spin-echo sequence, moving blood in the lumina of vessels appears dark (no signal), providing considerable natural contrast for visualization of the internal surfaces of the blood vessels and walls of the cardiac chambers (Fig. 10-1) . Because contrast medium is not required to mark the blood pool, MRI is a totally noninvasive technique for cardiovascular diagnosis. When blood velocity is such that protons move through the thickness of the tomogram (usually 5 to 10 mm) in the time between the 90-degree and 180-degree pulses of the spin-echo sequence, signal is lost from the blood. When using standard spin-echo sequences, this time (TE/2) is usually 5 to 15 milliseconds for the first such image. Any residual signal in the blood flow can be nulled on spin-echo images by applying a preparatory (inversion) pulse with the spin-echo technique to create black blood images (Fig. 10-1) . For the gradient-echo pulse sequence, signal is received from blood flowing at normal velocities in the cardiac chambers and all blood vessels. The signal of flowing blood increases in proportion to the rate of flow (velocity) over a moderate range of velocities until a plateau of nearly constant signal is reached. In this circumstance, blood appears substantially brighter (white) than the cardiac walls (Fig. 10-2) . With jet flow at very high velocities, signal is lost. This loss of signal from high-velocity disturbed flow in jets can be minimized by the use of short TE (5 milliseconds). High-velocity jets produced by flow across stenotic or regurgitant valves can be recognized as a signal void within the signal-filled cardiac chambers (Fig. 10-3) .

Cardiovascular Imaging Techniques

Cardiac imaging usually requires some form of physiological gating of the imaging sequence. Acquisition of MR signals of the thorax without gating results in poor cardiac images, owing to loss of the signal from moving structures and to the variable position of the cardiac structure relative to imaging pixels when data are acquired indiscriminately throughout the cardiac cycle.

Figure 10-1 Fast spin-echo image in the short-axis plane. The blood pool is black (signal void), producing sharp demarcation of the endocardium. *(Courtesy of Kevin King, General Electric Medical Systems.)*

GATING WITH MRI.

Gating during MRI presents unique challenges. Sensors, wire leads, and transducers are usually composed of ferromagnetic materials, which can generate noise or may grossly distort the images within the RF-shielded room containing the MRI device. Consequently, gating with MRI requires the use of a nonferromagnetic physiological signal-sensing circuit. An electronically isolated electrocardiogram (ECG) electrode-lead circuit containing very little metal has been used for repetitive synchronization (i.e., ECG gating) of pulse sequences to fixed segments of the cardiac cycle. ECG gating is done prospectively for some sequences (spin-echo) or

retrospectively for others (cine gradient-echo).

ECG-GATED SPIN-ECHO IMAGING.

The techniques used in MRI of the heart depend on the primary goals of the procedure. When the evaluation of anatomical abnormalities is paramount, the use of the ECG-gated spin-echo technique provides static images with high signal-to-noise ratios. The spin-echo technique is used with prospective ECG gating; each R wave initiates a new 90-degree pulse. Thus, the TR is equal to the RR interval. The signal is sampled at the TE time. In the center of each TE interval, a 180-degree refocusing RF pulse is applied to accentuate the signal. With standard spin-echo imaging, one line of the image matrix is acquired at each anatomical level for each RR interval. This sequence usually displays flowing blood as black on the image (signal void) (see Fig. 10-1) . Another approach is to acquire multiple echoes from the same anatomical level during each RR interval. This decreases the time for acquisition of an image and is called fast spin-echo imaging.

ECG-REFERENCED GRADIENT ECHO (CINE MRI).

Cine MRI is important for the evaluation of ventricular and valvular functions. This technique uses narrow flip angles (<90 degrees) and gradient-refocused echoes. Because the TR and TE values are 5 to 30 milliseconds and 1 to 15 milliseconds, respectively, the cardiac cycle can be divided into about 16 time-frame slices. Lacing these slices together in a cinematic format permits construction of tomograms of the beating heart. The blood pool has bright signal on cine MR images (see Fig. 10-2) .

The cine MRI techniques is used to measure ventricular volumes and ejection fraction and for quantification of regional contraction. It also provides identification of abnormal flow across valves, cardiac defects, and vascular stenoses.

Figure 10-2 A series of gradient echo (cine MR) images in the short-axis plane acquired at end-diastole extending from the base *(top left)* to the apex *(bottom right)* of the heart. The blood pool is white, producing sharp demarcation of the endocardium. This three-dimensional data set can be used to measure directly ventricular volumes and mass. a=aorta; la=left atrium; lv=left ventricle; P=pulmonary artery; ra=right atrium; rv=right ventricle. *(From Higgins CB, Hricak H, Helms C [eds]: MRI of the Body. 3rd ed. Philadelphia, Lippincott-Raven, 1998.)*

It permits identification of valvular stenosis and regurgitation (see Fig. 10-3) .

BREATH-HOLD (SEGMENTED) CINE MRI.

Fast gradient-echo imaging techniques are important for MRI of the heart. For conventional spin-echo and gradient techniques, one line of the imaging matrix (usually 128 to 256 lines compose the imaging matrix) is acquired for each TR interval (RR interval for gated acquisitions). With fast gradient-echo imaging, multiple lines (usually eight) are acquired for each RR interval. This reduces the acquisition time by a factor that equals number of lines acquired, so that a cine acquisition can be done in a breath-hold period of 12 to 14 seconds (breath-hold cine MR imaging).[2]

CONTRAST-PREPARED FAST GRADIENT-ECHO IMAGING.

This fast imaging method uses very short TR and TE intervals for gradient-echo acquisition with a course matrix (64 to 128 lines) to produce low spatial resolution images in about 600 to 2000 milliseconds. These are sometimes called fast gradient-echo or turbo gradient-echo images. These can be weighted for T1 and T2 contrast by applying a preparation pulse before the imaging sequence, such as an inversion recovery (180 degree) pulse before the image sequence to produce T1 weighting. These sequences have been initially applied to provide 1- to 2-second monitoring of the initial passage of injected contrast medium through the central circulation and myocardium to evaluate regional myocardial perfusion.[3] [4]

VELOCITY-ENCODED CINE MRI.

Blood flow volume and flow velocity can be quantified using velocity-encoded cine MRI (velocity flow mapping).[5] This technique provides a velocity image (velocity map or phase image) at evenly spaced intervals, usually 16, throughout the cardiac cycle. Analysis of the velocity image can be done to measure peak velocity or average velocity in any selected region of interest across the vascular lumen or flow channel. Velocity-encoded sequences can be used with either standard cine MRI or breath-hold cine MRI. Using the multiple phase images collected over the cardiac cycle, flow- or velocity-versus-time curves can be made.

ECHO-PLANAR IMAGING (EPI).

EPI is the fastest MRI technique. It can provide an image in an acquisition time of 40 to 50 milliseconds (Fig. 10-4) . The acquisition can be done so that all lines in the image matrix or K space are acquired in a single TR interval (single-shot EPI) or in a few (usually two to four) sequential TR intervals (multishot or interleaved EPI).[6] EPI sequences can be either spin-echo EPI or gradient-echo EPI. In addition, preparatory pulses can be used to increase the T1 weighting of the imaging; inversion recovery EPI is very sensitive to T1-contrast effects, such as those produced by low doses of MR contrast medium.[7]

MAGNETIC RESONANCE ANGIOGRAPHY (MRA).

MRA employs a variety of flow-sensitive MR sequences in an

Figure 10-3 Cine MR image in the coronal plane at mid diastole. There is aortoannular ectasia with an aneurysm of the ascending aorta and aortic insufficiency (flow void emanating from the closed aortic valve). *(From Higgins CB, Hricak H, Helms C [eds]: MRI of the Body. 3rd ed. Philadelphia, Lippincott-Raven, 1998.)*

attempt to maximize the signal from flowing blood and suppress the signal of surrounding tissue.[8] One type depends on the inflow of blood into a slice or a volume that is continuously exposed to repetitive RF pulses. The repetitive RF pulse depletes the signal of stationary tissue while the inflowing blood retains signal, causing high contrast between the vessels and surrounding tissue. This is called the time-of-flight technique. Another type depends on the difference in the change of phase of spins in motion compared with stationary spins during the RF pulse sequence. This is called the phase contrast technique. With either type, the data can be collected from multiple adjacent slices in a sequential manner (two-dimensional [2D]) or

Figure 10-4 Echoplanar images (interleaved acquisition) at end diastole *(left)* and end systole *(right)* in the short-axis plane. Note the sharp contrast between the blood pool and myocardium, permitting accurate measurement of ventricular volumes and regional wall thickening.

Figure 10-5 Contrast medium-enhanced three-dimensional MR angiogram of the chest. Maximum intensity projection image is shown in coronal plane.

simultaneously from a specified volume of tissue (three-dimensional [3D]). Thus, the MRA methods are 2D time-of-flight, 3D time-of-flight, 2D phase contrast, and 3D phase contrast techniques. At the current time, the most popular techniques are the time-of-flight methods.

The use of 3D time-of-flight method in the chest requires the use of MR contrast media. Moreover, data collection is done during a breath-hold period to avert breathing artifacts. The imaging data are acquired during the time of peak opacification of the arterial structures of interest. Acquisition of the 3D data set in a breath-hold period

is realistic for most patients (15 to 25 seconds) and is accomplished by employing very short TR (5 seconds or less). This technique can provide exquisite images of the thoracic aorta and pulmonary artery (Figs. 10-5 and 10-6).

IMAGING PLANES.

Imaging can be done in any plane desired. The plane is specified before imaging, and the tomograms

Figure 10-6 Contrast medium-enhanced three-dimensional MR angiogram of the chest in the coronal plane demonstrates partial anomalous pulmonary venous connection from left upper lobe to a vertical vein (arrow) connecting to the left brachiocephalic vein. A=ascending aorta; S=superior vena cava.

are produced in the specified plane. As opposed to some techniques, such as computed tomography (CT), the images obtained in the sagittal and coronal planes are directly acquired rather than reconstructed planes; there is no loss of spatial resolution in these planes in comparison to the transverse plane. Most MRI studies of the heart have been done in the transverse plane, with supplemental studies obtained in the coronal and sagittal planes in some instances. However, these three planes are orthogonal to the body as a reference structure but produce oblique sections of the heart, because the heart is oriented in the thorax at approximately a 45-degree angle to the sagittal plane. Consequently, images parallel (long axis) or perpendicular (short axis) to the long axis of the heart are sometimes needed. Preliminary images, usually in the transverse or coronal plane, are done to calculate the angle of the slice-selective gradient needed for acquiring short- or long-axis images (see Figs. 10-2 and 10-7).

EVALUATION OF SPECIFIC CARDIOVASCULAR DISEASES BY MRI

The clinical use of MRI has been primarily for the demonstration of pathological anatomy. However, in the past few years MRI has been used for the quantification of global and regional function of the right and left ventricles, for the quantification of valvular heart disease, for the measurement of blood flow in the heart and great arteries, and for the assessment of myocardial perfusion and even coronary blood flow. MRI also offers several approaches to evaluation of myocardial viability. Precise demonstration of anatomical abnormalities has been useful for the evaluation of patients with ischemic heart disease, cardiomyopathies, pericardial disease, neoplastic disease, right ventricular dysplasia, congenital heart disease, and thoracic aortic disease.

Figure 10-7 Cine MR images acquired in vertical long axis *(left)* and horizontal long-axis *(right)* planes.

Ischemic Heart Disease

Recent advances in technology provide capabilities by which MRI could evolve as a comprehensive imaging technique for ischemic heart disease (see also Chap. 13) .[9] In this regard, morphology can be assessed with the ECG-gated spin-echo and cine MRI techniques, permitting determination of the extent of wall thinning caused by previous infarctions and depiction of complications of infarctions, such as true and false aneurysms. Segmental myocardial function can be quantified by measuring the extent of regional wall thickening or wall motion on standard or breath-hold cine MRI. Moreover, regional myocardial ischemia can be demonstrated by analysis of regional myocardial wall thickening in the basal state and during pharmacological stress induced by dipyridamole or dobutamine.[10] [11] NMR spectroscopy may furnish a noninvasive way to evaluate myocardial ischemia due to microvascular disease in individuals with chest discomfort but lacking significant epicardial coronary artery disease.[11A] By using a variety of approaches, breath-hold cine MRI can produce images of the major coronary arteries. Breath-hold velocity-encoded techniques can be applied for measuring coronary blood flow or velocity at rest and during interventions intended to test coronary flow reserve.[12] [13] Finally, contrast-prepared fast gradient-echo imaging can be used to evaluate myocardial perfusion in the basal and vasodilated states to identify myocardium jeopardized by coronary arterial stenosis.[14] [15]

MORPHOLOGY.

MRI provides direct visualization of the myocardium with excellent delineation of the epicardial and endocardial interfaces. Consequently, it can define accurately segmental wall thinning that indicates previous myocardial infarction. In some patients with a history of transmural infarction, residual myocardium can be demonstrated at the site of the infarction. In others, MRI shows virtually complete absence of remnant muscle. Direct visualization of the myocardium can be used to determine whether sufficient residual myocardium remain in the region jeopardized by a coronary arterial lesion to warrant a bypass graft. Regional wall thickening can also be assessed. It has been shown that a wall thickness of less than 6 mm at end diastole and wall thickening of less than 1 mm

Figure 10-8 Gradient echo image in an oblique coronal plane demonstrates the small ostium (arrow) connecting the large false aneurysm (A) with the left ventricular chamber. Note the severe wall thinning in the posterior and diaphragmatic regions of the left ventricle. *(From Higgins CB, Hricak H, Helms C [eds]: MRI of the Body. 3rd ed. Philadelphia, Lippincott-Raven, 1998.)*

indicate myocardial scar when compared with uptake of technetium-99m sestamibi single-photon emission tomography, positron emission tomography, and recovery of region function after myocardial revascularization.[16] [17] [18] [19]

The recognition of decreased signal intensity of the myocardial wall at the site of old myocardial infarction suggests that MRI can identify the replacement of myocardium by fibrous scar. Gated MRI has also demonstrated complications of myocardial infarctions, such as left ventricular thrombus and aneurysms (Fig. 10-8) . Transverse or short-axis tomography facilitates the recognition of the small ostium connecting the left ventricular chamber and the false aneurysm (see Fig. 10-8); this is a distinguishing feature of the false compared with the true left ventricular aneurysm.

Acute myocardial infarctions have been demonstrated by gated MRI. The region of ischemically damaged myocardium

Figure 10-9 Coronal T1-weighted spin-echo images in the coronal plane before *(left)* and after *(right)* injection of a gadolinium chelate contrast medium in a patient with a recent infarction of the diaphragmatic wall of the left ventricle. The infarcted region is indiscernible before contrast medium. The infarcted myocardium (arrow) enhances to a greater degree than normal myocardium after contrast medium, resulting in demarcation of the infarcted region. *(From Higgins CB, Hricak H, Helms C [eds]: MRI of the Body. 3rd ed. Philadelphia, Lippincott-Raven, 1998.)*

Figure 10-10 Sets of short-axis cine MRI image acquired in the basal state *(left, A)* and after "pharmacological stress" induced by dipyridamole *(right, B).* In each set, images are shown at end diastole *(upper left),* early, mid, and late systole *(lower right).* In the basal state wall thickening is normal in all regions. After dipyridamole, there is markedly reduced wall thickening in the diaphragmatic region (open arrow). *(From Baer FM, et al: Coronary artery disease: Findings with cine GRE and Tc99m methoxy-isonitrile SPECT during simultaneous stress. Radiology 193:203, 1994.)*

displays increased signal intensity compared with normal myocardium.[20] [21] Contrast between infarcted and normal myocardium increases on images with greater T2 contribution to signal intensity. Administration of MR contrast medium (gadolinium chelates) with T1-weighted spin-echo images causes greater enhancement of infarcted than of normal myocardium[22] [23] (Fig. 10-9) .

Regional Contraction Abnormalities.

The major role of noninvasive imaging techniques in ischemic heart disease is the detection of ischemic myocardium and other features indicative of the presence of obstructive coronary arterial disease. Ischemic myocardium can be demonstrated directly or indirectly by MRI. Indirectly, it is shown by demonstrating a regional contraction abnormality, usually by wall thickening measurement, at rest or during pharmacological stress (Fig. 10-10) . Cine MRI in the basal state and during pharmacological intervention with dobutamine or dipyridamole has correlated closely with nuclear perfusion imaging and/or coronary arteriography for demonstrating potentially ischemic myocardial segments.[10] [11] Directly, the monitoring of the first-pass distribution of MR contrast medium with T1-sensitive fast gradient-echo imaging in

basal and vasodilated states has shown regions of decreased myocardial perfusion in association with coronary arterial stenosis.[14] [15]

Visualization of Coronary Arteries.

Among noninvasive imaging modalities used in ischemic heart disease, MRI promises to visualize the major coronary arteries, using newly developed MR angiographic techniques[24] [25] [26] (Fig. 10-11) . An early report has shown approximately 90 percent correlation between coronary MRA and coronary x-ray angiography for identifying hemodynamically significant coronary arterial stenoses or occlusions.[24] Subsequently, reports have shown variable sensitivities and specificities.[25] [26] [27] Coronary MRA has been improved in recent years by using respiratory motion compensation techniques such as navigators[26] and blood pool MR contrast media. Recent reports have suggested the feasibility of visualizing coronary atherosclerotic plaques using high-resolution MRI afforded by stronger magnetic gradients and focused fields of view.[28] Equally intriguing is the possibility of measuring volume or velocity of flow in the major coronary arteries using breath-hold gradient-echo or echo-planar velocity-encoded techniques[12] [13] (Fig. 10-12) . These techniques have already been used in human subjects to document an increase in volume flow or flow velocity in response to vasodilators; the exclusion or confirmation of coronary arterial disease by the noninvasive assessment of coronary flow may be an important future application of MRI in ischemic heart disease.

CORONARY ARTERY BYPASS GRAFTS.

Gated MRI has been used to evaluate the patency of bypass grafts. Because blood usually flows rapidly through the grafts, they appear as small circular structures with absence of a luminal signal. For visualization of grafts, ECG-gated images are acquired to minimize the effect of motion of the grafts. Generally, images are acquired at each anatomical level during multiple phases of the cardiac cycle to ensure that an image is acquired at a phase when the rate of flow through the graft is rapid. High flow rate in the graft produces a flow void in the lumen of the graft using spin-echo MRI and thus indicates patency of the graft. With the cine (gradient-echo) MRI and MRA techniques, flowing blood causes bright signal intensity; therefore, bright signal rather than flow void indicates graft patency with this technique. MRI has an accuracy of 80 to more than 90 percent for defining

graft patency.[29] [30] [31] [32] Phase-contrast gradient-echo techniques have been used to demonstrate flow and to estimate flow velocity in coronary bypass conduits[31] [33] [34] (Fig. 10-13) . Contrast medium-enhanced MRA acquired during breath-holding or with respiratory compensation using navigators with and without electrocardiographic gating have provided imaging of the entire or major segments of vein grafts and internal mammary arteries bypass[32] (Fig. 10-14) . The MR angiogram permits the identification of stenoses as well as merely indicating patency.

MYOCARDIAL PERFUSION.

Fast gradient-echo imaging or EPI is used to monitor the signal intensity changes of the myocardium during the first pass of MR contrast media to assess regional myocardial perfusion. Monitoring of the first-pass distribution of MR contrast medium with T1-sensitive fast gradient-echo imaging in basal and vasodilated states has shown regions of decreased perfusion in association with coronary arterial stenosis.[14] [15] [35] [36] [37] Methods have been developed and validated for quantifying regional perfusion using these MR techniques.[35] The detection and assessment of coronary artery disease may be improved by

Figure 10-13 *A,* Phase image of a breath-hold cine MRI acquisition in a patient with bilateral internal mammary artery--coronary conduits. Left internal mammary artery is indicated by arrow. *B,* Velocity-versus-time curve for the left internal mammary artery conduit. quantifying regional contractile function and perfusion during the same study.[37]

DETERMINATION OF MYOCARDIAL VIABILITY.

Several promising MR approaches to determining viability of hibernating and stunned myocardium have been pursued in recent years[19] [38] (see also Chap. 13) . They can be conveniently divided into two groups: assessment of contractile reserve in response to inotropic stimulation (low dose dobutamine)[16] [17] [18] [19] and tissue characterization using various MR contrast media.[38] [39] [40] [41] [42] The first MR approach for defining myocardial viability simulates techniques used with echocardiography by demonstrating residual contractile response to inotropic drugs in an ischemically injured or chronically ischemic region. This approach to predicting viability not only assesses contractile response but also incorporates the precise measurement of wall thickness afforded by MRI as an additional parameter. MRI-defined diastolic wall thickness (5.5 mm) and dobutamine-induced systolic wall thickening (2 mm) have been shown to predict contractile recovery after myocardial revascularization.[17] [18] [19] With the use of ^{19} F-fluorodeoxyglucose positron emission tomography as the determinant of residual viability (see also Chap. 9) , dobutamine transesophageal echocardiography and dobutamine cine MRI have been compared in patients with prior myocardial infarction.[16] Sensitivity and specificity of dobutamine transesophageal echocardiography and cine MRI for positron emission tomography-defined viability were 77 percent versus 81 percent and 94 percent versus 100 percent, respectively.

A potential advantage of MRI over echocardiography is that it is fully quantitative; the excellent edge definition of the epicardial and endocardial borders permits precise measurement of regional wall thickening (see also Chap. 13) . Recently, this edge definition has been improved by the use of double inversion pulses to completely null the signal of intracavitary blood producing black blood images. The precision of the assessment of regional functional reserve has been augmented by the use of myocardial tagging.[43] [44] Dobutamine cine MRI with myocardial tagging was found to have a sensitivity of 89 percent and a specificity of 93 percent for defining residual viability, as shown by recovery of segmental function after revascularization.[43] Myocardial tagging has also been used to demonstrate residual viability of subepicardial myocardium in putative transmural myocardial infarction that predicted subsequent improvement of regional and global left ventricular function[43] (see p. 343 for discussion of myocardial tagging).

A second MRI approach for determining myocardial viability in a region of ischemic injury uses MR contrast media to provide tissue characterization. Most MR contrast media have a molecular size such that they freely exit the vascular space and rapidly distribute in the extracellular space. Gadolinium (Gd)-based contrast media, such as gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA) usually increase the MRI signal of tissues. These contrast media have extracellular distribution and are excluded from myocardial cells with intact membranes. Recent reports have used this approach to estimate the distribution volume of Gd chelates in normal and

ischemically injured myocardium.[39] [40] Under optimal circumstances, measurement of the distribution volume of Gd chelates provides an index of the percentage of necrotic myocardial cells within a zone of ischemic injury.[39] [40] At equilibration, the relative concentration of Gd chelate in myocardium and blood is determined by the relative distribution volume in the tissue of interest. The distribution volume in ischemically injured myocardium is slightly expanded by interstitial edema but very substantially increased by loss of myocardial cellular membrane integrity, permitting entrance of the indicator, which can act on intracellular water.

Recent studies in rats with reperfused myocardial infarctions have shown that the distribution volume of both Gd chelates (Gd-DTPA-Boyden

Figure 10-14 Contrast medium-enhanced three-dimensional MR angiogram of the chest demonstrates a stenosis of a bypass graft to the right coronary artery. Stenosis is displayed on the maximum intensity projection *(left)* and on an individual partition *(right)* in the sagittal plane. *(Courtesy of Dr. Gus Bis)*

microchamber assay [BMA]) and ^{99} Tc-DTPA was 90 to 100 percent of the tissue space, indicating entrance of the indicators into all myocardial cells in the infarcted region.[39] [40] It has been proposed that this technique for estimating distribution volume of MR contrast media might be used to estimate the percentage of nonviable cells in a region of reperfused ischemic injury. Viability of ischemically injured tissue can also be assessed using MR contrast media that accumulate in necrotic tissue. The first of these necrosis-specific MR contrast media, gadophyrin 2, is a Gadodiamid-labeled porphyrin compound. In an experimental model of reperfused infarction, this agent precisely defined the volume of the infarcted myocardium.[41]

Another potential approach for defining myocardial viability involves the use of an MR contrast agent that enters and is retained in normal myocardial cells. Such an agent is manganese DPDP (MnDPDP, Teslacon), which mimics the characteristics of thallium-201 in that normal membrane integrity is a requisite for entering myocardial cells. In experimental animals with reperfused myocardial infarctions, MnDPDP gradually accumulated in normal myocardial cells while it cleared from the infarcted region at the same rate as it cleared from blood.[42] This viability agent produced sharp demarcation of the ischemically injured myocardium at 4 hours after administration.

The standard MR contrast medium, Gd-DTPA, has also been used to distinguish between viable and nonviable myocardial segments in patients with chronic coronary artery disease and left ventricular dysfunction.[45] Hyperenhancement was observed 3 to 15 minutes after administration of Gd more frequently in myocardial segments judged to be nonviable by thallium-201 scans and by dobutamine echocardiography compared with viable segments.[45] The absence of delayed hyperenhancement in regions with resting contractile dysfunction correlated with radionuclide and echocardiographic determinants of viability (see also Chap. 13) .

PROGNOSIS FOR FUNCTIONAL RECOVERY AFTER INFARCTION.

The contrast enhancement pattern of acute myocardial infarctions provides insight into the severity of the infarction. Wu and associates[46] reported greater postinfarction complications, morbidity, and mortality in patients with an enhancement pattern consisting of hyperenhancement of the periphery and lack of enhancement of the core of the infarction in comparison with patients with homogeneous enhancement of the entire infarction after administration of Gd-DTPA. Rodgers and coworkers[47] also showed prognostic significance to the enhancement pattern produced by Gd-DTPA using both early and delayed image acquisitions. A perfusion deficit with first-pass dynamic imaging and delayed hyperenhancement usually predicted poor recovery of regional function at 7 weeks after infarction. There is some controversy regarding the interpretation of hyperenhancement of the injured region on images acquired at several minutes after contrast medium administration; contrast media at this time reaches a pseudoequilibrium state in the myocardium but can be influenced by delayed washout kinetics. Some studies[46] have concluded that delayed hyperenhancement with Gd-DTPA indicates irreversible injury (infarction), whereas others indicate recovery of function in part of the hyperenhanced region.[47] The latter notion is supported by observation in experimental animals showing that the size of the hyperenhanced region demarcated by Gd-DTPA, a nonspecific MR contrast medium, was significantly larger than the area enhanced by a necrosis-specific MR contrast medium, a Gd porphyrin compound.[48]

IMAGING OF ATHEROSCLEROTIC PLAQUES.

The feasibility of MRI for imaging and characterizing atherosclerotic plaque has been shown.[49] [50] This has been done using both intravascular coils and surface coils.

Cardiomyopathies (See also Chap. 48)

HYPERTROPHIC CARDIOMYOPATHIES.

MRI has been used to define the presence, distribution, and severity of the left and right ventricular hypertrophy in hypertrophic cardiomyopathies.[51] [52] It has displayed the extent of septal involvement and has been particularly useful for identifying the unusual distribution of hypertrophy in the variant forms of hypertrophic cardiomyopathy[51] (Fig. 10-15) . Left ventricular and right ventricular mass and wall thickness can be quantified precisely using spin-echo and cine MRI. Substantial right ventricular hypertrophy has been shown by MRI measurements in patients with hypertrophic cardiomyopathy. Cine MRI has also been used to assess ventricular diastolic parameters by constructing volume-time curves during the cardiac cycle; reduced filling rate and time to peak filling have been demonstrated in patients with hypertrophic cardiomyopathy.[52] Measurement of coronary sinus flow using breath-hold velocity-encoded MRI has disclosed abnormal coronary flow reserve in hypertrophic cardiomyopathy.[53]

DILATED CARDIOMYOPATHY.

MRI has depicted the morphological and functional alterations in congestive (dilated) cardiomyopathy.[54] [55] [56] Cine MRI has been used to quantify left ventricular volume and systolic wall stress in patients with congestive cardiomyopathies.[54] [55] Cine MRI has also been performed sequentially to monitor the effect of drug therapy in patients with congestive cardiomyopathy; it has demonstrated significant decreases in left ventricular volume, mass, and systolic wall stress during 3 months of treatment with an angiotensin-converting enzyme inhibitor.[55] Because MRI provides excellent discrimination of the edges of the myocardium, it can also assess myocardial mass and wall thickness in patients with cardiomyopathies; several studies have indicated the accuracy of MRI for quantifying myocardial mass in both normally and abnormally shaped left ventricles.[56] [57] Cine MRI has also been

Figure 10-15 Spin-echo MR image in the coronal plane displays severe symmetrical hypertrophy in a patient with hypertrophic cardiomyopathy. *(From Higgins CB, Hricak H, Helms C [eds]: MRI of the Body. 3rd ed. Philadelphia, Lippincott-Raven, 1998.)*

found to be highly reproducible in measuring left ventricular mass and volumes between two studies in the same subject.[56] [57] The interstudy variability of mass measurements is less than 5 percent.[56] Cine MRI has demonstrated considerable increase in left ventricular mass and markedly elevated end-systolic wall stress in patients with dilated cardiomyopathy.[54] [55] [56] Cine MRI has demonstrated both a decrease in the extent of wall thickening and a change in the regional pattern of wall thickening in patients with dilated cardiomyopathy compared with normal subjects.

Quantification of ventricular volumetric changes during the cardiac cycle by cine MRI and volume flow across the atrioventricular valve during diastole by velocity-encoded cine MRI have demonstrated abnormal diastolic filling parameters in the right and/or left ventricle in patients with hypertrophic,[52] congestive,[58] and restrictive[59] cardiomyopathies.

RESTRICTIVE CARDIOMYOPATHY.

ECG-gated spin-echo MRI has displayed features considered to be characteristic for restrictive cardiomyopathy.[60] There is substantial enlargement of the atria and the inferior vena cava, with usually less prominent ventricular enlargement. Because of resistance caused by the noncompliant ventricles with atrial emptying during diastole, prominent signal is observed in the atrial blood. Such intraatrial signals originate from slowly moving blood on spin-echo MR images. The major contribution of MRI to establishing the diagnosis of restrictive cardiomyopathy is the demonstration of normal pericardial thickness, which essentially excludes the alternate diagnosis

of constrictive pericarditis.

In *amyloid heart disease,* MRI has demonstrated thickened myocardial walls and diminished wall thickening during the cardiac cycle.[61] [62] Thickening of the right atrial wall and atrial septum on MR images is highly suggestive of this disease. Cine MRI indicates apparent hypertrophy of the left ventricle with normal or decreased left ventricular contraction rather than hypercontractile left ventricle expected in left ventricular hypertrophy. MRI has also demonstrated granulomatous involvement of the myocardium in sarcoidosis.[63] [64] It has been used to monitor the cardiac response to therapy for sarcoidosis.[64] Abnormally low signal of the myocardium on T2-weighted spin-echo and gradient-echo images due to high iron content of the myocardium is a characteristic feature of myocardial involvement by hemochromatosis.[65]

RIGHT VENTRICULAR DYSPLASIA.

Right ventricular dysplasia is represented pathologically by variable replacement or infiltration of right ventricular myocardium by fatty or fibrous tissue. Aside from suggestive clinical and electrophysiological features, the diagnosis has been definitively established by tissue examination after endomyocardial biopsy. The major differential diagnoses for ventricular arrhythmias of right ventricular origin in the presence of a grossly normal right ventricle are right ventricular dysplasia and right ventricular outflow tract tachycardia. ECG-gated spin-echo MRI has been used to identify transmural or focal fat in the right ventricular free wall to establish the diagnosis of right ventricular dysplasia.[66] Focal or generalized wall thinning of the right ventricle is also consistent with this diagnosis.[66] Cine MRI demonstrates focal dyskinesis or aneurysm at sites of wall thinning. Focal wall thinning and focal bulging (aneurysm) of the right ventricular outflow tract have been shown also on MRI in right ventricular outflow tract tachycardia.[67] One report has shown that MRI actually demonstrates fat in the right ventricular free wall in less than half of patients with right ventricular dysplasia, but a regional contractile abnormality is demonstrated by cine MRI in a majority.[68] The sensitivity of MRI for the diagnosis of right ventricle dysplasia has not been established. Transmural fat in the right ventricular free wall occurs in the absence of this disease; this entity has been referred to as benign fatty infiltration of the right ventricle. [69]

MYOCARDITIS.

MRI has demonstrated abnormal signal intensity of the myocardium in acute myocarditis.[70] [71] In acute and subacute myocarditis, there is high signal of the myocardium at the site of inflammation displayed on Gd-enhanced T1-weighted spin-echo images[71] and on nonenhanced T2-weighted images. High signal intensity foci[72] in the myocardium have also been demonstrated in Chagas disease[72] and Lyme myocarditis. [73]

Pericardial Disease (See also Chap. 50)

Gated MRI provides direct visualization of the pericardium[74] (see also Chap. 50) . It has been effective for the assessment of patients with suspected pericardial disease. Normal pericardium is composed primarily of fibrous tissue and has low MRI signal intensity. The thickness of pericardial line measured in normal subjects was 1.5 ± 0.4 mm (SD) with a range from 0.8 to 2.6 mm. A variation of thickness of the low-intensity line has been observed during the cardiac cycle in normal subjects. These latter observations, along with information from postmortem studies, indicate that the normal pericardium measures less than 3.0 mm and suggest that the low-intensity pericardial line consists of pericardium and some adherent pericardial fluid. A thickness of 4 mm or greater is abnormal. This is probably responsible for the pericardial line observed on CT as well, because normal CT measurements of pericardial thickness are similar to MRI measurements. On spin-echo MR images, pericardial effusion causes a low signal intensity space separating the heart and pericardium (Fig. 10-16) . The distinction between the pericardium itself and pericardial fluid can also be achieved on cine MR images, on which the fluid has bright signal and the pericardium is a dark line (Fig. 10-17) . MRI can establish the diagnosis of congenital absence of the left pericardium.[75] Pericardial thickening and effusions are characteristic features of acute pericarditis.

Gated MRI has been useful for demonstrating pericardial thickness in patients with suspected constrictive pericarditis.[76] [77] The signal intensity of the thickened pericardium is variable. The purely fibrous or calcified pericardium in chronic constrictive pericardial disease has low signal intensity. However, in subacute forms of constrictive pericarditis caused by irradiation, surgical trauma, or uremia, the thickened pericardium has moderate to high intensity on spin-echo images. The effusive-constrictive form of pericardial disease has thickened pericardium and pericardial effusion. One study[77] has demonstrated a diagnostic accuracy of 93 percent for MRI in distinguishing between constrictive pericarditis and restrictive cardiomyopathy by demonstrating thickened pericardium (>4 mm) in the former disease.

MRI demonstrates even the small amount of pericardial fluid present in normal subjects. Fluid in the superior pericardial recesses is commonly seen even when fluid is not evident posterior to the left ventricle. The appearance of pericardial fluid is different on spin-echo and cine MRI (gradient-echo) images (see Fig. 10-17) . Nonhemorrhagic fluid shows low intensity on short-TR, short-TE sequences (T1-weighted) and has high intensity on long-TR, long-TE sequences (T2-weighted). On the other hand, pericardial hematoma has high intensity on T1-weighted images (Fig. 10-18) and may have high intensity on T2-weighted images, depending on the age of the hematoma and the magnetic field strength of the imager. On cine MRI, the nonhemorrhagic effusion is bright and the hemorrhagic one may be low intensity.

Figure 10-16 ECG-gated spin-echo images in coronal *(left)* and transverse *(right)* planes of a patient with constrictive pericarditis. The pericardium is substantially thickened. Thick pericardium can be visualized extending over the pulmonary artery on the coronal image.

In pericardial disease the role of MRI must be considered in the light of the established effectiveness of echocardiography. An advantage of MRI over echocardiography is the capability to differentiate pericardial hematoma from other types of effusions. Because of the wide field of view, MRI seems to be useful in locating loculated effusions. Determination of pericardial thickening seems to be a clear indication for the use of MRI.

Neoplastic Disease (See also Chaps. 49 and 69)

Several reports have documented the clinical utility of gated MRI for the evaluation of intracardiac and paracardiac masses.[78] [79] [80] [81] Because of the unequivocal delineation of the pericardium, myocardial walls, and chambers of the heart on MR images, the precise relationship of tumors to cardiovascular structures can be defined. Tumors within the myocardial wall may be identified by virtue of a difference in signal intensity (usually higher) compared with the myocardium. In this regard, MR contrast media can be used in an attempt to accentuate differences in signal intensity between tumor and myocardium (Fig. 10-19) .[80]

Secondary cardiac involvement by tumors is about 40 times more frequent than primary tumors (see also Chap. 49) . Secondary involvement occurs by three routes: (1) direct extension from the mediastinum and lungs, (2) metastases to the pericardium or cardiac chambers, and (3) direct extension of upper abdominal tumors through the inferior vena cava or lung tumors through the pulmonary veins. MRI appears to be superior to CT for assessing the extent and effect of mediastinal masses adjacent to cardiovascular structures. MRI is the imaging procedure of choice for identifying paracardiac masses, defining their nature, and determining invasion of the pericardium. The intensity on spin-echo images can differentiate such masses from innocuous lipomas, the pericardial fat pad, pericardial cysts, loculated pericardial effusions, and unusual enlargement or displacement of cardiac chambers.

Intracardiac tumors can be clearly identified within the signal void of the cardiac blood pool (Fig. 10-20) . Because of its wide field of view, MRI is ideal for defining both the intracardiac and extracardiac extent of masses. For the evaluation of intracardiac masses, it is advisable to acquire spin-echo and gradient-echo MR images and to obtain images with at least two planes perpendicular to each other. Intracardiac or intravascular tumors can be distinguished from thrombus using cine MRI in most instances[81] (Fig. 10-21) . Tumors are represented by medium signal (higher signal or similar signal compared with myocardium), whereas thrombus produces very low signal (less than myocardium). This low signal is due to elements in the thrombus, e.g., hemosiderin, deoxyhemoglobin, that induce a magnetic susceptibility effect and vitiate signal from the region. The cine MRI sequence is very sensitive to this effect. Some myxomas contain a considerable amount of iron and can show the same effect, so confident distinction between myxoma and clot may not always be possible. Differentiation between tumor and thrombus has not been possible using the ECG-gated spin-echo sequence. Differentiation between tumor and blood clots can also be done using MR contrast media. The contrast medium enhances the signal of tumor but not that of clots.[80]

Valvular Heart Disease (See also Chap. 46)

Magnetic resonance imaging can be used to identify the presence of valvular stenosis and regurgitation.[82] [83] [84] [85] [86] [87] [88] [89] [90] [91] This is done using cine MRI to depict the signal void caused by

Figure 10-17 Spin-echo *(left)* and gradient-echo (cine MR) *(right)* images of a patient with a large pericardial effusion.

Figure 10-18 ECG-gated spin-echo images show a pericardial hematoma (H). The hemorrhagic pericardial effusion causes bright signal intensity on the T1-weighted (TE=30 msec) image. The right atrium and right ventricle are compressed by the hematoma. Pericardium (arrow) is thickened. R=right ventricle; shaded letters indicate right (R) and left (L) for orientation.

high velocity jet flow across a narrow valvular orifice associated with the opened valve in stenosis and the incompletely closed valve in regurgitation. The high velocity jet causes a signal void that is projected into the ascending aorta in systole with aortic stenosis and into the left ventricle during diastole in aortic regurgitation (see Fig. 10-3). Mitral regurgitation produces a signal void in the left atrium during systole whereas mitral stenosis causes a signal void emanating from the mitral valve into the left ventricle during diastole (Fig. 10-22) .

Velocity-encoded cine MRI has been employed to measure the volume of valvular regurgitation.[84] [85] [86] [87] [88] [89] [90] This technique typically provides images corresponding to 16 phases of the cardiac cycle. These images can distinguish between antegrade and retrograde flow. Thus, measurement of retrograde flow in the ascending aorta and pulmonary artery during diastole can be used to quantify the volume of aortic and pulmonary regurgitation, respectively (Fig. 10-23) . The same approach has been applied at the level of the mitral and tricuspid annuli to quantify mitral and tricuspid regurgitation, respectively. This approach is sometimes problematic for quantifying atrioventricular valvular regurgitation, owing to directional unpredictability of the regurgitant jet

Figure 10-19 ECG-gated spin-echo images before *(left)* and after *(right)* injection of gadolinium chelate in a patient with a sarcoma of the ventricular septum. A fat saturation technique was used after contrast medium to accentuate the effect of the contrast medium. The tumor is enhanced to a greater degree than myocardium.

Figure 10-20 Spin-echo image demonstrates an angiosarcoma of the right atrium with extension (arrow) through the right atrial wall.

into the left atrium. Another approach is to measure the systolic outflow from the left ventricle by velocity-encoded cine MRI at the level of the ascending aorta and the diastolic inflow to the left ventricle by velocity-encoded cine MRI at the level of the mitral annulus; the difference between the two is a measure of the volume of mitral regurgitation[89] (Fig. 10-24) .

Velocity-encoded cine MRI has also been used to measure the peak flow velocity (V_p) across aortic and mitral stenoses. [86] [88] [91] Similar to the echo Doppler echocardiographic approach, the transvalvular pressure gradient is estimated by the modified Bernoulli equation ($DeltaP=4V_p^2$). The MR measurement is subject to several potential inaccuracies related to marginal temporal resolution, slice thickness, and signal loss. The accuracy of this measurement can be improved by using small voxels, thin slices, and very short echo delay time.

Cine MRI can be employed for the evaluation and monitoring of ventricular function, mass, and wall stress in patients with valvular heart disease.[84] [86] Because of the excellent interstudy reproducibility of the 3D data set provided by cine MRI for quantifying ventricular volumes and mass, it is an attractive method for evaluating the effect of therapy.

Figure 10-21 Gradient-echo (cine MR) images in two patients with intracardiac masses. *Left,* Metastatic tumor in the right ventricle has medium intensity. *Right,* Thrombus at the left ventricular apex has low intensity. *(From Higgins CB, Hricak H, Helms C: MRI of the Body. 2nd ed. New York, Raven Press, 1992.)*

Figure 10-22 Cine MR image in the transaxial plane during diastole displays a signal void emanating from the mitral valve (arrows) caused by the high velocity "jet" flow of mitral stenosis. *(From Higgins CB, Hricak H, Helms C [eds]: MRI of the Body. 3rd ed. Philadelphia, Lippincott-Raven, 1998.)*

In addition, velocity-encoded cine MRI has been used to document the efficacy of angiotensin-converting enzyme inhibitors for decreasing the volume of aortic regurgitation.[85]

Congenital Heart Disease (See also Chaps. 43 and 44)

Magnetic resonance imaging has multiple capabilities for the evaluation of congenital heart disease.[92] Morphological information is provided by ECG-gated spin-echo and cine MRI. Ventricular volumes, mass, and function can be obtained using cine MRI. The volumes of shunts, valvular function, and pressure gradients across valves and conduits can be estimated using velocity-encoded cine MRI (velocity-flow mapping). However, the clinical use of these capabilities is influenced by the widespread application of echocardiography and Doppler techniques for many of these same purposes. Consequently, the current clinical role of MRI is to supplement the information acquired by echocardiography.

Figure 10-23 *A,* Magnitude *(above)* and phase *(below)* images in systole *(left)* and diastole *(right)* of a patient with aortic regurgitation on phase images. Bright signal in the ascending aorta in systole represents antegrade flow. In diastole, dark signal in the ascending aorta represents retrograde flow due to aortic regurgitation. *B,* Flow-versus-time curve in a patient with aortic regurgitation. Reverse flow in diastole represents aortic insufficiency. The area under this curve provides a direct measurement of the volume of aortic regurgitation. *(From Higgins CB, Caputo GR: MRI of valvular heart disease. In Pohost GM [ed]: Cardiovascular Applications of Magnetic Resonance. Mt. Kisco, NY, Futura Publishing, 1993.)*

Figure 10-24 *A,* Magnitude and phase images at the level of the mitral annulus. The phase image is used to measure mitral inflow. *B,* Magnitude *(left)* and phase *(right)* images at the level of the proximal aorta. *C,* Flow-versus-time curve for mitral inflow and aortic outflow in a normal subject. *D*, Flow-versus-time curve in a patient with mitral regurgitation. By using phase images, flow is calculated as the spatial average velocity in the region of interest (i.e., aorta) and the cross-sectional area of the region of interest. The areas under the two curves in *C* are nearly equal. In *D,* the area under the mitral inflow curve is considerably greater than the area of the aortic outflow curve. The difference between the two areas is the volume of mitral regurgitation. *(From Fujita N, Chazouilleres AF, Hartiala JJ, et al: Quantification of mitral regurgitation by velocity-encoded cine magnetic resonance imaging. J Am Coll Cardiol 23:951-958, 1994.)*

Reports from several centers indicate the effectiveness of MRI for the evaluation of both children and adults with congenital heart disease.[92] [93] [94] [95] [96] [97] [98] [99] [100] [101] In several studies in which the results of MRI were corroborated by angiography and/or 2D echocardiography, accurate anatomical diagnosis of anomalies was achieved by MRI in more than 90 percent of patients.[97] [98] [99] MRI has also shown substantial capability for anatomical and functional evaluation of congenital heart disease after palliative and total correction.[95] [101] [102]

Visceroatrial situs, the type of ventricular loop, and the relationship of the great vessels can be identified in all patients in whom studies encompassing the entire heart were done.[99] The diagnostic accuracy of MRI exceeded 90 percent for abnormalities of arterioventricular connections,

Figure 10-25 Transverse *(left)* and coronal *(right)* spin-echo images of a patient with transposition of the great arteries, pulmonary atresia, and ventricular septal defect. The transverse image acquired at the base of the heart shows only the aortic valve (A). Coronal image shows the right subclavian to pulmonary arterial anastomosis (curved arrow). The right pulmonary artery is aneurysmal while the left pulmonary artery is absent. The heart is shifted to the left, owing to decreased size of the left lung. AA=aortic arch; I=innominate artery; RP=right pulmonary artery.

great vessel anomalies such as coarctation and vascular rings, ventricular and atrial septal defects, and abnormalities of venous connections.[99] Likewise, determination of visceroatrial situs and type of ventricular loop reached an accuracy of nearly 100 percent with MRI.[99]

Much of the diagnostic information provided by MRI can also be shown by 2D echocardiography. The role of MRI must therefore be considered in respect to the established role of echocardiography. Among noninvasive modalities, the unique capabilities of MRI in congenital heart disease are visualization of the central pulmonary arteries in cases of pulmonary atresia[92] [98] [103] (Fig. 10-25) and assessment of anomalies of the thoracic aorta[92] [99] ; complete definition of complex anomalies involving both the great vessels and ventricles[92] [96] [100] ; and the postoperative evaluation of patients who have undergone complicated supracardiac operations for cyanotic congenital heart disease.[95] [101] [102] [103] [104] [105] [106] MRI has been shown to be reliable for both preoperative and postoperative evaluation of coarctation of the aorta; angiography can be obviated in most patients. Several reports[95] [101] [102] [103] [104] [105] [106] [107] have shown the effectiveness of MRI for the postoperative evaluation of the Fontan, Rastelli, Norwood, Damus, Glenn, and Jatene procedures. MRI has been used to quantitatively monitor the size of the pulmonary arteries after surgical procedures that either involve the pulmonary arteries or are intended to increase their size by altering pulmonary blood flow.[106] [108] A comparative study between echocardiography and MRI for the evaluation of the pulmonary arteries after surgery showed that MRI was superior for the evaluation of right and left pulmonary stenoses and dimensions (Fig. 10-26) .[108] MRI has been used to monitor pulmonary arteries through multiple-staged surgeries such as the Fontan[106] and Norwood[104] procedures. Velocity-encoded MRI has been effective for estimating and monitoring the gradient across Rastelli conduits.[107]

In postoperative patients, velocity-encoded cine MRI has been useful for measuring blood flow to each lung in patients with residual unilateral pulmonary stenosis (Fig. 10-27) and for measuring retrograde flow in conduits or reconstructed outlet regions to quantify the volume of pulmonary regurgitation.[95]

MRA has been shown in recent years to be valuable for depicting thoracic aortic anomalies, pulmonary arterial stenoses, and connections of pulmonary veins. Contrast medium-enhanced MRA is additive to spin-echo MRI for unraveling the anatomy of unusual coarctations (Fig. 10-28) . This technique is likely the most sensitive for the identification of partial anomalous pulmonary venous connections (see Fig. 10-6 .)

The capability of MRI in congenital heart disease has been extended by cine MRI and velocity-encoded cine MRI. The former technique can provide multiple images per cardiac cycle so that ventricular function can be evaluated, whereas the latter technique permits measurement of blood flow and velocity in the aorta and pulmonary artery and across valves and conduits. Functional evaluation of congenital heart disease using MR techniques is discussed later.

Diseases of the Thoracic Aorta (See also Chap. 40)

MRI and CT are now the procedures most frequently used for the diagnosis and monitoring of thoracic aortic diseases.

Figure 10-26 Oblique coronal spin-echo image in a patient after repair of tetralogy of Fallot. There is dilatation of the right ventricular outlet tract (open arrow) and stenosis (solid arrow) of the proximal right pulmonary artery.

Figure 10-27 *A,* Systolic *(above)* and diastolic *(below)* images at the level of the right pulmonary artery (RPA) in a patient after repair of tetralogy of Fallot. The systolic image shows a flow void due to high-velocity jet flow through the stenosis in the RPA. *B,* Flow-versus-time curve for the main, right, and left pulmonary arteries derived from the phase images in each of 16 evenly spaced intervals of the cardiac cycle. Flow in the RPA is severely reduced by the stenosis. MPA=main pulmonary artery; LPA=left pulmonary artery.

The roles of these noninvasive tomographic techniques have rapidly evolved in the past decade and have replaced x-ray aortography for the definitive diagnosis of thoracic aortic diseases.[109] [110] For a number of thoracic abnormalities, especially aortic dissection, transesophageal echocardiography has been used frequently and is competitive with these tomographic imaging modalities.

A number of MRI sequences have been used in the evaluation of aortic diseases (see Figs. 40-12 , 40-13 , and 40-14). These include ECG-gated spin-echo MRI; standard cine MRI; segmented K space (breath-hold) cine MRI; and contrast medium-enhanced 3D time-of-flight MRA. The introduction of breath-hold cine MRI and contrast medium-enhanced MRA has permitted rapid imaging of thoracic aortic emergencies.

A number of reports attest to the effectiveness of MRI for the evaluation of aortic dissection, true and false aneurysms, periaortic abscess, aortic arch anomalies, and coarctation of the aorta.[109] [110] [111] [112] [113] In aortic dissection, MRI can depict the intimal flap and the proximal extent of the dissection, and it can distinguish true from false channels (Fig. 10-29) . On spin-echo MRI images, intraluminal signal is usually seen in the false channel as a result of thrombus, slow blood flow, or both. Differentiation between slow flow and thrombus is evident on cine MRI (gradient-echo) images because the former produces high or moderate intraluminal signal whereas thrombus causes low signal on this type of image. Velocity-encoded cine MRI provides a measurement of the differential flow velocity in the true and false channels. By using multiple images per cardiac cycle, a velocity-time curve can be generated to display the disparate flow pattern in the two channels.

MRI has been very effective for identifying intramural hematoma, which is dissection without intimal rupture.[114] [115] Spin-echo MR images display wall thickening due to the intramural hematoma. It is confined to the descending aorta in type B and involves the ascending aorta in type A. The hematoma usually shows high intensity on T1=weighted images and sometimes very low intensity on gradient-echo images (cine MR). MRI can monitor the resolution or detect recurrence of intramural hemorrhage.[114]

A report[110] has shown high sensitivity for transesophageal echocardiography, CT, and MRI for the diagnosis of aortic dissection. However, the specificity of CT and MRI was significantly better than that of transesophageal echocardiography. The wide field of view of CT and MRI is an additional advantage for showing the extent of the dissection. On the other hand, transesophageal echocardiography has the important advantage of portability.

MRI has been used to monitor the size of the thoracic aorta in patients with Marfan syndrome and to exclude the presence of an occult dissection[116] (see also Chaps. 40 and 56) . An aortic diameter of greater than 4 cm is considered enlarged, and a diameter exceeding 5 cm is considered aneurysmal. Because MRI is a completely noninvasive technique, it is ideal for monitoring patients with aortic diseases and patients who have undergone surgical or medical treatment of aortic dissection.[117] [118]

MRI has been used to detect periaortic abscess complicating bacterial endocarditis. The 3D tomographic nature of the technique permits precise localization of these abscesses.

MRI and MRA are now employed to monitor patients with thoracic aortic dissection and aneurysms.[117] [118] [119] It is recognized that the false channel remains patent distal to the ascending aortic graft after surgical repair of type A dissections. [117] , [118] Because most patients with type B dissection are managed medically, the false channel frequently persists in these patients as well. The complications caused by long-term patency of the false channel are aneurysm of the false channel (Figs. 10-30 and 10-31) and obstruction of aortic branches by the intimal flap. Consequently, noninvasive imaging studies are necessary to monitor the status of the false channel and intimal flap.

MRI and MRA are also used to monitor the maximum diameter and extent of the thoracic aortic aneurysms; a maximum diameter exceeding 6 cm indicates the need for surgical repair.[120] Regular monitoring is also important in patients with Marfan syndrome and other conditions associated with progressive aortic dilatation. Because MRI and MRA are noninvasive and provide images along both the short and long axis of the thoracic aorta, they are now the preferred method for follow-up of thoracic aortic diseases. MRA in the sagittal plane is very effective for depicting the origins of the arch branches

Figure 10-28 Three-dimensional reconstruction of a contrast medium-enhanced MR angiogram of the thoracic aorta displays a severe juxtaductal coarctation of the aorta.

and visceral arteries of the abdominal aorta and their relationship to the aneurysm.

Velocity-encoded cine MRI can be used in thoracic aortic disease to quantify the volume of concomitant aortic regurgitation in patients with aortoannular abnormalities (see Fig. 10-3) . It can also measure the velocity and volume of flow in the true and false channels.

Figure 10-29 Spin-echo image in type A aortic dissection demonstrates the intimal flap in the aorta (solid arrows) and innominate artery (open arrow).

Evaluation of Cardiovascular Function (See also Chap. 15)

A variety of MRI techniques has been employed for the evaluation of several aspects of cardiovascular function. These include standard cine MRI for the quantitation of global and regional contraction of the left and right ventricles. The cine MRI technique usually produces gradient-echo images at 16 to 30 evenly spaced intervals through the cardiac cycle (Fig. 10-32) . With standard cine MRI, the data acquisition period occupies 256 cardiac cycles. A fast version can be performed in only 16 cardiac cycles and has been called breath-hold cine MRI or segmented fast cine gradient-echo imaging.[2]

Blood flow volume and flow velocity can be quantified using velocity-encoded cine MRI (velocity flow mapping).[5] [121] [122] [123] This technique provides a velocity image (velocity map, phase image) at evenly spaced intervals, usually 16, throughout the cardiac cycle. Analysis of the velocity image can be done to measure peak velocity or average velocity in any selected region of interest in the flow channel. Velocity-encoded sequences can be coupled with either standard cine MRI or breath-hold cine MRI. Using the multiple phase images collected over the cardiac cycle, flow- or velocity-versus-time curves can be made.

ECHO-PLANAR IMAGING.

The most attractive technique for evaluating cardiovascular function is EPI, which essen

Figure 10-30 Spin-echo images early *(left)* and late *(right)* after repair of type A aortic dissection depict interval development of an aneurysm of the persistently patent false channel (F). *(From Higgins CB, Hricak H, Helms C [eds]: MRI of the Body. 3rd ed. Philadelphia, Lippincott-Raven, 1998.)*

Figure 10-31 Sagittal partition (3 mm thickness) from a three-dimensional MR angiogram in the sagittal plane in a patient after repair of type A aortic dissection. The intimal flap (arrow) separates the dilated false channel from the compressed true channel in the descending aorta. After repair, the diameter of the ascending aorta is normal.

tially constitutes real-time MRI. It can be used in "single shot" or "multishot" modes.[6] [124] [125] The "single-shot" mode acquires the entire image in about a 40- to 80-millisecond interval of a single heartbeat. The "multishot" mode acquires the image in 20- to 40-millisecond intervals of two to four consecutive heartbeats (see Fig. 10-4) . Thus, a cine version of EPI can be done during a single cardiac cycle or acquired over two to four cardiac cycles. Velocity-encoded EPI can also be done. Thereby, analysis of contractile function of the ventricles and blood flow quantification are possible in essentially real time and on a nearly beat-to-beat basis using cine and velocity-encoded cine versions of EPI.

Because MRI is a 3D imaging technique, it can provide direct measurements on which the clinical evaluation of global left ventricular function has been based. By using sets of images encompassing the left ventricle, it is possible to calculate end-diastolic, end-systolic, and stroke volumes and ejection fraction. This can be done directly and does not depend on the geometric assumptions used for such measurements from echocardiograms and x-ray angiograms. Moreover, MRI provides a 3D direct visualization of the myocardium with excellent mural edge discrimination, thereby allowing quantitation of a left ventricular mass.[55] [56] [57] MRI measurements have correlated closely with postmortem measurements of left ventricular mass. Measurements of volumes and mass using a single MR image acquired in the long-axis plane of the left ventricle or in two perpendicular long- or short-axis planes, assuming various geometric models, have been validated.[126]

RIGHT VENTRICULAR FUNCTION.

Because MRI also defines the right ventricular myocardium, it may serve as the preferred technique for the accurate determination of right ventricular mass.[127] Reasonable accuracy has been shown for the measurement of right ventricular end-diastolic, end-systolic, and stroke volumes as well as ejection fraction.[128] [129] Moreover, comparison of right and left ventricular stroke volumes has been used to estimate the regurgitant fraction in patients with aortic and mitral regurgitation.

MYOCARDIAL TAGGING.

Myocardial tagging is the most useful method for quantitation of myocardial motion with MRI.[130] [131] [132] Specified regions of the myocardium can be labeled by restricted localized RF pulses; these are placed perpendicular to the myocardial wall. These RF pulses are followed by a conventional imaging sequence after a short, specified delay. The labeled or "tagged" myocardial regions can be tracked precisely during systolic contraction. Myocardial motion occurring between RF excitation of the tag and image formation can be expressed as the displacement and distortion of the tagged regions, which appear as dark stripes (Fig. 10-33) .

The extent of the displacement of the tagged myocardium can be measured as the distance between a given tag and its original position at end diastole. Heterogeneous myocardial motion among various segments of the left ventricle has been shown in normal subjects. The longitudinal displacement of the tag during systole is significantly greater at the basal layer than at the mid or apical layers of the left ventricle. Short-axis images with tagging showed heterogeneous rotation of the wall with an increasing degree of counterclockwise rotation from the base to the apex. This technique has been used to characterize abnormal contraction and twisting of various myocardial regions in hypertrophic cardiomyopathy.[131] It has also demonstrated tethering and compensatory regional contraction of normal myocardial segments after acute myocardial infarction.[132] This technique provides the first noninvasive method for quantitating the complex multidirectional motion of myocardial segments.

Quantification of Valvular Regurgitation (See also Chap. 46)

Accurate determination of the severity of valvular regurgitation is important for the evaluation of medical therapy and timing of surgical interventions. Among various methods, Doppler echocardiography has been used as the main diagnostic tool to detect valvular regurgitation because of its high sensitivity and specificity. However, quantification of severity has been less successful. Mapping of the spatial extent of the disturbed flow in the regurgitant chamber with pulse Doppler or color Doppler is useful for routine serial evaluation but provides only a semiquantitative estimate of the severity of valvular regurgitation. In this regard, cine MRI provides several methods for quantifying the extent of

Figure 10-32 Cine MR images in the short-axis plane acquired at end diastole (ED) and end systole (ES) near the base *(upper panels),* middle *(middle panels),* and apex *(lower panels)* of the left ventricle. These images demonstate symmetrical wall thickening of the left ventricle. From such images encompassing the length of both ventricles, measurement of ventricular volume and global function can be made.

Figure 10-33 Composite of six short-axis views of the left ventricle (LV) from end diastole *(upper left)* to end systole *(lower right)* in a patient with left ventricular hypertrophy. The pattern of diagonal lines is a saturation grid created in the tissue with spatial modulation of magnetization (SPAMM). Initially the grid moves with the underlying tissue, enabling analysis of regional wall motion within separate delineated elements of the wall. *(Courtesy of Dr. Leon Axel, University of Pennsylvania Medical School.)*

valvular regurgitation, including measurement of signal void on cine MRI and determination of the difference in stroke volumes of the two ventricles.[83] [84] In addition, velocity-encoded cine MRI can be used to measure the volume of retrograde flow in the ascending aorta or pulmonary artery in aortic and pulmonary regurgitation, respectively.[84] [87] [93] [95]

The difference between end-diastolic and end-systolic volume for a ventricle with a regurgitant valve includes both the forward stroke volume and the regurgitant volume. Because the forward or net stroke volume is equal to the volume ejected from normal ventricle, the difference in stroke volumes between a regurgitant ventricle (e.g., left ventricle with aortic and mitral regurgitation) and normal ventricle (e.g., right ventricle) is the regurgitant volume. The sum of the forward and regurgitant volume is called total stroke volume of the regurgitant ventricle.

Ventricular volume can be accurately measured from cine MRI images. In the absence of regurgitation, the stroke volumes of the right and left ventricle are nearly equal. However, in patients with aortic and/or mitral regurgitation, the stroke volume of the left ventricle exceeds that of the right ventricle by a value equivalent to the regurgitant volume. The regurgitant fraction can be calculated as the regurgitant volume divided by the total stroke volume of the regurgitant ventricle. The stroke volume ratio can also be calculated from the stroke volumes of the two ventricles. These measurements derived from cine MRI have distinguished patients with mild, moderate, and severe left-sided regurgitant lesions, as shown by independent imaging techniques.[82] [84]

The major limitation of utilizing stroke volume difference for quantification of regurgitation is in the presence of multiple valve disease. If both aortic and mitral regurgitation are present, the calculation determines only the total volume of regurgitation. If regurgitation coexists on both sides of the heart, this calculation is not meaningful.

The most effective MR technique for quantifying valvular function is velocity-encoded cine MRI or velocity-flow mapping. It has been used to quantify the volumes of aortic[84] [85] [86] [87] and mitral[89] [90] and pulmonic regurgitation[93] [94] and to estimate the pressure gradients in aortic[88] and mitral[88] [91] stenosis.

QUANTIFICATION OF AORTIC REGURGITATION.

This has been accomplished by velocity-encoded cine MRI in two ways.[84] [85] [86] [87] Measurement of blood flow in the ascending aorta and main pulmonary artery provides stroke volume for the left and right ventricles, respectively. The difference between the two stroke volumes is the aortic regurgitant volume. Moreover, because retrograde as well as antegrade flow can be determined from the instantaneous flow changes throughout the cardiac cycle using velocity-encoded cine MRI, the volume of aortic regurgitation or pulmonary regurgitation can be measured directly by the time integration of diastolic regurgitant flow (see Fig. 10-23) .

QUANTIFICATION OF MITRAL REGURGITATION.

This has been quantified by measuring diastolic inflow to the left ventricle by a velocity-encoded cine MR acquisition in a short-axis plane positioned at the level of the mitral annulus and systolic outflow by a velocity-encoded cine MR acquisition positioned at the level of the proximal ascending aorta (Fig. 10-24) . The difference between the two volumes is the volume of mitral regurgitation.[89]

Measurement of Blood Flow

Measurement of blood flow velocity with MRI has been done using a technique under several names, including phase contrast MRI, velocity flow mapping, and velocity-encoded cine MRI. This method is principally based on the phase shifts of moving spins in the magnetic field gradient.[5] The extent of phase shifts of moving spins is proportional to velocity along the velocity-encoding direction. Velocity encoding is performed by using bipolar gradient pulses. The direction of velocity encoding can be done in any orthogonal or oblique axis of the body.

Velocity encoding of blood flow in each pixel provides 2D quantitative velocity mapping of the vascular system (see Figs. 10-23 , 10-24 , and 10-34). The instantaneous flow in the ascending aorta can be determined by the product of the cross-sectional area and mean velocity of the blood within the aorta. The integration of the instantaneous flow at the base of the aorta through the cardiac cycle provides a measure of left ventricular stroke volume, and the same done at the proximal pulmonary artery is a measure of right ventricular stroke volume. The stroke volumes measured in this manner have correlated well with ventricular stroke volumes measured by planimetry of the multiple adjacent cine MR images. Measurement of flow by velocity-encoded cine MRI should be very accurate provided that the flowing blood generates enough signal to calculate phase; the velocity phase-encoding gradients are accurately calibrated; and the correct range of velocity in the vessels being interrogated has been selected.

VELOCITY-ENCODED CINE MRI.

Measurement of flow by velocity-encoded MRI has been tested for an array of applications, including measurement of stroke volume of both ventricles, quantification of valvular regurgitation[84] [85] [86] [87] (see Figs. 10-23 and 10-24), estimation of the gradient across valvular and vascular stenoses,[88] [91] and measurement of the volume of left-to-right shunts[133] (see Fig. 10-34) . Velocity encoding can be used with the breath-hold cine MRI sequence[12] [13] (see Fig. 10-12) and with EPI. Some pitfalls accompany the use of the velocity-encoded cine MRI technique for measuring blood flow. These include aliasing due to setting of the maximum velocity range to less than the actual velocity. The finite slice thickness also results in volume averaging, causing underestimation of peak velocity. Furthermore, orientation may not provide optimal interrogation of the jet, so that velocity is underestimated.

Velocity-encoded cine MRI can be used to measure flow in the ascending aorta and pulmonary artery simultaneously to quantify the volume of some left-to-right shunts and to calculate the pulmonary-to-systemic flow ratio (Qp/Qs) of cardiovascular shunts (see Fig. 10-34) . The MR measurement of Qp/Qs has correlated closely with that derived from oximetric data acquired during cardiac catheterization in patients with atrial septal defects.[133] Measurement of blood flow separately in the right and left pulmonary arteries can be used to quantify the distribution of pulmonary blood flow in lesions causing unequal flow. This technique can also be applied to estimate the gradient across pulmonary vascular stenosis, stenosis of branches of the pulmonary artery, coarctation of the aorta, and Rastelli conduits.

Velocity-encoded cine MRI has been used to provide an estimate of the collateral circulation in coarctation.[134] In healthy subjects the total flow in the distal part of the descending aorta is slightly decreased compared with the flow in the proximal part of the descending aorta because of runoff through the intercostal arteries. In patients with hemodynamically significant coarctation, the MR measurements have revealed a substantial increase in flow in the distal compared with the proximal part of the descending aorta. This increase in flow is presumably due to retrograde flow in the branches of the descending aorta.

Figure 10-34 *A,* Phase image at level of ascending aorta and main pulmonary artery. Flow is calculated as the spatial average velocity of the vessel and the cross-sectional area of the vessel. *B,* Flow-versus-time curves for the aorta and pulmonary artery. The difference in area under the two curves is the volume of the left-to-right shunt in a patient with an atrial septal defect.

COMPUTED TOMOGRAPHY

TECHNICAL ASPECTS

Computed tomography of the heart usually requires modification of the standard CT techniques used for investigating other parts of the body. For some purposes, such as evaluation of thoracic aortic disease, pericardial disease, paracardiac and intracardiac tumors, and patency of coronary arterial bypass grafts, newer spiral and multiple array CT scanners with exposure times of less than 1 second are usually adequate. Continuously rotating (spiral) CT scanners have an exposure time of 1 second or less for each image with no interscan delay between images at sequential anatomical levels, producing images of the entire heart in 12 to 20 seconds. Multiple-array CT scanners can acquire images of the entire heart and proximal aorta in several seconds. Although adequate anatomical depiction of cardiovascular anatomy is attained with spiral and multidetector CT scanners, scans corresponding to precise phases of the cardiac cycle cannot be obtained. For the assessment of cardiac dimensions and function in addition to morphology, millisecond CT scanners are required.[135] [136] [137] [138] The evolution of CT of the heart in the early stages also involved ECG gating of CT data acquisition. However, such gating techniques proved to be cumbersome and never received clinical acceptance. The use of ECG triggering of the acquisition is now being used again with the new multiple array (multislice) CT scanner.

SPIRAL CT SCANNING.

CT scans at multiple adjacent anatomical levels are obtained during a breath-hold period. Each CT scan is acquired in approximately 1 second. This is accomplished by multiple rotations of the CT scanner gantry while the table is continuously moved through the gantry. This permits multiple transaxial scans, 3 to 10 mm in thickness, of most or the entire thorax during a single breath-hold period at the time of peak contrast medium enhancement of the cardiovascular structures. Eighty to 100 ml of contrast medium at a rate of 2 to 3 ml/sec is injected intravenously, and CT acquisition is started at 15 to 30 seconds after the start of the injection (circulation time).

Electron-Beam (Cine, Ultrafast) CT Scanner

The electron-beam (EB) CT scanner employs a scanning focused x-ray beam that provides complete cardiac imaging in 50 milliseconds without the need for electrocardiographic gating (Fig. 10-35) . This CT scanner is not limited by the inertia associated with moving mechanical parts. It uses a focused electron beam that is successively swept across four cadmium tungstate target arcs at the speed of light. Each of the four targets generates a fan beam of photons that pass from beneath the patient to a bank of photon detectors arranged in a semicircle above the patient.

The EBCT scanner can be operated in three different modes: (1) the *cine mode* is used to assess global and regional myocardial function. The scans are obtained at an exposure time of 50 milliseconds and at a rate of 17 scans per second[135] (Fig. 10-36) . The *triggered mode,* used for flow analysis, employs a series of 20 to 40 successive scans in which each 50-millisecond exposure is triggered at a specific phase of the cardiac cycle of successive heartbeats or every other heartbeat. From such a series of scans, time-density curves can be constructed for specific regions of interest in the cardiac chamber or myocardium, providing an estimate of transit time, perfusion, or blood flow.[140] The *volume mode* provides eight scans by the use of all four target arcs in an imaging period of approximately 200 milliseconds. These eight transverse scans can sometimes encompass the entire left ventricular chamber and thereby provide an estimate of left ventricular volume and mass. Usually 10 to 12 tomographic levels are needed to entirely encompass the heart.

Because multiple images can be acquired at multiple levels, EBCT permits the acquisition of images at end diastole and end systole because both are approximately 60 milliseconds in duration. Real-time sequential imaging is accomplished within a single heartbeat at multiple levels, and these images can then be displayed in a close-loop cine format (cine CT display).

CONTRAST ENHANCEMENT.

For nearly all purposes, intravenous injection of iodinated contrast medium is used to

Figure 10-35 Diagram of cine CT scanner. Electron gun produces a stream of electrons that are magnetically focused and directed onto four tungsten target rings. Each target ring emits two fan beams of x-ray. Transmission of x-rays through the subject is registered by detectors arranged over a 180-degree arc.

delineate the blood pool on CT scans. The contrast medium can be given as an intravenous bolus injection or a rapid infusion. For evaluation of the heart and great vessels, contrast medium is usually delivered in a bolus over several seconds and in a volume of 40 to 80 ml. Scans are exposed at the estimated time of peak enhancement of the structure of interest. To identify the time of arrival of contrast medium in the left-sided cardiac chamber and aorta, a preliminary bolus injection of a small volume of contrast medium or indocyanine green dye can be given to define circulation time. This time is then used to specify the time of acquisition of the series of EBCT scans. Scans are sometimes obtained without contrast medium to identify calcification of cardiac structures.

Figure 10-36 Series of CT scans of the same anatomical level acquired every 50 msec during a single cardiac cycle in a patient with hypertrophic cardiomyopathy. These are 9 of 17 scans acquired in approximately one cardiac cycle. Frame at upper left is near end diastole (ED) and middle frame is near end systole (ES). Note the change in ventricular volumes during the cardiac cycle and wall thickening during systole. *(Courtesy of J. Rumberger, PhD, MD, Mayo Clinic.)*

EVALUATION OF CARDIAC DIMENSIONS AND FUNCTION (See also Chap. 15)

Computed tomography has the capability of identifying not only the inner endocardial wall but also the epicardial surface. Wall thickness and myocardial mass have been estimated accurately with EBCT.[138] A close correlation has been found between CT measurements and postmortem anatomical measurements of wall thickness and mass.[138] It has also been employed to estimate right ventricular mass by measuring the mass of the free wall.[142] [143] Right ventricular mass was demonstrated to be substantially increased in patients with pulmonary arterial hypertension compared with measurements in normal subjects.[143]

CT can be used in the assessment of the dynamics of *regional myocardial wall thickening* (see Fig. 10-36) . [142] [144] A series of tomograms in a short-axis plane acquired during multiple phases of the cardiac cycle permits measurement of area ejection fraction and wall thickening at various levels of the left ventricle, extending from the base to the apex. In normal human subjects, a variation in both regional ejection fraction and extent of wall thickening has been defined; a gradient in both area ejection fraction and extent of wall thickening increases progressively from basal to apical layers.[141] Cine CT has demonstrated dysfunction of wall thickening and wall motion in global and regional myocardial abnormalities.[136] [145] [146]

Left ventricular volumes and *ejection fraction* can be estimated by contrast angiography, echocardiography, and gated blood pool nuclear images. Whereas the quantitation of ventricular volumes and ejection fraction by EBCT is not a unique capability, the accuracy of CT can potentially exceed that of the other techniques. Other cardiac imaging techniques such as echocardiography and left ventricular angiography estimate left ventricular volume, making geometric assumptions from measurements performed in one or two planes. These assumptions lead to inaccuracies of volume measurement in the presence of left ventricular conformational abnormalities. EBCT directly measures chamber volumes by planimetry of the cardiac blood pool on each tomogram, allowing precise volume determination. Left ventricular volume, ejection fraction, and stroke volume can be acquired by EBCT with high accuracy and close reproducibility among observers and among studies on different occasions in the same subject.[147] [148] In normal subjects the stroke volumes of the right and left ventricle as measured by ultrafast CT were equal.[148]

EBCT provides a measurement of total ventricular *stroke volume.* If an independent technique is used for the measurement

of forward (effective) stroke volume, then these measurements can be combined to estimate regurgitant volume; regurgitant volume is the difference between total stroke volume and forward stroke volume. EBCT can also be applied for the simultaneous quantification of the right and left ventricular stroke volumes.[148] [149] The difference in the stroke volume between the ventricles is equal to the total regurgitant volume of valves on one side of the heart. The method is not relevant for circumstances in which valvular regurgitation is present in both the right and left ventricles.

EVALUATION OF SPECIFIC CARDIAC DISEASES

Ischemic Heart Disease

After myocardial infarction, CT can be used to demonstrate regional wall thinning and complications of infarction, such as left ventricular aneurysm (Figs. 10-37 and 10-38) and mural thrombus (see also Chap. 35) . EBCT demonstrates reduced wall thickening and wall motion as evidence of left ventricular segmental dysfunction in ischemic heart disease.[150] EBCT has also been used to monitor left ventricular remodeling after acute myocardial infarction[151]

CT provides unequivocal spatial separation between various regions of the left ventricle, enabling better localization and estimation of the extent of wall thinning after infarction compared with projectional techniques such as left ventriculography and most scintigraphic techniques. Likewise, the site and extent of anterior and posterior aneurysms of the left ventricle can be well demonstrated (see Figs. 10-37 and 10-38). The differentiation by CT between true aneurysm and pseudoaneurysm depends on the identification of the small ostium connecting the left ventricular cavity and the aneurysm. False aneurysms are usually substantially larger than true aneurysms and frequently arise from the posterior or inferior wall of the left ventricle.

CT has been found to be as accurate as 2D echocardiography

Figure 10-37 Cine (ultrafast) CT images at four adjacent anatomical levels (cranial [*upper left*] to cranial [*lower right*]) in a patient with inferior left ventricular aneurysm. The CT images demonstrate the location and extent of the aneurysm. *(Courtesy of Imatron, Inc.)*

Figure 10-38 Cine (ultrafast) CT images at four adjacent anatomical levels (cranial [*upper left*] to cranial [*lower right*]) demonstrate an anterior left ventricular aneurysn. There is severe thinning of the anteroseptal and anterior walls and bulging of the left ventricle anteriorly. *(Courtesy of Imatron, Inc.)*

for identifying left ventricular *mural thrombus.*[152] Moreover, comparative studies have shown greater accuracy of CT compared with 2D echocardiography in demonstration of thrombus in the left atrium.[153] The comparative accuracy of CT and transesophageal echocardiography has not been established.

REGIONAL WALL MOTION.

For the evaluation of regional myocardial function, the cine mode of the ultrafast CT scanner is used to acquire images at 17 scans per second at the time of peak opacification of the left ventricle. Quantitation of systolic myocardial wall thickening appears to be a particularly useful technique for evaluating regional myocardial contractile function in patients with ischemic heart disease. Identification of regional contraction abnormalities in patients with hemodynamically significant stenoses has been done using EBCT performed at rest and during exercise.[146]

MYOCARDIAL PERFUSION.

EBCT may also be able to provide an indication of *regional myocardial perfusion.*[139] [140] [154] [155] Estimates of myocardial perfusion are obtained by drawing regions of interest over various sites of the myocardium displayed on the transverse CT scans. The density of the myocardial regions is measured on sequential 50-millisecond scans acquired during an appropriate duration of the myocardial contrast medium-enhancement phase. From these measurements, time-density curves are constructed; analyses of these curves in regard to contrast appearance and washout are used to estimate regional myocardial perfusion. Thus, EBCT has the potential of providing both regional function and perfusion in a single study. Experiments have shown that flow can be reliably estimated under variable physiological (vasodilatation) and pathological (stenosis) states in comparison to radiolabeled microspheres.[140] [155] Measurements of regional flow in response to a vasodilator can be used to test coronary flow reserve in various regions and to identify a region served by an artery with a critical stenosis by failure of flow to rise in response to a vasodilator.

DETECTION OF MYOCARDIAL ISCHEMIA.

EBCT can be used to detect regional myocardial dysfunction or a regional

Figure 10-39 *Left,* Sequential cine CT scans show patent bypass grafts (arrows) to the left anterior descending artery and acute diagonal. *Right,* Graft to the obtuse marginal branch of the circumflex artery (arrow). Note that the grafts opacify simultaneously with the ascending aorta. Each set of four images was obtained at the same anatomical level. The images were done with the passage of contrast medium through the central circulation. Early images *(A, B)* show contrast in the pulmonary artery and later images *(C, D)* show contrast in the aorta and bypass grafts.

myocardial perfusion deficit caused by ischemia. Thus, this technique has the capability of combining functional and perfusion approaches for the detection of regional myocardial ischemia. It has improved edge definition compared with echocardiography, permitting measurement of wall thickening before and after pharmacological stress. It also has considerably better spatial resolution than radionuclide imaging.

PATENCY OF CORONARY ARTERY BYPASS GRAFTS (CABG).

Several reports have indicated high accuracy of EBCT for defining the patency of coronary artery bypass grafts.[156] [157] [158] The diagnostic accuracy of EBCT for defining the patency of saphenous grafts and internal mammary bypasses has been shown to be greater than 90 percent in a multicenter study.[156] High accuracy was shown for defining patency of grafts to the left anterior descending, circumflex branches, and right coronary arterial branches.

The site of the bypass graft on contrast medium-enhanced CT scans can be related to a clock. The grafts to the right coronary artery are situated between 9 and 11 o'clock; grafts to the left anterior descending artery system are situated at 12 to 2 o'clock; and the grafts to the circumflex coronary system are located at 2 to 4 o'clock (Fig. 10-39) . Diagnostic confidence is enhanced by visualizing the grafts at two adjacent anatomical levels and by showing contrast medium enhancement of the graft with aortic opacification.

CORONARY ARTERIAL CALCIFICATION (See also Chap. 8) .

Calcification in the coronary arteries usually indicates the presence of atherosclerosis. Although the early stages of atherosclerosis exist without calcification and calcification occurs in the coronary arteries in the absence of hemodynamically significant arterial obstruction, the detection of calcification increases the likelihood of significant coronary arterial obstructive disease in a specified population of patients. Older studies[159] [160] [161] have revealed that in patients being studied by coronary arteriography, the absence of fluoroscopically detectable coronary arterial calcification is usually associated with no significant arterial stenoses and the presence of calcification with significant stenoses (50 percent reduction in luminal diameter).

EBCT has been used in the past few years for the detection of calcification in the coronary arteries. It can be performed more rapidly than can fluoroscopy, without the presence of a physician, which potentially makes it feasible as a low-cost screening test. It is more sensitive than fluoroscopy in detecting calcification, with excellent intraobserver and interobserver and interstudy reproducibility.[141] [162] Several studies using excised hearts or excised coronary arteries have shown a nearly one-to-one correlation between sites of coronary calcification depicted by EBCT and postmortem histomorphometry.[163] [164] [165] [166] The total volume of calcification by EBCT correlates more closely with total burden of atherosclerotic plaque than lumen stenosis.[167]

A close correlation has been found between the total mass of calcium in the coronary arteries as reflected in the calcium score (area of calcium on scan times density of calcium as expressed by the range of CT density numbers) and the total mass of atherosclerotic plaques, numbers of arterial segments with stenosis, and numbers of arteries and segments with greater than 75 percent reduction in luminal diameter.[163] [164] [165] [166] [167] In one postmortem study, greater than 97 percent of arterial segments without calcification were free of hemodynamically significant stenosis (<75 percent area stenosis) and no hemodynamically significant stenosis was shown in any vessel without calcification in any segment.[163] Thus, EBCT examination of postmortem specimens shows that the technique detects coronary calcification when it is present and can accurately quantify the mass of calcium in the coronary arteries. The mass of the calcium as measured by EBCT is closely related to the number of arterial segments and number of arteries containing nonobstructive and obstructive atherosclerotic plaques and the total atherosclerotic burden of the coronary arterial system.

PREDICTION OF PRESENCE OF CORONARY STENOSIS.

The presence of coronary arterial calcification, the number of coronary arteries with calcification, and the total mass of coronary calcification in the coronary circulation have been used to predict the presence of any degree of coronary arterial stenosis and hemodynamically significant stenosis compared with coronary arteriography.[168] [169] [170] The sensitivity for predicting any degree of stenosis or hemodynamically significant stenosis has been high, usually exceeding 90 percent, but the specificity is only fair. The mass of calcium is quantified by calculating the calcium score (total area of calcium×density weighting) (Fig. 10-40) .[162]

The prevalence of coronary arterial calcification detected by EBCT in women is half that of men until the age of 60; the distribution of calcium scores of men between the ages 40 and 69 years was nearly identical to that of women between ages 50 and 79.[170] Because the presence of coronary calcification and the calcium score increase with age,[162] the usefulness of EBCT for identifying patients at a higher risk for significant coronary arterial disease decreases with increasing age (Fig. 10-41) . Although the sensitivity remains high even in patients younger than age 50 years, the specificity for predicting significant stenosis is still only fair.[171]

In one report,[167] investigators found that coronary calcium quantification by EBCT is an effective method for defining atherosclerotic burden at individual arterial sites and the total amount of calcium correlates with the atherosclerotic burden in the coronary arteries. Rumberger and associates[172] have proposed coronary artery calcium

Figure 10-40 Cine CT scans obtained without contrast medium used to detect the presence, severity, and extent of coronary arterial calcification. Adjacent images extending from cranial *(upper left)* to caudal *(lower right)*. Sites of calcification are labeled A to H. There are multiple sites of calcification in the proximal and mid left anterior descending artery.

scores (CAC scores) for individual coronary arteries that maximize the sensitivity and specificity for predicting the severity of coronary arterial stenosis on coronary angiography (Fig. 10-42) . A calcium score of 80 predicts a 50 percent stenosis with a sensitivity and specificity of 84 percent.

Coronary arterial calcium quantification has been compared with electrocardiographic and thallium exercise testing for predicting stenoses in 251 consecutive patients before elective coronary arteriography.[173] A cut-off score of total coronary arterial calcium was at least as useful and better in some patient groups for predicting stenoses compared with the other two tests. Coronary arterial calcium scoring has also been found to be a reliable test for distinguishing between patients with ischemic and nonischemic cardiomyopathies.[174]

Figure 10-41 Plot of coronary arterial calcium score versus decade of age for groups of patients with and without known (symptomatic) coronary disease. *(From Agatston AS, Janowitz WR, Hildner EJ, et al: Quantification of coronary artery calcium using ultrafast computed tomography. Because an absolute correspondence has not been shown for calcification and an obstructive lesion at a specific site, this test cannot be substituted for coronary arteriography. Consequently, the additive value of EBCT in symptomatic patients in the era of cost containment has been questioned. The role of EBCT for detecting calcification in asymptomatic patients is also still controversial, although it is being performed with increasing frequency. A number of studies have shown significant correlations between several risk factors for coronary artery disease and the presence and amount of coronary artery calcium defined by EBCT in asymptomatic patients. Coronary artery calcification has been related to age, gender, cigarette smoking, hypertension, diabetes, and hypercholesterolemia. EBCT-defined calcification was found in high-risk asymptomatic adults to be about equivalent to but no better than risk factors assessment in identifying patients who will incur coronary events over a 3- to 4-year follow-up period.[175] Some studies also suggest that coronary events in both symptomatic patients referred for coronary arteriography [176] and asymptomatic individuals[177] [178] could be related to coronary artery calcification score.

The role of EBCT in identifying patients at higher risk for the development of symptomatic coronary arterial disease, cardiac morbidity, and death remains somewhat controversial. As a potential screening test, it does have high sensitivity and can be performed rapidly, inexpensively, and noninvasively. Perhaps its role at the current time is to indicate patients with some degree of atherosclerotic coronary arterial disease who should enter strict risk-reduction programs. The absence of coronary arterial calcification by EBCT makes the presence of significant coronary arterial disease very unlikely. However, it does not exclude such disease.

EBCT CORONARY ARTERIOGRAPHY.

In the past few years, contrast medium-enhanced EBCT has been shown to be effective for visualizing the lumen of the major coronary arteries.[179] [180] [181] [182] [183] This is done by acquiring contiguous or overlapping

Figure 10-43 Electron-beam CT coronary angiography sliding slab reconstruction of four 3-mm slices through the proximal portion of the coronary arteries during peak opacification of the coronary arteries after intravenous injection of contrast medium. The proximal left and right arteries are shown. *(From Chernoff D, Ritchie CT, Higgins CB: Evaluation of electron beam CT coronary angiography*

in healthy subjects. AJR Am J Roentgenol 169:93, 1997.)

thin CT scans at the same phase of diastole during breath holding (Fig. 10-43) . From this 3D data set, projectional images can be produced that display the major coronary arterial branches (Fig. 10-44) . Postprocessing of the data set can be done to subtract the heart from the image and thereby provide an isolated projectional image of the coronary arteries.

EBCT coronary arteriography in normal volunteers has shown the capability of the technique for displaying about 8 cm of the three major coronary arteries with good contrast-to-noise ratio.[179] Several studies[180] [181] [182] [183] have now shown a sensitivity of 74 to 92 percent and specificity of 79 to 94 percent for identifying hemodynamically significant coronary arterial stenosis as defined by selective coronary arteriography.

Pericardial Disease (See also Chap. 50)

Computed tomography provides distinct visualization of the pericardium in most patients. Discrimination of the pericardial line from the myocardium depends on the presence of some epicardial and pericardial fat; it has been reported to be visible on CT scans of 95 percent of normal subjects.[184] Although visible over the right atrium and ventricle in most subjects, it is frequently not detectable on the lateral and posterior walls of the left ventricle. The mean width of the line in normal subjects is 2.2 mm at its thinnest portion and is always less than 4 mm. Pericardial thickness is usually normal near its diaphragmatic attachments. CT also frequently demonstrates the superior recesses of the pericardium extending over the ascending aorta and lateral to the main pulmonary artery. These recesses may be distended in the presence of a pericardial effusion.

2D echocardiography is an extremely effective technique for the diagnosis of pericardial abnormalities and is the primary modality for evaluation of suspected pericardial disease (see also Chap. 7) . Although it is extremely sensitive for the detection of pericardial effusion, it has some limitations in defining loculated effusions, hemorrhagic effusions, and especially pericardial thickening. CT is especially effective in depicting these features.[185] [186] Consequently, it is complementary to echocardiography in the diagnosis and assessment of pericardial disease.

CONGENITAL ABNORMALITIES AND CYSTS OF THE PERICARDIUM.

Congenital abnormalities, such as absence of the pericardium[187] and pericardial cyst[185] [186] can be well demonstrated by CT. The pericardial defect (usually partial or complete absence of left-sided pericardium) is recognized on CT by the discontinuity of the pericardial line over the left aspect of the heart, with shift of the heart leftward or bulging of the left atrial appendage through the defect. CT demonstrates interposition of a tongue of lung tissue between the proximal ascending aorta and main pulmonary artery at the base of the heart in the absence of the left-sided pericardium.

A pericardial cyst appears as a paracardiac mass with a thin capsule that is occasionally partially or completely calcified and has a homogeneous internal density nearly equivalent to that of water. However, rarely the cyst contains mucoid material, causing the density to be higher than water; such a cyst usually cannot be reliably distinguished from a solid mass. *Thymic* and *bronchogenic cysts,* which may be adjacent to the pericardium, also may show homogeneous water density on CT densitometry and may be indistinguishable from pericardial cysts.

PERICARDIAL FLUID.

Fluid in the pericardial space may be reliably detected by CT.[185] [188] This technique can also provide an accurate estimate of the volume of this fluid.[188] Although 2D echocardiography is sufficient and, for economic and logistic reasons, more clinically efficacious for the primary evaluation of most pericardial effusions, CT is indicated in some special situations. Loculated effusions (especially anterior loculations), which may pose difficulty

Figure 10-44 Elecron-beam CT coronary angiography. Shaded surface displays three-dimensional reconstruction of the left coronary artery. The reconstruction is done from 3-mm transaxial CT scans. LAD=left anterior descending artery; LCX=left circumflex artery.

Figure 10-45 Calcific constrictive pericarditis. Cine CT scans at the base of the heart *(left)* and at mid ventricular level *(right)*. Note the heavy calcification at multiple sites of the pericardium and extending into the posterior atrioventricular grove. *(Courtesy of Imatron, Inc.)*

for echocardiography, are readily demonstrated on CT because of the wide field of view provided and the potentially 3D nature of the technique.[186] CT can be effective not only for diagnosing loculated effusions but also for guiding pericardiocentesis.[189] CT density measurements provide some degree of characterization of pericardial fluid. Density numbers (Hounsfield numbers) exceeding water density (water density=0 to 12 units) are suggestive of hemopericardium, purulent exudate, or effusions associated with hypothyroidism. Low-density pericardial effusions have been reported in the presence of chylopericardium.[188]

CONSTRICTIVE PERICARDITIS.

The establishment of the diagnosis of constrictive pericarditis can be substantially aided by CT.[185] [186] Because CT shows the pericardium, it can document pericardial thickening, defined as thickness greater than 4 mm. Focal plaques of thickening or the greater thickness of the pericardium near the diaphragm should not be confused with the more extensive pericardial thickening associated with constrictive pericarditis. However, the pericardial thickening may be limited to the right side of the heart, a form that appears to be more prevalent in patients who have undergone coronary arterial bypass surgery.

The documentation of pericardial thickening is the major discriminatory feature between constrictive pericarditis and restrictive cardiomyopathy (Fig. 10-45) . However, thickened pericardium per se is not indicative of constrictive disease. Pericardial thickening without constriction is frequently observed in the early postoperative period and may persist for several months after operation in patients with the postpericardiotomy syndrome.[185] Thickened pericardium without constriction has also been observed in association with inflammation of the pericardium caused by a variety of conditions, including uremia, rheumatic heart disease, rheumatoid arthritis, sarcoidosis, and postmediastinal irradiation. Pericardial thickening may also be caused by metastatic carcinoma, thymoma, and lymphoma and mesothelioma. These conditions are usually associated with effusion. Likewise, primary sarcoma of the heart and mediastinal and lung malignant tumors extending to the pericardium produce local or diffuse pericardial thickening and loculated or generalized pericardial effusion. Moreover, thickened pericardium is to be expected in many patients for several weeks after cardiac surgery. It may be present for a prolonged period in patients afflicted by the postpericardiotomy syndrome.

EFFUSIVE-CONSTRICTIVE PERICARDITIS.

This condition is demonstrated by an effusion in association with thickened pericardium; however, it may not always be possible to distinguish a small effusion from thickened pericardium.[185] Pericardial thickening alone usually measures between 5 and 20 mm, whereas greater thickening generally indicates associated effusion or effusion alone. Contrast medium enhancement of the thickened pericardium is indicative of pericardial inflammation[190] (Fig. 10-46) . Additional CT findings in constrictive pericarditis often reflect the anatomical and physiological consequences of the thickened pericardium on the cardiac chambers.[191] [192] [193] CT shows substantial dilatation of the inferior vena cava and some enlargement

Figure 10-46 Cine CT scans at the levels of the right pulmonary artery *(A)* and at the ventricles *(B)* in a patient with a pericardial inflammation and large effusion. The effusion extends over the pulmonary artery as well as the ventricles. There is contrast enhancement of the pericardium (arrows), suggesting pericardial inflammation. *(Courtesy of Imatron, Inc.)*

of the atria, especially the right atrium (see Fig. 10-45) . The ventricles tend to have a small volume and a narrow tubular configuration.[192] In some cases, a sigmoid-shaped ventricular septum or prominent leftward convexity of the septum has been observed. Unusual contours, such as straightening or focal indentation of the free wall of either the right or left ventricle, have been noted on CT.[192]

The density resolution of CT makes it the most sensitive technique for identifying pericardial calcification. Pericardial calcific deposits are usually residuals of pericardial inflammation and are most commonly found in the visceral layer along the atrioventricular and interventricular grooves. Extensive calcification of the pericardium suggests but does not prove the presence of cardiac constriction.

Paracardiac, Pericardial, and Cardiac Masses

Computed tomography is useful for the evaluation of pericardial and paracardiac masses. CT and, more recently, MRI have emerged as the preferential techniques for defining the site and extent of such masses and in some cases even indicate their nature.[185] [186] CT may show the water density of pericardial cysts; this is an especially useful finding when the cyst is located in an unusual mediastinal location or when it protrudes inwardly, displacing the atrial wall. CT and MRI are currently the best techniques for defining the extension of mediastinal neoplasms (including lymphoma) and of carcinoma of the lung into the pericardium. Metastatic involvement of the pericardium is suggested by the CT findings of effusion with an irregularly thickened pericardium or the actual demonstration of a mass involving the pericardium. An effusion with high CT density (hemopericardium) along with pericardial thickening also suggests metastatic pericardial involvement.[186]

CT sometimes provides insight into the nature of the mass by demonstrating the shape, defining the density measurements, or showing multiple masses. The CT demonstration of multiple pericardial nodules suggests metastatic tumor or, rarely, multicentric mesothelioma. Pericardial cysts have water density, whereas lipomas have a very low density value (-55 or fewer Hounsfield units). Demonstration of calcium or bone and fat in a paracardiac mass by CT suggests teratoma.

Intracardiac masses can be detected very well by echocardiography and angiography. However, CT not only can detect masses within the cardiac chambers but also can define fully their extent (Fig. 10-47) . CT can demonstrate components of the mass within the myocardial wall and extending outside of the heart. The contrast resolution of CT may provide some insight into the composition of the mass, such as demonstrating the presence of fat or calcium. CT readily demonstrates simple intracardiac masses such as atrial myxoma and complex masses involving the myocardial wall with extracardiac extension. Finally, by defining clearly the myocardial wall, CT can demonstrate an extracardiac location of tumors that produce compression and invagination of cardiac walls, simulating an intracardiac origin.[194]

INTRACARDIAC THROMBUS.

The most frequent intracardiac mass is a thrombus. Intracardiac thrombi are usually located in the left atrium in patients with mitral valve disease or patients with atrial fibrillation from any cause and in the left ventricle in patients with recent myocardial infarction or patients with dilated (congestive) cardiomyopathy. Although transthoracic echocardiography is usually the initial study used to detect intracardiac thrombi or an intracardiac source of peripheral embolism, recent studies have revealed that CT is as sensitive but more specific for identifying ventricular thrombus[152] and more sensitive for defining left atrial thrombus.[153] Thrombi in the left atrial appendage and lateral wall of the atrium are more readily detected with MRI and CT than with transthoracic echocardiography. MRI and CT are very effective techniques for the detection of intracardiac thrombus; however, their accuracy compared with transesophageal echocardiography has yet to be systematically evaluated.

Congenital Heart Disease (See also Chaps. 43 and 44)

Standard CT, EBCT, and MRI are useful noninvasive techniques for the visualization of cardiovascular anatomy in patients with congenital heart disease. EBCT and MRI can also provide assessment of cardiovascular function in these patients. MRI appears to be the most suitable of these techniques for assessing congenital heart disease. The x-ray exposure, contrast media requirement, and inability to image in multiple plane are limitations of CT for the evaluation of congenital heart disease.

STANDARD CT.

This technique has been found to be useful for evaluation of suspected *anomalies of the aortic arch.* [195] [196] Contrast medium-enhanced CT is usually required to show the vascular tissue surrounding the trachea in the presence of double aortic arch and the retroesophageal vascular structure indicating anomalous origin of the subclavian artery. Double arch is also suggested by the presence of four paratracheal vessels arranged symmetrically at the cervicothoracic junction.

EBCT.

At a few centers EBCT has also been tested for its potential for the evaluation of congenital heart disease.[197] [198] EBCT accurately defined systemic and pulmonary venous connections. Likewise, it has demonstrated atrial and ventricular septal defects. Transverse tomograms provide clear spatial separation of the inflow and outflow portions of the ventricular septum. This permits localization of defects and facilitates the detection of multiple ventricular septal defects. In addition, an assessment of the hemodynamic effects of septal defects (and of other lesions) can be made by evaluation of chamber dimension and wall thickness. Because of the absence of overlying structures defined on CT

Figure 10-47 Cine CT scans of left atrial myxoma. *Left,* The attachment of the myxoma to the atrial septum and prolapsing across the mitral valve are shown. *Right,* Malignant tumor invading the left atrium.

Figure 10-48 Type A aortic dissection, cine CT scans at level of right pulmonary artery *(left)* and 1 cm caudal *(right)* demonstrate intimal flap in ascending and descending aorta. scans and the 3D nature of CT acquisition, the size of the ventricles can be measured.

Normal and abnormal atrioventricular valves can be demonstrated by EBCT,[197] [198] which can be used to diagnose both tricuspid and mitral atresia. It can also demonstrate the size of the atrium above the atretic valve. EBCT has been effective for demonstrating abnormal arterioventricular connections, including transposition complexes and double-outlet right ventricle.[197] [198] Abnormalities of the pulmonary arteries, such as congenital absence, peripheral coarctations, and hypoplasia, have been demonstrated by this technique. However, EBCT is not recommended for this purpose because multiplanar MRI has been shown in recent years to be the most effective technique for assessing pulmonary arterial anomalies.

Congenital anomalies of the coronary arteries have been demonstrated very well using EBCT scans positioned at the base of the heart.[199] Ectopic origin of coronary arteries and coronary arteriovenous fistulas have been effectively demonstrated by this technique. Contrast medium-enhanced EBCT and MRI are probably the noninvasive procedures of choice for the diagnosis and exclusion of major or minor anomalies of origin and course of the coronary arteries. They can display both the anomalous origin and course of coronary arteries. This is especially important for showing a course in the ventricular septum or between the base of the aorta and pulmonary artery when the left anterior descending branch arises from the right coronary artery.

EVALUATION OF CARDIAC FUNCTION IN CONGENITAL HEART DISEASE.

This can be accomplished in patients with congenital heart disease by EBCT, which, along with cine MRI, may be the best technique for quantitating right ventricular volumes and ejection fraction. In addition, EBCT can be used to estimate the volume of shunts. This is accomplished by measuring density of contrast medium within a cardiac chamber receiving shunt flow on sequential CT scans obtained during passage of contrast medium through the central circulation. A density-versus-time curve can be generated for such a region of interest. The normal curve is unimodal as contrast medium enters and leaves a cardiac chamber. A bimodal time-density curve may be generated from the region-of-interest cursor placed over any chamber involved in a shunt. By using a gamma variate fit method, the areas under the primary and secondary portions of the curve can be measured to calculate pulmonary-to-systemic flow ratios.

Another method for calculating the net shunt is to compare the difference in stroke volume between the two ventricles. For a left-to-right shunt at the ventricular level, the difference between the larger left ventricular stroke volume and right ventricular stroke volume indicates the net shunt value. Such an approach can be used also to calculate net volume and fraction of regurgitant lesions.

EBCT appears to be an excellent technique for the evaluation of both right and left ventricular function in surgically corrected congenital heart disease. Because

volumes and mass of both ventricles can be measured accurately by CT, this technique can be used to evaluate the expected regression of ventricular dilatation and hypertrophy after corrective procedures.

Disease of the Thoracic Aorta (See also Chap. 40)

Computed tomography has been shown to be extremely accurate for the diagnosis of thoracic aortic aneurysm, aortic dissection, intramural hematoma, and atherosclerotic ulcerating plaque.[110] [200] [201] [202] [203]

AORTIC DISSECTION.

CT has an accuracy of greater than 95 percent and is equivalent to MRI and better than x-ray angiography for the diagnosis of a variety of diseases of the thoracic aorta.[110] A study comparing CT, MRI, and transesophageal and transthoracic echocardiography has shown greater diagnostic accuracy of CT and MRI than of the echocardiographic techniques.[110] However, some instances of false-negative CT examination in aortic dissection have been reported. Diagnosis of dissection requires the demonstration of the intimal flap, appearing as a lucency within the lumen of the contrast-enhanced aortic lumen on CT scans (Fig. 10-48) . Supportive findings for the diagnosis of aortic dissection are differential temporal enhancement of the true and false aortic channels or compression of the opacified true lumen by a thrombosed false channel. Inward displacement of calcium in the aortic wall is also a sign of aortic dissection. CT can distinguish between dissections that involve the ascending aorta and those that are limited to the descending aorta. In the former, the intimal flap can be demonstrated in the ascending aorta. It may be difficult to differentiate a dissection with thrombus of the false channel from an aortic aneurysm with mural thrombus. A dissection is more likely when CT scans at multiple levels show the thrombus extending for more than 10 cm longitudinally. Also, dissection usually results in a compressed true aortic lumen whereas aneurysm has a normal or increased lumen (see Figs. 40-13 and 40-14).

Intramural hematoma has been reported as a feature of aortic dissection without entry into the lumen of the aorta.[202] It is likely that this is an early stage of some acute dissections, but not all intramural hematomas progress to the typical feature of acute dissection.[202] [204]

CT also may be used for following the course of thoracic aortic dissections after initial treatment.[205] [206] [207] [208] After surgical placement of an ascending aortic graft, the false channel beyond the distal anastomosis of the graft frequently remains patent. Sequential CT studies have also revealed persistent patency of the false channel after medical as well as surgical therapy. Eventual thrombosis of the false channel or even its disappearance is seen in some patients.[207] [208] CT has also been used to follow the alterations in the false channel of untreated type B dissections; in a minority of patients the aorta reverts to a normal appearance after months to years.[206]

AORTIC ANEURYSM.

This is characterized by an increase in aortic diameter and by outward displacement of calcium of the aortic wall (Fig. 10-49) . CT is an effective method for defining the maximum diameter of the aneurysm and monitoring the diameter over time. A diameter exceeding 4 cm is considered aneurysmal, and one exceeding 6 cm is usually an indication for surgery of thoracic aortic aneurysm.[120]

PULMONARY EMBOLISM.

EBCT[209] and spiral[210] [211] [212] CT have been used in recent years for establishing or excluding the diagnosis of pulmonary embolism (Fig. 10-50) . Both techniques have been shown to provide high diagnostic accuracy for this purpose. It has been proposed that CT scanning be used to confirm the diagnosis of pulmonary embolism in patients with intermediate likelihood of the diagnosis by nuclear pulmonary perfusion scans. At some centers, EBCT or spiral CT has replaced x-ray angiography and nuclear perfusion imaging for the definitive diagnosis of pulmonary embolism.

Chapter 11 - Cardiac Catheterization

CHARLES J. DAVIDSON
ROBERT O. BONOW

INDICATIONS FOR DIAGNOSTIC CARDIAC CATHETERIZATION

As with any procedure, the decision to recommend cardiac catheterization is based on an appropriate risk-benefit ratio. In general, diagnostic cardiac catheterization is recommended whenever it is clinically important to define the presence or severity of a suspected cardiac lesion that cannot be adequately evaluated by noninvasive techniques. Intracardiac pressure measurements and coronary arteriography are procedures that, as of this writing, can be performed only by catheterization, although some intracardiac pressures and rudimentary coronary artery anatomy can be evaluated with echocardiography and magnetic resonance imaging, respectively (see Chaps. 7 and 10) . Because the mortality from cardiac catheterization is approximately 0.1 percent in most laboratories, there are few patients who cannot be studied safely in an active laboratory.

The guidelines for diagnostic coronary angiography have been reported by a joint task force of the American College of Cardiology and the American Heart Association.[1] These guidelines describe a three-tiered priority classification for specific disease states. Class I applications exist for those conditions about which there is general agreement that coronary angiography is justified, although this may not be the only appropriate diagnostic procedure. Class II indications apply to those conditions in which coronary angiography is frequently performed but about which there is divergence of opinion with respect to justification of the usefulness or efficacy of the procedure. Class IIa applies to situations in which the weight of evidence is in favor of usefulness. Class IIb indications are less well established by evidence or opinion. Class III conditions are those about which there is general agreement that cardiac catheterization is not ordinarily useful or effective and in some cases may be harmful. Diseases are grouped under several categories: known or suspected coronary heart disease, atypical chest pain, acute myocardial infarction, valvular heart disease, congenital heart disease, and other conditions. Table 11-1 summarizes the Class I and IIa recommendations of the task force.

The indications for cardiac catheterization are changing and are likely to continue to evolve. A trend has been in two divergent directions. In one, many critically ill and hemodynamically unstable patients are being studied during acute myocardial ischemia and/or severe heart failure. At the other end of the spectrum, an increasing number of studies are being performed in an outpatient setting. The result has been the expansion of traditional indications for cardiac catheterization to include both critically ill patients and ambulatory patients.

Cardiac catheterization should be considered to be a diagnostic test for use in combination with complementary noninvasive tests in cardiology. For example, cardiac catheterization in patients with valvular or congenital heart disease is best done with full echocardiographic knowledge and any other functional information. Then, catheterization can be directed and simplified without obtaining redundant anatomical information.

Identification of coronary artery disease and assessment of its extent and severity are the most common indications for cardiac catheterization in adults. The information obtained by catheterization is crucial to optimize the care of patients with various chest pain syndromes. In addition, the presence of dynamic coronary vascular lesions, such as spasm or thrombosis, may be identified. The consequences of coronary heart disease, such as ischemic mitral regurgitation or left ventricular dysfunction and aneurysm, can be defined. In the current era of acute catheter intervention for acute coronary syndromes, patients may be studied during myocardial infarction or unstable angina or in the early period after acute myocardial injury. The aggressiveness of individual centers in approaching such patients depends on local facilities and treatment philosophies as well as the availability of appropriate therapy and surgical support.

In patients with myocardial disease, cardiac catheterization may provide critical information. It can exclude coronary artery disease as the cause of symptoms and evaluate left ventricular dysfunction in patients with cardiomyopathy. Cardiac catheterization also permits quantification of the severity of both diastolic and systolic dysfunction (see Chap. 15) , differentiation of myocardial restriction from pericardial constriction, assessment of the extent of valvular regurgitation, detection of active myocarditis by endomyocardial biopsy, and observation of the cardiovascular response to acute pharmacological intervention.

In patients with valvular heart disease, cardiac catheterization provides data both confirmatory and complementary to noninvasive echocardiography and nuclear studies. Roberts[2] and Rahimtoola[3] have emphasized that the risk-benefit ratio of preoperative cardiac catheterization is weighted heavily in favor of the cardiac catheterization. Catheterization may be unnecessary in some preoperative situations, such as in patients with an atrial myxoma or young patients with endocarditis or acute mitral or acute aortic regurgitation. Nevertheless, additional confirmation of the severity of the valvular lesion, identification of associated

TABLE 11-1 -- INDICATIONS FOR CORONARY ANGIOGRAPHY

KNOWN OR SUSPECTED CORONARY DISEASE (Known: previous myocardial infarction, or coronary bypass surgery or PTCA. Suspected: rest- or exercise-induced ECG abnormalities suggesting silent ischemia)

Asymptomatic or Stable Angina

Class I
1. Evidence of high risk on noninvasive testing.
2. Canadian Cardiovascular Society (CSS) class III or IV angina on medical treatment.

Class IIa
1. CCS class III or IV angina that improves to class I or II on medical therapy.
2. Serial noninvasive testing showing progressive abnormalities.
3. Patient with disability or illness that cannot be stratified by other means.
4. CCS Class I or II with intolerance or failure to respond to medical therapy.
5. Individuals whose occupation involves safety of others (e.g., pilots, bus drivers) with abnormal stress test results or high-risk clinical profile.

Nonspecific Chest Pain

Class I

High-risk findings on noninvasive testing.

Class IIa

None.

Class IIb

Recurrent hospitalizations for chest pain with abnormal or equivocal noninvasive test results.

UNSTABLE CORONARY SYNDROMES

Class I

1. High or intermediate risk for adverse outcome in patients with unstable angina refractory to initial adequate medical therapy, or recurrent symptoms after initial stabilization. Emergent catheterization is recommended.
2. High risk for adverse outcome in patients with unstable angina. Urgent catheterization is recommended.
3. High- or intermediate-risk unstable angina that stabilizes after initial treatment.
4. Initially low short-term-risk unstable angina that is subsequently high risk on noninvasive testing.
5. Suspected Prinzmetal's variant angina.

Class IIa

None.

PATIENTS WITH POSTREVASCULARIZATION ISCHEMIA

Class I

1. Suspected abrupt closure or subacute stent thrombosis after percutaneous revascularization.
2. Recurrent angina or high-risk criteria on noninvasive evaluation within 9 mo of percutaneous revascularization.

Class IIa

1. Recurrent symptomatic ischemia within 12 mo of CABG.
2. Noninvasive evidence of high-risk criteria occurring at any time postoperatively.
3. Recurrent angina inadequately controlled by medical means after revascularization.

DURING THE INITIAL MANAGEMENT OF ACUTE MI (MI SUSPECTED AND ST SEGMENT ELEVATION OR BUNDLE BRANCH BLOCK PRESENT)

Coronary Angiography Coupled with the Intent to Perform Primary PTCA

Class I

1. As an alternative to thrombolytic therapy in patients who can undergo angioplasty of the infarct-related artery within 12 hr of the onset of symptoms or beyond 12 hr if ischemic
symptoms persist, *if performed in a timely fashion by individuals skilled in the procedure and supported by experienced personnel in an appropriate laboratory environment.*
2. In patients who are within 36 hr of an acute ST elevation/Q wave or new LBBB MI who develop cardiogenic shock, who are younger than 75 years, and in whom revascularization can be performed within 18 hr of the onset of the shock.

Class IIa

As a reperfusion strategy in patients who are candidates for reperfusion but who have a contraindication to fibrinolytic therapy, if angioplasty can be performed as outlined earlier in class I.

Early Angiography in the Patient With Suspected MI (ST Segment Elevation or Bundle Branch Block Present) Who Has Not Undergone Primary PTCA

Class I

None

Class IIa

Cardiogenic shock or persistent hemodynamic instability.

Early Angiography in Acute MI (MI Suspected But No ST Segment Elevation)

Class I

1. Persistent or recurrent (stuttering) episodes of symptomatic ischemia, spontaneous or induced, with or without associated ECG changes.
2. The presence of shock, severe pulmonary congestion, or continuing hypotension.

Class II

None

Coronary Angioplasty During the Hospital Management Phase (Patients with Q Wave and Non-Q-Wave Infarction)

Class I
