Chapter 44 - Congenital Heart Disease in Adults

JUDITH THERRIEN
GARY D. WEBB

Adult patients with congenital heart defects are a growing patient population.[1] [1A] [1B] There are about 1 million affected Americans in the year 2000, compared with an estimated 300,000 in 1980, and 1.4 million are anticipated in 2020. About half of these patients are at significant risk of premature mortality, reoperation, or future complications of their conditions and their treatments.

One of the special challenges in this field is that there are about 100 separate main diagnostic groups. Each patient may have one or more of such diagnoses. The cardiologist may meet these patients in the office, the emergency department, the hospital, or the diagnostic laboratories. Dealing appropriately with these patients is a challenge. For many patients, especially those with "high-risk conditions," the preferred method is to have them seen by an expert. At present, there are not enough such individuals or facilities to make this possible. The cardiologist may then need access to educational material as a reminder of the anatomy, the clinical issues, the treatments, and expected residua and sequelae for the specific patient needing informed attention.[2]

This chapter has been written for the practicing cardiologist to provide the essential information to draw on when seeing such patients. The information here is fully compatible with the only existing expert recommendations for the care of adult patients with congenital cardiac defects.[2] These and further guidelines are/will be available on the Internet at www.cachnet.org and at www.library.utoronto.ca/nevilthomas/. For congenital cardiac defects not included in this chapter, such as anomalous origin of coronary arteries,[2A] see Chapter 43 .

GENERAL PRINCIPLES

All patients should have been taught in adolescence about their condition, their future outlook, and the possibility of further surgery and complications, and they also should have been advised about their responsibilities in ensuring self-care and professional surveillance. This is not always the case, and staff in adult clinics may have to take the patient through this process. Patients may wish to continue their own education through Internet sites or to join a chat line or listserver.

Some of the most important data in the files of adult patients with congenital heart defects are prior operative reports. Heart catheterization reports may be important as well. These should all be obtained. They may be invaluable when clinical questions arise. Those patients believed to be at significant risk of future complications, future surgery, and premature death should be monitored life long.

Congenital heart disease in the adult is not a simple continuation of the childhood experience. The patterns of many lesions change in adult life. Arrhythmias are more frequent and of a different character. Cardiac chambers often enlarge, and ventricles tend to develop systolic dysfunction. Bioprosthetic valves, prone to quick failure in childhood, last longer when implanted at an older age. The patient is planning or involved in a career and may need advice on types of work to avoid. The comorbidities that tend to develop in adult life often become an important factor needing attention.

As a result, the needs of these patients are often best met by a physician or a team familiar with both pediatric and adult cardiology issues. Surgery and interventional catheterization procedures should usually be performed at centers with adequate surgical and institutional volumes of congenital heart cases at any age.[3] Diagnostic heart catheterizations, electrophysiological studies, and even magnetic resonance imaging (MRI)[3A] and other imaging of complex cases are best done where qualified staff have relevant training, experience, and equipment. Patient care in the ideal world should be multidisciplinary. Skilled cardiology and echocardiography skills are essential, but other individuals with special training, experience, and interest should also be accessible. This includes nurses, reproductive health staff, mental health professionals,[3B] anesthesiologists, medical imaging technicians, respiratory consultants, and others. Beyond the issues raised by individual lesions, these patients may also wish to have normal sex lives and to have children.

Pregnancy

Many female patients will need confirmation that they can safely carry a pregnancy. The literature offers guidance for certain lesions,[3] but, for many, certain principles can be reasonable guides.[4] Maternal risks for pregnancy include pulmonary hypertension, obstructive lesions, ventricular dysfunction, heart failure, and ascending aortic aneurysms (mainly in patients with Marfan syndrome). In severe cases, termination and sometimes sterilization may be recommended to protect the mother. Fetal risks are high in the presence of maternal cyanosis and medication exposure (e.g., warfarin and angiotensin-converting enzyme [ACE] inhibitors).

Delivery should usually be vaginal unless there is an obstetrical reason for cesarean section. Women at moderate and high risk for pregnancy should usually be evaluated

and treated in a high-risk pregnancy unit. The staff in such units will know how to obtain templates for the management of specific patients with lesions of concern.

Patients will wish advice on contraception and on recurrence risks of congenital heart disease in their offspring. Referral to a geneticist may be helpful. As a rule, the recurrence risk is 3 to 4 percent, compared with the risk in the general population of 0.8 percent (range, 0.5-1.2 percent).[5] [6] In some patients, such as those with chromosome 22 microdeletion or Marfan syndrome, the risk is 50 percent.

Cardiac Arrhythmias (see also Chap. 25)

These are a major clinical challenge in adult congenital heart patients. They are the most frequent reason for emergency department visits/admissions. They are usually chronically recurrent and may worsen or become less responsive to treatment with time.[7] Treatment options are often limited and of limited efficacy.

Atrial flutter and, to a lesser degree, atrial fibrillation are most common. Atrial flutter tends to reflect right atrial, and atrial fibrillation left atrial, abnormalities. Atrial flutter in such patients is often atypical in appearance and behavior and is better called intraatrial reentrant tachycardia. We will use the simpler term. Recognition of atrial flutter may be difficult, and the observer will need to be vigilant in recognizing 2:1 conduction masquerading as sinus rhythm. Recurrence is likely and should not be assumed to represent failure of the management strategy. The conditions in which atrial flutter is most likely are Mustard/Senning repairs of transposition of the great

arteries (TGA),[8] [9] repaired or unrepaired atrial septal defects (ASDs), repaired tetralogy of Fallot, Ebstein's anomaly of the tricuspid valve, and Fontan operation. Atrial flutter may reflect hemodynamic deterioration in patients who have had Mustard/Senning, tetralogy of Fallot, or Fontan repairs. Its arrival is usually associated with more symptoms and functional limitation.

The pharmaceutical agents most commonly used in therapy are warfarin, beta blockers, amiodarone, sotalol, propafenone, and digoxin. As a rule, patients with good ventricular function can receive sotalol or propafenone, whereas those with depressed ventricular function should receive amiodarone. Other therapies, including pacemakers, ablative procedures, and innovative surgery, are being both applied and refined. Sustained ventricular tachycardia or ventricular fibrillation occur less often, usually in the setting of ventricular dilation and scarring. Although sudden death is common in several conditions, the mechanism is poorly understood.

SPECIFIC CARDIAC DEFECTS

Atrial Septal Defect (See also Chap. 43)

ASDs are the most common congenital cardiac malformation first diagnosed in adults.

ANATOMY.

Four types of ASDs occur: ostium primum, ostium secundum, sinus venosus, and coronary sinus. Ostium primum is discussed later (see Atrioventricular Septal Defect). Ostium secundum defects occur from either excessive resorption of the septum primum or from deficient growth of the septum secundum and are occasionally associated with anomalous pulmonary venous drainage (<10 percent). Sinus venosus/superior vena cava (SVC) type defect occurs inferior to the orifice of the SVC, giving rise to an SVC connected to both atria and always associated with anomalous pulmonary venous drainage (usually from the right lung). Sinus venosus/inferior vena cava (IVC) type defects abut the junction of the IVC, inferior to the fossa ovalis. Coronary sinus septal defects are rare and arise from an opening in the wall of the distal portion of the coronary sinus, allowing left-to-right atrial shunting (see Fig. 43-9). In any type of ASD, the degree of left-to-right atrial shunting depends on the size of the defect and the relative diastolic filling properties of the two ventricles. Any condition causing reduced left ventricular compliance (e.g., systemic hypertension, cardiomyopathy or myocardial infarction) or increased left atrial pressure (e.g., mitral stenosis and/or regurgitation) will tend to increase the left-to-right shunt.

NATURAL HISTORY OF THE UNOPERATED PATIENT.

A significant shunt (Qp/Qs > 1.5/1.0) probably causes symptoms over time, and symptomatic patients become progressively more limited as they age. Effort dyspnea is seen in about 30 percent of patients by the third decade and over 75 percent of patients by the fifth decade. Supraventricular arrhythmias (atrial fibrillation or flutter) and right-sided heart failure develop by age 40 in about 10 percent of patients. The development of pulmonary hypertension, although probably not as common as originally thought, can occur at an early age. Life expectancy is probably reduced, although not nearly as severely as was quoted in an early article. Data regarding the natural history of ASD should be interpreted carefully because much of the data relates predominantly to sicker patients and the follow-up information was often inadequate.[10]

CLINICAL MANIFESTATIONS.

The most common symptoms are exercise intolerance (dyspnea and fatigue) and palpitations (usually from atrial fibrillation, less often atrial flutter or sick sinus syndrome). Paradoxical embolism resulting in transient ischemic attack or cerebrovascular accident can call the diagnosis to attention. Right ventricular failure can be the presenting symptom in older patients. The presence of cyanosis should alert one to the possibility of shunt reversal and Eisenmenger syndrome (see p. 1614) or, alternatively, to a prominent eustachian valve directing IVC flow to the left atrium through a secundum or sinus venosus/IVC ASD. On examination, there is "left atrialization" of the jugular venous pressure (a wave=v wave). A hyperdynamic right ventricular impulse can be felt at the left sternal border at the end of expiration or in the subxiphoid area on deep inspiration. A dilated pulmonary artery trunk can be palpated in the second left intercostal space. A wide and fixed split S_2 is the auscultatory hallmark of ASD. A systolic ejection murmur, usually grade 2, is best heard at the second left intercostal space, and a mid-diastolic rumble, from increased flow through the tricuspid valve, can be present at the left lower sternal border. When right ventricular failure ensues, a holosystolic murmur of tricuspid regurgitation is usual.

DIAGNOSTIC TESTING

Electrocardiogram.

Sinus rhythm or atrial fibrillation/flutter may occur. The QRS axis is normal or rightward in secundum ASD (see Fig. 43-10). Negative P waves in the inferior leads indicate a low atrial pacemaker and are often seen in sinus venosus/SVC type defects, which are located in the area of the sinoatrial node rendering it deficient. Partial to complete right bundle branch block can prolong the QRS duration (Fig. 44-1).

Chest Radiography.

The classic radiographic features are cardiomegaly (from right atrial and ventricular enlargement), dilated central pulmonary arteries with pulmonary plethora indicating increased pulmonary flow, and a small aortic knuckle (Fig. 44-2) .

Echocardiography (see Figs. 7-81 and 43-11).

Transthoracic echocardiography (TTE) documents the type(s) and size (defect diameter) of the ASD(s) and the direction(s) of the shunt and perhaps can determine the presence or absence of anomalous pulmonary venous return. The functional importance of the defect can be estimated by the size of the right ventricle, the presence or absence of right ventricular volume overload (paradoxical motion of the septum), and the calculation of pulmonary artery blood flow

Figure 44-1 Typical electrocardiogram of a sinus venosus atrial septal defect of the superior vena cava type showing low atrial rhythm, mild right-axis deviation, and right bundle branch block.

relative to systemic blood flow (Qp/Qs). Indirect measurement of the pulmonary artery pressure can be obtained from the Doppler velocity of the tricuspid regurgitation jet. Transesophageal echocardiography (TEE) permits better visualization of the interatrial septum and may be required when device closure is contemplated or assessment of pulmonary venous drainage is incomplete (see Fig. 43-11).

Catheterization.

Cardiac catheterization may be required when the hemodynamic significance of an ASD is questioned or when assessment of pulmonary artery pressures and resistances is needed.

Open-Lung Biopsy.

Open-lung biopsy should only be considered when the reversibility of the pulmonary hypertension is uncertain from hemodynamic data (see section on Eisenmenger syndrome).

INDICATIONS FOR INTERVENTION.

Hemodynamically "nonsignificant" ASDs (Qp/Qs<1.5) do not require closure, with the possible exception of trying to prevent paradoxical emboli.[11] "Significant" ASDs (Qp/Qs > 1.5, or ASDs associated with right ventricular volume overload) require closure when symptoms are present.[12] [13] [14] In the absence of symptoms, indications for closure are somewhat controversial. In patients younger than age 40 years, "significant" ASDs should probably be closed, although this practice has been challenged by some.[15] The proper therapeutic strategy for asymptomatic patients > 40 years old with "significant" ASDs is still disputed. For patients with pulmonary

hypertension (pulmonary artery pressure [PAP] > two thirds of systemic arterial blood pressure [SABP], or pulmonary arteriolar resistance more than two thirds of systemic arteriolar resistance), closure can be recommended if there is a net left-to-right shunt of at least 1.5:1, evidence of pulmonary artery reactivity when challenged with a pulmonary vasodilator (e.g., oxygen or nitric oxide), or evidence on lung biopsy that pulmonary arterial changes are potentially reversible (see Chap. 53).

Transvenous pacing should be avoided when possible in patients with ASDs, because paradoxical emboli can occur. For the same reason, venous thromboemboli from any site are potential sources of systemic emboli. If a source of paradoxical embolism is found, anticoagulation and/or ASD closure may be recommended.

INTERVENTIONAL OPTIONS AND OUTCOMES

Device Closure.

The use of devices to close ASDs percutaneously under fluoroscopy and TEE guidance[16] is gaining popularity. Indications for device closure are the same as for surgical closure but selection criteria are stricter. This technique is available mainly for patients with single secundum ASD with a stretched diameter of less than 50 percent of the diameter of the biggest available device and with adequate septal margin for proper device support. Anomalous pulmonary venous drainage or proximity of the defect to the atrioventricular (AV) valves, coronary sinus, or systemic venous drainage precludes the use of this technique. It is a safe and effective procedure in experienced hands, with major complications (e.g., device embolization, atrial perforation) occurring in less than 1 percent of patients and echo closure achieved in 85 percent or more of patients. Using "older" devices, silent residual shunts, more than half of which are trivial or mild, are still seen in 19 to 53 percent of patients at 6 to 12 months' follow-up.[17] Long-term follow-up data are not available.[17] Notwithstanding, device closure can be attractive to a patient wishing to avoid the consequences of surgery (general anesthesia, pain, and a scar) or to a patient believed to be at high surgical risk (see Fig. 43-12).

Surgery.

Surgical closure of ASDs can be performed by primary suture closure or using an autologous pericardial

Figure 44-2 Chest radiograph in an adult with ostium secundum atrial septal defect. Arrows point to the enlarged right and left pulmonary arteries. Note the increase in peripheral pulmonary perfusion.

or synthetic patch. The procedure is usually performed through a midline sternotomy, but the availability of an inframammary or minithoracotomy approach to a typical secundum ASD should be made known to potentially interested patients. Surgical mortality in the adult without pulmonary hypertension should be less than 1 percent with a low morbidity related mainly to the development of perioperative arrhythmias (atrial flutter/fibrillation or junctional rhythm).[12] [18] Surgical closure of an ASD improves functional status and exercise capacity in symptomatic patients[12] and improves survival, especially when patients are operated on at an earlier age.[13] [15] The incidence of late congestive heart failure is probably also reduced.[13] However, surgical closure of ASD does not prevent atrial fibrillation/flutter or stroke[13] especially when patients are operated on after the age of 40 years.[12] The role of a concomitant Cox/Maze procedure (see Chaps. 23 and 25) in patients older than the age of 40 years with a prior history of atrial flutter/fibrillation is unclear.[19] Patients with persistent atrial fibrillation should undergo anticoagulation.

Follow-Up.

Patients who have had surgical or device repair as adults, with or without elevated pulmonary artery pressures at the time of operation, patients with atrial arrhythmias preoperatively or postoperatively, and patients with ventricular dysfunction preoperatively should remain under long-term cardiology surveillance.

Isolated Ventricular Septal Defect (see also Chap. 43)

Ventricular septal defects (VSDs) are the second most common congenital malformation of the heart, accounting for approximately 20 percent of all congenital cardiac malformations. Surgical repair of large defects and spontaneous closure of smaller defects during childhood decrease the overall incidence of VSDs in adulthood.

ANATOMY.

The ventricular septum is composed of a muscular septum that can be divided into three major components (inlet, trabecular, and outlet) and a small membranous septum lying just underneath the aortic valve. VSDs are classified into three main categories according to their location and margins. *Muscular* VSDs are bordered entirely by myocardium and can be trabecular, inlet, or outlet in location. *Membranous* VSDs often have inlet, outlet, or trabecular extension and are bordered in part by fibrous continuity between the leaflets of an AV valve and an arterial valve. *Doubly committed subarterial* or *outlet* VSDs are situated in the outlet septum and are bordered by fibrous continuity of the aortic and pulmonary valves (see Fig. 43-15). In this section, we will deal with VSDs occurring in isolation from major associated cardiac anomalies.

NATURAL HISTORY OF THE UNOPERATED PATIENT.

A *restrictive* VSD is defined as a defect that produces a significant pressure gradient between the left ventricle and the right ventricle, is accompanied by a small (<1.5/1.0) shunt, and does not cause significant hemodynamic derangement. A *moderately restrictive* VSD is accompanied by a moderate shunt (Qp/Qs=1.5-2.5/1.0) and will pose a hemodynamic burden on the left ventricle. This will lead to left atrial and ventricular dilation and dysfunction as well as a variable increase in pulmonary vascular resistance. Important atrial arrhythmias and, less often, ventricular arrhythmias can occur. A large or *nonrestrictive* VSD results initially in left ventricular volume overload early in life with a progressive rise in pulmonary artery pressure. In turn, this leads to higher pulmonary vascular resistance and eventually irreversible pulmonary vascular changes and systemic pulmonary pressures, the so-called Eisenmenger syndrome (see p. 1614).

Spontaneous closure of a perimembranous VSD (from tricuspid leaflet tissue apposition) or of a small muscular VSD during adulthood is uncommon (<10 percent). Small VSDs pose an ongoing and relatively high risk of endocarditis.[20] Perimembranous or outlet VSDs can be associated with progressive aortic valve regurgitation due to prolapse of the aortic cusp(s) into the defect. Late development of subaortic and subpulmonary stenosis has also been reported.[21]

CLINICAL MANIFESTATIONS.

Most adult patients with a small *restrictive* VSD are asymptomatic. Physical examination reveals a harsh or high-frequency holosystolic murmur, usually grade 3 to 4/6, heard with maximal intensity at the left sternal border in the third or fourth intercostal space. Patients with a *moderately restrictive* VSD often present with dyspnea in adult life. Physical examination typically reveals a displaced cardiac apex with a similar holosystolic murmur as well as an apical diastolic rumble and third heart sound (S_3) at the apex from the increased flow through the mitral valve. Patients with large *nonrestrictive* VSDs are discussed in the section on Eisenmenger syndrome.

DIAGNOSTIC TESTING

Electrocardiogram.

The ECG mirrors the size of the shunt and the degree of pulmonary hypertension. Small *restrictive* VSDs usually produce a normal tracing. *Moderate-sized* VSDs produce a broad, notched P wave characteristic of left atrial overload as well as signs of left ventricular volume overload, namely, deep Q and tall R waves with tall T waves in lead V_5 and V_6 , and often atrial fibrillation. Large VSDs will produce right ventricular hypertrophy with right axis deviation (see section on Eisenmenger syndrome, p. 1614).

Chest Radiography.

The chest radiograph reflects the magnitude of the shunt as well as the degree of pulmonary hypertension. A moderate-sized shunt causes signs of left ventricular dilation with some pulmonary plethora. A large-sized shunt will over time produce pulmonary hypertension with enlarged central pulmonary arteries and peripheral

pruning (see section on Eisenmenger syndrome, p. 1614).

Echocardiography (see also Chap. 43).

TTE can identify the location, size, and hemodynamic consequences of the VSD as well as any associated lesions (aortic regurgitation, right ventricular outflow tract obstruction [RVOTO], or left ventricular outflow tract obstruction [LVOTO]).

INDICATIONS FOR INTERVENTION.

The presence of a significant VSD (the symptomatic patient; Qp/Qs > 1.5/1.0; pulmonary artery systolic pressure > 50 mm Hg; increased left ventricular and left atrial size, or deteriorating left ventricular function) in the absence of irreversible pulmonary hypertension warrants surgical closure.

If severe pulmonary hypertension is present (defined as pulmonary arteriolar resistance greater than two thirds of systemic arteriolar resistance), surgical closure can be safely undertaken if there is a net left-to-right shunt of at least 1.5/1.0, strong evidence of pulmonary reactivity when challenged with a pulmonary vasodilator (oxygen, nitric oxide), or lung biopsy evidence that pulmonary artery changes are reversible.

Other relative indications for VSD closure include the presence of a perimembranous or outlet VSD with more than mild aortic regurgitation and a history of endocarditis, especially if recurrent.[22]

INTERVENTIONAL OPTIONS

Surgery.

Surgical closure, by direct suture closure or with a Dacron patch, has been used for over 50 years with low perioperative mortality--even in adults--and a very high closure rate.[6]

Device Closure.

Successful transcatheter device closure of trabecular (muscular) and perimembranous VSDs has been reported.[23] Trabecular VSDs have proven more amenable to this technique because of their relatively straightforward anatomy and muscular rim to which the device attaches

well. The closure of perimembranous VSDs is technically more challenging and should be considered experimental.

INTERVENTIONAL OUTCOMES.

For patients with good to excellent functional class and good left ventricular function before surgical closure, life expectancy after surgical correction is close to normal. The risk of progressive aortic regurgitation is markedly reduced after surgery, as is the risk of endocarditis, unless a residual VSD persists. Intraventricular conduction disturbances are slightly increased after surgical closure and may be responsible for the slight increase in risk of sudden death encountered in this patient population.[24]

FOLLOW-UP.

Yearly cardiac evaluation is suggested for patients with associated cardiac lesions (RVOTO, LVOTO, aortic regurgitation) not undergoing surgical repair, Eisenmenger syndrome patients, and adults with significant atrial or ventricular arrhythmias. Cardiac surveillance is also recommended for patients who had late repair of moderate or large defects, which are often associated with left ventricular impairment and elevated pulmonary artery pressure at the time of surgery. Residual patch or device leaks are seldom hemodynamically important but can predispose to endocarditis. Maintenance of good dental hygiene and antibiotic prophylaxis in these patients is very important.

Atrioventricular Septal Defect (see also Chap. 43)

Unlike secundum ASDs, unoperated atrioventricular septal defects (AVSDs) are seldom first diagnosed in adults.

ANATOMY.

AVSDs comprise a spectrum of anomalies caused by abnormal development of the endocardial cushions, which may give rise to partial, intermediate, or complete AVSDs (Table 44-1) . In AVSD, the AV valves are fundamentally abnormal, being derived from five leaflets (a right anterosuperior leaflet, a right inferior leaflet, a superior bridging leaflet, an inferior bridging leaflet, and a left mural leaflet). This arrangement may result in separate but

TABLE 44-1 -- DEFINITIONS OF TYPES OF ATRIOVENTRICULAR SEPTAL DEFECTS (AVSD)

PARTIAL AVSD
Ostium primum ASD
Two separate AV valves
"Cleft" left AV valve
Intact ventricular septum
Rarely, no ASD with only a "cleft" in the left AV valve
Associated anomalies: Down syndrome (<10%), unroofed coronary sinus, left superior vena cava, and patent ductus arteriosus
INTERMEDIATE AVSD
Primum ASD
Restrictive VSD
Separate, abnormal AV valves
COMPLETE AVSD
Contiguous primum ASD
Nonrestrictive VSD
Common AV valve
Rastelli type A: Superior bridging leaflet with a cleft with chordal attchment to the crest of the ventricular septum
Rastelli type B: Superior bridging leaflet with a cleft with chordal attachment to a papillary muscle in the right ventricle
Rastelli type C: Superior bridging leaflet without a cleft and with no chordal attachment. The superior bridging leaflet is therefore "free floating." Associated anomalies include Down syndrome (>90%).

ASD=Atrial septal defect; *AV*=atrioventricular; VSD=ventricular septal defect.

Figure 44-3 Right- and left-sided atrioventricular valve in normal heart *(A),* partial atrioventricular septal defect *(B),* and complete atrioventricular septal defect *(C).* Rastelli type A: Superior bridging leaflet (RSL and LSL) has a cleft with ventricular septal attachment. Rastelli type B: Superior bridging leaflet has a cleft with right papillary muscle attachment. Rastelli type C: Superior bridging leaflet has no cleft and no attachment. New York, Churchill Livingstone, 1993.)*

abnormal right and left AV valves (primum and intermediate AVSD) or a common valve (complete AVSD) (Fig. 44-3) . The left AV valve is invariably abnormal, having a "cleft" at the conjunction of the superior and inferior bridging leaflets. Rarely, a double orifice left (mitral) AV valve is also encountered. The "unwedged" anteriorly located aorta, coupled to an apically displaced left AV valve (at the same level as the right AV valve), gives rise to an elongated left ventricular outflow tract, often characterized as a "gooseneck deformity." AVSD may occur in association with Down syndrome, tetralogy of Fallot, and other forms of complex congenital heart disease, including univentricular hearts.

NATURAL HISTORY OF THE UNOPERATED PATIENT

Partial and Intermediate AVSD.

Patients with partial and intermediate AVSDs have a course similar to that of patients with large secundum ASDs, with the caveat that symptoms may appear sooner when significant mitral regurgitation occurs through the cleft left AV valve. Patients are usually asymptomatic until their third or fourth decade, but progressive symptoms related to congestive heart failure, atrial arrhythmias, complete heart block, and variable degrees of pulmonary hypertension develop in virtually all of them by the fifth decade.

Complete AVSD.

Most patients with complete defects have had surgical repair in infancy. Some patients may have had palliative surgery in the past with pulmonary artery bands and have variable degrees of pulmonary vascular obstructive disease. When presenting de novo, most adults have established pulmonary vascular disease (see Eisenmenger Syndrome). Patients with Down syndrome have a propensity to develop pulmonary hypertension at an even earlier age than do other patients with AVSD.

Clinical Manifestations.

Clinical presentation depends on the presence and size of the ASD, on the VSD, and on the competence of the left AV valve. A large left-to-right shunt gives rise to symptoms of heart failure (dyspnea or fatigue on exertion) or, worse, pulmonary vascular disease (exertional syncope, cyanosis). Severe chronic left or right AV valve insufficiency leads to pulmonary congestion, hepatic congestion, and peripheral edema. Palpitations from atrial arrhythmias are very common. Down syndrome is seen in 35 percent of patients with AVSD. Almost all have the complete form. Cardiac findings on physical examination for patients with partial AVSD are similar to those of patients with secundum ASD, with the important addition of a prominent left ventricular apex and holosystolic murmur when significant left AV valve regurgitation is present. The murmur of left AV valve regurgitation can sometimes be heard radiating to the left sternal border if the regurgitant jet is directed into the right atrium (the Gerbode defect). Intermediate AVSDs resemble partial AVSD with the addition of a holosystolic VSD murmur heard best at the left sternal border, sometimes difficult to differentiate from a left AV valve regurgitant murmur. Complete AVSDs have a single first heart sound (S_1) (common AV valve), a mid-diastolic murmur from augmented AV valve inflow, and findings of pulmonary hypertension and/or a right-to-left shunt.

DIAGNOSTIC TESTING

Electrocardiogram.

Because of the posteriorly located AV node and hence the closer proximity of the left posterior fascicle, most patients have first-degree AV block and left-axis deviation from late left anterior fascicular depolarization. Complete AV block and/or atrial fibrillation/flutter can be present in older patients. Partial or complete right bundle branch block is usually associated with right ventricular dilation (Fig. 44-4) .

Chest Radiography.

Cardiomegaly and pulmonary plethora are the rule with an enlarged left atrium commonly present.

Echocardiography.

Echocardiography is essential to document the type of AVSD; assess the magnitude and direction of intracardiac shunting, the degree of AV valve regurgitation, the presence/absence of subaortic stenosis; and estimate pulmonary artery pressure (Fig. 43-13) . The lack of "offsetting" between the left and right AV valves (the right AV valve being apically displaced in normal hearts) is readily seen in the four-chamber view and is the echocardiographic hallmark of AVSD (Fig. 44-5) . TEE may be needed to further define the underlying anatomy of the defect (Rastelli type, see Table 44-1) and associated lesions (e.g., double orifice mitral valve) if unclear after TTE.

Cardiac Catheterization.

Heart catheterization to determine the severity of pulmonary vascular disease, the presence and magnitude of intracardiac shunts, and the severity of subaortic stenosis may be necessary. The typical "goose neck" deformity of the left ventricular outflow tract is readily demonstrated on angiography.

Open-Lung Biopsy.

This should only be considered when the reversibility of the pulmonary hypertension is uncertain from the hemodynamic data (see Eisenmenger Syndrome, p. 1614).

INDICATIONS FOR INTERVENTION.

The patient with an unoperated or newly diagnosed AVSD and significant hemodynamic defects, manifested by atrial arrhythmias and impaired ventricular function or right ventricular volume overload, requires surgical repair. Equally, patients with symptoms, reversible pulmonary hypertension, or significant

Figure 44-5 Transesophageal echocardiogram of intermediate atrioventricular septal defect illustrates the lack of offsetting between the left-sided and right-sided atrioventricular valves. Single arrow points at the primum atrial septal defect; double arrows point at the restrictive ventricular septal defect. RA\m4\right atrium; LA\m4\left atrium; RV\m4\right ventricle; LV\m4\left ventricle.

Figure 44-4 Typical electrocardiogram of partial atrioventricular septal defect shows first-degree atrioventricular block, left-axis deviation, and complete right bundle branch block.

subaortic obstruction (peak gradient of at least 50 mm Hg at rest) require surgical intervention.

INTERVENTIONAL OPTIONS

Partial AVSD.

Pericardial patch closure of the primum ASD with concomitant suture (±annuloplasty) of the "cleft" left AV valve is usually performed. When "mitral" valve repair is not

possible, "mitral" valve replacement may be necessary.

Intermediate/Complete AVSD.

The "staged approach" (pulmonary artery banding followed by intracardiac repair) has been supplanted by primary intracardiac repair. The goals of intracardiac repair are ventricular and atrial septation with adequate mitral and tricuspid reconstruction. Both "single" and "double" patch techniques to close atrial and ventricular septal defects have been described with comparable results.[25] "Tricuspidization" of the left AV "mitral" valve (making a trileaflet left AV valve) at the time of surgery has been advocated by some,[26] [27] but a bileaflet repair is preferred by most. [28] [29] Patch augmentation of the tissue-deficient "bridging leaflets" forming the mitral valve is sometimes performed.[30] Occasionally, left AV valve replacement is necessary when valve repair is not possible. In patients with complete heart block, endocardial transvenous pacing should be avoided when intraatrial or intraventricular communications are present, because paradoxical emboli may occur.

INTERVENTIONAL OUTCOMES.

Surgical mortality in adults with partial AVSDs varies between 0 and 6 percent with 5- and 10-year survivals of 87 percent and 72 percent, respectively.[31] [32] [32A] The worst outcome occurs in patients with pulmonary arterial hypertension, severe AV valve regurgitation,

and an enlarged heart.[32B] Improvement in functional class after surgical repair is the rule.[31] [32] Postoperative complications include patch dehiscence or residual septal defects (1 percent), the development of complete heart block (3 percent), late atrial fibrillation/flutter, left AV valve dysfunction, and progressive or de novo subaortic stenosis. Recurrent left AV valve regurgitation is the principal cause of late morbidity after surgical repair of AVSDs, necessitating reoperation in at least 10 percent of patients.[28] [29] [31] [32] [32A] [32B] [33] Left AV stenosis from overly zealous cleft suturing may occur. The development or progression of subaortic stenosis after AVSD surgery occurs in about 5 percent of cases.[34] The morphological features of AVSD (the long, narrow left ventricular outflow tract) promote actual or potential subaortic stenosis. Subaortic stenosis can be discrete or tunnel-like, and surgical repair is often necessary. An operation tailored to the underlying cause of obstruction has been advocated because of the high risk of recurrence after surgical resection[34] (see Subaortic Stenosis, p. 1599).

FOLLOW-UP.

All patients require periodic follow-up by a cardiologist because of the possibility of progressive AV valve regurgitation (or stenosis), the development of subaortic stenosis, significant atrial arrhythmias, or progression of the commonly present first-degree AV block. Particular attention should be paid to those patients with pulmonary hypertension, severe AV valve regurgitation, and an enlarged heart.

Patent Ductus Arteriosus (see also Chap. 43)

The incidence of isolated persistent patency of the ductus arteriosus has been estimated at 1:2000 to 1:5000 births, or about 10 to 12 percent of all varieties of congenital heart disease.

ANATOMY.

The ductus arteriosus derives from the left sixth primitive aortic arch and connects the proximal left pulmonary artery to the descending aorta, just distal to the left subclavian artery. Occasionally, the ductus fails to close at birth and presents as a potential clinical problem.

NATURAL HISTORY OF THE UNOPERATED PATIENT.

Physiological consequences of a patent ductus arteriosus (PDA) depend on the degree of left-to-right shunting, which is determined by both the size of the duct and the difference between systemic and pulmonary vascular resistances.[35] A small ductus accompanied by a small shunt does not cause significant hemodynamic derangement but may predispose to endarteritis, especially if accompanied by an audible murmur.[2] A moderate-sized duct and shunt pose a volume load on the left atrium and ventricle with resultant left ventricular dilation and dysfunction and eventual atrial fibrillation. A large duct results initially in left ventricular volume overload, with a progressive rise in pulmonary artery pressure leading to high pulmonary vascular resistance and eventually irreversible pulmonary vascular changes and systemic pulmonary pressures (see Eisenmenger Syndrome, p. 1614).

CLINICAL MANIFESTATIONS.

Patients with *silent* PDAs are asymptomatic, and the PDAs are detected by nonclinical means, usually echocardiography. A small audible duct usually causes no symptoms but may rarely present as an endovascular infection. Physical examination reveals a grade 1-2 continuous murmur, peaking in late systole, and best heard in the first or second left intercostal space. Patients with a moderate-sized duct may present with dyspnea or palpitations from atrial arrhythmias. A louder

Figure 44-6 Short-axis left parasternal transthoracic echocardiogram of systolic flow traveling toward the pulmonary valve (arrow) in the main pulmonary artery from a patent ductus arteriosus. RV\m4\right ventricle; RA\m4\right atrium; AV\m4\aortic valve; PV\m4\pulmonary valve; MPA\m4\main pulmonary artery; LPA\m4\left pulmonary artery; RPA\m4\right pulmonary artery.

continuous "machinery" murmur in the first or second left intercostal space is typically accompanied by a wide systemic pulse pressure from aortic diastolic runoff into the pulmonary trunk and signs of left ventricular volume overload, such as a displaced left ventricular apex and sometimes a left-sided S_3 . With a moderate degree of pulmonary hypertension, the diastolic component of the murmur disappears, leaving a systolic murmur. Adults with a large uncorrected PDA eventually present with Eisenmenger syndrome physiology (see p. 1614).

DIAGNOSTIC TESTING

Electrocardiogram.

The ECG reflects the size and degree of shunting occurring through the duct. A small duct produces a normal ECG. A moderate-sized duct may show left ventricular volume overload with broad, notched P waves together with deep Q waves, tall R waves, and peaked T waves in V_5 and V_6 . A large duct produces findings of right ventricular hypertrophy (see Eisenmenger syndrome, p. 1614).

Chest Radiography.

A small duct produces a normal chest radiograph. A moderate-sized duct causes moderate cardiomegaly with left-sided heart enlargement and increased pulmonary perfusion. A large duct produces right ventricular hypertrophy and enlarged central pulmonary arteries with peripheral pruning (see Eisenmenger syndrome, p. 1614).

Echocardiography.

This will determine the presence, size, and degree of shunting and the physiological consequences of the shunt. Suprasternal and parasternal short-axis views will best identify the duct. In the absence of Eisenmenger physiology, color flow Doppler shows a jet that travels on the lateral wall of the main pulmonary artery toward the pulmonary valve in systole and diastole (Fig. 44-6 ; see also Fig. 43-18). Direction and timing of the flow as well as the Doppler-derived gradient obtained from the jet provide estimates of the pulmonary artery pressure.

INDICATIONS FOR INTERVENTION.

Closure of a clinically detectable PDA, in the absence of irreversible pulmonary hypertension, is usually recommended to avoid its associated morbidity and premature mortality. The risk of endarteritis in a patient with a *silent* PDA is considered negligible, and closure of such ducts is not recommended for that reason.[2] In the presence

of pulmonary hypertension (PAP > two thirds of SAP, or pulmonary arteriolar resistance > two thirds of systemic arteriolar resistance), PDA closure should be carried out if there is a net pulmonary/systemic blood flow greater than 1.5/1.0, evidence of pulmonary artery reactivity when challenged with a pulmonary vasodilator (e.g., oxygen, nitric oxide), or lung biopsy evidence that pulmonary arterial changes are potentially reversible (Heath-Edwards grade II or less). Contraindications to ductal closure include irreversible pulmonary hypertension or active endarteritis.[2]

INTERVENTIONAL OPTIONS AND OUTCOMES

Transcatheter Treatment.

Over the past 20 years, the efficacy and safety of transcatheter device closure for ducts less than 8 mm has been established,[36] [37] [38] with complete ductal closure achieved in more than 85 percent of patients by 1 year after device placement at a mortality rate of less than 1 percent. The avoidance of general anesthesia, thoracotomy, postoperative pain, and prolonged convalescence makes transcatheter closure a very attractive modality. In centers with appropriate resources and experience, transcatheter device occlusion should be the method of choice for ductal closure (see Chap. 43 , Fig. 43-19).

Surgical Treatment.

Surgical closure, by ductal ligation and/or division, has been performed for over 50 years with a marginally greater closure rate than device closure but somewhat greater morbidity and mortality. Immediate clinical closure (no shunt audible on physical examination) is achieved in more than 95 percent of patients.[39] Surgical mortality in adults is 1.0 to 3.5 percent and relates to the presence of pulmonary artery hypertension and the difficult

ductal morphology (calcified or aneurysmal) often seen in adults. Surgical closure of a duct should be reserved for patients with larger ducts (> 8 mm diameter) or at centers without access to interventional expertise. Emerging procedures such as muscle-sparing minithoracotomy and video-assisted thoracoscopic surgery may further broaden therapeutic surgical choices in the future.

FOLLOW-UP.

Patients with a silent PDA do not require follow-up. Patients with device occlusion or after surgical closure should be examined periodically for possible recanalization. Silent residual shunts may be found by TTE. The risk of late endarteritis from a clinically silent residual shunt after device implantation or surgical closure is unclear,[40] [41] and the clinical management of such patients remains problematic. Until long-term follow-up data become available, it may be prudent to continue antibiotic endocarditis prophylaxis in such patients.[36] [40] [41]

Bicuspid Aortic Valve (see also Chap. 43)

The bicuspid aortic valve remains the most common congenital malformation of the heart (1-2 percent of the population). This lesion accounts for approximately half the cases of surgically important isolated aortic stenosis in adults.

ANATOMY.

A bicuspid aortic valve consists of two cusps, often of unequal size, the larger usually containing a false raphe. There is a male preponderance of 4:1. It usually occurs in isolation but is associated with other abnormalities in 20 percent, the most common being coarctation of the aorta and PDA. There is also a high prevalence of aortic root enlargement in patients with bicuspid aortic valve that occurs irrespective of altered hemodynamics or age.[42] [42A] [42B]

NATURAL HISTORY OF THE UNOPERATED PATIENT.

Patients with a bicuspid aortic valve may not experience any problems, although there is always the risk of endocarditis. Mild aortic stenosis from bicuspid aortic valve commonly progresses as the patient ages, but the rate is variable.[43] Late aortic stenosis from calcification of the valve in the sixth decade is common. Other patients can develop aortic regurgitation, aneurysmal aortic root dilation, and possibly aortic dissection.[44]

DIAGNOSTIC TESTING

Electrocardiogram.

The ECG ranges from normal to showing marked left ventricular hypertrophy from severe aortic stenosis or regurgitation. (see Fig. 43-31).

Chest Radiography.

Dilation of the ascending aorta is common. Valvar calcification can sometimes be detected. The left ventricle is enlarged in proportion to the degree of aortic regurgitation.

Echocardiography.

This permits identification of the bileaflet aortic valve and quantification of the severity of obstruction and/or regurgitation. It also provides information on left ventricular size and function as well as aortic root size. Concomitant defects such as coarctation or dissection of the aorta should be sought (see Fig. 43-32).

INDICATIONS FOR INTERVENTION.

Bicuspid aortic valves require intervention for stenosis when symptoms (exertional dyspnea, angina, presyncope or syncope) are present. Intervention for asymptomatic "critical" aortic stenosis (valve area<0.6 cm^2) is debatable. Patients with moderate or severe regurgitation associated with deteriorating ventricular function, a dilating ventricle, or symptoms are surgical candidates. Prophylactic surgery for proximal aortic dilation (> 55 mm) seems better than waiting for the aorta to dissect or rupture, although there is no agreement on the diameter at which referral for surgery is appropriate.

INTERVENTIONAL OPTIONS.

Bicuspid aortic stenosis can be treated with balloon valvuloplasty if the valve is noncalcified.[45] Other treatment options include open aortic valvotomy or valve replacement using a mechanical valve, a biological valve, or a pulmonary autograft. The pulmonary autograft (Ross procedure), introduced by Donald Ross in 1967, consists of replacing the aortic valve with the patient's pulmonary valve and implanting a homograft in the pulmonary position. The advantages of this procedure--avoidance of anticoagulation and much reduced risk of thromboembolism--need to be weighed against the greater technical complexity of the procedure, the risk of early and late autograft dysfunction, and homograft failure.[46] [47] The choice of intervention depends on the availability and skills of the team involved and the preference of the patient. Aortic valve repair has been reported for aortic regurgitation from a prolapsing aortic valve leaflet. Short-term results are promising, but long-term data are awaited.[48]

FOLLOW-UP.

All patients, treated and untreated, require skilled follow-up, the frequency being determined by the severity of the pathology.

Subaortic Stenosis (see also Chap. 43)

ANATOMY.

Subvalvar LVOTO can be either *discrete* (most common) or *tunnel* shaped. Discrete obstruction is due to a membranous ridge or fibromuscular narrowing partially or completely encircling the left ventricular outflow tract beneath the base of the aortic valve.[49] Tunnel-like obstruction is produced by a fibromuscular channel that involves a long segment of the left ventricular outflow tract and is usually associated with a small aortic root. Rarely, abnormal insertion of the mitral valve or an accessory mitral leaflet will cause subvalvar obstruction. Subvalvar LVOTO can also be seen after repair of AVSD (see p. 1596). The concurrence of subvalvar LVOTO, coarctation, and mitral stenosis (parachute mitral valve and supramitral ring) is known as Shone syndrome. VSD is sometimes associated with subvalvar LVOTO.

NATURAL HISTORY OF THE UNOPERATED PATIENT.

Subvalvar LVOTO, discrete or tunnel-like, usually progresses at variable rate, resulting in left ventricular hypertrophy and the development of symptoms.[50] It is often associated with progressive aortic regurgitation (up to 60 percent of cases) from a bicuspid aortic valve or an otherwise normal valve damaged by the subvalvar jet of blood. Aortic regurgitation in this setting is seldom more than moderate. These patients are particularly vulnerable to endocarditis.

CLINICAL MANIFESTATIONS.

Patients can be asymptomatic or can present with angina, syncope, or heart failure. On examination, the pulse pressure may be diminished if the obstruction is severe. A_2 may be normal or diminished depending on the severity of the stenosis. A systolic ejection murmur may be heard at the mid-left sternal edge in cases of tubular stenosis and in the second right intercostal space in cases of discrete stenosis. A blowing diastolic murmur from concomitant aortic regurgitation is often present. A systolic ejection click is not present in subvalvar aortic stenosis, and the systolic murmur does not radiate to the carotid arteries.[51]

DIAGNOSTIC TESTING

Electrocardiogram.

Left ventricular hypertrophy may be present.

Chest Radiography.

An inconspicuous cardiac silhouette and ascending aorta are the rule unless LVOTO is associated with a bicuspid aortic valve (see bicuspid valve/ascending aortopathy) or significant aortic regurgitation.

Echocardiography.

Two-dimensional echocardiography permits identification of the morphology of the obstruction and any associated anomalies (e.g., bicuspid aortic valve, VSD, coarctation, or mitral inflow obstruction).[52] The severity

of LVOTO can be determined by continuous-wave Doppler and the severity of aortic regurgitation by Doppler and color flow imaging.

Angiography.

An angiogram to assess the severity of obstruction may be needed when noninvasive means are not adequate.

INDICATIONS FOR INTERVENTION.

Whereas patients with symptomatic subvalvar LVOTO require intervention, indications for intervention in asymptomatic patients are less well defined. A resting peak-to-peak angiographic gradient greater than 50 mm Hg as well as progressive or moderate to severe aortic regurgitation have been used as criteria for intervention.[6] Some advocate earlier relief of subvalvar obstruction to minimize early aortic valve damage and prevent progressive regurgitation.[53]

INTERVENTIONAL OPTIONS

Surgical.

For discrete obstruction, membranectomy with concomitant myomectomy or myotomy is usually performed. For tunnel-like obstruction, the left ventricular outflow tract often requires surgical augmentation using the modified Konno procedure (aortoventriculoplasty with aortic valve sparing).[54] In patients with significant aortic stenosis or moderate/severe aortic regurgitation, the Konno procedure (aortoventriculoplasty with aortic valve replacement) or the Konno-Ross procedure (aortoventriculoplasty with pulmonary autograft)[55] for younger patients or those with a contraindication to anticoagulation should be performed. Left ventricular apex-to-aorta valved conduits, bypassing the LVOTO, have been used in the past, but the long-term durability is unacceptable and the procedure has largely been abandoned.

Transcatheter.

Transluminal balloon dilation of discrete subaortic stenosis has been described with good short- and intermediate-term results,[56] but long-term data have not been reported. At present, a surgical approach is still recommended.

INTERVENTIONAL OUTCOMES.

Complications related to surgery include complete AV block, creation of VSD, or mitral valve regurgitation from intraoperative damage to the mitral valve apparatus. Long-term complications include recurrence of fibromuscular subvalvar LVOTO (up to 20 percent), particularly with tunnel-like obstruction or following isolated membranectomy for discrete obstruction. Clinically important aortic regurgitation is also not uncommon (up to 25 percent of patients).

FOLLOW-UP.

Particular attention should be paid to patients with recurrent subvalvar stenosis or patients with an associated bicuspid aortic valve or progressive aortic regurgitation because they are most likely to require eventual surgery. Patients with bioprosthetic aortic valves in the aortic position (after the Konno procedure) or the pulmonic position (after the Konno-Ross procedure) need close follow-up. Reoperation is required in up to 25 percent of patients in the 20 years[57] [58] after surgical repair. Endocarditis prophylaxis should be used for prosthetic valves or in the presence of any residual lesions.

Coarctation of the Aorta (see also Chap. 43)

This left-sided obstructive lesion occurs most frequently in males, with a sex ratio approaching 3:1.

ANATOMY.

Coarctation of the aorta is a narrowing usually in the region of the ligamentum arteriosum (see Fig. 43-27). It may be discrete or associated with hypoplasia of the aortic arch and isthmus. The specific anatomy, severity, and degree of hypoplasia proximal to the coarctation are highly variable. "Complex" coarctation is used to describe coarctation in the presence of other important intracardiac anomalies (e.g., VSD, LVOTO, and mitral stenosis) and is usually detected in infancy. "Simple"

coarctation refers to coarctation in the absence of such lesions. It is the most common form detected de novo in adults. Associated abnormalities include bicuspid aortic valve in 50 to 85 percent of cases, intracranial aneurysms (most commonly of the circle of Willis), and acquired intercostal artery aneurysms. One definition of "significant" coarctation is one with a gradient greater than 20 mm Hg across the coarctation site at angiography with or without proximal systemic hypertension. A second definition of "significant" coarctation requires the presence of proximal hypertension in the company of echocardiographic or angiographic evidence of aortic coarctation. Of note, if there is an extensive collateral circulation, there may be minimal or no pressure gradient and acquired aortic atresia.

NATURAL HISTORY OF THE UNOPERATED PATIENT.

A significant coarctation causes a pressure load proximally with consequent left ventricular hypertrophy and ultimately heart failure. Most patients will develop systemic hypertension, typically during childhood, and are at risk of premature coronary artery disease. The mean survival of patients with untreated coarctation is 35 years, with 75 percent mortality by 50 years of age.[59] Death in patients who do not undergo repair is usually due to heart failure (usually beyond 30 years of age), coronary artery disease, aortic rupture/dissection, concomitant aortic valve disease, infective endarteritis/endocarditis, or cerebral hemorrhage.[59]

CLINICAL MANIFESTATIONS.

Patients may be asymptomatic or present with minimal symptoms of epistaxis, headache, leg weakness on exertion, or more serious symptoms of congestive heart failure, angina, aortic stenosis, aortic dissection, or unexplained intracerebral hemorrhage. Leg claudication is rare unless there is concomitant abdominal aortic coarctation (Somerville J, personal communication, 1998). A thorough clinical examination reveals upper limb systemic hypertension as well as a differential systolic blood pressure of at least 10 mm Hg (brachial > popliteal artery pressure). Radial-femoral pulse delay is evident unless significant aortic regurgitation coexists. Auscultation may reveal an interscapular systolic murmur emanating from the coarctation site and a widespread crescendo-decrescendo systolic murmur throughout the chest wall from intercostal collateral arteries. Fundoscopic examination can reveal "corkscrew" tortuosity of retinal arterioles. [60]

DIAGNOSTIC TESTING

Electrocardiogram.

Left ventricular hypertrophy is common. Concomitant left atrial enlargement may be present.

Chest Radiography.

Prestentotic and poststenotic dilation of the aorta gives the "3 sign" appearance on a chest radiograph. Rib notching appearing as sclerotic scalloping on the inferior surface of ribs number 3 through 8 from dilated intercostal arteries may be present, usually bilaterally, unless the left or right subclavian artery arises aberrantly below the coarctation, giving rise to unilateral right-sided or left-sided rib notching, respectively.

Echocardiography.

The coarctation site can be visualized from the suprasternal view and its severity assessed by Doppler mode (see Fig. 43-28). A peak gradient greater than 20 mm Hg, especially if accompanied by continuous forward flow during diastole in the descending or abdominal aorta, suggests significant aortic coarctation. In addition, the echocardiographer should evaluate other cardiac lesions--notably aortic, mitral, or subaortic abnormality and the status of left ventricular function.

Angiography.

Angiography with hemodynamic measurements can be done to assess the location, type, and severity of coarctation and to determine the presence/absence of collaterals or aneurysm formation. Associated stenoses in other great vessels (carotids and subclavian arteries) can also be detected by this modality. Coronary angiography should be performed if surgery is planned because of the risk of premature coronary artery disease in these patients.

Magnetic Resonance Imaging (MRI).

MRI (two-dimensional and velocity mapping) provides as good anatomical and hemodynamic details as angiography and may obviate the need for angiography, unless coronary artery disease needs to be excluded.

INDICATIONS FOR INTERVENTION.

All patients with significant coarctation or re-coarctation (arm > leg systolic pressure difference
10 mm Hg; radial-femoral pulse delay; peak transcoarctation gradient > 20 mm Hg at angiography) including those with long-standing hypertension (regardless of age), whether symptomatic or asymptomatic, warrant intervention to reduce or eliminate the gradient.[59]

INTERVENTIONAL OPTIONS

Surgical.

Surgical techniques include end-to-end repair, subclavian flap plasty, patch repair, interposed graft, or bypass graft and varies according to the underlying anatomy of the coarctation.[61] Patients with significant aortic valve stenosis may also require valve surgery that may or may not be done at the same time as coarctation repair. If lesions are operated on separately, the more severe lesion should be dealt with first.

Transcatheter.

Balloon dilation with or without stent insertion in patients with native coarctation and re-coarctation has been performed with good immediate and medium-term results in children and adolescents.[62] [63] [64] However, it should still be considered experimental in the adult population and should only be performed in centers and by individuals with expertise in this domain (Fig. 44-7) .

INTERVENTIONAL OUTCOMES

Surgical.

After surgical repair of simple coarctation, the obstruction is usually relieved with minimal mortality (<1 percent). Paraplegia due to spinal cord ischemia is uncommon (0.4 percent) and may occur in patients who do not have well-developed collateral circulation. The prevalence of recoarctation reported in the literature varies widely, from 7 to 60 percent depending on the definition used, the length of follow-up, and the age at surgery.[65] The appropriateness of the surgical repair for a given anatomy is probably the main factor dictating the chance of recoarctation, rather than the type of surgical repair itself.[66] True aneurysm formation at the site of coarctation repair is also a well-recognized entity with a reported incidence between 2 and 27 percent.[67] Aneurysms are particularly common after Dacron patch aortoplasty and usually occur in the native aorta opposite the patch. Late dissection at the repair site is rare but false aneurysms, usually at the suture line, can occur.

Prior hypertension resolves in up to 50 percent of patients but may recur later in life, especially if the intervention is performed at an older age. In some of these patients this may be "essential hypertension," but a hemodynamic basis should be sought and blood pressure control attained. Systolic hypertension is also common with exercise and may be related to residual arch hypoplasia or more likely to increased renin and catecholamine activity from residual functional abnormality of the precoarctation vessels.[69] [70] Late cerebrovascular events occur, notably in those patients undergoing repair as adults and in those with residual hypertension. Endocarditis/endarteritis can occur at the coarctation site or on intracardiac lesions; and if this occurs at the coarctation site, embolic manifestations are restricted to the legs.

Long-term follow-up after surgical correction of coarctation of the aorta still reveals an increased incidence of premature cardiovascular disease and death.

Transcatheter.

After balloon dilation, aortic dissection, restenosis, and aneurysm formation at the site of coarctation have all been documented.[62] [63] [64] These complications may well be reduced if stents are used. The significance of aneurysm formation is unknown,[68] and longer-term data are needed.

FOLLOW-UP.

All patients should have follow-up every 1 to 3 years. Particular attention should be directed toward residual hypertension, heart failure, or intracardiac disease, such as an associated bicuspid aortic valve, which can become stenotic or regurgitant later in life, or an ascending aortopathy (due to cystic medial necrosis) sometimes seen in the presence of bicuspid aortic valve. Complications at the site of repair such as restenosis and aneurysm formation should also be sought using clinical examination, chest radiography, echocardiography, or, preferably, MRI.[68A] Patients with Dacron patch repair should probably undergo an MRI or spiral computed tomographic (CT) examination every 3 to 5 years or so to detect subclinical aneurysm formation. Hemoptysis from a leaking/ruptured aneurysm is a serious complication requiring immediate investigation

Figure 44-7 Angiograms of coarctation of the thoracic aorta *(A)* and transcatheter stent placement in the treatment of coarctation of the aorta *(B).*

and surgery. New or unusual headaches should raise the possibility of berry aneurysm. Endocarditis prophylaxis is recommended for any residual turbulent flow.

Right Ventricular Outflow Tract Obstruction (see also Chap. 43)

Right ventricular outflow tract obstruction (RVOTO) can occur at supravalvar, valvar, and subvalvar levels.

ANATOMY.

Supravalvar RVOTO seldom occurs in isolation. It may occur in tetralogy of Fallot, Williams syndrome, Noonan syndrome, VSD, or arteriohepatic dysplasia (Alagille syndrome) (Table 44-2) . *Branch* pulmonary artery stenosis may occur in the setting of congenital rubella syndrome and tetralogy of Fallot. *Subvalvar* (infundibular) RVOTO usually occurs in combination with other lesions, particularly ventricular septal defect, as part of tetralogy of Fallot, or in association with subaortic stenosis. The "*double-chambered right ventricle*" is different from infundibular RVOTO. It consists of a midcavity obstruction, often from a prominent moderator band, and may be associated with a small VSD. *Valvar* RVOTO (pulmonic stenosis) is the most common form of RVOTO. It is almost always congenital in origin. It usually occurs as an isolated anomaly but it can be part of a syndrome (see Table 44-2). Typically, the stenotic pulmonic valve is a thin, pliable, dome-shaped structure, with a narrow opening at its apex. In 15 percent of cases, the stenotic valve is dysplastic with thickened and immobile cusps. The severity of stenosis is classified by the level of the peak systolic pressure gradient (Table 44-3) .

NATURAL HISTORY OF THE UNOPERATED PATIENT.

Supravalvar RVOTO can progress in severity and should be monitored. *Subvalvar* (infundibular and double-chamber) RVOTO often progresses in severity, causing worsening right ventricular hypertrophy, symptoms, and critical gradients requiring surgical repair. Patients with trivial and mild *valvar* RVOTO rarely become worse with time. [71] Moderate valvar RVOTO can progress in 20 percent of unoperated

TABLE 44-2 -- SYNDROMES ASSOCIATED WITH PULMONARY VALVE STENOSIS

Williams Syndrome
Cardiac: Pulmonary stenosis, pulmonary artery stenosis, supravalvar aortic stenosis
CNS: Mental retardation, "cocktail personality"
Facies: Small chin, large mouth, upturned and blunt nose, wide-set eyes, broad forehead, baggy cheeks, and malformed teeth
Other: Infantile hypercalcemia, short stature
Noonan Syndrome
Cardiac: Dysplastic pulmonary stenosis, hypertrophic cardiomyopathy, atrial septal defect
CNS: Mental retardation (1 in 3 patients)
Facies: Short webbed neck, low-set ears, low posterior hair line, high-arched palate, micrognathia, eye abnormality (ptosis/hypertelorism)
Other: Short stature; thoracic, penile, and testicular abnormality
Congenital Rubella
Cardiac: Pulmonary stenosis, pulmonary artery stenosis, patent ductus arteriosus
CNS: Mental retardation, hypotonia, hearing loss
Facies: Cataracts, retinopathy
Alagille Syndrome
Cardiac: Pulmonary stenosis, pulmonary arterial stenosis
Facies: Prominent overhanging forehead, deep-set eyes, small pointed chin

TABLE 44-3 -- HEMODYNAMIC SEVERITY GRADING FOR RIGHT VENTRICULAR OUTFLOW TRACT OBSTRUCTION (PEAK GRADIENT)

Trivial	<25 mm Hg
Mild	25-49 mm Hg
Moderate	50-79 mm Hg
Severe or critical	>80 mm Hg

patients, especially as adults because of calcification of the valve, and may require intervention.[71] Some of these patients can also become symptomatic, particularly in later life, because of atrial arrhythmias resulting from right ventricular pressure overload and tricuspid regurgitation. Patients with severe valvar RVOTO will have had valvotomy (balloon or surgical) to survive to adult life. Long-term survival in patients with repaired pulmonic valvar stenosis is similar to that of the general population, with excellent to good functional class at long-term follow-up in the vast majority of patients.[71]

CLINICAL MANIFESTATIONS.

Patients with isolated mild to moderate RVOTO of any type are usually asymptomatic. Patients with severe RVOTO may present with exertional fatigue, dyspnea, lightheadedness, and chest discomfort (right ventricular angina). Physical examination may reveal a prominent jugular a wave, a right ventricular lift, and possibly a thrill in the second left interspace. Auscultation reveals a normal S_1 , a split second heart sound (S_2) with a diminished pulmonic component (P_2) (unless the obstruction is supravalvular in which case the intensity of the P_2 does not change), and a systolic ejection murmur best heard in the second left intercostal space. When the pulmonic valve is thin and pliable, a systolic ejection click, which decreases on inspiration, is heard. As the severity of stenosis progresses, the interval between the

S_1 and the systolic ejection click becomes shorter, the S_2 becomes widely split, the P_2 diminishes or disappears (but remains the same if the obstruction is supravalvular), and the systolic ejection murmur lengthens and peaks later in systole, often extending beyond the aortic component of the S_2 (A_2). An ejection click seldom occurs with dysplastic pulmonic stenosis or subvalvar or supravalvar RVOTO. Typically, the systolic murmur of subvalvar stenosis is located lower on the left chest (third to fifth intercostal space) and that of supravalvular stenosis (pulmonary artery/branches stenosis) has a wide thoracic distribution. Mild cyanosis may be present when a patent foramen ovale or ASD permits right-to-left shunting.

DIAGNOSTIC TESTING

Electrocardiogram.

A peaked P wave consistent with right atrial overload and evidence of right ventricular hypertrophy may be present.

Chest Radiography.

Dilation of the main and left pulmonary arteries is the radiographic hallmark of valvar pulmonary stenosis. Pulmonary valvar calcification occasionally is seen. Dilation of the pulmonary trunk is not a feature of subvalvar and supravalvar RVOTO. Peripheral pulmonary vascular markings may be diminished when RVOTO is severe.

Echocardiography.

Echocardiography is useful to document the level(s) of obstruction and quantitate the severity (see Fig. 43-42). Associated abnormalities such as ASD, PDA, VSD, and tetralogy of Fallot can be identified.

Diagnostic Catheterization.

Cardiac catheterization can be useful to assess the hemodynamics and severity of obstruction as well as to delineate the extent and site of pulmonary artery branch stenoses.

INDICATIONS FOR INTERVENTION.

Intervention is recommended when the peak gradient across the right ventricular outflow tract is more than 50 mm Hg at rest[2] [72] or when the patient is symptomatic. Intervention may be indicated

occasionally for other reasons (e.g., a person with a lesser degree of obstruction who wishes to play vigorous sports, scuba dive, or become pregnant). An associated ASD should be closed at the time of intervention.

INTERVENTIONAL OPTIONS

Balloon Valvuloplasty.

Balloon valvuloplasty is the treatment of choice for valvar RVOTO. It is a highly effective procedure that can be carried at low risk.[73]

Surgical Valvotomy.

Surgical valvotomy may be required for pulmonary stenosis when the valve is calcified or dysplastic.[74] Pulmonary valvectomy or pulmonary valve replacement is seldom performed.

Relief of peripheral pulmonary stenosis can be accomplished by balloon dilation with or without stent placement.

Relief of obstruction in a double-chambered right ventricle is accomplished by surgical resection of right ventricular muscle bands.

INTERVENTIONAL OUTCOMES

Balloon Valvuloplasty.

The prognosis and outcomes of pulmonic valvuloplasty compare favorably with those of surgical valvotomy.[75] A 55 to 75 percent immediate reduction in transvalvular gradient is the rule, and usually the benefit persists at up to 9 years of follow-up. After pulmonic valvuloplasty, dynamic RVOTO from residual subvalvular hypertrophy is sometimes seen but usually regresses by 3 to 12 months and can be treated with a beta blocker in the meantime.[76] Severe pulmonic regurgitation as a consequence of valvuloplasty is rare. The results of balloon dilation for dysplastic pulmonary valves are less satisfactory.[74]

Surgical Valvotomy.

The long-term results of surgical pulmonary valvotomy are well known and excellent. Relief of valvar RVOTO is usually permanent, but residual obstruction can progress. Significant pulmonary regurgitation is reportedly more frequent after surgery and can become severe enough to warrant re-intervention.

Subvalvar and supravalvar RVOTO seldom recur after adequate intervention.

FOLLOW-UP.

Patients with moderate or greater RVOTO require annual monitoring because intervention or re-intervention may be required. After intervention, severe pulmonic regurgitation associated with reduced exercise capacity, arrhythmias, or evidence of deteriorating right ventricular function may necessitate pulmonary valve replacement.

Ebstein Anomaly (see also Chap. 43)

ANATOMY.

Ebstein anomaly results from apical displacement of the septal, posterior, or (rarely) anterior leaflet of the tricuspid valve, resulting in "atrialization" (functioning as an atrial chamber) of the inflow tract of the right ventricle and consequently a variably small functional right ventricle (Figs. 7-89 , and 44-55). Varying degrees of tricuspid regurgitation (or in exceptional cases tricuspid stenosis) result from this abnormal tricuspid leaflet morphology with consequent further right atrial enlargement. Infundibular dilation can also be present. Associated anomalies include patent foramen ovale or ASD in approximately 50 percent of patients, accessory conduction pathways in 25 percent, and, occasionally, varying degrees of RVOTO, VSD, coarctation of the aorta, PDA, or mitral valve disease.

Natural History of the Unoperated Patient.

The natural history of patients with Ebstein anomaly depends on its severity.[77] Adults with Ebstein anomaly can remain asymptomatic throughout their life if the anomaly is mild--survival to the ninth decade has been reported. With moderate tricuspid valve deformity and dysfunction, patients will usually develop symptoms

during late adolescence or young adult life.

Figure 44-8 (Figure Not Available) Diagrammatic representation of Ebstein anomaly. RA=right atrium; RV=right ventricle; LA=left atrium; LV=left ventricle; Ao=aorta; PA=pulmonary artery. *(From Mullins CE, Mayer DC: Congenital Heart Disease: A Diagrammatic Atlas. New York, Wiley-Liss, 1988.)*

Clinical Manifestations.

Most adult patients present with exercise intolerance (dyspnea and fatigue), palpitations of supraventricular origin, or cyanosis from a right-to-left shunt at the atrial level.[1] Occasionally, a paradoxical embolus resulting in a transient ischemic attack or cerebrovascular accident can call attention to the diagnosis. End-stage right-sided cardiac failure from severe tricuspid regurgitation and right ventricular dysfunction is possible. Sudden death (presumed to be arrhythmic in nature) is known to occur.[78] Physical examination reveals an unimpressive jugular venous pressure because of the large and compliant right atrium and atrialized right ventricle, a widely split S_1 with a loud tricuspid component (the "sail sound"), a widely split S_2 from the right bundle branch block, and a right-sided S_3 . A holosystolic murmur increasing on inspiration from tricuspid regurgitation is best heard at the lower left sternal border. Cyanosis from a right-to-left shunt at the atrial level may or may not be present.[79]

DIAGNOSTIC TESTING

Electrocardiogram.

The ECG presentation of Ebstein anomaly varies widely. Low voltage is typical. Peaked P waves in lead II and V_1 reflect right atrial enlargement. The PR interval is usually prolonged, but a short PR interval and a delta wave from early activation through an accessory pathway can be present. An rsr pattern consistent with right ventricular conduction delay is typically seen in lead V_1 (Fig. 44-9) . Atrial flutter and fibrillation are common. Alternatively, the ECG may be normal.

Chest Radiography.

A rightward convexity from an enlarged right atrium and atrialized right ventricle coupled with a leftward convexity from a dilated infundibulum give the heart a "water bottle" appearance on a chest radiograph. Cardiomegaly, highly variable in degree, is the rule. The aorta and the pulmonary trunk are inconspicuous. The pulmonary vasculature is usually normal to reduced.

Echocardiography.

The diagnosis of Ebstein anomaly can often be made by echocardiography. Apical displacement of the septal leaflet of the tricuspid valve by 8 mm/m^2 or more, combined with an elongated sail-like appearance of the anterior leaflet, confirms the diagnosis[80] (Figs. 44-10 , 7-90 , and 43-56). The size of the atrialized portion of the right ventricle (identified between the tricuspid annulus and the ventricular attachment of the tricuspid valve leaflets)

Figure 44-9 Electrocardiogram typical of Ebstein anomaly. Accessory pathway exemplified by the short PR interval, delta wave, and wide QRS complex. Note the peaked P wave in V_2 representing right atrial overload.

and the systolic performance of the functional right ventricle can be determined. The degree of tricuspid regurgitation (and more rarely stenosis) can be assessed. Associated defects such as ASDs as well as the presence and direction of shunting can also be identified.

Angiography.

Heart catheterization is required mainly when concomitant coronary artery disease is suspected. When performed, selective right ventricular angiography shows the extent of tricuspid valve displacement, the size of the functional right ventricle, and configuration of its outflow tract.

INDICATIONS FOR INTERVENTION.

Indications for intervention include deteriorating functional capacity (NYHA Class III), progressive cyanosis, right-sided heart failure, and the occurrence of paradoxical emboli. Recurrent supraventricular arrhythmias not controlled by medical or ablation therapy (see Chap. 23) and asymptomatic cardiomegaly (cardiothoracic ratio > 65 percent) are relative indications.[78] [81]

INTERVENTIONAL OPTIONS.

Tricuspid valve repair when feasible is preferable to tricuspid valve replacement. The feasibility of tricuspid valve repair depends primarily on the experience and skill of the surgeon, as well as on the adequacy of the anterior leaflet of the tricuspid valve to form a monocusp valve.[81] [82] Tricuspid valve repair is possible when the edges of the anterior leaflet of the tricuspid valve are not severely tethered down to the myocardium and when the functional right ventricle is of adequate size (>35 percent of the total right ventricle). If the tricuspid valve cannot be repaired, valve replacement with either a bioprosthetic or mechanical tricuspid valve is necessary. It is controversial whether the atrialized portion of the right ventricle should be plicated at the time of surgery to reduce the risk of atrial arrhythmias. For "high-risk" patients (those with severe tricuspid regurgitation, an inadequate functional right ventricle [because of size or function], and/or chronic supraventricular arrhythmias), a bidirectional cavopulmonary connection can be added to reduce right ventricular preload (see Glen procedure, Chap. 43).[83] Occasionally, a Fontan operation may be the best option in patients with tricuspid stenosis and/or hypoplastic right ventricle (see Fontan operation, p. 1607). Concomitant right atrial maze procedure at the time of surgery should be considered in patients with chronic atrial flutter/fibrillation.[84] If an accessory pathway is present, it should be mapped and obliterated either at the time of surgical repair or preoperatively in the catheter laboratory (see Chaps. 23 and 25). An atrial communication, if present, should be closed.

INTERVENTIONAL OUTCOMES.

With satisfactory valve repair, with or without plication of the atrialized right ventricle or bidirectional cavopulmonary connection, the medium-term prognosis is excellent.[81] [82] Late arrhythmias can occur. With valve replacement, results are less satisfactory. Valve re-replacement may be necessary because of a failing bioprosthesis or thrombosed mechanical valve. Long-term anticoagulation with mechanical valves is mandatory. Complete heart block after tricuspid valve replacement can occur.

FOLLOW-UP.

All patients with Ebstein anomaly should have regular follow-up, the frequency dictated by the severity of their disease. Particular attention should be paid to patients with cyanosis, cardiomegaly, worsening right ventricular function, and important atrial arrhythmias. Patients with tricuspid regurgitation after tricuspid valve repair need close follow-up, as do patients with recurrent atrial arrhythmias, degenerating bioprostheses, or dysfunctional mechanical valves.

Tetralogy of Fallot (see also Chap. 43)

Tetralogy of Fallot is the most common form of cyanotic congenital heart disease after 1 year of age, with an incidence approaching 10 percent of all forms of congenital heart disease.

ANATOMY.

The defect is due to anterocephalad deviation of the outlet septum resulting in four features: (1) nonrestrictive VSD; (2) overriding aorta (but<50 percent); (3) RVOTO, which may be infundibular, valvar, or (usually) a combination of both, with or without supravalvar or branch pulmonary artery stenosis; and (4) consequent right ventricular hypertrophy. The so-called pentalogy of Fallot also has an ASD. Accompanying features can include additional VSDs, anomalous coronary arteries, right-sided aortic arch, PDA, aortic root dilation, aortic regurgitation, and aortopulmonary collaterals (Figs. 44-11 (Figure Not Available) and 43-47).

NATURAL HISTORY OF THE UNOPERATED PATIENT.

To reach adulthood, most patients will have had surgery, either palliative or, more commonly, reparative. A few patients however will present as adults with uncorrected tetralogy of Fallot. Natural survival into the fourth decade is rare (approximately 3 percent).

SURGICAL PROCEDURES.

These are usually done in childhood.

Palliation.

Palliative procedures in tetralogy of Fallot serve to increase pulmonary blood flow. The types of palliative procedures include the Blalock-Taussig shunt (classic or modified--subclavian artery to pulmonary artery end-to-side shunt or interposition graft), Waterston shunt (ascending aorta to right pulmonary artery shunt), Potts shunt (descending aorta to left pulmonary artery shunt), or a central interposition tube graft (see shunt procedure, Chap. 43). The Brock procedure (infundibular resection), pulmonary valvotomy, or right ventricle to pulmonary artery conduit without VSD closure or with fenestrated closure were occasionally performed.

Repair.

Reparative surgery involves closing the VSD with a Dacron patch and relieving the RVOTO. The latter

Figure 44-11 (Figure Not Available) Diagrammatic representation of tetralogy of Fallot. 1, Pulmonary stenosis; 2, ventricular septal defect; 3, overriding aorta; 4, right ventricle hypertrophy. RA=right atrium; RV=right ventricle; LA=left atrium; LV=left ventricle; Ao=aorta; PA=pulmonary artery. *(From Mullins CE, Mayer DC: Congenital Heart Disease: A Diagrammatic Atlas. New York, Wiley-Liss, 1988.)*

Figure 44-12 (Figure Not Available) Diagrammatic representation of the surgical repair of tetralogy of Fallot. Patch closure of ventricular septal defect (1); right ventricular outflow/main pulmonary artery outflow patch (transannular patch) (2). RA=right atrium; RV=right ventricle; LA=left atrium; LV=left ventricle; Ao=aorta; PA=pulmonary artery. *(From Mullins CE, Mayer DC: Congenital Heart Disease: A Diagrammatic Atlas. New York, Wiley-Liss, 1988.)*

may involve resection of infundibular muscle and insertion of a right ventricular outflow tract or transannular patch--a patch across the pulmonary valve annulus that disrupts the integrity of the pulmonary valve and causes important pulmonary regurgitation (Fig. 44-12) (Figure Not Available) . Occasionally, the pulmonic valve is replaced with a pericardial monocusp valve. When an anomalous coronary artery crosses the right ventricular outflow tract and precludes transection of the latter, an extracardiac conduit is placed between the right ventricle and pulmonary artery, bypassing the RVOTO. A patent foramen ovale or secundum ASD is closed. Additional treatable lesions such as muscular VSDs, PDA, and aortopulmonary collaterals should also be addressed at the time of surgery or in the catheterization laboratory.

CLINICAL MANIFESTATIONS

Unoperated.

The pathophysiology varies depending on the degree of RVOTO. With mild obstruction, the presentation is of increased pulmonary blood flow and minimal cyanosis, the so-called pink, or acyanotic, tetralogy of Fallot. This is a rare presentation in adults. Progressive cyanosis from worsening RVOTO along with cerebrovascular accidents, endocarditis, supraventricular arrhythmias, and aortic regurgitation are the most common presenting features. On physical examination, the length and loudness of the systolic murmur are inversely related to the severity of the RVOTO. As the RVOTO increases toward occlusion, the right ventricular blood flow is directed through the VSD into the aorta and the pulmonic stenosis murmur becomes shorter and softer.[85] P_2 is faint and delayed in patients with mild cyanosis and inaudible with severe cyanosis. An ejection sound from aortic dilation and a diastolic murmur from consequent aortic regurgitation can be heard. Central cyanosis and clubbing are present to varying degrees.

Palliated.

Progressive cyanosis with its complications (see p. 1608) can result from worsening RVOTO, gradual stenosis and occlusion of palliative aorto-pulmonary shunts, or development of pulmonary hypertension (sometimes seen after Waterston or Potts shunts). Left ventricular dilation and failure from long-standing left-to-right shunting can also occur. On physical examination, central cyanosis

and clubbing invariably are present. Continuous murmurs should be sought to assess shunt patency.

Repaired.

After intracardiac repair, over 85 percent of patients are asymptomatic on follow-up. Palpitations from atrial and ventricular tachycardias, with or without dizziness or syncope, and dyspnea from progressive right ventricular dilation secondary to chronic pulmonary regurgitation or severe residual RVOTO occur in 10 to 15 percent of patients at 20 years after initial repair.[86] An ascending aortic aneurysm and progressive aortic regurgitation from a dilated aortic root can also be present. Physical examination may reveal a parasternal right ventricular lift from right ventricular dilation, a normal S_1 , but a soft and delayed P_2 with a low-pitched diastolic murmur from pulmonary regurgitation at the left sternal border. A systolic ejection murmur from RVOTO, a high-pitched diastolic murmur from aortic regurgitation, and a holosystolic murmur from a VSD patch leak can also be heard.

DIAGNOSTIC TESTING

Electrocardiogram

Unoperated.

Right ventricular hypertrophy with right-axis deviation is the rule. Right bundle branch block can be present.

Palliated.

A prominent R wave in V_5 to V_6 can be present and represents left ventricular hypertrophy.

Repaired.

Complete right bundle branch block after repair is the rule. QRS width reflects the degree of right ventricular dilation[87] (Fig. 44-13) .

Figure 44-13 Electrocardiogram of tetralogy of Fallot after surgical repair. Note the wide right bundle branch block (160 msec). First-degree atrioventricular block is also present.

Chest Radiography

Unoperated.

The distinctive "coeur en sabot" or "boot-shaped heart" configuration results from a small main pulmonary artery and a hypertrophied right ventricle coupled to a small to normal-sized left ventricle. Pulmonary vascularity is reduced. A right-sided aortic arch in present in 25 percent.

Palliated.

Increased pulmonary blood flow with rib notching on the side of the shunt (Blalock-Taussig) or evidence of unilateral pulmonary hypertension (Waterston or Potts shunt) may be seen.

Repaired.

Cardiomegaly from right ventricular dilation can be present, along with dilation of the ascending aorta.

Echocardiography

Unoperated.

The malaligned, nonrestrictive VSD and overriding aorta (<50 percent override) are readily identified in the left parasternal long-axis or four-chamber views. Additional muscular VSDs should be sought on two-dimensional and color flow Doppler. The presence and degree of RVOTO (infundibular, valvar, and/or pulmonary arterial stenosis) are best assessed using two-dimensional and Doppler modes (see Figs. 7-86 and 43-48).

Palliated.

Aortopulmonary shunts can be detected from a suprasternal view, by color flow and Doppler mode, as turbulent flow entering the right or left pulmonary artery.

Repaired.

Residual pulmonary stenosis and regurgitation, residual VSD, right and left ventricular sizes and function, aortic root size, and the degree of aortic regurgitation should be assessed (Fig. 44-14) .

Catheterization

Unrepaired/Palliated.

Cardiac catheterization should be performed before surgical repair in patients in whom the presence of an anomalous coronary artery, significant aortopulmonary collaterals, additional muscular VSDs, peripheral pulmonary artery stenosis, and pulmonary hypertension have not been excluded by other modalities.

Repaired.

Complete heart catheterization including coronary angiography (for patients with risk factors for coronary artery disease) should be done if surgical re-intervention is planned or when adequate assessment of the hemodynamics is not obtainable by noninvasive means.

INDICATIONS FOR INTERVENTION

Unoperated.

For unoperated adults, surgical repair is still recommended because the results are gratifying and the operative risk is comparable to pediatric series (provided there is no serious coexisting morbidity).[88]

Palliated.

Palliation was seldom intended as a permanent treatment strategy, and most of these patients should undergo surgical repair. In particular, palliated patients with increasing cyanosis and erythrocytosis (from gradual shunt stenosis or development of pulmonary hypertension), left ventricular dilation, or aneurysm formation in the shunt should undergo intracardiac repair with takedown of the shunt unless irreversible pulmonary hypertension has developed.

Repaired.

The following situations *may* warrant intervention after repair: a residual VSD with a shunt greater than 1.5/1.0; residual pulmonary stenosis with right ventricular pressure two thirds or more of systemic pressure (either the native right ventricular outflow or valved conduit if one is present); or free pulmonary regurgitation associated with important right ventricular enlargement and/or dysfunction, exercise intolerance, or sustained arrhythmias. The development of major cardiac arrhythmias, most commonly atrial flutter/fibrillation or sustained ventricular tachycardia, usually reflects hemodynamic deterioration and should be treated accordingly.[87] Surgery is necessary for significant aortic regurgitation associated with symptoms

and/or progressive left ventricular dilation and perhaps for aortic root enlargement of 55 mm or more in diameter.[89] Rapid enlargement of a right ventricular outflow tract aneurysm or evidence of infection or false aneurysm needs surgical attention.

INTERVENTIONAL OPTIONS

Surgery.

Reoperation is necessary in 10 to 15 percent of patients after reparative surgery over a 20-year follow-up, mainly due to long-term complications of the RVOT.[86] For persistent RVOTO, resection of residual infundibular stenosis or placement of an RV outflow or transannular patch, with or without pulmonary arterioplasty, can be performed. Occasionally, an extracardiac valved conduit may be necessary. Pulmonary valve replacement (either homograft or xenograft) often is used to treat severe pulmonary regurgitation. Concomitant tricuspid valve annuloplasty may be performed for moderate or severe tricuspid regurgitation. Concomitant cryoablation should be performed at the time of surgery for patients with either preexisting atrial or ventricular arrhythmias.[86] [90]

Interventional.

Significant branch pulmonary artery stenosis can be managed with balloon dilation and usually stent insertion.

INTERVENTIONAL OUTCOMES.

The overall survival of patients who have had initial operative repair is excellent, provided the VSD has been closed and the RVOTO has been relieved. A 25-year survival of more than 94 percent has been reported.[91] [95] [97] Pulmonary valve replacement for chronic pulmonary regurgitation or RVOTO after initial intracardiac repair can be done safely with a mortality rate of 1 percent.[97] Pulmonic valve replacement, when performed for significant pulmonary regurgitation, leads to an improvement in functional class and may lead to improvement in right ventricular dimension and function.[93] [93A] Death, however, can occur from congestive heart failure or can be sudden, presumably arrhythmic, from either ventricular tachycardia or complete heart block. Ventricular tachycardia can arise at the site of the right ventriculotomy, from VSD patch suture lines, or from the right ventricular outflow tract. Patients at high risk for sudden death include those with right ventricular dilation and a QRS duration of 180 milliseconds or more on their ECG.[87] [94] The reported incidence of sudden death is approximately 5 percent, which accounts for approximately one third of late deaths over 20 years of follow-up.[91] [95]

FOLLOW-UP.

All patients should have expert cardiology follow-up every 1 to 2 years.[96] [97]

Post-Fontan Procedure

SURGICAL PROCEDURES.

Since its description for the surgical management of tricuspid atresia in 1971, the Fontan procedure has become the definitive palliative surgical treatment when a biventricular repair is not feasible (e.g., for pulmonary atresia with intact ventricular septum or univentricular hearts). The principle is diversion of the systemic venous return directly to the pulmonary arteries without passing through a subpulmonary ventricle. Over the years, many modifications of the original procedure have been described and performed, namely, direct atriopulmonary connection (Fig. 44-15 *A*), total cavopulmonary connection (see Chap. 43 , Fig. 43-54), and extracardiac tunnel/conduit (see Fig. 44-15 *B*). Fenestration (5 mm diameter) of the Fontan circuit into the left atrium is sometimes performed at the time of surgery in "high-risk" patients, permitting right-to-left shunting and decompression of the Fontan circuit. A right atrium to right ventricular conduit for tricuspid atresia is sometimes performed when right ventricular size and function are adequate.

FONTAN POSTOPERATIVE HISTORY.

Patient selection is of utmost importance and has a major impact on clinical outcome. Long-term survival in "ideal candidates" (see Table 44-4) [98] is 81 percent at 10 years,[99] compared with 60 to 71 percent in "all comers."[100] Death occurs mostly from congestive heart failure and atrial arrhythmias. The Fontan procedure remains a palliative, not curative, procedure.

CLINICAL MANIFESTATIONS.

The majority of patients (
90 percent) present with functional Class I to II at 5 years follow-up after a Fontan procedure.[99] [101] Progressive deterioration of functional status with time is the rule.[99] [100] Supraventricular arrhythmias such as atrial tachycardia, flutter, and fibrillation are common. Physical examination in an otherwise uncomplicated patient will reveal an elevated,

TABLE 44-4 -- IDEAL CANDIDATES FOR THE FONTAN PROCEDURE

Preoperative mean pulmonary artery pressure 15 mm Hg
Pulmonary resistance 4 units/m^2
Pulmonary artery-aortic diameter ratio 0.75
Systemic ventricular ejection fraction 60%
Systemic atrioventricular regurgitation mild

usually nonpulsatile jugular venous pulse (10 cm above the sternal angle, needed to provide the hydrostatic pressure to drive cardiac output through the pulmonary circulation), a quiet apex, a normal S_1 , and a single S_2 (the pulmonary artery having been tied off). A heart murmur should not be present, and its identification suggests the presence of systemic AV valve regurgitation or subaortic obstruction. Generalized edema may be a sign of protein-losing enteropathy (see Protein-Losing Enteropathy).

DIAGNOSTIC TESTING

Electrocardiogram.

Sinus rhythm, atrial flutter, junctional rhythm, or complete heart block may be present. The QRS complex reflects the basic underlying cardiac anomaly. In patients with tricuspid atresia, left-axis deviation is the norm. In patients with univentricular hearts, the conduction pattern varies widely and depends on the morphology and relative position of the rudimentary chamber.

Chest Radiography.

Mild bulging of the right lower heart border from a dilated right atrium is often seen in patients with atriopulmonary connection. A prominent inferior vena cava is sometimes visualized (Somerville J, personal communication, 1998).

Echocardiography.

The presence or absence of right atrial stasis, thrombus, patency of a fenestration, and Fontan circuit obstruction should be sought. SVC/IVC biphasic and pulmonary artery triphasic flow pattern that varies with respiration suggests unobstructed flow in the Fontan circuit, whereas a mean gradient between the Fontan circuit and the pulmonary artery of 2 mm Hg or more may represent significant obstruction. Assessment of the pulmonary venous flow pattern is important in detecting pulmonary vein (PV) obstruction (right PV > left PV) sometimes caused by an enlarged right atrium (often 80 by 60 mm or so in adults with atriopulmonary connections). Concomitant assessment of systemic ventricular function and AV valve regurgitation can be readily accomplished. TEE may be required if there is inadequate visualization of the Fontan anastomosis or to exclude thrombus in the right atrium.[102]

Diagnostic Catheterization.

Complete heart catheterization is advised if surgical re-intervention is planned or if adequate assessment of the hemodynamics is not obtained by noninvasive means.

MRI.

MRI may be needed as a complement to or replacement for TEE and sometimes even heart catheterization if the Fontan circuit cannot be assessed otherwise.

COMPLICATIONS AND SEQUELAE

Arrhythmia.

Atrial flutter/fibrillation is common (15-20 percent at 5 years follow-up)[103] [104] and increases with duration of follow-up.[103] [105] Atrial flutter/fibrillation carries significant morbidity, can be associated with profound hemodynamic deterioration, and needs prompt medical attention (see later). The combination of atrial incisions and multiple suture lines at the time of Fontan surgery combined with increased right atrial pressure and size probably explains the high incidence of atrial arrhythmias in such patients. Patients at greater risk for atrial tachyarrhythmias are those who were operated on at an older age, with poor ventricular function, systemic AV valve regurgitation, or increased pulmonary artery pressure.[103] [105] It has been suggested that the exclusion of the right atrium from elevated systemic venous pressure (as in total cavopulmonary connection [TCPC] or extracardiac conduit) leads to a decrease in the incidence of atrial arrhythmias.[106] [107] This apparent benefit may, however, be due exclusively to the shorter length of follow-up in this group of patients.[103] Sinus node dysfunction and complete heart block can occur and require pacemaker insertion (see later).

Thrombosis and Stroke.

The reported incidence of thromboembolic complications in the Fontan circuit varies from 6 to 25 percent, depending on the diagnostic method used and the length of follow-up.[108] Thrombus formation may relate to the presence of supraventricular arrhythmias, right atrial dilation, right atrial "smoke," and the presence of artificial material used to construct the Fontan circuit[112] (Fig. 44-16) . Accordingly, a similar incidence of thrombus formation had been reported for all types of Fontan circuits.[107] Systemic arterial embolism in patients with and without a fenestrated Fontan has also been reported. Protein C deficiency has been reported in these patients and may explain in part their propensity to thromboembolism.[108] [109]

Protein-Losing Enteropathy.

Protein-losing enteropathy, defined as severe loss of serum protein into the intestine, occurs in 4 to 13 percent of patients after a Fontan procedure.[110] Patients present with generalized edema, ascites, pleural effusion, or chronic diarrhea.[110] Protein-losing enteropathy is thought to result principally from chronically elevated systemic venous pressure causing intestinal lymphangiectasia with consequent loss of albumin, protein, lymphocytes, and immunoglobulin into the gastrointestinal tract. The diagnosis is confirmed by finding low serum albumin and protein, low plasma alpha$_1$ -antitrypsin level and lymphocyte counts, and, most important, a high alpha$_1$ -antitrypsin stool clearance. It carries a dismal prognosis, with a 5-year survival of 46 to 59 percent.[110]

Right Pulmonary Vein Compression/Obstruction.

Right pulmonary vein obstruction/compression can occur from the enlarged right atrium or atrial baffle bulging into the left atrium and can lead to increased pulmonary artery pressure with further dilation of the right atrium.

Fontan Obstruction.

Stenosis/partial obstruction of the Fontan connection leads to exercise intolerance, atrial tachyarrhythmias, and right-sided heart failure. Sudden total obstruction can present as sudden death.

Ventricular Dysfunction and Valvar Regurgitation.

Progressive deterioration of systemic ventricular function, with or without progressive AV valve regurgitation, is common. Patients with morphological systemic right ventricles tend to fare less well than those with morphological left ventricles.

Hepatic Dysfunction.

Mildly raised hepatic transaminase levels from hepatic congestion are frequent but seldom clinically important.

Cyanosis.

Worsening cyanosis may relate to worsening of ventricular function, the development of venous collateral

Figure 44-16 Transesophageal echocardiogram of a large thrombus located in the right atrium of a patient with a right atrium to pulmonary artery Fontan connection. RA=right atrium.

channels draining to the left atrium, or the development of pulmonary arteriovenous malformations (especially if a classic Glenn procedure (see Chap. 43) remains as part of the Fontan operation).

TREATMENT OPTIONS

Arrhythmias.

Atrial tachyarrhythmias are very difficult to manage, and should quickly raise the thought of long-term warfarin therapy. When atrial flutter/fibrillation are present, an underlying hemodynamic cause should *always* be sought, and, in particular, evidence for obstruction of the Fontan circuit needs to be sought. Prompt attempts should be made to restore sinus rhythm. Antiarrhythmic medications, alone or combined with an antitachycardia pacing device, and radiofrequency catheter ablation techniques have had limited success.[111] Surgical conversion from an atriopulmonary Fontan to a total cavopulmonary connection with concomitant atrial cryoablation therapy at the time of surgery has been reported with good short-term success.[112] [112A] Pacemaker insertion for sinus node dysfunction and/or complete heart block may be necessary. Endovenous ventricular pacing through the coronary sinus is possible, but epicardial AV sequential pacing should be employed whenever possible.[113]

Anticoagulant Therapy.

The use of prophylactic long-term anticoagulation is contentious.[114] It is recommended that patients with a history of documented arrhythmias, fenestration in the Fontan connection, or spontaneous contrast ("smoke") in the right atrium on echocardiography be anticoagulated. For established thrombus, thrombolytic therapy versus surgical removal of the clot and conversion of the Fontan circuit have been described.

Protein-Losing Enteropathy.

Treatment modalities include a low-fat, high-protein, medium-chain triglyceride diet to reduce intestinal lymphatic production; albumin infusions to increase intravascular osmotic pressure; and/or the introduction of diuretics, afterload reducing agents, and positive inotropic agents to lower central venous pressure. Catheter-based interventions such as balloon dilation of pathway obstruction or creation of an atrial fenestration[115] as well as surgical interventions from conversion or takedown of the Fontan circuit to cardiac transplantation[116] have also been advocated. Newer treatment modalities include subcutaneous heparin,[117] octreotide treatment,[118] and prednisone therapy. [119]

Right Pulmonary Vein Compression/Obstruction.

When hemodynamically significant, Fontan conversion to a total cavopulmonary connection or extracardiac conduit may be recommended.[120] [121]

Fontan Obstruction.

Surgical revision for obstructed right atrium-pulmonary artery, SCV/IVC-pulmonary artery, or right atrium-right ventricle connection is recommended. Alternatively, balloon angioplasty with or without stenting may be used when appropriate and feasible.

Ventricular Failure and Valvar Regurgitation.

ACE inhibitors are of unproven benefit and do not appear to enhance exercise capacity.[122] Patients with systemic AV valve regurgitation may require AV valve repair or replacement. Cardiac transplantation should also be considered.

Cyanosis.

In the setting of a fenestrated Fontan, surgical or preferably transcatheter closure of the fenestration can be attempted. Pulmonary arteriovenous fistulas from a classic Glenn may be improved by surgical conversion to a bidirectional Glenn connection.[123]

FOLLOW-UP.

Close and expert follow-up is recommended with particular attention to ventricular function and systemic AV valve regurgitation. The development of atrial tachyarrhythmia should instigate a search for possible obstruction at the Fontan anastomosis, right pulmonary vein obstruction, or thrombus within the right atrium.

Complete Transposition of the Great Arteries (see also Chap. 43)

ANATOMY.

In patients with complete TGA, the connections between the atria and ventricles are concordant and the connections between ventricles and great arteries are discordant. Consequently, the pulmonary and systemic circulations are connected in parallel rather than the normal in-series connection. In one circuit, systemic venous blood passes to the right atrium, the right ventricle, and then to the aorta. In the other, pulmonary venous blood passes through the left atrium and ventricle to the pulmonary artery. The aorta arises from the morphological right ventricle and usually lies anterior and to the right of the pulmonary artery, whereas the pulmonary artery arises from the morphological left ventricle (Fig. 44-17 (Figure Not Available) and see Fig. 43-57). This situation is incompatible with life unless mixing of the two circuits occurs.

Approximately two thirds of patients have no major associated abnormalities ("simple" transposition) and one third have associated abnormalities ("complex" transposition). The most common associated abnormalities are VSD and pulmonary/subpulmonary stenosis.

NATURAL HISTORY OF THE UNOPERATED PATIENT.

Survival before surgical repair is dependent on mixing of the circulations at one level or another, whether natural (VSD, ASD, PDA) or by intervention (Blalock-Hanlon atrial septectomy or Rashkind balloon atrial septostomy). Unoperated (simple) transposition is a lethal condition, with 90 percent mortality by 1 year. Nearly all patients seen as adults will have had surgical intervention (atrial switch, arterial switch, or Rastelli operation--see later), with the exception perhaps of patients with a large VSD who may survive into adulthood without intervention and present with pulmonary vascular disease.

SURGICAL PROCEDURES

Atrial Switch.

The most common surgical procedure in patients who are currently adults is the atrial switch operation. Patients will have had either a Mustard or a Senning procedure. Blood is redirected at the atrial level using a

Figure 44-17 (Figure Not Available) Diagrammatic representation of complete transposition of the great arteries. RA=right atrium; RV=right ventricle; LA=left atrium; LV=left ventricle; Ao=aorta; PA=pulmonary artery. *(From Mullins CE, Mayer DC: Congenital Heart Disease: A Diagrammatic Atlas. New York, Wiley-Liss, 1988.)*

baffle made of Dacron or pericardium (Mustard operation) or atrial flaps (Senning operation), achieving physiological correction. Systemic venous return is diverted through the mitral valve into the subpulmonary morphological left ventricle, and the pulmonary venous return is rerouted through the tricuspid valve into the subaortic morphological right ventricle. By virtue of this repair, the morphological right ventricle is left to support the systemic circulation (Fig. 44-18) (Figure Not Available) .

Arterial Switch.

The atrial switch operation has gradually been supplanted by the arterial switch operation (Jatene) since the late 1970s, but few of these patients have yet become

adults. Blood is redirected at the great artery level by switching the aorta and pulmonary arteries (often using the Lecompte maneuver) such that the morphological left ventricle becomes the subaortic ventricle and supports the systemic circulation and the morphological right ventricle becomes the subpulmonary ventricle (see Chap. 43 , Fig. 43-61). The coronary arteries, with a sleeve of surrounding tissue, are translocated to the proximal neoaorta (formerly the proximal pulmonary artery), with the loss of tissue from the former coronary ostia of the neopulmonary artery (formerly the aorta) made good with pericardial patches.

Rastelli Procedure.

Patients (<10 percent of all TGA patients) who have VSD and pulmonary/subpulmonary stenosis may have been corrected by the Rastelli operation. This procedure consists of redirecting the blood at the ventricular level with the left ventricle tunneled to the aorta through the VSD and a valved conduit placed from the right ventricle to the pulmonary artery. By virtue of this procedure, the left ventricle supports the systemic circulation.

Palliative Atrial Switch.

Uncommonly, in patients with a large VSD and established pulmonary vascular disease, a palliative atrial switch operation will be done to improve oxygenation. The VSD is left open or enlarged at the time of atrial baffle surgery. These patients resemble patients

Figure 44-18 (Figure Not Available) Diagrammatic representation of atrial switch surgery (Mustard/Senning procedure). Superior vena cava (SVC) and inferior vena cava (IVC) blood is redirected into the morphological left ventricle (LV), which pumps blood into the pulmonary artery (PA), whereas the pulmonary venous blood flow is rerouted to the morphological right ventricle (RV), which empties into the aorta (Ao). RA=right atrium; LA=left atrium; 1=transposition of the great arteries; 2=atrial baffles; 3=pulmonary vein blood flow through tricuspid valve to RV; 4=IVC and SVC blood flow through mitral valve to LV. *(From Mullins CE, Mayer DC: Congenital Heart Disease: A Diagrammatic Atlas. New York, Wiley-Liss, 1988.)*

with Eisenmenger VSDs and should be managed as such (see p. 1614).

POSTOPERATIVE CLINICAL PICTURE

Atrial Switch.

After atrial baffle surgery, most patients who reach adulthood are in NYHA Classes I and II.[124] [125] Over 25 years of follow-up, some will present with symptoms of congestive heart failure (2-15 percent) despite objective evidence of moderate or severe systemic right ventricular dysfunction in up to 40 percent of patients.[129] [129A] [130] [131] More than mild systemic tricuspid regurgitation is present in 10 to 40 percent,[125] exacerbating right ventricular dysfunction. Palpitations or near-syncope/syncope from rhythm disturbances is common. Atrial flutter occurs in 20 percent of patients by age 20,[9] [124] [125] [126] and progressive sinus node dysfunction is seen in half of the patients by that time.[9] [125] [126] These rhythm disturbances are thought to be a consequence of direct and indirect atrial and sinus node damage at the time of atrial baffle surgery.

Shortened life expectancy is the rule with 70 to 80 percent survival at 20 to 30 years follow-up.[8] [9] [124] Patients with "complex" TGA in general fare much worse than "simple" TGA.[89] [91] Sudden cardiac death is the clinical presentation in about 5 percent of these patients[8] [9] [127] and may relate to systemic right ventricular dysfunction,[8] [125] the presence of atrial flutter,[8] [128] and pulmonary hypertension.[125] Significant pulmonary vascular disease can develop over time and relates to older age at the time of atrial switch operation, particularly in patients with a substantial VSD, as well as in those with long-standing left-to-right shunts through a baffle leak. Rarely, cyanosis can be the presenting symptom due to atrial baffle leak with right-to-left shunting. Superior vena cava or inferior vena cava baffle obstruction often goes undetected because collateral drainage through the azygos vein prevents systemic venous congestion. Pulmonary baffle obstruction causes elevated pulmonary artery pressure, and patients can present with dyspnea and pulmonary venous congestive features. Physical examination of a patient whose condition is otherwise uncomplicated reveals a right ventricular parasternal lift, a normal S_1 , a single S_2 (P_2 is not heard because its posterior location), a holosystolic murmur from tricuspid regurgitation if present (best heard at the left lower sternal border, but not increasing with inspiration), and a right-sided S_3 when severe systemic ventricular dysfunction is present.

Arterial Switch.

Data on clinical presentation in adults who have undergone the arterial switch procedure are lacking, because most patients have not yet reached adulthood. Clinical arrhythmia promises to be less of a problem in this group of patients.[129] Concerns about the development of supra-neopulmonary artery stenosis, ostial coronary artery disease, and progressive neoaortic valve regurgitation remain to be addressed over the long term.[129A] Cardiac examination in uncomplicated patients is normal.

Rastelli Procedure.

Progressive right ventricular to pulmonary artery conduit obstruction can cause exercise intolerance or right ventricular angina. Left ventricular tunnel obstruction can present as dyspnea or syncope. Physical examination in uncomplicated patients reveals, in contrast to atrial switches, no right ventricular lift, an ejection systolic murmur from the conduit, and two components to the S_2 .

DIAGNOSTIC TESTING

Electrocardiogram.

Atrial flutter, sinus bradycardia, or junctional rhythm, in the absence of a right atrial overload pattern, with evidence of right ventricular hypertrophy and right axis deviation is characteristically present in patients after the atrial switch procedure (Fig. 44-19) . The ECG is typically normal in patients after the arterial switch procedure. The ECG typically shows right bundle branch block after a Rastelli procedure.

Chest Radiography.

On the posteroanterior film, a narrow vascular pedicle with an oblong cardiac silhouette ("egg on its side") is typically seen in patients after the

Figure 44-19 Electrocardiogram of a patient with complete transposition of the great arteries after an atrial switch procedure. Note the atrial flutter at 200 beats/min, the right ventricular hypertrophy, and the right-axis deviation. There is an incidental ventricular premature beat.

atrial switch procedure (Fig. 44-20) . On the lateral view, the anterior aorta is seen to fill the retrosternal air space. For the arterial switch, normal mediastinal borders are present despite the Lecompte maneuver. After the Rastelli procedure, the chest radiograph is normal unless the conduit becomes calcified or a nonhomograft prosthesis is employed.

Echocardiography.

After the atrial switch procedure, parallel great arteries are the hallmark of TGA. They are best visualized from a long parasternal view (running side-by-side) or from a short parasternal view (seen en face, with the aorta anterior and rightward) (Fig. 44-21) . Qualitative assessment of systemic right ventricular function, the degree of tricuspid regurgitation, and the presence or absence of subpulmonic left ventricular obstruction (dynamic or fixed) is possible. Assessment of baffle leak or obstruction is best done using color and Doppler flow imaging. Normal baffle flow should be phasic in nature and varies with respiration, with a peak velocity less than 1 m/sec.[130] After arterial switch, neoaortic valve regurgitation, supra-neopulmonary valve stenosis, and segmental wall motion abnormality from ischemia due to coronary ostial stenosis should be sought. In patients who have undergone the Rastelli operation, left ventricular to aorta tunnel obstruction as well as right ventricular to pulmonary artery conduit degeneration (stenosis/regurgitation) must be sought.

Diagnostic Cardiac Catheterization.

Diagnostic cardiac catheterization may be required for assessing the presence or severity of systemic/pulmonary baffle obstruction, baffle leak, and pulmonary hypertension; coronary ostial stenosis; or tunnel or conduit obstruction when not diagnosed by noninvasive means.

INDICATIONS FOR RE-INTERVENTION.

After the atrial switch procedure, severe symptomatic right ventricular dysfunction *may* warrant surgical treatment in the form of

Figure 44-20 Chest radiograph of an adult with complete transposition of the great arteries after a Mustard procedure. Note the narrow mediastinum with the "egg-on-its-side" configuration of the cardiac silhouette.

"two-stage arterial switch" procedure (see Two-Stage Arterial Switch)[131] [132] [133] or cardiac transplantation. Tricuspid valve replacement can be performed for severe systemic (tricuspid) AV valve regurgitation providing right ventricular function is adequate.[128] Baffle leak resulting in a significant left-to-right shunt (>1.5/1.0), any right-to-left shunt, or symptoms requires surgical or transcatheter closure. SVC or IVC pathway obstruction may require intervention. SVC stenosis

Figure 44-21 Left parasternal transthoracic echocardiogram of a patient with complete transposition of the great arteries shows the typical arrangement of the great arteries in parallel. AO=aorta; AV=aortic valve; RVOT=right ventricular outflow tract; PA=pulmonary artery; PV=pulmonary valve; LV=left ventricle; MV=mitral valve.

is usually benign, whereas IVC stenosis may be life threatening. Balloon dilation of SVC or IVC stenosis is an option, but success is limited in adults. Pathway obstruction after the Senning operation is usually more amenable to balloon dilation and stenting. Pulmonary venous obstruction, although usually seen early and reoperated on in childhood, may present in adulthood. Consideration for the "two-stage arterial switch" procedure in these patients is warranted (see Two-Stage Arterial Switch).[134] [135] Symptomatic bradycardia warrants permanent pacemaker implantation, whereas tachyarrhythmias may require catheter ablation, antitachycardia pacemaker device, or medical therapy. After an atrial switch, transvenous pacing leads must traverse the upper limb of the baffle to enter the morphological left ventricle. Active fixation is required because coarse trabeculation is absent in the morphological left ventricle. Transvenous pacing should be avoided in patients with residual intracardiac communications because paradoxical emboli can occur.

After an arterial switch procedure, significant RVOTO at any level (peak gradient > 50 mm Hg or RV/LV pressure ratio >0.6) may require surgical or catheter augmentation of the right ventricular outflow tract. Myocardial ischemia from coronary artery obstruction may require coronary artery bypass grafting, preferably with arterial conduits. Significant neoaortic valve regurgitation[136] may warrant aortic valve replacement. In patients who have had the Rastelli operation, significant right ventricle-to-pulmonary artery conduit stenosis (peak gradient<50 mm Hg) or significant regurgitation necessitates conduit replacement. Subaortic obstruction across the left ventricle-to-aorta tunnel necessitates left ventricle-to-aorta baffle reconstruction. A significant residual VSD (shunt > 1.5/1.0) may require surgical closure.[137] Patients with clinical deterioration and a palliative atrial switch should be considered for lung or heart-lung transplantation.

INTERVENTIONAL OPTIONS

Medical Therapy.

The role of afterload reduction with ACE inhibitors to preserve systemic right ventricular function is as yet unknown. In light of the effects of these drugs on dysfunctional systemic left ventricles, it seems logical to assume that similar beneficial effects on systemic right ventricles may occur.

Two-Stage Arterial Switch.

Patients with symptomatic, severe systemic (right) ventricular dysfunction with or without severe systemic (tricuspid) AV valve regurgitation, following an atrial switch procedure, may require consideration of a conversion procedure to an arterial switch ("two-stage arterial switch") or heart transplantation. The "two-stage arterial switch" or "switch-conversion" procedure consists of banding the pulmonary artery in the first stage, to induce morphological pulmonary left ventricular hypertrophy and "train" the left ventricle to support systemic pressure. Once left ventricular systolic pressure is more than 75 percent of systemic pressure and the left ventricular mass is considered adequate, in the second stage, the atrial baffles and the pulmonary band are taken down, the atrial septum is reconstructed, and the great arteries are switched, leaving the morphological left ventricle as the systemic ventricle. This procedure, however, is still experimental in adults, with little data available to assess its short- and long-term efficacy.[133]

Cardiac Transplantation.

Heart transplantation should be considered as an alternative, given its relatively good 5- to 10-year survival.[7]

FOLLOW-UP.

Regular follow-up by physicians with special expertise in adult congenital heart disease is recommended.

Atrial Switch.

Serial follow-up of systemic right ventricular function is warranted. Echocardiography, radionuclide angiography, and MRI can be used.[138] [139] ACE inhibitors are often recommended empirically for moderate to severe right ventricular dysfunction and may be helpful to all atrial switch patients. Asymptomatic baffle obstruction should be sought with echocardiography or MRI. Regular Holter monitoring is recommended to diagnose unacceptable bradyarrhythmias or tachyarrhythmias.

Arterial Switch.

Regular follow-up with echocardiography is recommended.

Rastelli Procedure.

Regular follow-up with echocardiography is warranted given the inevitability of conduit degeneration over time.

Congenitally Corrected Transposition of the Great Arteries (see also Chap. 43)

ANATOMY.

Congenitally corrected TGA is a rare condition, accounting for less than 1 percent of all congenital heart disease. In congenitally corrected TGA, the connections of both the atria to ventricles and of the ventricles to the great arteries are discordant. Systemic venous blood passes from the right atrium through a mitral valve to the left ventricle and then to the right-sided posteriorly located pulmonary artery. Pulmonary venous blood passes from the left atrium through a tricuspid valve to the right ventricle and then to an anterior, left-sided aorta (Fig. 44-22) (Figure Not Available) . The circulation is thus "physiologically" corrected but the morphological right ventricle supports the systemic circulation. Associated anomalies occur in up to 95 percent of patients and consist of VSD (75 percent), pulmonary or subpulmonary stenosis (75 percent), and left-sided (tricuspid and often "Ebstein-like") valve anomalies (>75 percent).[140]

Because of the inherently abnormal conduction system (anterior origin of the AV node and anterior course of the His bundle [anterior to the pulmonary artery and down the morphological left ventricular side of the septum]), 5 percent of patients with congenitally corrected TGA are born with congenital complete heart block. Congenitally

corrected transposition may exist in the setting of univentricular heart.

NATURAL HISTORY OF THE UNOPERATED PATIENT.

Patients with no associated abnormalities ("isolated" congenitally corrected TGA) can survive until the seventh or eighth

Figure 44-22 (Figure Not Available) Diagrammatic representation of congenitally corrected transposition of the great arteries. AV and VA discordance (1). Note intact ventricular septum (2). RA=right atrium; RV=right ventricle; LA=left atrium; LV=left ventricle; Ao=aorta; PA=pulmonary artery. *(From Mullins CE, Mayer DC: Congenital Heart Disease: A Diagrammatic Atlas. New York, Wiley-Liss, 1988.)*

decade and can go unrecognized until cardiac problems arise.[141] Progressive systemic (tricuspid) AV valve regurgitation and systemic (right) ventricular dysfunction tend to occur from the fourth decade onward, whereas atrial tachyarrhythmias are more common from the fifth decade onward.[142] In addition to those born with congenital complete heart block, acquired complete AV block continues to develop at a rate of 2 percent per year. Patients with associated anomalies (VSD, pulmonary stenosis, left-sided [tricuspid] valve anomaly) often have undergone surgical palliation (systemic-to-pulmonary artery shunt for cyanosis) or repair of the associated anomalies (see surgical procedures).

SURGICAL PROCEDURES

"Classic" Repair.

VSD patch closure for hemodynamically significant VSD, left ventricular to pulmonary artery valved conduit insertion for significant pulmonary valvar or subvalvar stenosis, and systemic tricuspid valve replacement for significant regurgitation may have been performed. VSD patch closure is carried out with a particular attention to avoid the anterior conduction system (coursing anterior to the VSD). In isolated pulmonary/subpulmonary stenosis, direct enlargement of the outflow tract and valve is seldom possible and a pulmonary (morphological left) ventricle to pulmonary artery conduit is required. Patients who have undergone this "classic" repair continue to have a morphological right ventricle supporting the systemic circulation.

CLINICAL MANIFESTATIONS

Unoperated.

Patients with no associated defects (1 percent of all such patients) can be asymptomatic until late adulthood. Dyspnea, exercise intolerance from developing congestive heart failure, and palpitations from supraventricular arrhythmias may arise in the fifth or sixth decade. Patients with well-balanced VSD/pulmonary stenosis can present with paradoxical emboli or cyanosis, especially if pulmonary stenosis is severe. Physical examination of a patient whose condition is otherwise uncomplicated reveals a somewhat more medial apex due to the side-by-side orientation of the two ventricles. The A_2 is often palpable in the second left intercostal space due to the anterior and leftward location of the aorta. A single S_2 (A_2) is heard, with P_2 being silent due to its posterior location. The murmur of an associated VSD or of left AV valve regurgitation may be heard. The murmur of pulmonary stenosis will radiate upward and to the right given the rightward direction of the main pulmonary artery. If there is complete heart block, cannon a waves with an S_1 of variable intensity are present.

"Classic" Repair.

The majority of patients are in functional Class I at 5 to 10 years after surgery[143] [144] despite the common development of tricuspid regurgitation and systemic right ventricular dysfunction after surgical repair (>30 percent of patients at 3 years after surgery).[143] [145] [146] Dyspnea, exercise intolerance, and palpitations from supraventricular arrhythmia can occur in the fourth decade.[147] Complete heart block may complicate surgery in an additional 25 percent.[6] [7] [8] [144] [145] [146] Physical examination reflects the basic cardiac malformation with or without residual coexisting anomalies.

DIAGNOSTIC TESTING

Electrocardiogram.

Complete AV block can be present in up to 40 percent of adults. A delta wave from a left-sided accessory bypass tract (associated with "Ebstein-like" anomaly of the left-sided AV valve) can be seen. The presence of Q wave in leads V_1 and V_2 combined with an absent Q wave in leads V_5 and V_6 is typical and reflects the initial right-to-left septal depolarization occurring in the setting of "ventricular inversion" (Fig. 44-23) . This should not be mistaken for evidence of previous anterior myocardial infarction.

Chest Radiography.

Because of the unusual position of the great vessels (pulmonary artery to the right and aorta to the left), the pulmonary trunk is inconspicuous and an abnormal

Figure 44-23 Electrocardiogram of a patient with congenitally corrected transposition of the great arteries. Note the presence of Q wave in V_1 and the absence of Q wave in V_{5-6} . Low atrial rhythm and left-axis deviation are also present.

bulge along the left side of the cardiac contour reflects the left-sided ascending aorta rising to the aortic knuckle. A shallow indentation or "septal notch" can be seen above the left hemidiaphragm reflecting the apical portion of the interventricular groove (Fig. 44-24) .

Echocardiography.

Echocardiography permits the identification of the basic malformation as well as any associated anomalies. The morphological pulmonary left ventricle is characterized by its smooth endocardial surface and is guarded by a bileaflet AV (mitral) valve with no direct septal attachment. The morphological systemic right ventricle is recognized by its apical trabeculation and moderator band and is guarded by a trileaflet apically displaced AV valve (tricuspid valve) with direct attachment to the septum (Fig. 44-25) . "Ebstein-like" malformation of the left (tricuspid) AV valve is defined by excessive (>8 mm/m^2) apical displacement of the left (tricuspid) AV valve, with or without dysplastic features.

Diagnostic Cardiac Catheterization.

This may be required to assess the hemodynamic significance or consequences of associated anomalies.

INDICATION FOR INTERVENTION OR RE-INTERVENTION.

If moderate or severe systemic (tricuspid) AV valve regurgitation develops, valve replacement is usually required. Left AV valve replacement should be performed before systemic right ventricular function deteriorates, namely at an ejection fraction of 45 percent or more.[148] When tricuspid regurgitation is associated with poor systemic (right) ventricular function, the "double switch" procedure (see Double Switch Procedure) should perhaps be considered.[131] [149] [150] [151] [152]

Patients with end-stage symptomatic heart failure should be referred for cardiac transplantation. The presence of a hemodynamically significant VSD (Qp/Qs > 1.5:1.0)

or residual VSD with significant native or postsurgical (conduit) pulmonary outflow tract stenosis (peak gradient >50 mm Hg) may require surgical correction. Left AV valve replacement at the time of VSD and pulmonary stenosis surgery should be considered if concomitant left AV valve regurgitation is present.[153] Complete AV block may require pacemaker implantation for symptoms, progressive or profound bradycardia, poor exercise heart rate response, or cardiac enlargement. The optimal pacing modality is DDD. Active fixation electrodes are required, owing to the lack of apical trabeculation in the morphological pulmonary left ventricle. Transvenous pacing should be avoided if there are intracardiac shunts because paradoxical emboli may occur. Epicardial leads are preferred under these circumstances.[154]

INTERVENTIONAL OPTIONS

Medical Therapy.

ACE inhibitor therapy for patients with systemic ventricular dysfunction is recommended. The role of afterload reduction with an ACE inhibitor to preserve systemic right ventricular function is as yet unknown. The results of clinical trials are awaited.

Classic Repair.

Tricuspid valve replacement for significant regurgitation is preferable to tricuspid valve repair. Valve repair is usually unsuccessful because of the abnormal, often "Ebstein-like" anatomy of the valve.

Double Switch Procedure.

This procedure has been successfully performed in children. It should be considered for patients with severe tricuspid regurgitation and systemic ventricular dysfunction. Its purpose is to relocate the left ventricle into the systemic circulation and the right ventricle into the pulmonary circulation, achieving "anatomical" correction. An atrial switch procedure (Mustard or Senning) together with either an arterial switch procedure (when pulmonary stenosis is not present, see Chap. 43) or a Rastelli-type repair, the so-called Ilbawi procedure (left ventricle tunneled to aorta and right ventricular to pulmonary artery valved conduit when VSD and pulmonary stenosis are present), can be performed after adequate left ventricular

Figure 44-24 Chest radiograph of a patient with congenitally corrected transposition of the great arteries. Note the left-sided ascending aorta (AO), transvenous pacemaker and mechanical left-sided (tricuspid) atrioventricular valve, and enlarged right atrium.

Figure 44-25 Transthoracic echocardiographic picture of a patient with congenitally corrected transposition of the great arteries. *A,* Single arrow points to the normally apically displaced left-sided tricuspid valve. Double arrows point to the left-sided right ventricular trabeculations. RA=right atrium; MV=mitral valve; LV=right-sided morphologic left ventricle; LA=left atrium; TV=tricuspid valve; TR=tricuspid regurgitation; RV=left-sided morphologic right ventricle.

retraining, leaving the regurgitant tricuspid valve and failing right ventricle on the pulmonary side.

Cardiac Transplantation.

Patients with deteriorating systemic (right) ventricular function should be treated aggressively with medical therapy but may need to be considered for transplantation.

INTERVENTIONAL OUTCOMES

"Classic" Repair.

After "classic" surgical repair, median survival of patients reaching adulthood is 40 years.[143] [144] [145] [147] [155] Usual causes of death are sudden (presumed arrhythmic) or, more commonly, progressive systemic right ventricular dysfunction with systemic (tricuspid) AV valve regurgitation. The major predictor of poor outcome is the presence of left AV (tricuspid) valve regurgitation.[155] Reoperation is common (15-25 percent), with left AV valve replacement usually being the primary reason.[143] [144] [146] [147]

Double Switch Procedure.

Data in adults using the "double switch" procedure is lacking, and this procedure should be considered experimental in this patient population.

FOLLOW-UP.

All patients should have at least annual cardiology follow-up with an expert in the care of adult patients with congenital cardiac defects. Regular assessment of systemic (tricuspid) AV valve regurgitation by serial echocardiographic studies and systemic ventricular function by echocardiography, MRI, or radionuclide angiography should be done. Holter recording may be useful if paroxysmal atrial arrhythmias or transient complete AV block is suspected.

Eisenmenger Syndrome (see also Chaps. 43 and 53)

DEFINITION.

Eisenmenger syndrome, a term coined by Paul Wood, is defined as pulmonary vascular obstructive disease that develops as a consequence of a large preexisting left-to-right shunt such that pulmonary artery pressures

approach systemic levels and the direction of the flow becomes bidirectional or right to left. Congenital heart defects that can result in Eisenmenger syndrome include "simple" defects such as ASD, VSD, and PDA as well as more "complex" defects such as AVSD, truncus arteriosus, aortopulmonary window, and univentricular heart. The high pulmonary vascular resistance is usually established in infancy (by age 2 years, except in ASD) and sometimes is present from birth.

NATURAL HISTORY OF THE UNOPERATED PATIENT.

Patients with defects that allow free communication between the pulmonary and systemic circuits at the aortic or ventricular levels usually have a fairly healthy childhood and gradually become progressively cyanotic during their second or third decade. Exercise intolerance (dyspnea and fatigue) is proportional to the degree of hypoxemia or cyanosis. In the absence of complications, these patients generally have an excellent to good functional capacity up to their third decade[156] [157] and thereafter usually experience a slowly progressive decline in their physical abilities. Most patients survive to adulthood,[157] [158] with a reported 77 percent and 42 percent survival rate at 15 and 25 years of age.[157]

Complications from Eisenmenger syndrome tend to occur from the third decade onward. Congestive heart failure, the most serious complication, usually occurs after age 40.[156] The most common modes of death are sudden death (30 percent), congestive heart failure (25 percent), and hemoptysis (15 percent). Pregnancy, perioperative mortality after noncardiac surgery, and infectious causes (brain abscesses and endocarditis) account for most of the remainder.[156] [157]

CLINICAL MANIFESTATIONS.

Patients can present with the following complications: those related to their cyanotic state (see p. 1617); palpitations in nearly half the patients (atrial fibrillation/flutter--35 percent, ventricular tachycardia--10 percent); hemoptysis in about 20 percent; pulmonary thromboembolism, angina, syncope, and endocarditis in about 10 percent; and congestive heart failure.[156] Hemoptysis is usually due to bleeding bronchial vessels or pulmonary infarction. Physical examination reveals central

cyanosis and clubbing of the nail beds. Patients with Eisenmenger PDA can have pink nail beds on the right (± left) hand and cyanosis and clubbing of both feet (± the left hand), so-called "differential cyanosis." This occurs because venous blood shunts through the ductus and enters the aorta distal to the right subclavian artery. The jugular venous pressure in Eisenmenger syndrome patients can be normal or elevated--especially with prominent v waves when tricuspid regurgitation is present. Signs of pulmonary hypertension--a right ventricular heave, palpable and loud P_2 , and a right-sided S_4 --are typically present. In many patients, a pulmonary ejection click and a soft and scratchy systolic ejection murmur, attributable to dilation of the pulmonary trunk, and a high-pitched decrescendo diastolic murmur of pulmonary regurgitation (Graham Steelle) are audible. Peripheral edema is absent until right-sided heart failure ensues.

DIAGNOSTIC TESTING

Electrocardiogram.

Peaked P waves consistent with right atrial overload and evidence of right ventricular hypertrophy with right axis deviation are the rule. Atrial arrhythmias can be present (Fig. 44-26) .

Chest Radiography.

Dilated central pulmonary arteries with "pruning" of the peripheral pulmonary vasculature are the radiographic hallmarks of Eisenmenger syndrome (Fig. 44-27) . Pulmonary artery calcification may be seen and is diagnostic of long-standing pulmonary hypertension. Eisenmenger syndrome due to VSD or PDA usually has a normal or slightly increased cardiothoracic ratio. Eisenmenger syndrome due to an ASD typically has a large cardiothoracic ratio due to right atrial and ventricular dilation, along with

Figure 44-26 ECG of a patient with Eisenmenger syndrome due to a VSD. Note the peaked P wave in lead II, right ventricular hypertrophy, and right-axis deviation.

an inconspicuous aorta. Calcification of the duct may be seen in Eisenmenger PDA.

Echocardiography.

The intracardiac defect should be seen readily along with bidirectional shunting. Evidence of pulmonary hypertension will be found. Assessment of pulmonary right ventricular function adds prognostic value.

Catheterization.

Cardiac catheterization not only provides direct measurement of the pulmonary artery pressure, documenting the existence of severe pulmonary hypertension, but also may allow assessment of reactivity of the pulmonary vasculature. Administration of pulmonary arterial vasodilators (O_2 , nitric oxide, prostaglandin I_2) can discriminate between patients in whom surgical repair is contraindicated and those with reversible pulmonary hypertension who may benefit from surgical repair. Radiographic contrast material may cause hypotension and worsening cyanosis and should be used cautiously.

Open-Lung Biopsy.

Open-lung biopsy should only be considered when the reversibility of the pulmonary hypertension is uncertain from the hemodynamic data. An expert opinion will determine the severity of the changes, usually using the Heath-Edwards classification.

INDICATIONS FOR INTERVENTION.

The underlying principle of clinical management in patients with Eisenmenger syndrome is to avoid any factors that may destabilize the delicately balanced physiology. In general, an approach of nonintervention is recommended. The main interventions, therefore, are directed toward preventing complications (e.g., flu shots to reduce the morbidity of respiratory infections) or to restore the physiological balance (e.g., iron replacement for iron deficiency; antiarrhythmic management of atrial arrhythmias; digoxin and diuretics for right-sided

Figure 44-27 Typical chest radiograph of a patient with Eisenmenger syndrome due to a ventricular septal defect. Note the enlarged central pulmonary arteries and the peripheral pruning of the pulmonary vasculature. *A,* Posteroanterior view. LPA=left pulmonary artery; RPA=right pulmonary artery.

heart failure). As a general rule, the first episode of hemoptysis should be considered an indication for hospital admission and investigation. Bed rest should be implemented; and, although usually self-limiting, each such episode should be regarded as potentially life threatening, and a treatable cause sought. When patients are severely incapacitated from severe hypoxemia or congestive heart failure, the main intervention available is lung (plus repair of the cardiac defect) or heart-lung transplantation. This is generally reserved for individuals without contraindications who are thought to have a 1-year survival of less than 50 percent. Such assessment is fraught with difficulty because of the unpredictability of the time course of the disease and the risk of sudden death.

Noncardiac surgery should be performed only when absolutely necessary because of its high associated mortality.[156] [159] Eisenmenger syndrome patients are particularly vulnerable to alterations in hemodynamics induced by anesthesia or surgery, such as minor decrease in systemic vascular resistance that can increase right-to-left shunting and possibly potentiate cardiovascular collapse. Local anesthesia should be used whenever possible. Avoidance of prolonged fasting and especially dehydration, the use of antibiotic prophylaxis when appropriate,[160] and careful intraoperative monitoring (sometimes with an arterial line ± a central venous line to allow early detection of sudden pressure and volume changes during surgery) are recommended. [159] [161] The choice of general versus epidural-spinal anesthesia is controversial. An experienced cardiac anesthetist with an understanding of Eisenmenger syndrome physiology should administer anesthesia. Additional risks of surgery include excessive bleeding, postoperative arrhythmias, and deep venous thrombosis with paradoxic emboli. An "air filter" or "bubble trap" should be used for any intravenous lines. Early ambulation is recommended.[159] [161] Postoperative care in an intensive care unit setting is optimal.

INTERVENTIONAL OPTIONS AND OUTCOMES

Oxygen.

In a small prospective nonrandomized study of 15 children with pulmonary vascular disease, chronic administration of oxygen (12 hours a day for up to 5 years) resulted in an increased survival in the treatment group (n=9).[162] The impact of supplemental oxygen on survival in adult patients with Eisenmenger syndrome has never been studied, and its role is unclear. Chronic oxygen therapy can perhaps help raise oxygen saturation and reduce symptoms, but this should be counterbalanced with the potential effect of mucosal dehydration and increased incidence of epistaxis. Supplemental oxygen during commercial air travel is often recommended, but the scientific basis for this recommendation is lacking.[163]

Transplantation.

Lung transplant may be undertaken in association with repair of existing cardiovascular defect(s). Alternatively, heart-lung transplantation may be required if the intracardiac anatomy is not correctable. The outcome of transplantation in these patients is generally less satisfactory than for transplant recipients without Eisenmenger syndrome. The 1-year survival rate for adults undergoing lung transplantation with primary intracardiac repair is 70 to 80 percent, and less than 50 percent of patients are alive 4 years after transplantation.[164] [165] The outcome after heart-lung transplantation is not better, with a 1-year survival rate of 60 to 80 percent and a 10-year survival rate of less than 30 percent.[164] These options, however sobering, may be relatively attractive to individuals who are confronting death and have an intolerable quality of life.

INVESTIGATIONAL THERAPY

Calcium Channel Blockers.

The chronic use of nifedipine in a small group of patients with Eisenmenger syndrome demonstrated a small but significant increase in exercise tolerance[166] and a decrease in pulmonary vascular resistance, especially in children.[167] This therapy is still considered investigational and should only be prescribed in a clinical research setting.

ACE Inhibitors.

Data available on a highly selected group of 10 patients with cyanotic congenital heart disease showed no change in oxygen saturation despite a subjective improvement in functional capacity.[168] Proponents of the use of ACE inhibitors in these patients argue that, by decreasing systemic vascular resistance, one improves the cardiac output and thus oxygen delivery. The counter argument is that these agents are potentially dangerous because they lower systemic vascular resistance without changing pulmonary vascular resistance and lead to an increase in right-to-left shunting. The use of this medication remains highly experimental and again should only be administered within the boundaries of a study trial guided by rigorous monitoring.

Prostacyclin.

A recent study of chronic prostacyclin administration in such patients showed improvement in hemodynamics (lower pulmonary vascular resistance and increased cardiac output) and a somewhat increased exercise capacity.[169] Further research in this field is needed before recommendations on the use of prostaglandins in these patients can be made.

Pulmonary Artery Banding.

Pulmonary artery banding in one patient with biopsy-proven irreversible pulmonary vascular changes led to regression of pulmonary vascular changes, which made surgical closure of the defects possible.[170] Further data regarding this revolutionary practice are awaited.

FOLLOW-UP.

Patient education is critical. Avoidance of over-the-counter medications, dehydration, smoking, high-altitude exposure, and excessive physical activity should be stressed. Avoidance of pregnancy is of paramount importance (see Chap. 65). Annual flu shots and use of endocarditis prophylaxis together with proper skin hygiene (avoidance of nail biting) are recommended. A yearly assessment of complete blood cell count and uric acid, creatinine, and ferritin levels should be done to monitor treatable causes of deterioration.

Medical Management of Cyanotic Congenital Heart Disease

PATHOPHYSIOLOGY OF CYANOSIS.

Patients with cyanotic congenital heart lesions, either unoperated or palliated, have chronic hypoxemia as a result of persistent systemic venous to arterial shunting. Ensuing physiological adaptive mechanisms to enhance oxygen delivery include, among others, an increase in red blood cell mass to improve systemic oxygen transport. Erythropoietin production is stimulated as a result of exposure of renal oxygen sensors to hypoxemia. Red blood cell production is enhanced, oxygen content (hemoglobin×O_2 saturation) increases, and oxygen delivery (cardiac output×O_2 saturation) is reestablished, albeit at the cost of a higher hematocrit. Erythrocytosis, in the setting of chronic cyanotic congenital heart disease, is thus an adaptive physiological mechanism.[171]

HYPERVISCOSITY SYNDROME.

Symptoms of hyperviscosity include headaches, altered mentation, visual disturbances, tinnitus, paresthesias, fatigue, dizziness, and myalgias.[171] These symptoms can be mild, moderate, or severe. They usually present in patients with an elevated hematocrit (>65 percent) or can present at a hematocrit less than 65 percent if the patient is iron deficient. The patient usually experiences the same hyperviscosity symptoms each time (e.g., headache, visual disturbances, fatigue), and they must be relieved by phlebotomy to qualify as hyperviscosity symptoms.

An increased hematocrit level, in the absence of symptoms, does not constitute an indication for phlebotomy. Repeated phlebotomy under these circumstances will lead to iron deficiency, and perhaps cerebral arterial events. Dehydration secondary to excessive heat, illness, fever, diarrhea, or vomiting can be the cause of hyperviscosity symptoms and should be managed appropriately with volume replacement.

If dehydration or iron deficiency is not the cause of hyperviscosity symptoms, phlebotomy becomes the treatment of choice. Removal of 500 ml of blood over 30 to 45 minutes preceded by or simultaneous with a 500- to 1000-ml volume replacement with normal saline (or dextran for patients with congestive heart failure) can usually be performed in an outpatient setting. The goal of phlebotomy is symptom control. The patient having phlebotomy is at risk of iron deficiency. As a rule, iron supplementation should be prescribed.

IRON DEFICIENCY AND REPLACEMENT.

Iron deficiency is an important and common finding in cyanotic adults. The etiology can be multifactorial and includes excessive bleeding from hemoptysis, epistaxis, or excessive menses, but by far the most distressing cause is inappropriate phlebotomy. Microcytosis from iron deficiency results in an increase in whole blood viscosity because microspheres are much less deformable than the normal biconcave disc-shaped iron-replete red blood cell.

In contrast to normocytic erythrocytosis, which seldom causes symptoms at hematocrit levels less than 65 percent, iron deficiency can present as hyperviscosity symptoms at hematocrit levels well below 65 percent. The treatment of choice in this case is iron repletion and not phlebotomy. If iron deficiency is confirmed, supplemental iron should be administered until a rise in hematocrit is registered, or until the iron-replete state has been achieved. Intravenous iron preparations are an alternative for patients intolerant of oral iron supplementation.[171]

HEMOSTATIC ABNORMALITIES.

Hemostatic abnormalities have been documented in cyanotic patients with erythrocytosis.[171] Any bleeding tendency is usually mild and superficial, leading to easy bruising, petechiae, or mucosal bleeding. However, at times, bleeding can be moderate, with epistaxis or hemoptysis, or can even be life threatening, particularly in the postoperative setting. An increase in prothrombin time (PT) and partial thromboplastin time (PTT) from decreased levels of factors V, VII, VIII, and X, from quantitative and qualitative platelet disorders, and from increased fibrinolytic activity have all been described.

The management of a bleeding diathesis can be subdivided into two clinical categories: spontaneous bleeding and perioperative prevention. Spontaneous, superficial bleeding usually is self-limited. Avoidance of aspirin, nonsteroidal antiinflammatory drugs, and heparin is an important prophylactic measure. The treatment of severe spontaneous bleeding is dictated by the specific hemostatic disturbances. Platelet transfusions, fresh-frozen plasma, vitamin K, and cryoprecipitate have all been used.

It is recommended that cyanotic patients facing major surgery undergo prophylactic phlebotomy if the hematocrit level is greater than 65 percent to minimize hemostatic abnormalities intraoperatively and postoperatively. Isovolumetric phlebotomy of 500 ml can be performed every 24 hours until the hematocrit levels decrease below 65 percent. Blood that has been withdrawn should be kept for autologous transfusion if needed.

CEREBROVASCULAR EVENTS.

Cerebrovascular events including stroke secondary to thrombosis or embolus have been recognized as a complication of cyanosis in adults with congenital heart disease. The risk of stroke caused by cerebral arterial thrombosis has usually been seen in patients with iron deficiency and not iron-replete erythrocytosis.[172] [173] Cerebral hemorrhage can occur due to hemostatic defects and is most often observed after the use of often dangerous anticoagulant therapy. Patients with right-to-left shunts can also be at risk for paradoxical emboli. Focal brain injury can provide a nidus for brain abscess if bacteremia supervenes. Brain abscess patients can present with headaches with fever and focal neurological findings or seizures.[174] It follows from the previous discussion that prophylactic phlebotomy has no place in the prevention of cerebral arterial thrombosis. Avoidance of microcytosis is of paramount importance.[172] [173] Meticulous attention should be paid to the use of air filters in peripheral intravenous lines to avoid paradoxical emboli through a right-to-left shunt.[174] Anticoagulants should usually be avoided in chronically cyanotic cardiac patients. In the uncommon patient with atrial fibrillation or a mechanical prosthesis, a risk-benefit dilemma must be addressed.

RENAL DYSFUNCTION.

Renal dysfunction can present as proteinuria, hyperuricemia, and, rarely, overt renal failure.[175] Hyperuricemia, commonly observed in patients with cyanotic congenital heart disease, is caused mainly by increased reabsorption of uric acid rather than by overproduction from erythrocytosis. Fortunately, urate nephropathy, uric acid nephrolithiasis, and gouty arthritis are rare. Asymptomatic hyperuricemia need not be treated. Acute gouty arthritis responds to intravenous colchicine. Corticosteroid therapy is a viable alternative. Nonsteroidal antiinflammatory drugs should be avoided, given the baseline hemostatic anomalies in these patients. Symptomatic hyperuricemia and chronic gouty arthritis can be treated with probenecid or sulfinpyrazone, which are uricosuric agents, or with allopurinol, which decreases uric acid production. Most diuretics are relatively contraindicated because they reduce renal tubular secretion of uric acid and may aggravate existing hyperuricemia.

ARTHRALGIA.

Hypertrophic osteoarthropathy is thought to be the mechanism responsible for the arthralgias affecting up to one third of patients with cyanotic congenital heart disease. In patients with right-to-left shunting, megakaryocytes released from the bone marrow can bypass the lung. The entrapment of megakaryocytes in the systemic arterioles and capillaries induces the release of platelet-derived growth factor, promoting local cell proliferation.

New osseous formation with periostitis ensues and gives rise to arthralgia and bony pain.[175] Arthralgias can be managed with salsalate, a nonacetylated analog of aspirin. This medication does not appear to interfere with platelet function and, therefore, is an ideal antiinflammatory medication for patients with bleeding tendencies.

FOLLOW-UP.

Patients with cyanotic congenital heart disease should be followed regularly by experts. Hemoglobin levels, mean corpuscular volume, ferritin, renal function, and uric acid should be checked at least annually to avoid treatable causes of deterioration. Annual flu shots are recommended. Avoidance of unnecessary phlebotomies and anticoagulant therapy is key. Smoking is to be strongly discouraged because it impairs oxygen-carrying capacity and worsens oxygen delivery.

Chapter 45 - Acquired Heart Disease in Children

STEVEN D. COLAN
JANE W. NEWBURGER

The purpose of this chapter is to review cardiac diseases acquired in childhood. Congenital cardiac defects are discussed in Chapters 43 and 44 , while neurological diseases that affect the heart are described in Chapter 71 . Here we focus on cardiomyopathies, Kawasaki disease, hypertension, and hyperlipidemias.

CARDIOMYOPATHIES (see also Chap. 48)

This diverse group of disorders has historically been understood to represent "heart muscle diseases of unknown etiology,"[1] clearly excluding secondary processes such as hypertension, ischemic heart disease, and valvar and congenital heart disease. In addition, the World Health Organization definition also specifically excluded myocardial disease related to a known systemic disorder. Clinical practice does not concur with these exclusions, and secondary forms of cardiomyopathy are referred to as "anthracycline cardiomyopathy," "infectious cardiomyopathy," and other descriptive terms. Even etiologies that were intended to be specifically excluded have been incorporated under names such as "ischemic cardiomyopathy" and "cardiomyopathy of overload," a term that embodies the clinically familiar concept of load-induced myocyte dysfunction. Cardiomyopathy is now more familiarly taken to imply a disease process involving the heart muscle that results in intrinsic myocardial dysfunction, subcategorized as primary and secondary forms. Classification of the cardiomyopathies as dilated, hypertrophic, and restrictive has fared the test of time somewhat better, although this terminology clearly has problems as well. The mixture of morphology and physiology inherent within this classification is unquestionably problematic because many overlapping cases are encountered. Furthermore, it is clear that the same etiology can be manifested as dilated cardiomyopathy (DCM) in some patients and as hypertrophic cardiomyopathy (HCM) in others and that individual patients can transition between the two. Although this effort at categorization is merely a general, descriptive approach that cannot be relied on for unambiguous classification, it nonetheless provides a clinically useful framework and will be used in this presentation.

Dilated Cardiomyopathy (see also Chap. 48)

DCM has numerous etiologies, clinical manifestations, and outcomes that vary depending on both the pathogenesis and host response. Multiple associations have been described in children, but most cases remain idiopathic. Although the true frequency of the various causes of DCM is currently unknown, improved methods of diagnosis have enabled determination of the cause for a progressively larger proportion of the previously idiopathic cases. Between one-third and one-half of cases are thought to be familial.[2] Inflammatory heart disease caused by viral myocarditis or an abnormal immunologic response to viral infection is believed to be a common cause, but problems in confirming this diagnosis beyond the acute stage have hampered determination of the true incidence. Progress in molecular identification of viral presence in diseased human heart tissue[3] has created new opportunities to define the relationship between viral infections and myocarditis.

It is generally assumed clinically that the primary functional change at the myofiber level in DCM is depression of contractile function. Despite how commonly this assumption is believed, several groups have shown that isolated cardiac muscle harvested from patients with end-stage heart failure is capable of normal force-generating capacity under ideal conditions and low stimulation frequencies,[4] even when force generation deteriorates at higher stimulation frequencies.[5] In contrast, diastolic abnormalities are a constant property of failing heart muscle.[6] The molecular event or events that account for myocardial failure remain elusive, although many metabolic abnormalities have been described. Numerous abnormalities often coexist, and their relative importance is not known. Although most investigators have sought a single final pathway to contractile dysfunction, this approach may not be correct. Since DCM appears as the end result of many quite different processes, it is likely that numerous metabolic disturbances may have contractile dysfunction as the final common manifestation. Clarification of the disease-specific pathogenesis of contractile failure has no doubt been hampered by our very limited ability to determine etiology.

Clinical Features and Diagnostic Evaluation

Regardless of the underlying cause of the ventricular dysfunction, the congestive cardiomyopathies have a similar mode of expression. Older children experience exercise intolerance, dyspnea on exertion, tachycardia, palpitations, abdominal distention, syncope or near-syncope, and occasionally, cardiovascular collapse and sudden death. Although many symptoms parallel those seen in adults, primary complaints of peripheral edema and paroxysmal nocturnal dyspnea are uncommon in children. Infants are generally recognized on the basis of respiratory distress, abdominal distention, and poor feeding, but occasionally the process is subacute and failure to thrive is present at the time of diagnosis. Secondary cardiomyopathies can manifest a broad spectrum of noncardiac abnormalities, depending on the nature of the primary disorder.

PHYSICAL FINDINGS.

Physical findings depend on the severity of clinical compromise. Patients with mild ventricular dysfunction can have reduced exercise capacity but no

abnormal physical findings. Congestive heart failure is nearly always accompanied by tachypnea and tachycardia. Peripheral cyanosis is noted only in the presence of severe compromise. Peripheral pulses are often weak and can be difficult to palpate because of narrow pulse pressure and occasionally hypotension. Cool extremities and poor capillary refill can be noted, particularly in infants. Intercostal retractions are a common finding in infants and young children, but in contrast to adults, pulmonary auscultation rarely reveals rales, even when frank pulmonary edema is present on chest radiographs. Wheezing can be heard at all ages because of attenuated airway relaxation, a process that appears to result from the generalized desensitization of beta-adrenergic receptors that is characteristic of congestive heart failure.[7] Hepatomegaly is a seminal finding and can be massive in infants but changes rapidly in response to therapy. Neck vein distention and peripheral edema are almost never observed in infants but become more common with age. The cardiac impulse is often displaced laterally and is frequently diffuse. Gallop rhythm with a third heart sound is common, as is a murmur of mitral regurgitation.

LABORATORY DATA.

Cardiomegaly, pulmonary venous congestion, pulmonary edema, atelectasis, and pleural effusions are common radiographic findings. The electrocardiogram (ECG) shows sinus tachycardia in most patients. Nonspecific ST-T wave changes and left ventricular hypertrophy are noted in about half of patients,[8] with atrial and right ventricular hypertrophy in 25%. Just under 50% of patients have arrhythmias on initial evaluation, including atrial fibrillation and flutter, ventricular ectopic beats, and

nonsustained ventricular tachycardia on Holter recording. DCM must be differentiated from tachycardia-induced cardiomyopathy, a process that can have similar features but responds to arrhythmia control with complete recovery.[9]

Echocardiography.

Diagnostic findings on echocardiography are a dilated left ventricle with diminished systolic performance. Dysfunction is global, although moderate regional variation in wall motion is usually present. Quantitative assessment of systolic and diastolic functional parameters and ventricular morphology is diagnostically and prognostically useful. Pericardial effusions are frequent. Intracardiac thrombi have been reported in as many as 23% of children, although rarely in infants.[10] Color flow and spectral Doppler examinations are useful for assessment of mitral regurgitation, as well as diastolic function. The echocardiogram is equally critical for excluding valvar and structural cardiac disease. Anomalous origin of the left main coronary artery from the pulmonary artery can be reliably recognized through the combined use of imaging and color flow Doppler.[11]

Cardiac Catheterization.

This procedure is performed primarily for endomyocardial biopsy. Occasionally, the possibility of a coronary anomaly remains in doubt, in which case coronary arteriography is mandatory. Assessment of hemodynamics is rarely useful for patient management unless the clinical findings are discrepant from the echocardiographic findings, but hemodynamic evaluation has important prognostic implications and is needed if organ transplantation is considered. Biopsy findings in idiopathic DCM are nonspecific and demonstrate myocyte hypertrophy and variable amounts of fibrosis without evidence of inflammatory infiltrates. The primary importance of biopsy is detection of known causes of DCM, including histological or polymerase chain reaction evidence of myocarditis, infiltrative or mitochondrial disorders, cytoskeletal protein defects,[12] and endocardial fibroelastosis (EFE).[10] Numerous rare disorders can be diagnosed only by tissue analysis. A finding of inflammatory heart disease justifies a delay in consideration of transplantation because myocarditis in children is generally associated with a more favorable prognosis,[10] including the potential for complete recovery. The safety of transvenous biopsy has been amply demonstrated, and extensive experience in its use has been gained through routine application in cardiac transplant recipients. The highest risk is noted in infants,[13] in whom perforation by the stiff biopsy catheters is a recognized complication. However, this patient group is exactly the one in which the results can be most helpful, with the risk-benefit ratio shifted in favor of the test, even in this age group.

DIFFERENTIAL DIAGNOSIS.

In children and infants with DCM the differential diagnosis is complex because of the imposing array of possible rare disorders. An ordered and logical algorithm for diagnostic evaluation based on standard and widely available laboratory screening tests has been published[14] and has led to targeted specific testing for particular disorders of metabolism. This field is rapidly evolving as new enzymatic disorders are recognized and must be incorporated within this algorithm.[14A] [14C] Certain disorders, such as the mitochondrial disorders,[15A] [15C] can be particularly difficult to diagnose because of tissue-selective and heterogeneous expression related to either tissue-specific isoenzyme or to unbalanced segregation of mutated and wild-type mitochondrial DNA. The defect is biochemically manifested when a certain threshold of mutated mitochondrial DNA is reached. The situation is rendered even more complex by the age-dependent accumulation of mitochondrial DNA deletions that appear to have no causal relation to DCM.[16]

Treatment

In the absence of an identifiable cause, treatment is supportive, nonspecific, and targeted at controlling the symptoms of congestive heart failure. The severity of clinical compromise determines the level of support needed. Critically ill children will generally require mechanical ventilation and inotropic support. Management at centers that have extracorporeal membrane oxygenator and ventricular assist device support available is advised for these patients. Some patients can experience sufficient recovery within a period of days to permit withdrawal of mechanical myocardial support, and the method can at times be used as a bridge to transplantation.[17] Once the patient is stabilized, or in patients who are not critically compromised at the time of initial assessment, oral therapy with digoxin, angiotensin-converting enzyme (ACE) inhibitors, and diuretics remains the mainstay of treatment. Recent data in adults indicate a 30% reduction in deaths when spironolactone is included in the diuretic scheme.[18] This medication is well tolerated in children, and despite the absence of specific data in this age group, these results are fairly compelling for its use. No consensus has been reached regarding which of these agents to institute first in children who do not require multidrug therapy, but asymptomatic ventricular dysfunction is often managed with ACE inhibitors alone because of the absence of significant reported risk.

Arrhythmias are common in children with DCM,[8] and their management is not substantially different from that of adults. Data concerning the utility of ventricular stimulation protocols are rare in children, but the available data suggest that it is useful in risk stratification but not clearly effective in guiding therapy.[19] Intermittent infusion of inotropes such as dobutamine, a common practice in the management of children with severe chronic congestive heart failure, has been based on practice in adult clinics. Although the results in adult studies are mixed, with some trials reporting that survival can be adversely affected, most studies continue to note symptomatic improvement.[20] Intermittent inotrope infusion appears to be a reasonable alternative to achieve stabilization and symptom control in patients awaiting transplantation.

Carnitine deficiency and disorders of carnitine transport can result in DCM and HCM, and in some cases, dietary carnitine supplementation can lead to dramatic cardiac and clinical improvement. In an attempt to avoid delays in ther

apy, it is not uncommon for clinicians to initiate empirical carnitine supplementation prior to biochemical confirmation of this disorder. In fact, cardiomyopathy is not a prominent feature of myopathic carnitine deficiency, in which skeletal muscle weakness and recurrent metabolic crises dominate. In addition to potentially obscuring diagnostic evaluation, other inborn errors of metabolism have been described that are manifested as DCM but deteriorate rapidly in response to carnitine supplementation.[21] Plasma carnitine concentrations and fatty acid metabolism byproducts should be evaluated in all infants with cardiomyopathy of unknown etiology, but empirical therapy is not advised.

Children with DCM are at risk for intracardiac thrombus formation and systemic embolization. Intracardiac thrombi were seen in 46 to 84 percent of children at autopsy, but their relationship to premorbid findings is unclear since one of these studies documented no intracardiac thrombi during life.[22] Clinical series report the presence of intracardiac thrombi in 0 to 23 percent.[10] [22] [23] Comparison of these studies indicates an age-related trend toward a higher incidence, but none of the series have been large enough to draw firm conclusions. Guidelines for antithrombotic therapy are derived from and parallel those in adults.

Mitral valve regurgitation is common in DCM and in some instances can be moderate or more pronounced in severity. Clinical improvement in symptoms, ventricular function, and survival after mitral valvuloplasty has, however, been reported in patients with DCM.[24] [25] The repair represents a form of afterload reduction, with a fall in wall stress consequent to ventricular remodeling. In patients with moderate to severe mitral regurgitation associated with DCM, valve repair should be seriously considered, but valve replacement generally entails excessive risk.

Several forms of therapy are currently investigational in children. Two recent large and favorable experiences with beta blockers in adults with congestive heart failure[26] [26A] have not been adequately replicated in children. There is ample theoretical justification for their use, and preliminary results in children have been reported,[27] but data on risk-benefit analysis, appropriate dosing schedule, and patient selection criteria are limited. The combination of an ACE inhibitor and beta blocker has been found to result in a synergistic effect in adult patients with asymptomatic dysfunction,[28] an issue that has not been addressed in children. Trials of angiotensin II receptor antagonist[29] use in children have not been reported. Early reports of potential benefits of growth hormone therapy in adults with DCM[30] have not been confirmed in children. Patients with DCM often have markedly asynchronous ventricular activation resulting in a diminished peak force of contraction.[30A] Biventricular DDD pacing with optimized atrioventricular synchrony can improve ventricular performance and has been tried as a therapeutic modality in several small series of adult patients.[31] [31A] Again, no data are available in children. The recent advent of ventricular volume reduction surgery as a means of afterload reduction in patients with end-stage DCM has been attempted in a few children,[32] but the numbers are too few to draw any conclusions. This procedure improves systolic function at the expense of further impairing diastolic function,[33] [33A] with an unpredictable net impact on overall cardiac function. Infants and children with DCM have a marked dominance of systolic dysfunction with less evidence of diastolic dysfunction than is generally noted in adult studies, thus suggesting that they might indeed benefit from this procedure.

Predictors of Outcome

Negative predictors of outcome in children with DCM include the severity of dysfunction, spherical ventricular shape, coexistence of right ventricular dysfunction, familial cardiomyopathy, tissue diagnosis of EFE, persistent cardiomegaly, and persistent congestive heart failure. Tissue diagnosis of myocarditis has been associated with a better outcome. Ventricular size and mass at initial evaluation have not been found to be predictive of outcome. Younger age at diagnosis has been reported to

be associated with a better outcome by some groups,[34] has been associated with a worse outcome by other groups,[35] and in other series has not been found to be a significant factor.[36] One motivation for defining factors predictive of outcome is to facilitate early recommendation for cardiac transplantation. It is therefore disturbing that so little agreement has been found in the many studies to date. Given the heterogeneity of the disorder itself and the small number of patients included in many series, it is likely that the patient samples are quite dissimilar. Entry criteria have also varied substantially among these studies, with specific inclusion of myocarditis in some but exclusion in others. Many of the variables are likely to have a real association with outcome, but the relationship is weak. The fact that commonly used measures of ventricular performance are only weakly predictive of survival severely limits their utility in decisions concerning transplantation.

OUTCOME.

Survival statistics for infants (Fig. 45-1) and older children (Fig. 45-2) with idiopathic DCM have varied, with 1-, 2-, 5-, and 10-year survival rates of 41 to 94 percent, 20 to 88 percent, 34 to 86 percent, and 52 to 84 percent, respectively, having been reported. In those who survive, nearly half have full normalization of ventricular function, 25 percent have improved but abnormal function, and 25percent have persistently severely depressed function.[37] Recovery of function is generally complete within the first year, but occasional patients experience continued late improvement.[10] [38]

Infective Myocarditis (see also Chap. 48)

Myocardial inflammatory diseases are an important cause of DCM in children. Myocarditis cannot be reliably distinguished from other forms of DCM on clinical grounds alone because both the acute and chronic forms have symptoms and functional consequences related to the severity of ventricular dysfunction. A significant number of cases of myocarditis have manifestations that are subclinical and associated with ECG changes or arrhythmias, and in a significant number the myocarditis can be occult or cause sudden death.[39] Nearly all the organisms that cause common infectious illnesses in children can also cause myocarditis,[40] although fewer have been associated with the manifestations of DCM. In addition, myocarditis can occur as a hypersensitivity or toxic reaction and is associated with a number of important systemic diseases such as rheumatic fever.

Management of myocarditis is similar to management of other forms of DCM in that etiology-specific therapy is not generally available. Considerable evidence indicates that the immune response and autoimmunity may play a central role in the acute and chronic myocardial damage,[41] thus suggesting a role for immunosuppressive therapy. Small, uncontrolled trials of corticosteroid therapy in children with evidence of myocarditis[42] [43] have reported favorable outcomes. Similar to trials of these and other immunosuppressive agents in adults, these uncontrolled studies in a disease with a high rate of spontaneous resolution are impossible to interpret. In some centers, administration of high-dose intravenous gamma globulin to children with findings indicative of acute myocarditis has led to improved survival and more rapid recovery of function.[44]

Endocardial Fibroelastosis (see also Chap. 48)

Diffuse thickening of the left ventricular endocardium secondary to proliferation of fibrous and elastic tissue is an

uncommon but nonspecific response to a variety of inciting agents. The finding was at one time thought to represent a specific disease, but as emphasized by Lurie,[45] it is now clear that EFE represents a final common pathway for many different myocardial stressors. An association with mumps virus infection has been suspected for many years, a theory supported by detection of the mumps virus genome in the myocardium of infants and children.[46] This proposed etiology for a significant proportion of cases is further supported by the observed fall in EFE incidence coincident with implementation of widespread vaccination. Despite the reduction in frequency, this histological finding continues to be reported in association with a wide variety of cardiac diseases, including prenatal and postnatal left ventricular outflow tract obstruction, numerous other forms of congenital heart disease, and many forms of DCM and HCM, as well as being a focal finding in adults with various cardiac disorders.[47] Among the various associations, no single theme emerges, which supports the interpretation that EFE represents a nonspecific tissue response. The pathophysiology of the response is of interest inasmuch as it can provide clues to pathways of injury shared by various diseases.

Clinically, more than 80 percent of cases occur in the first year of life, with features dependent on which form of the disease is manifested. Most patients have a dilated ventricle with increased wall thickness and depressed systolic function. The clinical manifestations of the dilated form are similar to findings in other types of DCM. Rarely, patients have a contracted form characterized by a small left ventricle and a clinical picture of restrictive cardiomyopathy. The diagnosis of EFE is most commonly made at autopsy. Although EFE is often suspected on echocardiography (see Chap. 7) when the ultrasound signal from the endocardial surface is unusually strong, echocardiography has not been found to be a reliable diagnostic technique.[48] EFE can be recognized on endomyocardial biopsy, and despite greater involvement of the left ventricle in many patients, the diagnosis can frequently be confirmed on right ventricular biopsy. An autopsy series found that most patients with EFE had right ventricular involvement, although to a lesser extent than on the left,[49] but the diagnostic accuracy of endomyocardial biopsy of the right ventricle has not been systematically tested. The purpose of the diagnosis is primarily for prognosis since in some clinical situations the finding of EFE has been associated with a poor outcome. For example, in case series of DCM, EFE is often identified as one of the risk factors for death.[10] [23] Nevertheless, in a group of patients with idiopathic EFE, the 4-year survival rate was 77 percent, which is not worse than rates reported in other forms of DCM.

Doxorubicin Cardiomyopathy (see Chaps. 48 and 69)

The anthracycline antibiotics include a number of valuable antitumor agents, with doxorubicin (Adriamycin) in particular having the broadest spectrum of antitumor activity of the available cancer chemotherapeutic agents. Thousands of children have received doxorubicin over the past 30 years for several of the most common pediatric oncological disorders, including acute lymphocytic leukemia. A dramatic improvement in long-term survival after childhood cancer has occurred during the same time interval. As a result, late residua from therapy often represent the most important clinical problem for these patients. Among these residua is doxorubicin-associated cardiomyopathy, the consequences of which continue to unfold as the length of follow-up increases. The magnitude of this problem has escalated to the point that for many pediatric centers, doxorubicin cardiomyopathy accounts for the majority of cases of DCM.

CLINICAL FEATURES.

Clinically, the most significant problems relate to a chronic, dose-related cardiomyopathy. Historically, cardiomyopathy was manifested by left ventricular dysfunction, elevated filling pressure, and reduced cardiac output 2 to 4 months after completion of therapy. The myocardial insult is often delayed for a period after the last dose of the drug because of a time delay in the full cytotoxic effect of the drug, with a mean latency between 3 and 8 weeks. More recently, new onset of congestive heart failure has been described in patients years after completion of therapy.[50] As a group, these patients manifest a low incidence of depressed contractility. The dominant abnormality is elevated afterload related to inadequate hypertrophy in the absence of significant dilation.[50] [51] Total cumulative dose, age at the time of doxorubicin therapy, and duration since completion of therapy each relate to the incidence of cardiac abnormalities. Excess afterload is a particular risk for young children; it appears gradually and is manifested as inadequate myocardial growth when compared with the rate of somatic growth. This form of doxorubicin-mediated cardiac injury appears to represent impaired growth capacity of the myocardium, a problem of particular importance to a small child.

Numerous clinical studies have identified certain factors that place patients at increased risk for the adverse cardiac effects of doxorubicin. Patients younger than 4 years have an increased risk.[50] Females are at higher risk on a dose-matched basis.[52] [53] Mediastinal irradiation increases toxicity,[54] although the effect is not marked. However, the factor that has been consistently found to bear the strongest relationship to the incidence of cardiotoxicity is the total cumulative dose. The relationship between the total cumulative dose of doxorubicin and symptomatic cardiotoxicity is nonlinear, with an inflection point somewhere between 400 and 600 mg/m[2] . For example, in one study the incidence of cardiomyopathy was 7 percent in subjects who received less than 550 mg/m[2] , but it increased to 18 percent in the group that received 700 mg/m[2] .[55] Although some variation is seen in the dose at which the incidence of congestive heart failure has been observed to rise, this general pattern has been observed in the numerous studies that have examined it.

PREVENTION.

Recognition of the dose-related nature of early-onset congestive heart failure has resulted in nearly universal limitation of the cumulative dose to less than 350 to 450 mg/m[2] , which successfully reduces this complication to 1 percent or less. Although late toxicity also appears to be dose related, doses as low as 90 to 220 mg/m[2] still represent a measurable risk,[50] [51] with no "safe" dose having been demonstrated. In addition to uniform dose reduction for all patients, alternative means of toxicity reduction that have been reported include dosing regimens designed to reduce peak serum levels (such as continuous infusion), coadministration of agents aimed at providing cardioprotection, and programmed dose reduction as dictated by one of several monitoring programs. Numerous agents with the potential to reduce doxorubicin cardiotoxicity have been tried in animal and human trials, but at present the most promising is dexrazoxane (ICRF-187). Dexrazoxane has a plausible mechanism of action (iron chelation),[56] evidence of reduced early and late toxicity in animals, and promising early results in clinical trials in children.[57]

Cardiac monitoring programs that attempt to detect cardiotoxicity on an individual basis, thereby permitting individual dosing regimens and dose reduction in patients with evidence of cardiac injury, are both widely used and highly contentious.[58] [59] Although the means used to detect myocardial injury has varied from study to study, in other regards the monitoring programs that have been recommended are quite similar. The basic approach is to evaluate patients periodically during doxorubicin therapy and to delay or discontinue treatment with the drug in patients with abnormal test results. It is generally agreed that the onset of congestive heart failure justifies cessation of doxorubicin therapy. However, the more typical scenario is a patient who has received some fraction of the intended cumulative dose of doxorubicin, at which time an asymptomatic drop in left ventricular function is detected. For patients treated by set protocols, if the fall in function exceeds some predefined criteria, cessation of anthracycline therapy is advised. This approach is advocated to minimize adverse cardiac outcomes.[58] However, opponents of published criteria voice concern that the impact of these programs on overall outcome has not been addressed.[59] Fundamentally, it is important to recognize that administration of anthracyclines is intrinsically a compromise between cancer cure and cardiac injury such that any reduction in the total cumulative dose decreases the antitumor effect. Even a reduction in cumulative dose from 270 to 180 mg/m[2] has been shown to have a detectable impact on the cancer cure rate.[51] Similarly, cardiotoxicity is a progressive phenomenon, with mild but detectable injury even at very low doses.[50] [51] Evaluation of the success of any cardiac monitoring program must include a decision regarding what severity of cardiac injury is unacceptable to achieve the desired antitumor effect. At

perhaps the most simplistic level, dose reduction in response to a monitoring program should result in verifiable net improvement in survival. However, at present the benefits of serial cardiac assessment for doxorubicin-induced cardiomyopathy as a means of dose adjustment remain enticing but unproven.

Hypertrophic Cardiomyopathy (see Chap. 48)

HCM is defined as the presence of ventricular hypertrophy without an identifiable hemodynamic cause such as hypertension, valvular heart disease, catecholamine-secreting tumors, hyperthyroidism, or any other condition that could secondarily stimulate cardiac hypertrophy. It is clear that HCM represents a heterogeneous group of disorders, and this diversity is more apparent in childhood than at any other age. These disorders can be subdivided into primary and secondary forms, where the primary form is a familial disorder ("familial HCM") typically devoid of findings outside of the heart. Secondary forms include diseases such as Friedreich ataxia, where ventricular hypertrophy is common but not the dominant clinical manifestation (see Chap. 71) , and others such as glycogenosis type IX, in which a systemic disorder has primarily or exclusively cardiac manifestations.

Familial Hypertrophic Cardiomyopathy

CLINICAL DESCRIPTION.

In about half of affected patients, it is possible to elicit a history of another family member with familial HCM or a family history of sudden death at a young age. Although many young patients are asymptomatic, the full spectrum of symptoms associated with this disease can be present from early childhood. Limitation of exercise capacity because of either dyspnea or chest pain is often the primary and most disabling symptom in familial HCM. As a group, exercise performance is impaired, even when asymptomatic patients are included.[60] Chest pain, which is an extremely unusual finding in most forms of heart disease in children, is common in children with familial HCM and can have characteristics of angina; however, the chest pain is often atypical in that it occurs at rest, has a variable threshold of onset, and is at times prolonged. Infants with familial HCM often have clinical features more typical of congestive heart failure, with a history of tachypnea, hepatomegaly, and poor feeding and growth. Palpitations are common in adults but rarely noted by children. Syncope occurs in 15 to 25 percent of adult subjects. Although syncope is less common in childhood, it is strongly associated with the risk of sudden death.

PHYSICAL FINDINGS.

Most children and young adults are remarkably healthy, with a frequent predilection for athletics. Although many physical findings have been described in this disease, most relate to dynamic ventricular outflow obstruction and are absent in subjects without obstruction. Therefore, a completely normal physical examination in a healthy patient who may be quite athletic does not exclude the presence of this potentially fatal disorder, an observation that has led some observers to suggest echocardiographic screening as part of an evaluation prior to sports participation. The apical and parasternal cardiac impulses are often augmented but rarely displaced. Hepatomegaly is common in infants but is generally not seen beyond this age. In the presence of outflow obstruction, a bisferious carotid pulse can be encountered that corresponds to the "spike-and-dome" aortic pulse contour of patients with dynamic outflow obstruction. Parasternal and carotid systolic thrills are frequent in patients with left or right ventricular outflow obstruction. The murmur of dynamic left ventricular outflow obstruction can be noted, and it rises in intensity with physiological maneuvers that lower preload or afterload or increase contractility. Very loud systolic murmurs are usually found in subjects with subpulmonary stenosis, which is more common in infants and children. The murmur of mitral regurgitation is frequent in patients with subaortic stenosis, although difficult to separate from the outflow murmur. Aortic regurgitation can be heard but is less commonly encountered than in discrete subaortic stenosis.

ELECTROCARDIOGRAM AND HOLTER RECORDING.

Although the vast majority of patients with familial HCM and obstruction to left ventricular outflow have an abnormal ECG, about 25 percent of patients without obstruction have a normal ECG. The most common abnormalities are left ventricular hypertrophy, ST segment and T wave abnormalities, and abnormal Q waves. Atrial fibrillation develops in approximately 15 percent of adults with familial HCM but is unusual in children. Symptomatic ventricular tachycardia on Holter recording or induced at electrophysiology study appears to identify a high-risk subgroup.[61] Although syncope is a risk factor for sudden death,[62] the presence of asymptomatic ventricular tachycardia on Holter recording is not a risk factor.[63] In children, ventricular arrhythmias on Holter recording are less frequent than in adults.

ECHOCARDIOGRAM.

The echocardiogram permits noninvasive assessment of ventricular size, wall thickness, systolic and diastolic function, outflow obstruction, and valvar insufficiency. Localized hypertrophy of the anterior septum is seen in 10 to 15 percent of patients, and 20 to 35 percent of patients have involvement of both anterior and posterior portions of the septum. At least 50 percent of patients have involvement of the anterolateral free wall in addition to the septum. The incidence of isolated involvement of the posterior and apical portions of the septum or anterolateral free wall without hypertrophy of the anterior septum is as much as 20 percent. The reported incidence of concentric hypertrophy is quite variable but can be as much as 20 percent. The anatomical pattern has not proved to be predictive of outcome but is a primary determinant of outflow obstruction and is an important factor in surgical planning.[64]

EXERCISE TESTING.

Quantitative assessment of functional capacity is useful for documenting clinical status, as well as for objectively assessing the response to therapeutic interventions. High-grade arrhythmias are elicited in some patients and have a negative prognostic implication. A hypotensive response to exercise appears to represent a risk for sudden death,[65] but more definitively, a normal exercise blood pressure response identifies a low-risk cohort.[66] Children and young adults with thallium scintigraphic

evidence of ischemia have been reported to be at increased risk of sudden death.[67] Unfortunately, ECG changes with exercise are an unreliable marker of ischemia because they occur with equal frequency in patients with and without inducible ischemia.

CATHETERIZATION.

The hemodynamic findings in familial HCM depend on the presence or absence of obstruction. The right ventricle can be involved, particularly in infants and children, and can demonstrate outflow gradients and elevated diastolic pressure. In infants, the septum often impinges on right ventricular outflow, and right ventricular cavity obliteration in systole can be noted. Myocardial bridges, i.e., muscle bands overlying epicardial coronary arteries, are congenital and sufficiently common (having been observed in 20 to 66 percent of hearts) that they are considered an anatomical variant rather than a congenital anomaly.[68] Despite angiographic evidence of systolic compression of the underlying coronary artery, little evidence supports the hypothesis that myocardial bridges can be associated with ischemia. Compression of the coronary artery by myocardial bridges has been detected angiographically in 30 percent of adults with familial HCM,[69] with no evidence of adverse impact on outcome. In a recent provocative report of a relationship between sudden death and the presence of myocardial bridging in children with familial HCM, Yetman and associates suggested that surgical unroofing of the coronary artery can prevent sudden death.[70] These authors describe delayed diastolic filling of the affected coronary artery as a mechanism for ischemia. It is unclear why myocardial bridges would have a greater impact on children than has been described in adults, so further confirmation is required before myocardial bridging can be accepted as an adverse risk factor worthy of surgical intervention.

DIFFERENTIAL DIAGNOSIS.

Ultimately, the diagnosis of familial HCM depends on molecular identification of the offending gene or the abnormal gene product. Until this test is available on a commercial basis, reliance on current, less than perfect diagnostic tools is necessary. Although echocardiographic identification of hypertrophy is the primary diagnostic modality in current clinical use, familial HCM with an associated risk of sudden death can be present even in the absence of hypertrophy. Surprisingly, when a genotyped population is investigated, the usual ECG and echocardiographic criteria accurately detect disease in only 83 percent of adults and only 50 percent of children.[71] Under these circumstances, the need for alternative diagnostic modalities is apparent. Endomyocardial biopsy is useful for excluding other causes of HCM, including mitochondrial disorders and storage diseases, and is therefore recommended in infants and young children. However, the

primary histological abnormality of focal myocardial disarray is not unique to familial HCM and cannot be reliably detected on biopsy specimens.

Although isolated case reports have described HCM in association with many disorders, in a number of disorders HCM is seen with sufficient frequency to indicate that it is an intrinsic element of the disease (Table 45-1) . Patients with Friedreich ataxia have a 25 to 50 percent incidence of HCM, with clinical characteristics quite different from those of familial HCM (see also Chap. 71) . HCM is seen in up to 20 to 30 percent of patients with Noonan syndrome,[72] with findings similar to those in familial HCM. Although the risk of congestive heart failure is more common than in familial HCM, there is also at least some risk of sudden death.[73] Infants of diabetic mothers and neonates exposed to corticosteroids often have transient biventricular hypertrophy, sometimes with outflow tract obstruction and occasionally causing symptoms. Finally, many genetic disorders are often accompanied by cardiac hypertrophy. Generally, HCM in infants is associated with unique problems in the differential diagnosis. In various series, diseases other than familial HCM have accounted for 30 to 70 percent of HCM cases in patients younger than 2 years.[73] Hypertrophy with depressed function is rare in familial HCM and highly suggestive of a metabolic or mitochondrial disorder.[74] Myocardial biopsy is often necessary to distinguish among these disorders, is recommended in all patients younger than 2 years, and can be particularly helpful in children with symmetrical hypertrophy or depressed function who have no family history of familial HCM.[74] Mitochondrial disorders present a particular problem in diagnosis because of variable and often tissue-specific involvement.

Differentiation between physiological hypertrophy secondary to athletic participation and pathological hypertrophy in familial HCM is a frequent and important problem in children and young adults. The cardiac response to chronic, intense exercise has been well characterized and includes dilation and hypertrophy with preservation of myocardial contractility. The hypertrophic response is most intense in sports that elicit a marked rise in blood pressure during exercise, such as rowing, wrestling, and power lifting. Wall thickness greater than 13 mm, as occasionally found in athletes, and the not infrequent

Selenium deficiency

LEOPARD=lentigenes (multiple), electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness.

occurrence of mild left ventricular hypertrophy in patients with familial HCM result in a significant incidence of diagnostic ambiguity. ECG has not been particularly helpful in differentiation because of the frequent presence of ECG abnormalities in athletes.[75] Echocardiographic and clinical features that increase the probability of familial HCM include (1) a family history of HCM or early sudden death, (2) significant regional differences in hypertrophy, (3) diastolic dysfunction, (4) abnormal ultrasonic myocardial reflectivity, (5) absence of deconditioning-induced regression of hypertrophy, and (6) abnormalities in coronary flow reserve.[76] Ultimately, differentiation by available techniques is simply not possible in some subjects.

MANAGEMENT

The therapeutic options available in children are not fundamentally different from those in adults (see Chap. 48) . Although safety data from small series are available for most of these alternatives, no sufficiently large studies have independently addressed efficacy in infants or children. Chest pain and dyspnea are often relieved by propranolol, but improved exercise capacity is seen less often, and side effects such as fatigue and depression are often encountered. Calcium channel blockers can also reduce dyspnea and chest pain, and an increase in exercise capacity usually occurs. Although older patients with congestive heart failure can be intolerant of these drugs, pediatric tolerance has been excellent, even in neonates.[73] While several retrospective studies report a reduced risk of sudden death,[73] [77] [78] definitive controlled trials to support this finding are not available.

Each of the several interventions used to reduce outflow obstruction in adults with familial HCM and subaortic stenosis (surgery, asynchronous pacing, and septal ablation) are also available to children, but additional technical considerations affect the risk-benefit ratio. Often, clinicians attach too much significance to the presence or absence of outflow obstruction, as discussed by Criley.[79] Outflow obstruction is present in less than half of patients with familial HCM and is not predictive of outcome, with symptomatic patients without obstruction faring more poorly than those who have gradients. The magnitude of outflow obstruction is unrelated to the occurrence of ventricular tachycardia or risk of sudden death. Surgical or pharmacological reduction in the outflow gradient in symptomatic patients is usually associated with a reduction in symptoms, although the incidence of sudden death is not improved. In general, dynamic outflow obstruction is not a negative prognostic factor, and interventions aimed at reducing the gradient are justified only inasmuch as symptomatic benefit can be anticipated.

SEPTAL MYOTOMY-MYECTOMY.

In symptomatic HCM with subaortic stenosis, this procedure results in symptomatic improvement in nearly all patients despite the fact that symptoms are generally not correlated with the presence and degree of obstruction. Results in children have been similar to those reported in adults.[80] Although occasional studies have reported improved survival, most have documented no change. Consequently, surgery should be considered for relief of symptoms in patients with intractable and debilitating symptoms in spite of maximum medical therapy. Intervention based on gradient alone cannot be recommended.

ASYNCHRONOUS VENTRICULAR PACING.

This technique has emerged as an effective method of symptomatic treatment in some patients with left ventricular outflow tract obstruction.[81] Studies in small cohorts of children with outflow obstruction who were symptomatic despite medical therapy have reported symptomatic improvement, reduced outflow obstruction, and improved exercise tolerance.[82] [83] Controlled studies in adults found that only about 60 percent of patients improved, in two-thirds of these the benefit appeared to reflect a placebo effect, and an adverse effect on symptoms was seen in 5 percent.[84] Pacemaker implantation is associated with a significant incidence of complications,[85] particularly in growing children. Based on current information, dual-chamber pacing can be considered as an alternative to surgical or transcatheter septal reduction in patients with obstructive HCM who are symptomatic despite maximum medical therapy.

EXERCISE RESTRICTION.

Avoidance of strenuous exercise is generally recommended for patients with familial HCM. The rationale for this restriction is based on the observations that sudden death is the usual cause of death in familial HCM and has a higher than expected association with exercise,[86] and that familial HCM is believed to be the most common cause of sudden death in young, competitive athletes.[87] Nevertheless, the basis for this recommendation has several serious weaknesses.[88] The true incidence of familial HCM in athletes who experience sudden death is uncertain since genetic confirmation was not available and diagnosis was based on morphological criteria that cannot unequivocally differentiate familial HCM from physiological hypertrophy. It is clear that some patients with familial HCM tolerate intense, competitive athletic participation without symptoms or sudden death.[89] Population studies have documented the

Figure 45-3 Survival in infants with hypertrophic cardiomyopathy. *Maron (1982):* Maron BJ, Tajik AJ, Ruttenberg HD, et al: Hypertrophic cardiomyopathy in infants: Clinical features and natural history. Circulation 65:7, 1982; *Moran (1998):* Moran AM, Colan SD: Verapamil therapy in infants with hypertrophic cardiomyopathy. Cardiol Young 8:310, 1998.

apparent paradox that although patients with coronary artery disease who regularly participate in low- and high-level exertion have a transient increase in the risk for sudden death during intense exercise, these individuals experience an overall reduction in the risk for sudden death (see Chap. 26) .[90] In addition, patients who do not exercise regularly have an exaggerated risk of sudden death during exercise. Studies have not been conducted to determine whether athletic participation increases the overall risk for sudden death; it has not been shown that survival is improved in those who do not exercise, nor is the level of exercise that represents a safe limit known. Detraining and social stigmatization are particularly difficult problems for an adolescent who is excluded from the usual school activities and peer interactions. Competitive team sports elicit an emotional overlay that appears to increase the risk associated with the sport itself, in addition to demanding more intense exercise. Certain activities such as weightlifting are associated with high levels of circulating catecholamines that can predispose to arrhythmias and elicit a marked stimulus to eccentric cardiac hypertrophy. However, little evidence indicates that moderate aerobic-type exercise is a significant risk in these patients, and it does provide measurable hemodynamic and psychological benefits.

RISK STRATIFICATION.

Many prognostic factors for sudden death have been reported, but few have been confirmed. It is likely that the availability of genotyping will permit genetic risk stratification (see Fig. 48-11) (Figure Not Available) , but at present, four major risk factors have been identified: a family history of sudden death, exercise-induced hypotension, syncope, and symptomatic nonsustained ventricular tachycardia on Holter recording. Patients free of all risk factors are considered to be at low risk, and interventions (other than for symptoms such as chest pain or exercise intolerance) are not indicated. With two or more risk factors or with syncope alone in children, risk is considered high and aggressive management such as with an implantable cardioverter-fibrillator is recommended (see Chaps. 23 , 24 , and 25). No consensus has been reached on management of intermediate-risk patients. Additional negative prognostic factors such as evidence of ischemia on exercise thallium testing, marked QT dispersion, and myocardial bridging can also be useful in management decisions for these patients.[91]

CLINICAL COURSE.

The clinical course of familial HCM is highly age dependent. HCM in infancy appears to carry a worse prognosis than in older age groups. Symptomatic infants generally manifest congestive heart failure and cyanosis and have been reported to have a particularly poor

Figure 45-4 Survival in children with hypertrophic cardiomyopathy. *Maron (1976):* Maron BJ, Henry WL, Clark CE, et al: Asymmetric septal hypertrophy in childhood. outlook, with 9 of 11 dying within the first 5 years in one series[92] and 10 of 19 dying in the first year of life in another.[93] However, some series have noted survival not dissimilar to that in older children, with reported survival rates of 100 percent at 6 years[94] and 85 percent at 12 years,[73] probably representing differences related to small series and the numerous etiologies of HCM in this age group. The reported survival in several series of HCM in infants (Fig. 45-3) and older children (Fig. 45-4) illustrate the diversity of results in these several series. Ventricular hypertrophy can develop during childhood or adolescence, and ECG abnormalities can precede its appearance, but new appearance in a previously normal adult has not been described. The severity of hypertrophy can progress during periods of accelerated somatic growth, particularly during adolescence,[95] whereas in adults, progression does not appear to be a feature of the disease. Importantly, the increase in magnitude of hypertrophy that is sometimes seen does not have prognostic importance and does not justify an alteration in management.[96] Regression of hypertrophy is not generally considered a characteristic of the disease, although it has occasionally been reported in children.[97]

Systolic function is nearly always normal or hyperdynamic and generally does not change over time unless transition to a thin-walled congestive cardiomyopathy occurs, a transformation rarely observed during childhood[97] and invariably associated with a grim prognosis. In patients with obstruction, the pressure gradient is also generally stable in adult subjects, although progression does occur in children and adolescents.[98] Sudden death in patients referred to tertiary care centers is seen annually in 3 to 5 percent of adults and 6 to 8 percent of children.[99] Recent population studies indicate a much lower annual mortality (0.1 to 1 percent), which indicates a major referral bias in these statistics.[100] Asymptomatic adults appear to be at even lower risk,[101] although a similar relationship to symptoms has not been demonstrated in children. While improved survival has been reported with medical and surgical interventions, the studies are invariably retrospective and usually rely on historical controls. Definitive evidence of improved survival with any available therapy has not yet appeared.

Restrictive Cardiomyopathy (see also Chap. 48)

Restrictive cardiomyopathy is the least common form of cardiomyopathy and is quite rare among children. With the exception of occasional case reports, only four series in children with a total of 36 patients (8 patients in each of three studies[102] [103] [104] and 12 in the other[105]) have appeared. Clinical characteristics have been similar to those in adults, with a pattern of normal ventricular size and function, severe elevation in diastolic filling pressure, and marked atrial dilation. Numerous secondary causes of restrictive cardiomyopathy have been described in adults, but the pediatric cases have been uniformly idiopathic despite tissue analysis in nearly all, although several cases were familial. Differentiation from many of the secondary causes, such as myocardial noncompaction (persistence of embryonic or "spongy" myocardium[106]), can be made on morphological criteria. Tissue analysis is generally undertaken given the dismal prognosis of the disease and the desire to exclude any potentially treatable disorder. Methods of differentiation between restrictive cardiomyopathy and constrictive pericarditis have not been specifically investigated in children, primarily because constrictive pericarditis is virtually never encountered in children. The most striking characteristic of the reports in children has been the

uniformly poor prognosis, with a 1-year survival rate of approximately 50 percent in all four series. Survival therefore appears to be even more limited than has been described in adults. Anticoagulation is recommended because a 25 percent incidence of thromboembolism has been seen in children. Therapy is otherwise nonspecific and usually of very limited benefit. The onset of irreversible elevation in pulmonary vascular resistance can occur within 1 to 4 years in these patients, and early cardiac transplantation is therefore recommended to avoid the need for heart and lung transplantation.[105]

KAWASAKI DISEASE

Kawasaki disease is an acute vasculitis of unknown etiology that occurs predominantly in infants and young children. Kawasaki first described the illness in Japanese in l967,[107] but the entity is now recognized in both endemic and community-wide epidemic forms in children of all races throughout the world. Features of Kawasaki disease include fever, bilateral nonexudative conjunctivitis, erythema of the lips and oral mucosa, changes in the extremities, rash, and cervical lymphadenopathy. Coronary artery aneurysms or ectasia develop in approximately 15 to 25 percent of untreated children with the disease and may lead to myocardial infarction, sudden death, or chronic coronary artery insufficiency.[108] In the United States, acquired heart disease in children is now caused more commonly by Kawasaki disease than by acute rheumatic fever (see Chap. 66) .[109] The cause of Kawasaki disease remains unknown.

Clinical Features

The clinical criteria put forth in Kawasaki's first English language description of the disease are still in use today.[107] A child with Kawasaki disease must have fever lasting 5 or more days without another reasonable explanation and satisfy at least four of the following criteria: (1) bilateral, nonexudative conjunctival injection; (2) at least one of the following: mucous membrane changes, injected or fissured lips, injected pharynx, or "strawberry tongue"; (3) at least one of the following extremity changes: erythema of the palms or soles, edema of the hands or feet, or periungual desquamation; (4) polymorphous exanthem; and (5) acute nonsuppurative cervical lymphadenopathy (at least one node 1.5 cm or larger in diameter). An additional category of "atypical Kawasaki disease" includes patients with only four criteria and coronary artery abnormalities by echocardiography.[110] None of the clinical features of Kawasaki disease is pathognomonic. For this reason, the diagnosis of Kawasaki disease requires exclusion of other illnesses that might mimic its clinical features, including streptococcal and staphylococcal toxin-mediated illness; infection with adenovirus, enterovirus, and measles; and systemic allergic reactions to various medications. Many symptoms and signs apart from the diagnostic criteria are frequently present in children with Kawasaki disease and include arthralgias, arthritis, urethritis, aseptic meningitis, diarrhea, vomiting, and abdominal pain.

The conventional diagnostic criteria should be viewed as guidelines; they are especially useful in preventing overdiagnosis but may result in failure to recognize incomplete forms of illness. Signs and symptoms of Kawasaki disease may be particularly subtle or absent in infants younger than 6 months, a subgroup at high risk for coronary lesions. The frequent occurrence of coronary artery involvement among children with incomplete criteria suggests that echocardiography should be performed in all children with prolonged, unexplained fever and some signs of Kawasaki disease.

Cardiac Findings

CORONARY ARTERY ABNORMALITIES.

Coronary artery ectasia or aneurysms occur in 15 to 25 percent of children

with Kawasaki disease who do not receive treatment with intravenous gamma globulin (IVIG) in the acute phase.[111] [112] Dilatation of coronary arteries (Japanese Ministry of Health criteria)[113] may be detected by echocardiography beginning 7 days after the first appearance of fever, with the coronary diameter usually peaking around 4 weeks after illness onset. In general, clinical and laboratory indices of greater inflammation are associated with a higher likelihood of aneurysm development.

MYOCARDITIS.

Myocarditis has been demonstrated in autopsy and myocardial biopsy studies to be a universal feature of early Kawasaki disease. With high-dose IVIG treatment, myocardial function improves rapidly, i.e., within days, in patients with acute Kawasaki disease.[114] When myocardial dysfunction occurs after the acute phase of the disease, it is usually secondary to ischemia or infarction, with or without mitral regurgitation.

With the use of endomyocardial biopsy, myocardial abnormalities have been detected in all time periods after disease onset; their severity was unrelated to the presence of coronary artery abnormalities. In addition, electron microscopic examination of endomyocardial biopsy specimens has demonstrated histological abnormalities late after Kawasaki disease.[115] Assessment of the full impact of Kawasaki disease on heart function and structure must await the follow-up of these children into later adult life.

VALVAR REGURGITATION.

Mitral regurgitation may result from transient papillary muscle dysfunction, myocardial infarction, or valvulitis. Kato and colleagues reported mitral regurgitation in 1.0 percent of patients in their series.[116] The appearance of mitral regurgitation after the acute stage is usually secondary to myocardial ischemia, although late-onset valvulitis unrelated to ischemia has been documented.

Aortic regurgitation has been documented angiographically by Nakano and colleagues in approximately 5 percent of children with Kawasaki disease and was attributed to valvulitis.[117] Others have observed a much lower incidence of aortic regurgitation in the acute phase.[116] Late-onset aortic regurgitation has been reported as a rare finding after Kawasaki disease and may be associated with the need for aortic valve replacement.

Laboratory Data

GENERAL TESTS.

Laboratory findings in acute Kawasaki disease reflect the marked degree of systemic inflammation. Common initial findings include anemia, leukocytosis with a left shift, elevation of acute phase reactants, and mild elevation of liver transaminase levels. Thrombocytosis usually peaks in the third to fourth week after the onset of fever. Urinalysis may reveal the presence of white cells on microscopic examination. Since the white cells are mononuclear rather than polymorphonuclear, the dipstick test for nonspecific esterase activity (i.e., neutrophil enzyme) is usually negative. Examination of cerebrospinal fluid reveals a mild mononuclear cell pleocytosis with normal glucose and normal to mildly elevated protein.[118]

ELECTROCARDIOGRAPHY.

The ECG in acute Kawasaki disease may show mild abnormalities consistent with myocarditis, most commonly a prolonged PR interval and nonspecific ST and T wave changes.

TWO-DIMENSIONAL ECHOCARDIOGRAPHY.

Two-dimensional echocardiography has high sensitivity and specificity for proximal vessels of the right and left coronary arterial trees (see Chap. 7) . The initial echocardiogram should be obtained as soon as the diagnosis of Kawasaki disease is suspected.[110] Longitudinal echocardiographic follow-up should begin 10 to 14 days after the onset of illness, when early coronary dilation will first be noticed in the majority of children in whom aneurysms are destined to develop. In the absence of significant coronary dilation, cardiac ultrasound may be repeated approximately 6 to 8 weeks after illness onset. Follow-up of patients with coronary dilation should be adapted to their clinical course and the severity of their lesions.

Echocardiographers often find it difficult to reach an agreement on the exact configuration and extent of any given coronary artery lesion as seen by two-dimensional echocardiography. In 1984, the Japanese Ministry of Health established criteria for coronary artery abnormalities in Kawasaki disease.[113] These criteria classify coronary arteries as abnormal if the internal lumen diameter is greater than 3 mm in children younger than 5 years or greater than 4 mm in children at least 5 years of age, if the internal diameter of a segment measures at least 1.5 times that of an adjacent segment, or if the coronary artery lumen is clearly irregular. Current statistics on the prevalence of coronary dilation secondary to Kawasaki disease are based on these criteria. Recently, de Zorzi and colleagues showed, in patients with Kawasaki disease whose coronary arteries are classified as "normal" by Japanese Ministry of Health criteria, that body surface area-adjusted coronary dimensions are

larger than expected in the acute, convalescent, and late phases.[119] Thus, the Japanese Ministry of Health criteria may underestimate the true prevalence of coronary dilation following Kawasaki disease. Figure 45-5 *A* to *C* depicts normal left main, left anterior descending, and right coronary artery size, respectively, according to body surface area.

CORONARY ARTERIOGRAPHY.

Selective coronary arteriography can provide definitive delineation of coronary artery anatomy. This technique is especially useful for visualization of coronary artery stenoses or distal coronary artery lesions that are difficult to define by two-dimensional echocardiography.

Based on the coronary artery classification system used in the Coronary Artery Surgery Study,[120] Takahashi and colleagues defined coronary artery aneurysms imaged at angiography as either localized or extensive.[121] Localized aneurysms, i.e., confined to one arterial segment, are further classified as either fusiform (spindle shaped) or saccular (showing abrupt transition from the normal to the dilated state, e.g., spherical, dumbbell shaped, triangular, or sack-like). Extensive aneurysms involve more than one segment and may be either ectatic (uniformly dilated) or segmented (having multiple dilated segments joined by normal or stenotic segments). Coronary aneurysms in early Kawasaki disease usually occur in the proximal segments of the major coronary vessels; aneurysms that occur distally are almost always associated with proximal coronary abnormalities.

Aneurysms can also occur in arteries outside the coronary system, most commonly the subclavian, brachial, axillary, iliac, or femoral vessels and occasionally the abdominal aortic and renal arteries.[112] For this reason, abdominal aortography and subclavian arteriography are often performed in patients undergoing coronary arteriography for Kawasaki disease.

Treatment

ASPIRIN.

Aspirin has been a standard therapy for Kawasaki disease because of its antiinflammatory and antithrombotic effects, but it does not reduce the prevalence of coronary artery aneurysms.[122] Therapy with aspirin is usually initiated at the time of initial assessment in a dose of 80 to 100 mg/kg/day divided into four doses. Once fever has resolved, the dose is lowered to an antiplatelet regimen of 3 to 5 mg/kg/day orally for up to 6 to 8 weeks. For children in whom coronary aneurysms develop, aspirin (with or without anticoagulation or other antiplatelet agents) may be continued indefinitely.

INTRAVENOUS GAMMA GLOBULIN THERAPY.

Although its exact mechanism of action remains unknown, IVIG administered in the acute phase of Kawasaki disease reduces the prevalence of coronary artery abnormalities.[122] [123] Patients should be treated with IVIG 2 gm/kg in a single

Figure 45-5 Mean and 95% prediction limits for size of the left main coronary artery *(A),* left anterior descending coronary artery *(B),* and proximal right coronary artery *(C)* according to body surface area for children younger than 18 years, as derived from 152 normal children at Children's Hospital, Boston.

infusion, together with aspirin.[110] Ideally, this therapy should be instituted within the first 10 days of illness (optimally by day 7 of illness), but it should be administered after the 10th day of illness to any child with persistent fever[124] or with aneurysms and ongoing signs of inflammation. Even when treated with high-dose IVIG regimens within the first 10 days of illness, however, approximately 5 percent of children with Kawasaki disease experience at least transient coronary artery dilation, and giant aneurysms develop in 1 percent.[125] Most experts recommend retreatment with IVIG 2 gm/kg in patients with persistent or recrudescent fever 48 to 72 hours after initial therapy.

CORTICOSTEROIDS.

The subgroup of patients with Kawasaki disease resistant to IVIG therapy is at greatest risk for the development of coronary artery aneurysms and long-term sequelae of the disease.[126] [127] Although one early study showed a detrimental effect of steroid use in Kawasaki disease,[128] others have suggested that steroids may be beneficial in the prevention of coronary artery aneurysms.[129] [130] Further studies are needed to assess the risks and benefits of steroid administration in Kawasaki disease.

OTHER THERAPIES DURING THE ACUTE PHASE.

High-dose pentoxifylline, a vasodilator and inhibitor of platelet aggregation and neutrophil activation, has been shown in one study to reduce the incidence of coronary artery aneurysms.[131] Case reports suggest that plasmapheresis may produce dramatic improvement in severe Kawasaki disease[132] ; however, it is a technically complex intervention in young children and should be reserved for those who remain desperately ill despite multiple doses of IVIG and intravenous methylprednisolone.

ANTITHROMBOTIC THERAPY.

Paradoxically, the risk of coronary artery thrombosis is greatest *after* the acute phase subsides, when well-established coronary vasculitis occurs concomitantly with marked elevation of the platelet count and a hypercoagulable state. As above, low-dose aspirin (3 to 5 mg/kg/day given as a single dose) is the mainstay of antithrombotic therapy in Kawasaki disease. Other antiplatelet agents, such as clopidogrel or dipyridamole, may be substituted for aspirin when salicylates are contraindicated. For children without evidence of coronary artery ectasia or aneurysms, antiplatelet therapy is usually discontinued approximately 2 months after illness onset.

Children with coronary artery abnormalities require long-term antithrombotic therapy, usually with low-dose aspirin. The risk of coronary thrombosis and myocardial infarction is especially great in children with rapidly increasing coronary dimensions or with giant aneurysms during the subacute phase.[133] [134] During this period, some investigators advocate treatment with systemic heparin, together with an antiplatelet agent. For chronic antithrombotic therapy, therapeutic options include antiplatelet therapy with aspirin, with or without dipyridamole or another inhibitor of antiplatelet aggregation; anticoagulant therapy with warfarin; or a combination of anticoagulant and antiplatelet therapy, usually warfarin plus aspirin. No prospective data

exist to guide the clinician in choosing the optimal regimen. The most common regimen for patients with giant aneurysms is low-dose aspirin together with warfarin, with the international normalized ratio maintained at 2.0:2.5. Some physicians substitute low-molecular-weight heparin for warfarin, although this therapy requires subcutaneous injections twice daily.

THROMBOLYTIC THERAPY.

Despite the use of antithrombotic agents, myocardial infarction secondary to thrombotic occlusion of coronary aneurysms can develop in some children, especially those with giant aneurysms. Sometimes, coronary artery thrombus can be detected in asymptomatic patients by two-dimensional echocardiography. Because no large trials of thrombolytic therapy have been performed in children, the choice of thrombolytic agent for the treatment of infants and children with coronary thrombosis is derived from studies in adults with coronary thrombosis. Although effective in adults, the use of immediate coronary angioplasty has not been reported in children with Kawasaki disease and coronary artery thrombosis.

SURGICAL MANAGEMENT.

Surgical management in Kawasaki disease consists primarily of coronary artery bypass grafts for obstructive lesions.[134A] However, indications for coronary bypass

graft procedures in children have not been established. Such surgery should be considered when reversible ischemia is present on stress-imaging tests, the myocardium to be perfused through the graft is still viable, and no appreciable lesions are present in the artery peripheral to the planned graft site.

The earliest coronary artery bypass operations in children with Kawasaki disease were performed with autologous saphenous veins or veins obtained from parents. However, the late results with this technique have been relatively unsatisfactory, especially in very young children. Kitamura and coworkers reported improved results with the use of internal mammary artery grafts in pediatric patients.[135] The diameter and length of internal mammary grafts increase with the general somatic growth of the child, as opposed to the tendency of saphenous vein grafts to shorten somewhat over time. In children younger than 7 years, the arterial graft patency rate 90 months after surgery was 70 percent. Children who were older than 8 years at the time of coronary arterial grafting appeared to have even better long-term patency than seen in younger children; by 90 months after surgery, the arterial graft patency rate was 84 percent. Of note, 8 years after internal mammary artery grafting to the left anterior descending coronary artery, 98.7 percent of patients in the series of Kitamura and colleagues were still alive.

INTERVENTIONAL CARDIAC CATHETERIZATION TECHNIQUES.

Although results over the first decade after surgery are encouraging, graft patency in later adult life after coronary artery bypass grafting in childhood is still unknown. When it is preferable to delay the time until surgery, percutaneous transluminal coronary angioplasty (PTCA) may be performed in the stenotic coronary arteries of children with Kawasaki disease[136] [137] (Fig. 45-6) . PTCA is not as effective in patients with Kawasaki disease as in adults with atherosclerotic coronary artery disease because the stenotic lesions in long-term Kawasaki disease are very stiff and often associated with marked calcifications, especially many years after illness onset. The relatively high balloon pressures necessary under these circumstances can lead to late aneurysm formation.[137] Intravascular ultrasound imaging has been found to be a useful tool for evaluating internal morphology before and after PTCA.[136] Once calcification and stenosis have become severe, rotational ablation techniques may be necessary for the success of coronary angioplasty.

CARDIAC TRANSPLANTATION.

Cardiac transplantation has been performed in a small number of patients with severe ischemic heart disease resulting from Kawasaki disease.[138]

Figure 45-6 Left coronary arteriograms. *A,* Localized stenosis can be seen at a site just proximal to the aneurysm of the left anterior descending artery. *B,* The stenosis was dilated by conventional percutaneous transluminal coronary angioplasty (PTCA). *C,* Follow-up angiography performed 13 months after the initial PTCA revealed no significant restenoses. Pre=pre-PTCA; POST=post-PTCA. (From Ino T, Akimoto K, Ohkubo M, et al: Application of percutaneous transluminal angioplasty to coronary arterial stenosis in Kawasaki disease. Circulation 93:1711, 1996. By permission of the American Heart Association, Inc.)

This procedure should be considered only for individuals with severe, irreversible myocardial dysfunction and coronary lesions for which interventional catheterization procedures or coronary artery bypass is not feasible.

Clinical Course

REGRESSION AND EVOLUTION OF CORONARY LESIONS.

Coronary artery lesions resulting from Kawasaki disease change dynamically with time. Angiographic resolution 1 to 2 years after disease onset has been observed in approximately half to two-thirds of vessels with coronary aneurysms.[121] [139] The likelihood of resolution of the aneurysm appears to be determined in large measure by the initial

size of the aneurysm, with smaller aneurysms having a greater likelihood of regression.[133] Takahashi and coauthors reported other factors positively associated with regression of aneurysms, including age younger than 1 year, saccular (rather than fusiform) aneurysm morphology, and aneurysm location in a distal coronary segment.[121] Vessels that do not undergo apparent resolution of abnormalities may show persistence of aneurysmal morphology, development of stenosis or occlusion, or abnormal tortuosity.

PATIENTS WITH PERSISTENT CORONARY ARTERY ABNORMALITIES.

Whereas aneurysm size tends to diminish over time, stenotic lesions secondary to marked myointimal proliferation are frequently progressive.[112] In the series of Kato and coworkers, stenotic lesions were recognized within 2 years from disease onset in about half of the patients in whom coronary stenoses ultimately developed, but the prevalence of stenosis continued to rise almost linearly over time.[139] Kamiya and colleagues have also reported a steady increase in the presence of coronary artery stenoses with increasing duration since illness onset; the highest rate of progression to stenosis occurred among patients whose aneurysms were large.[140]

The worst prognosis occurs in children with so-called giant aneurysms, i.e., those with a maximum diameter greater than 8 mm.[141] In these aneurysms, thrombosis is promoted by sluggish blood flow within the massively dilated vascular space, together with frequent development of stenotic lesions at the proximal or distal end of the aneurysms.

Myocardial infarction caused by thrombotic occlusion in an aneurysmal and/or stenotic coronary artery is the principal cause of death in Kawasaki disease.[111] The highest risk of myocardial infarction occurs in the first year after disease onset, and most fatal attacks are associated with obstruction either in the left main coronary artery or in both the right main and left anterior descending coronary arteries.[111] Serial stress tests and myocardial imaging are mandatory in the management of patients with Kawasaki disease and significant coronary artery disease to determine the need for coronary angiography and for surgical or transcatheter intervention.

Late cardiac sequelae of Kawasaki disease may first become apparent in adulthood. Burns and associates identified 74 patients in the English and Japanese literature with Kawasaki disease in childhood whose first symptoms of coronary artery disease occurred in young adulthood.[142] A history of a Kawasaki-like illness in childhood should be sought in patients with coronary aneurysms in the absence of generalized atherosclerotic disease. However, adult patients may be unable to recall an illness that occurred so early in life.

PATIENTS WITH SPONTANEOUS REGRESSION OF ANEURYSMS.

Approximately half of vascular segments with coronary artery aneurysms show angiographic regression of the aneurysms. This regression usually occurs by myointimal proliferation, although more rarely the mechanism of regression can be organization and recanalization of a thrombus. Pathological examination reveals fibrous intimal thickening despite normal coronary artery diameter. Similarly, transluminal (intravascular) ultrasound of regressed coronary aneurysms shows marked symmetrical or asymmetrical myointimal thickening.[143] Regressed coronary artery aneurysms not only are histopathologically abnormal but also show reduced vascular reactivity.[144] [144A]

KAWASAKI DISEASE WITHOUT DETECTABLE CORONARY LESIONS.

Although coronary artery aneurysms produce the most serious sequelae of Kawasaki disease, vascular inflammation during the acute stage of the illness is diffuse. Generalized endothelial dysfunction has been suggested by the observation that plasma 6-ketoprostaglandin F_1 remains generally undetectable over an observation period of 8 weeks after the onset of Kawasaki disease.[145] In addition, Kawasaki disease produces altered lipid metabolism that persists beyond clinical resolution of the disease.[146] Histological data concerning the long-term status of coronary arteries in children who never had demonstrable abnormalities are few and difficult to interpret.[147]

Some investigators in Japan have studied coronary physiology in the population without aneurysms. Among children with a history of Kawasaki disease but with normal epicardial coronary arteries, Muzik and colleagues found lower myocardial flow reserve and higher total coronary resistance than in normal controls.[148] Children without a history of coronary aneurysms have also been reported to have abnormal endothelium-dependent brachial artery reactivity.[149] Data are conflicting regarding impairment in long-term endothelium-dependent relaxation of the epicardial coronary arteries among children with Kawasaki disease in whom coronary artery dilation was never detected.[150] [151]

From a purely clinical perspective, children without known cardiac sequelae during the first month after diagnosis of Kawasaki disease appear to return to their previous, usually excellent state of health, without signs or symptoms of cardiac impairment.[139] Meaningful knowledge about long-term myocardial function, late-onset valvar regurgitation, and coronary artery status in this population must await their careful surveillance over the coming decades.

SYSTEMIC HYPERTENSION

Hypertension is well recognized as a major risk factor for cardiovascular disease, including stroke, myocardial infarction, congestive heart failure, and renal failure. Because the precursors of these processes are likely to arise early in life, evaluation and treatment of pediatric hypertension are important. Estimates of significant hypertension in childhood have ranged from 0.26 to 2.0 percent.[152] The most common causes of hypertension change during childhood, with secondary causes of hypertension predominating in the youngest patients and those in whom systemic hypertension is the most severe. For many years, pediatricians focused solely on identification and treatment of secondary forms of hypertension, such as renal parenchymal disease and renal artery stenosis.[152] With recommendations for routine measurement of blood pressure during well-child visits to the pediatrician, as well as the publication of national norms for blood pressure in children, essential hypertension has been increasingly recognized, especially in adolescents with mild to moderate elevation of blood pressure. Children with higher blood pressure are more likely to have first-degree relatives with histories of hypertension, and the tracking correlation of blood pressure from childhood into young adult life is relatively high. Nonetheless, the sensitivities and predictive values for childhood blood pressure are only modest as a screening test for adult blood pressure.[153]

DEFINITION.

The distribution of blood pressure in the normal pediatric population is shown in Tables 45-2 and 45-3 . The National High Blood Pressure Education Program has recommended that blood pressure between the 90th and 95th percentiles be considered high-normal or borderline hypertension. Hypertension is defined as average systolic or diastolic blood pressure greater than or equal to the 95th percentile for sex, age, and height on at least three separate occasions. Thus, elevation of blood pressure must be sustained to establish a diagnosis of hypertension. Ideally, blood pressure should be measured with a standard sphygmomanometer, blood pressure cuff, and stethoscope. Many centers currently use automated oscillometric blood pressure monitoring devices for ease of use and elimination of interobserver variability. In addition, 24-hour ambulatory

blood pressure monitoring has been used when "white coat" hypertension is suspected and for management of known hypertension.[154] [155] [155A]

EVALUATION.

Evaluation of an asymptomatic child or adolescent with hypertension should focus on potential etiologies. The family history should be carefully probed for hypertension, premature cardiovascular disease, and renal disease, medical conditions, or drugs. In adolescents, the possibility of substance abuse should always be considered. The physical examination should be directed toward signs of definable causes of hypertension, as well as toward its sequelae.

Many adolescents whose blood pressure is at or just greater than the 95th percentile have family histories of hypertension and are overweight, but they have an otherwise negative history and physical examination.[152] For such patients, a work-up that includes urinalysis, urine culture, and electrolyte, serum creatinine (noting that normal values vary according to age), and blood urea nitrogen levels may be sufficient.[156] Such patients would also usually benefit from a lipid profile to exclude other risk factors for premature cardiovascular disease.[152] When children or adolescents with borderline high blood pressure are not obese and have no family history of hypertension, renal Doppler ultrasound provides a first-line screen for renovascular hypertension, parenchymal integrity, and hydronephrosis.

For patients in whom blood pressure is well above the 95th percentile, secondary causes of hypertension should be pursued aggressively, with targeting of conditions believed to be most likely on the basis of age (Table 45-4) or targeting of findings on initial assessment. Most children with secondary hypertension (60 to 80 percent) have renal parenchymal disease,[156] commonly reflux nephropathy, pyelonephritis, and obstructive uropathy. Less common renal etiologies include glomerulonephritis, nephrotic syndrome, congenital renal dysplasia, renal damage following hemolytic-uremic syndrome, and polycystic disease.[156] Renal parenchymal disease can be assessed with imaging studies, including renal ultrasonography, voiding cystourethrography, or renal scintiscanning.

Renovascular hypertension has been reported in 8 to 10 percent of children with secondary hypertension.[156] [157] In such patients, hypertension may be caused by stenosis of a main renal artery or by segmental renal artery stenoses in one or both kidneys.[156] Methods of evaluation of renovascular hypertension vary in different centers and include renal scanning before and after captopril challenge, intravenous digital subtraction angiography, captopril radionuclide renography, Doppler sonography, computed tomographic angiography, and magnetic resonance angiography. Conventional angiography and intraarterial digital subtraction angiography remain the gold standard for the diagnosis of renovascular hypertension and should be considered for children with severe, persistent hypertension without other findings, greatly elevated plasma renin activity, a bruit, or a solitary kidney and severe hypertension.[156]

*Blood pressure percentile was determined by a single reading.

Height percentile was determined by standard growth curves.

Coarctation of the aorta (see Chap. 43) , a common cause of hypertension in the first year of life, is present in one-third of infants with hypertension but accounts for only 2 percent of cases of secondary hypertension in childhood and adolescence.[156] This cause of hypertension is easily detected on physical examination by careful

measurement of upper and lower extremity blood pressures, together with palpation of radial and femoral pulses. Since 80 percent of patients with coarctation have an associated bicuspid aortic valve, physical examination often includes a constant early systolic ejection click at the apex and base. A soft early to midsystolic ejection murmur is frequently heard over the left lateral aspect of the chest, and older children with collateral circulation may have continuous murmurs over the back. The diagnosis of coarctation of the aorta may be confirmed by two-dimensional echocardiography or, in an older child or adolescent, by magnetic resonance imaging (MRI). After the coarctation is repaired, a residual gradient may either remain or recur, sometimes necessitating late procedures such as balloon dilation or stenting of the aorta. Some patients require chronic antihypertensive medication after adequate repair of coarctation.

More rarely, hypertension can be caused by endocrine disorders.[158] Pheochromocytoma alone causes approximately 0.5 to 2.0 percent of cases of secondary hypertension in children.[159] Most children with pheochromocytoma (88 percent) have sustained rather than episodic hypertension, and many have extraadrenal or multiple tumors (31 and 32 percent, respectively).[156] Elevation of urinary catecholamine levels in a 24-hour urine collection or elevation of plasma catecholamines points to a diagnosis of pheochromocytoma (or other types of neural crest tumor). Definitive diagnosis is made with MRI (T_2 weighted or gadolinium-labeled diethylenetriaminepentaacetic acid [DTPA] enhanced) or with meta-iodobenzylguaninine (MIBG) scanning.[156] [160] [161] Pheochromocytomas are removed surgically, after the hypertension is controlled.[159] [162] [163] Other endocrine causes of secondary hypertension (e.g., excess glucocorticoids or mineralocorticoids, hyperthyroidism) may be pursued if the history, physical examination, or screening tests are suggestive.

Hypertension may rarely be associated with abnormalities of the central nervous system (CNS). These abnormalities may be primary (e.g., brain tumors, familial dysautonomia) or secondary (e.g., hypercalcemia or lead poisoning). Because hypertension of CNS origin may have a fulminant manifestation, CNS-mediated causes of hypertension should always be considered by the clinician.[156] [164]

MANAGEMENT.

All children with blood pressure consistently above the 90th percentile should be introduced to nonpharmacological therapies, including a diet rich in fruits, vegetables, and low-fat dairy products, reduced intake

TABLE 45-4 -- MOST COMMON CAUSES OF SECONDARY HYPERTENSION, BY AGE

AGE GROUP	CAUSE
Newborn	Renal artery or venous thrombosis Renal artery stenosis Congenital renal abnormalities Coarctation of the aorta Bronchopulmonary dysplasia
First year	Coarctation of the aorta Renovascular disease Renal parenchymal disease Iatrogenic (medication, volume) Tumor
Infancy to 6 yr	Renal parenchymal disease Renovascular disease Coarctation of the aorta Endocrine causes* Iatrogenic* Essential hypertension*
Age 6-10 yr	Renal parenchymal disease Renovascular disease Essential hypertension Coarctation of the aorta Endocrine causes* Iatrogenic*
Age 12-18 yr	Essential hypertension Iatrogenic Renal parenchymal disease* Endocrine causes* Coarctation of the aorta*

*Uncommon for category.

of saturated fat,[165] and for obese children, weight modification. Children and their families should also be counseled regarding the benefits of aerobic physical activity and the hazards of smoking.[152] Treatment with medications should be instituted for patients with severe hypertension or evidence of end-organ damage (e.g., increased left ventricular mass by two-dimensional echocardiography). In addition, pharmacological treatment of hypertension should be guided by the presence of other cardiovascular risk factors (e.g., childhood diabetes, chronic renal disease).

When drugs are prescribed for children and adolescents with hypertension, the goal is to reduce blood pressure to below the 95th percentile for age, gender, and height.[152] Drug therapy should aim at prescribing the simplest regimen with the fewest adverse side effects. All antihypertensive medications should be individualized to the patient's medical history (including the etiology of the hypertension), severity of hypertension, response to therapy, and occurrence of side effects.[152] Thiazide diuretics and beta blockers have been used for years in children and adolescents and continue to have a role in the treatment of hypertension. Since publication of the Report of the Second Task Force on Blood Pressure Control in Children in 1987,[166] newer antihypertensive agents have come into common use in pediatric patients. These medications include ACE inhibitors and calcium channel blockers.[167] Use of the other classes of antihypertensive agents (e.g., central alpha-adrenergic agonists, alpha-adrenergic blocking drugs, direct vasodilators) is only rarely indicated in pediatric cardiology practice. Long-term clinical trials have not examined the benefits and risks of antihypertensive therapy in children and adolescents. Until such data are available, when choosing the optimal antihypertensive medication, physicians should draw on the adult experience.

HYPERLIPIDEMIAS (see also Chaps. 30 , 31 , 32 , and 33)

Abnormalities in plasma lipoproteins are an important cause of premature coronary artery disease. Because epidemiological and pathological observations have introduced the concept that the process of atherosclerosis begins early in life and progresses to cardiovascular morbidity and mortality in later life, efforts to prevent clinical disease have centered around the modification of plasma lipid concentrations in childhood and adolescence.[168]

RATIONALE FOR LIPID MODIFICATION IN CHILDHOOD.

The rationale for modification of cholesterol in childhood is based on postmortem and epidemiological data. In 1953, Enos and colleagues first reported that postmortem examination showed advanced lesions in the coronary arteries of young American soldiers killed in the Korean war.[169] The Pathobiological Determinants of Atherosclerosis in Youth (PDAY) Study, a multiinstitutional study of atherosclerosis in 15- to 34-year-old males and females, demonstrated that the conditions predicting risk of coronary heart disease in adults are also associated with the extent and severity of atherosclerosis in youth.[170] Recently, this group reported on the ubiquity of fatty streaks in the abdominal aortas and the frequency of fibrous plaques in the aortas and coronary arteries in the 15- to 19-year-old age group.[171] Other autopsy studies have shown that antemortem low-density lipoprotein (LDL) and total cholesterol are highly associated with aortic fatty streaks in subjects aged 7 to 24

years.[172] Recently, Berenson and associates reported that serum concentrations of total cholesterol, triglycerides, LDL cholesterol (LDL-C), and high-density lipoprotein cholesterol (HDL-C) were strongly associated with the extent of lesions in the aorta and coronary arteries at autopsy in young persons who died of various causes, principally trauma.[173] Among these subjects, greater numbers of cardiovascular risk factors were directly associated with increased severity of asymptomatic coronary and aortic atherosclerosis.[173]

Epidemiological investigations in children across and within different populations have provided further evidence of the importance of cholesterol in pediatrics. In cross-population studies, children from countries with a high incidence of coronary artery disease in adults have higher cholesterol levels than do children from countries where adults have a low incidence of coronary artery disease. Within populations, elevated levels of total cholesterol and LDL-C in children have been associated with coronary artery disease in their adult relatives. In a study of the progeny of individuals with premature coronary artery disease, half had abnormal lipid profiles.[174]

The importance of monitoring lipid levels in childhood is further supported by evidence that children and adolescents with severe dyslipidemia are more likely than the general population to have abnormal lipid profiles as they grow older. Furthermore, long-term prospective studies have shown a strong association between cholesterol levels in young adult life and later risk of cardiovascular disease.[175]

SCREENING FOR DYSLIPIDEMIAS.

The distribution of fasting lipid and lipoprotein levels in children and adolescents is displayed in Table 45-5 . The value of selective versus universal screening strategies for hyperlipidemia in childhood has been controversial. The National Cholesterol Education Program (NCEP) has advocated a selective screening strategy in which high-risk children older than 2 years are targeted for cholesterol screening.[176] High-risk children are defined as those whose parents or grandparents, at 55 years of age or younger, underwent diagnostic coronary arteriography and were found to have coronary atherosclerosis or suffered a documented myocardial infarction, angina pectoris, peripheral vascular disease, cerebrovascular

disease, or sudden cardiac death; those whose parent(s) have a total cholesterol level of 240 mg/dl or higher; those for whom the health history of a parent or grandparent is unknown; or those whose personal health includes risk factors (e.g., diabetes). In such a selective screening strategy, adult cardiologists should refer the children of their patients with premature atherosclerotic cardiovascular disease for cholesterol testing and follow-up.

Some experts continue to recommend universal screening based on the observation that almost half of children with elevated cholesterol levels would be missed if screening were performed only on children with a positive family history.[177] [178] Moreover, a family history does not selectively identify the most severely affected children.[178] The relationship of parental history to children's lipid profiles appears to be associated with race.[177] Specifically, the Bogalusa Heart Study found that white children with a parental history of heart attack or diabetes were significantly more likely than black children to have elevated levels of total cholesterol and LDL-C, whereas in black children, a parental history of cardiovascular disease was more likely to be associated with low levels of HDL-C than in white children. Only 40 percent of white children and 21 percent of black children with elevated levels of LDL-C had a parent with a history of vascular diseases.[173]

The NCEP formulated recommendations for the management of hypercholesterolemia in children.[176] When children or adolescents have a documented history of premature cardiovascular disease in a parent or grandparent, the initial test should be a fasting lipoprotein analysis. Random screening in the nonfasting state should always include both a total cholesterol and HDL-C level because total cholesterol alone is a poor screening test in childhood.[179]

SECONDARY CAUSES.

Dyslipidemia most commonly results from a combination of genetic and dietary factors, but it can also be secondary to other systemic disorders. Indeed, the lipid profile can be affected by the use of medications and by endocrine and metabolic disorders, obstructive liver disease, or renal disease. Viral and bacterial infections, so common in childhood, can have profound effects on the lipid profile in the month after the onset of infection. In the first year of life, the most common causes of secondary hyperlipidemia are congenital biliary atresia and glycogen storage disease. Endocrine disorders (e.g., hypothyroidism and diabetes mellitus) and renal disease are the most common secondary causes later in childhood. Especially in adolescents, exogenous causes, such as medications, smoking, or alcohol, can affect the lipid profile. Secondary causes are usually evident from a careful review of the medical history and use of medications, together with a physical examination. When a secondary cause is not apparent, it may be appropriate to measure blood levels of thyroid-stimulating hormone, perform liver function tests, and obtain a urinalysis.

MANAGEMENT.

Because atherosclerosis is a continuous process throughout life, expert panels have suggested guidelines to reduce the risk of cardiovascular disease beginning in childhood. With the rationale that symptomatic adult coronary heart disease might be prevented or retarded by lowering of the LDL-C level in childhood and adolescence, the NCEP published guidelines for detection and management of childhood hyperlipidemia in a 1991 Report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents.[176] The NCEP expert panel recommended initial nonpharmacological intervention in hyperlipidemic children, including diet modification. To lower the average population cholesterol levels, a so-called prudent diet was recommended for all children older than 2 years. In addition to providing adequate nutrients and calories to maintain ideal body weight, this diet restricts total fat calories to 30 percent or less, saturated fat calories to 40 percent or less, and cholesterol intake to 300 mg/day or less. Indeed, the long-term safety, efficacy, and acceptability of lower fat diets in high-risk pubertal children have been

demonstrated in the Dietary Intervention Study in Children (DISC).[180]

In children with severe familial hyperlipidemia, LDL-C rarely decreases by more than 15 percent with diet management alone. The NCEP guidelines recommended pharmacological therapy with bile acid sequestrants (cholestyramine or colestipol) for children older than 10 years who despite diet modification had an LDL-C level of 190 mg/dl or higher or a level of 160 mg/dl or higher with a family history of premature cardiovascular disease or with two other cardiovascular disease risk factors. Tonstad and coworkers studied 72 children in a randomized, placebo-controlled trial of cholestyramine and found only modest reductions (<20 percent) in LDL-C.[181] Furthermore, the inconvenience and unpalatability of bile acid sequestrants have limited the compliance and hence the usefulness of these agents in later childhood and adolescence.[182] In the pediatric population, alternative therapies with nicotinic acid are also poorly tolerated,[182] [183] and fibric acid derivatives have been associated with significant transaminase elevations.[181]

Since formulation of the NCEP guidelines, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) have become the most widely used cholesterol-lowering agents in adults and have been shown to be effective in reducing mortality and morbidity from coronary heart disease in both primary and secondary prevention trials. In children, investigations of the use of HMG-CoA reductase inhibitors have included both early observational studies[182] [184] and short-term therapeutic trials in heterozygous familial dyslipidemias. In a placebo-controlled study, Knipscheer and colleagues treated 72 patients aged 8 to 16 years with pravastatin in doses ranging from 5 to 20 mg/day.[185] LDL-C fell by 23 to 32 percent and no adverse effects were observed. Lambert and associates performed a multicenter 8-week trial in which 69 adolescent boys (weight >27 kg) were randomized to four doses of lovastatin ranging from 10 to 40 mg/day after a 4-week placebo period; LDL-C was reduced 21 to 36 percent in a dose-response relationship.[186] Increases in HDL-C and apolipoprotein A1 were also observed. Neither serious clinical adverse events nor important elevations in serum

transaminases or creatine kinase values were found. Most recently, in a randomized, placebo-controlled trial in 132 adolescent boys aged 10 to 17 years with familial hyperlipidemia, Stein and coauthors reported that lovastatin was effective in lowering LDL-C.[187] Comprehensive clinical and biochemical data on growth, hormonal, and nutritional status indicated no significant differences between the groups treated with lovastatin and placebo. Although HMG-CoA reductase inhibitor treatment of hyperlipidemic children and adolescents has been demonstrated to have short-term safety and efficacy in lowering the serum lipid profile, it is unknown whether such treatment affects preclinical disease in this age group.

Antioxidant vitamins may also have a role in the treatment of dyslipidemic children and adolescents. In a recent study in children with familial hyperlipidemia, impaired brachial vasoreactivity was improved after therapy with vitamin E and vitamin C.[188]

ASSESSMENT OF PRECLINICAL ATHEROSCLEROSIS.

Assessment of the effect of treatment of hyperlipidemia in childhood on vascular health is hampered by the long latency until occurrence of clinical disease. Therefore, the effects of therapies on preclinical markers of atherosclerosis are important. Methods of assessment of preclinical atherosclerosis that have been demonstrated to relate to risk factors in children include brachial artery flow-mediated dilation,[189] [189A] carotid intimal-medial thickness,[190] [191] and coronary artery calcification on electron beam computed tomography.[192]

Chapter 46 - Valvular Heart Disease

EUGENE BRAUNWALD

Mitral Stenosis

ETIOLOGY AND PATHOLOGY

The predominant cause of mitral stenosis (MS) is rheumatic fever[1] (see Chap. 66) , and rheumatic involvement is present in 99 percent of stenotic mitral valves excised at the time of mitral valve replacement.[2] Approximately 25 percent of all patients with rheumatic heart disease have pure MS, and an additional 40 percent have combined MS and mitral regurgitation (MR).[3] [4] [5] Two thirds of all patients with rheumatic MS are female.

Rheumatic fever results in four forms of fusion of the mitral valve apparatus leading to stenosis: (1) commissural, (2) cuspal, (3) chordal, and (4) combined.[3] [4] [5] Thickening of the commissures alone occurs in 30 percent of patients, of the cusps alone in 15 percent, and of the chordae tendineae alone in 10 percent; in the remaining patients, thickening of more than one of these structures is involved. Characteristically, mitral valve cusps fuse at their edges, and fusion of the chordae tendineae results in thickening and shortening of these structures. The leaflets exhibit fibrous obliteration and revascularization. The stenotic mitral valve is typically funnel-shaped, and the orifice is frequently shaped like a "fish mouth" or buttonhole, with calcium deposits in the valve leaflets sometimes extending to involve the valve ring, which may become quite thick (Fig. 46-1) . The thickened leaflets may be so adherent and rigid that they cannot open or shut, reducing or rarely even abolishing the first heart sound (S_1) and leading to combined MS and MR. When rheumatic fever results exclusively or predominantly in contraction and fusion of the chordae tendineae, with little fusion of the valvular commissures, dominant MR results.[6]

A debate continues about whether the anatomical changes in severe MS result from a smoldering rheumatic process or whether, once the valve has been deformed by the initial episode, the constant trauma produced by the turbulent blood flow leads to progressive fibrosis, thickening, and calcification of the valve apparatus.[7] Probably both processes are involved. Enlargement of the left atrium and resultant elevation of the left main stem bronchus, calcification of the left atrial wall, development of mural thrombi, and obliterative changes in the pulmonary vascular bed (see Chap. 53) may all result from chronic rheumatic MS.

Far less frequently, MS is congenital in etiology, and this form is observed almost exclusively in infants and young children (see Chap. 43) . Very rarely, MS is a complication of malignant carcinoid, systemic lupus erythematosus, rheumatoid arthritis,[8] the mucopolysaccharidoses of the Hunter-Hurler phenotype,[9] Fabry disease, and Whipple disease. Amyloid deposits may occur on rheumatic valves and contribute to the obstruction to left atrial emptying.[10] Methysergide therapy is an unusual but documented cause of MS.[11] Atrial septal defect is associated with MS, generally of rheumatic origin, in Lutembacher syndrome (see Chap. 43) . Obstruction to left atrial outflow may be caused by a left atrial tumor, particularly myxoma (see Chap. 49) ; ball-valve thrombus in the left atrium (usually associated with MS)[12] ; infective endocarditis with large vegetations; and a congenital membrane in the left atrium, i.e., cor triatriatum (see Chap. 43) . These conditions may simulate MS. Although calcification of the mitral annulus usually causes MR, MS may result when subvalvular or intravalvular extension is extensive.

PATHOPHYSIOLOGY

In normal adults, the cross-sectional area of the mitral valve orifice is 4 to 6 cm^2 . When the orifice is reduced to approximately 2 cm^2 , which is considered to represent *mild* MS, blood can flow from the left atrium to the left ventricle only if propelled by a small, although abnormal, pressure gradient. When the mitral valve opening is reduced to 1 cm^2 , which is considered to represent *critical* MS,[13] a left atrioventricular pressure gradient of approximately 20 mm Hg (and, therefore, in the presence of a normal left ventricular diastolic pressure, a mean left atrial pressure of approximately 25 mm Hg) is required to maintain normal cardiac

Figure 46-1 Rheumatic mitral stenosis. *A,* Moderate valvular changes including diffuse leaflet fibrosis, commissural fusion, and chordal thickening and fusion. In another patient, an atrial view (*B*) and subvalvular and aortic aspects (*C*) show prominent subvalvular involvement; severe subvalvular distortion is evident (arrow). *D,* Severe rheumatic mitral stenosis with specimen shown in apical four-chamber echocardiographic view, demonstrating small left ventricle (lv) and enlarged left atrium (la), right ventricle (rv), and right atrium (ra). Note the calcified stenotic valve (arrow) and prominent subvalvular changes (double arrows). *(A and D from Schoen FJ, St. John Sutton M: Contemporary issues in the pathology of valvular heart disease. Hum Pathol 18:568, 1987.)*

output at rest (Fig. 46-2 ; see also Fig. 11-14) . The elevated left atrial pressure, in turn, raises pulmonary venous and capillary pressures, resulting in exertional dyspnea. The first bouts of dyspnea in patients with MS are usually precipitated by exercise, emotional stress, sexual intercourse, infection, or atrial fibrillation, all of which increase the rate of blood flow across the mitral orifice and result in further elevation of the left atrial pressure.[14] [15]

In order to assess the severity of obstruction of the mitral valve (and, for that matter, of any valve), both the transvalvular pressure gradient and the transvalvular flow rate must be measured (see Chap. 11) .[16] The latter is a function not only of the cardiac output but also of the heart rate. An increase in heart rate shortens diastole proportionately more than systole and diminishes the time available for flow across the mitral valve. Therefore, at any given level of cardiac output, tachycardia augments the transmitral valvular pressure gradient and elevates left atrial pressures further.[17] This explains the sudden occurrence of dyspnea and pulmonary edema in previously asymptomatic patients with MS who develop atrial fibrillation with a rapid ventricular rate. It also accounts for the equally rapid improvement in these patients when the ventricular rate is slowed by cardiac glycosides, beta-blocking agents, and/or heart-rate-slowing calcium antagonists, even when the transvalvular flow rate per minute remains constant. Hydraulic considerations dictate that at any given orifice size the transvalvular pressure gradient is a function of the square of the transvalvular flow rate.[18] Thus, a doubling of flow rate quadruples the pressure gradient, so that a stress such as exercise in patients with moderate or severe MS causes a marked elevation of left atrial pressure.[19] Pregnancy, hypervolemia, and hyperthyroidism all increase mitral valve flow and thereby the transvalvular pressure gradient.

Atrial contraction augments the presystolic transmitral valvular gradient by approximately 30 percent in patients with MS. Withdrawal of atrial transport when atrial fibrillation develops reduces cardiac output by about 20 percent.

Although the Gorlin formula (see Chap. 11) has been the benchmark for evaluating stenotic valvular orifices since 1951,[18] there is increasing evidence that valvular orifices are not rigid and that, in fact, as transvalvular flow increases, the orifice becomes distended. Accordingly, it has been proposed that stenosis can also be

expressed as valvular resistance, the quotient of the mean transvalvular pressure gradient and the mean transvalvular flow.[20]

Figure 46-2 Schematic relationship of left ventricular, aortic, and pulmonary arterial wedge (PAW) pressures. Note that the higher the left atrial *v* wave, the earlier the pressure crossover and the earlier the mitral valve (MV) opening. The higher left atrial end-diastolic pressure with severe mitral stenosis (MS) also results in later closure of the mitral valve. PAW pressures are shown in severe mitral regurgitation (MR), mitral stenosis (MS), and normal (NL). The left ventricular diastolic pressure in mitral stenosis rises slowly, denoting the absence of a rapid filling wave. *(From Braunwald E, Turi ZG: Pathophysiology of mitral valve disease. In Wells FC, Schapiro LM [eds]: Mitral Valve Disease. London, Butterworths, 1996.)*

Intracardiac and Intravascular Pressures

LEFT ATRIAL AND RIGHT HEART PRESSURES.

In patients with MS and sinus rhythm, mean left atrial pressure is elevated, and the left atrial pressure pulse generally exhibits a prominent atrial contraction (*a*) wave and a gradual pressure decline after mitral valve opening (*y* descent). In patients with mild to moderate MS without elevated pulmonary vascular resistance, pulmonary arterial pressure may be normal or only minimally elevated at rest but rises during exercise. However, in patients with severe MS and those in whom the pulmonary vascular resistance is significantly increased, pulmonary arterial pressure is elevated when the patient is at rest. In very rare patients with extremely elevated pulmonary vascular resistance, pulmonary arterial pressure may exceed systemic arterial pressure. Further elevations of left atrial and pulmonary vascular pressures occur during exercise and/or tachycardia. With moderately elevated pulmonary arterial pressure (systolic pressure 30 to 60 mm Hg), right ventricular performance is usually maintained.[21] However, a greater elevation of pulmonary arterial pressure represents a serious impedance to emptying of the right ventricle. During exercise, patients with MS and severe pulmonary hypertension commonly fail to exhibit normal elevation of the right ventricular ejection fraction.

LEFT VENTRICULAR DIASTOLIC PRESSURE.

This pressure is normal in patients with isolated MS; however, coexisting MR, aortic valve lesions, systemic hypertension, ischemic heart disease, and cardiomyopathy may all be responsible for elevations of left ventricular diastolic pressure. In approximately 85 percent of patients with isolated MS, the left ventricular end-diastolic volume is within the normal range, whereas it is reduced in the remaining patients.[22] In approximately 25 percent of patients with isolated MS, the ejection fraction and other ejection indices of systolic performance (see Chap. 15) are below normal, most likely resulting in part from chronic reduction in preload and elevated afterload.[23] Regional hypokinesis is common,[24] perhaps caused by extension of the scarring process from the mitral valve into the adjacent posterior basal myocardium or by associated ischemic heart disease. Leftward displacement of the interventricular septum secondary to more rapid early filling of the right ventricle may be responsible for a reduction of left ventricular compliance (left ventricular stiffening).[25] The left ventricular mass is normal or slightly reduced.[22]

The bulk of available evidence suggests that other than the posterior basal myocardium, left ventricular contractility is normal or only slightly impaired in the majority of patients with isolated MS.[26] Most patients with MS have a normal elevation of ejection fraction and a reduction of end-systolic volume during exercise.[27] Associated ischemic heart disease may, however, be responsible for myocardial dysfunction.[28]

PULMONARY HYPERTENSION.

Pulmonary hypertension in patients with MS results from (1) passive backward transmission of the elevated left atrial pressure; (2) pulmonary arteriolar constriction, which presumably is triggered by left atrial and pulmonary venous hypertension (reactive pulmonary hypertension); and (3) organic obliterative changes in the pulmonary vascular bed, which may be considered to be a complication of longstanding and severe MS[29] (see Chap. 53) . In time, severe pulmonary hypertension results in right-sided heart failure, with dilatation of the right ventricle and its annulus and secondary tricuspid and sometimes pulmonic regurgitation. These changes in the pulmonary vascular bed may also exert a protective effect; the elevated precapillary resistance makes the development of symptoms of pulmonary congestion less likely by tending to prevent blood from surging into the pulmonary capillary bed and damming up behind the stenotic mitral valve, although this protection occurs at the expense of a reduced cardiac output. In patients with severe MS, pulmonary vein-bronchial vein shunts occur.[30] Their rupture may cause hemoptysis. Patients with severe MS manifest a reduction in pulmonary compliance, an increase in the work of breathing, and a redistribution of pulmonary blood flow from the base to the apex.

CLINICAL AND HEMODYNAMIC FEATURES.

At any given severity of stenosis, the clinical picture is dictated largely by the levels of cardiac output and pulmonary vascular resistance. The response to a given degree of mitral obstruction may be characterized at one end of the hemodynamic spectrum by a normal cardiac output and a high left atrioventricular pressure gradient or, at the opposite end of the spectrum, by a markedly reduced cardiac output and low transvalvular pressure gradient. Thus, in some patients with moderately severe MS (mitral valve area=1.0 to 1.5 cm^2), cardiac output at rest may be normal and rises normally during exertion. In these patients, the high transvalvular pressure gradient causes marked elevation of left atrial and pulmonary capillary pressures. This leads to severe pulmonary congestion during exertion. In contrast, in the majority of patients with severe MS, cardiac output rises subnormally during exertion, thus reducing the pulmonary venous pressure and the severity of symptoms of pulmonary congestion more than would be the case if the cardiac output rose normally. In patients with severe MS (mitral valve area 1.0 cm^2), particularly when pulmonary vascular resistance is elevated, cardiac output is usually depressed at rest and may fail to rise at all during exertion. These patients frequently have severe weakness and fatigue secondary to a low cardiac output.

LEFT ATRIAL CHANGES.

The combination of mitral valve disease and atrial inflammation secondary to rheumatic carditis causes (1) left atrial dilatation, (2) fibrosis of the atrial wall, and (3) disorganization of the atrial muscle bundles. The last leads to disparate conduction velocities and inhomogeneous refractory periods. Premature atrial activation, due either to an automatic focus or to reentry, may stimulate the left atrium during the vulnerable period and thereby precipitate atrial fibrillation. The development of this arrhythmia correlates independently with the severity of the MS and the height of the left atrial pressure.[31] Atrial fibrillation is often episodic at first, but then becomes more persistent. Atrial fibrillation per se causes diffuse atrophy of atrial muscle, further atrial enlargement,[32] and further inhomogeneity of refractoriness and conduction. These changes, in turn, lead to irreversible atrial fibrillation.

CLINICAL MANIFESTATIONS

History

The principal symptom of MS is exertional dyspnea, largely the result of reduced pulmonary compliance. Dyspnea may be accompanied by cough and wheezing. Vital capacity is reduced, presumably owing to the presence of engorged pulmonary vessels and interstitial edema. Patients who have critical obstruction to left atrial emptying and dyspnea with ordinary activity (New York Heart Association [NYHA] Class III) generally have orthopnea as well and are at risk of experiencing attacks of frank pulmonary edema. The latter may be precipitated by effort, emotional stress, respiratory infection, fever, sexual intercourse, pregnancy, or atrial fibrillation with a rapid ventricular rate or other tachyarrhythmia. Indeed, pulmonary edema may be caused by any condition that increases flow across the stenotic mitral valve, either by increasing total cardiac output or by reducing the time available for blood flow across the mitral orifice to occur. In patients with a markedly elevated pulmonary vascular resistance, right ventricular function is often impaired.[33]

HEMOPTYSIS.

Wood has differentiated between several kinds of *hemoptysis* complicating MS.[14]

1. Sudden hemorrhage (previously called "pulmonary apoplexy"). Although the hemorrhage is often profuse, it is only rarely life-threatening.[34] It results from the rupture of thin-walled, dilated bronchial veins,[30] usually as a consequence of a sudden rise in left atrial pressure. With persistence of pulmonary venous hypertension, the walls of these veins thicken appreciably. This form of hemoptysis tends to disappear as MS progresses.
2. Blood-stained sputum associated with attacks of paroxysmal nocturnal dyspnea.

3. Pink, frothy sputum characteristic of acute pulmonary edema with rupture of alveolar capillaries.
4. Pulmonary infarction, a late complication of MS associated with heart failure.
5. Blood-stained sputum complicating chronic bronchitis. The edematous bronchial mucosa in patients with chronic MS increases the likelihood of chronic bronchitis, which is a common complication of MS, particularly in Great Britain.

CHEST PAIN.

A small percentage, perhaps 15 percent, of patients with MS experience chest discomfort that is indistinguishable from angina pectoris.[14] This symptom may be caused by severe right ventricular hypertension secondary to the pulmonary vascular disease or by concomitant coronary atherosclerosis.[28] Rarely, chest pain may be secondary to coronary obstruction caused by coronary embolization.[35] In many patients, however, a satisfactory explanation for the chest pain cannot be uncovered even after complete hemodynamic and angiographic studies.

SYSTEMIC EMBOLISM.[36] [36A]

Before the advent of surgical treatment, this serious complication of MS developed in at least 20 percent of patients at some time during the course of their disease.[37] Before the era of anticoagulant therapy and surgical treatment, approximately 25 percent of all fatalities in patients with mitral valve disease were secondary to systemic embolism. The tendency for development of systemic embolization correlates directly with the patient's age and the size of the left atrial appendage and inversely with the cardiac output; 80 percent of patients with MS in whom systemic emboli develop are in atrial fibrillation. When embolization occurs in patients in sinus rhythm, the possibility of transient atrial fibrillation or underlying infective endocarditis should be considered. There is no simple correlation between the incidence of embolism on the one hand and the size of the mitral orifice on the other. Indeed, embolism may be the first symptom of MS and may occur in patients with mild MS even before the development of dyspnea.

Because thrombi are found in the left atrium at operation in only a minority of patients with a history of recent embolism, it is likely that only fresh clots are discharged. Approximately half of all clinically apparent emboli are found in the cerebral vessels. Coronary embolism may lead to myocardial infarction and/or angina pectoris, and renal emboli may be responsible for the development of systemic hypertension. Emboli are recurrent and multiple in approximately 25 percent of patients who develop this complication. Rarely, massive thrombosis develops in the left atrium, resulting in a pedunculated ball-valve thrombus, which may suddenly aggravate obstruction to left atrial outflow when a specific body position is assumed or may cause sudden death.[12] Similar consequences occur in patients with free-floating thrombi in the left atrium. These two conditions are usually characterized by variability in the physical findings, often on a positional basis. They are very hazardous and require surgical treatment, often as an emergency.

INFECTIVE ENDOCARDITIS (see also Chap. 47) .

This complication tends to occur *less frequently* on rigid, thickened, calcified valves and is therefore more common in patients with mild MS than those with severe MS.

OTHER SYMPTOMS.

Compression of the left recurrent laryngeal nerve by a greatly dilated left atrium, enlarged tracheobronchial lymph nodes, and a dilated pulmonary artery may cause hoarseness (Ortner syndrome).[38] A history of repeated hemoptysis is common in patients with pulmonary hemosiderosis. Systemic venous hypertension, hepatomegaly, edema, ascites, and hydrothorax are all signs of severe MS with elevated pulmonary vascular resistance and right-sided heart failure.

Physical Examination[39] [40]

Patients with severe MS, a low cardiac output, and systemic vasoconstriction may exhibit the so-called *mitral facies,* characterized by pinkish-purple patches on the cheeks.[14] The *arterial pulse* is usually normal, but in patients with a reduced stroke volume, the pulse may be small in volume. The *jugular venous pulse* usually exhibits a prominent *a* wave in patients with sinus rhythm (see Fig. 4-5) and elevated pulmonary vascular resistance. In patients with atrial fibrillation, the *x* descent of the jugular venous pulse disappears, and there is only one crest, a prominent *v* or *c-v* wave, per cardiac cycle. *Palpation* of the cardiac apex usually reveals an inconspicuous left ventricle; the presence of either a palpable presystolic expansion wave or an early diastolic rapid filling wave speaks strongly against serious MS. A readily palpable, tapping S_1 suggests that the anterior mitral valve leaflet is pliable. When the patient is in the left lateral recumbent position, a diastolic thrill of MS may be palpable at the apex. Often a right ventricular lift is felt in the left parasternal region in patients with pulmonary hypertension. A markedly enlarged right ventricle may displace the left ventricle posteriorly and produce a prominent apex beat that can be confused with a left ventricular lift. A loud pulmonic closure sound (P_2) may be palpable in the second left intercostal space in patients with MS and pulmonary hypertension.

AUSCULTATION.

The auscultatory features of MS (Fig. 46-3; see also Figs. 4-16 *B* and 4-34) include an accentuated S_1 with prolongation of the Q-S_1 interval, correlating with the level of the left atrial pressure. Accentuation of S_1 occurs when the mitral valve leaflets are flexible. [41] It is caused, in part, by the rapidity with which left ventricular pressure rises at the time of mitral valve closure as well as by the wide closing excursion of the leaflets.[42] Marked calcification and/or thickening of the mitral valve leaflets reduces the amplitude of S_1 , probably because of diminished motion of the leaflets. As pulmonary arterial pressure rises, P_2 at first becomes accentuated and widely transmitted and can often be readily heard at both the mitral and the aortic areas. With further elevation of pulmonary arterial pressure,

Figure 46-3 The classic auscultatory signs of MS in patients in sinus rhythm. These include a presystolic murmur, a loud S_1 , an opening snap (OS), and a mid-diastolic murmur (DR, low-pitched, decrescendo diastolic rumble). These signs may be accentuated or at times may only be heard by placing the patient in the left lateral decubitus position. These signs are helpful in assessing the severity of MS; as MS becomes more severe, the S_2 -OS interval is shortened, and the length of the mid-diastolic rumble is increased. *(From Kawanishi DT, Rahimtoola SH: Mitral stenosis. In Rahimtoola SH [ed]: Valvular Heart Disease. Atlas of Heart Diseases, vol. 11. Braunwald E, series ed. Philadelphia, Current Medicine, 1997, pp 8.1-8.24.)*

splitting of S_2 narrows because of reduced compliance of the pulmonary vascular bed, and this shortens the "hangout interval." Finally, S_2 becomes single and accentuated. Other signs of severe pulmonary hypertension include a nonvalvular pulmonic ejection sound that diminishes during inspiration, owing to dilatation of the pulmonary artery; a systolic murmur of tricuspid regurgitation; a Graham Steell murmur of pulmonic regurgitation; and an S_4 originating from the right ventricle. An S_3 originating from the left ventricle is absent in patients with MS unless significant mitral or aortic regurgitation coexists.

The *opening snap* (OS) of the mitral valve is caused by a sudden tensing of the valve leaflets after the valve cusps have completed their opening excursion. The OS occurs when the movement of the mitral dome into the left ventricle suddenly stops.[42] It is most readily audible at the apex, using the diaphragm of the stethoscope. The OS can usually be differentiated from P_2 because the OS occurs later, unless right bundle branch block is present. The mitral valve cannot be totally rigid if it produces an OS, which is usually accompanied by an accentuated S_1 . Calcification confined to the tip of the mitral valve leaflets does not preclude an OS, although calcification of both the body and the tip does. The mitral OS follows A_2 by 0.04 to 0.12 second; this interval varies inversely with the left atrial pressure.[41] A short A_2 -OS interval is a reliable indicator of severe MS.

The Diastolic Murmur of MS.

This murmur is a low-pitched, rumbling murmur, best heard at the apex, with the bell of the stethoscope and with the patient in the left lateral recumbent position. When this murmur is soft, it is limited to the apex, but when louder, it may radiate to the left axilla or the lower left sternal area. Although the intensity of the diastolic murmur is not closely related to the severity of stenosis, the *duration* of the murmur is a guide to the severity of mitral valve narrowing. The murmur persists for as long as the left atrioventricular pressure gradient exceeds approximately 3 mm Hg. The murmur usually commences immediately after the OS. In mild MS, the early diastolic murmur is brief, but in the presence of sinus rhythm it resumes in presystole. In severe MS, the murmur is holodiastolic.

The *diastolic rumbling murmur* of MS may be masked by the presence of a thick chest wall, pulmonary emphysema, and a low cardiac output with a low flow rate across the mitral valve. This murmur may be sharply localized and thus missed unless palpation is used to detect the apex of the left ventricle and to pinpoint the area

at which auscultation should be carried out. In so-called "silent" MS, there is usually marked right ventricular enlargement. Consequently, the right ventricle occupies the cardiac apex, the left ventricle is rotated posteriorly, and cardiac output is reduced, so that the murmur either is not audible at all or can be heard only in the mid- or posterior axillary line. Auscultation of the murmur is facilitated by placing the patient in the left lateral position and auscultating during expiration after having the patient do a few sit-ups, walk up a flight of stairs, or other maneuvers described later.

DYNAMIC AUSCULTATION (See also Chap. 4) .

The diastolic murmur and OS of MS are often reduced during inspiration and augmented during expiration,[39] [40] which is the opposite of what occurs when these findings are secondary to tricuspid stenosis (see p. 1690). During inspiration, the A_2 -OS interval widens, and three sequential sounds (A_2 , P_2 , and OS) may be audible. Sudden standing and the resultant reduction of venous return lower the left atrial pressure and widen the A_2 -OS interval; this maneuver is useful in distinguishing an A_2 -OS combination from a split S_2 , which narrows on standing. In contrast, the A_2 -OS interval is significantly narrowed during exercise as left atrial pressure rises. The diastolic rumbling murmur of MS is reduced during the strain of a Valsalva maneuver and in any condition in which transmitral valve flow rate declines. Amyl nitrite inhalation, coughing, isometric or isotonic exercise, and sudden squatting are all useful in accentuating a faint or equivocal murmur of MS.

DIFFERENTIAL DIAGNOSIS.

The *Carey-Coombs murmur* of acute rheumatic fever is a sign of active mitral valvulitis and can be confused with the murmur of MS. The Carey-Coombs murmur is a soft early diastolic murmur, usually varies from day to day, and is higher pitched than the diastolic rumbling murmur of established MS. In pure, severe MR--indeed in any condition in which flow across a nonstenotic mitral valve is increased--there may also be a short diastolic murmur following an S_3 . *Left atrial myxoma* may produce auscultatory findings similar to those in rheumatic valvular MS (see Chap. 49) .

A high-frequency early systolic murmur is audible along the lower left sternal border in one-third of patients with MS. This should be distinguished from the apical (often holosystolic or late systolic) murmur of MR. In addition, a *pansystolic murmur of tricuspid regurgitation* and an S_3 originating from the right ventricle may be audible in the 4th intercostal space in the left parasternal region in patients with severe MS. These signs, which are secondary to pulmonary hypertension, may be confused with the findings of MR. However, the inspiratory augmentation of the

murmur and of the S_3 and the prominent *v* wave in the jugular venous pulse aid in establishing that the murmur originates from the tricuspid valve. A high-pitched decrescendo diastolic murmur along the left sternal border in patients with MS and pulmonary hypertension is usually due to aortic regurgitation but occasionally represents a Graham Steell murmur of pulmonary regurgitation. The latter, when present, characteristically increases during inspiration.

LABORATORY EXAMINATION

ELECTROCARDIOGRAPHY (See also Chap. 5) .

The electrocardiogram (ECG) is relatively insensitive for detecting mild MS, but it does show characteristic changes in moderate or severe obstruction.[43] Left atrial enlargement (P-wave duration in lead II
 0.12 sec and/or a P-wave axis between +45 and -30 degrees) is a principal ECG feature of MS and is found in 90 percent of patients with significant MS and sinus rhythm.[44] The ECG signs of left atrial enlargement correlate more closely with left atrial volume than with left atrial pressure and often regress following successful valvotomy.[14] Atrial fibrillation usually develops in the presence of preexisting ECG evidence of left atrial enlargement and is related to the size of the chamber, the extent of fibrosis of the left atrial myocardium, the duration of atriomegaly, and the age of the patient.

Whether or not there is ECG evidence of right ventricular hypertrophy depends largely on the height of right ventricular systolic pressure. Approximately half of all patients with right ventricular systolic pressures between 70 and 100 mm Hg manifest the ECG criteria for right ventricular hypertrophy, including both a mean QRS axis greater than 80 degrees in the frontal plane and an R:S ratio greater than 1.0 in lead V_1 . Other patients with this degree of pulmonary hypertension have no frank evidence of right ventricular hypertrophy, but the R:S ratio fails to increase from the right to the midprecordial leads. When right ventricular systolic pressure is greater than 100 mm Hg in patients with isolated or predominant MS, ECG evidence of right ventricular hypertrophy is found quite consistently.

The *QRS axis in the frontal plane* correlates roughly with the severity of valve obstruction and with the level of pulmonary vascular resistance in patients with pure MS. Thus, a mean frontal axis between 0 and +60 degrees suggests that the mitral valve area is greater than 1.3 cm^2 , whereas an axis of more than 60 degrees suggests that the valve area is less than 1.3 cm^2 . In patients in whom pulmonary vascular resistance exceeds 650 dyne-sec·cm^{-5} , the mean axis is usually greater than +110 degrees. In patients whose pulmonary artery systolic pressure approaches systemic levels, the mean axis averages +150 degrees.[45]

RADIOLOGICAL FINDINGS (See also Figs. 8-7 *B* and 8-25) .

Although their cardiac silhouette may be normal in the frontal projection, patients with hemodynamically significant MS almost invariably have evidence of left atrial enlargement on the lateral and left anterior oblique views. Extreme left atrial enlargement rarely occurs in pure MS; when it is present, MR is usually severe. Enlargement of the pulmonary artery, right ventricle, and right atrium (as well as the left atrium) is commonly seen in patients with severe MS. Occasionally, calcification of the mitral valve is evident on the chest roentgenogram, but, more commonly, fluoroscopy is required to detect valvular calcification.

Radiological changes in the lung fields indirectly reflect the severity of MS. Interstitial edema, an indication of severe obstruction, is manifested as Kerley B lines (dense, short, horizontal lines most commonly seen in the costophrenic angles). This finding is present in 30 percent of patients with resting pulmonary arterial wedge pressures less than 20 mm Hg and in 70 percent of patients with pressures greater than 20 mm Hg. Severe, longstanding mitral obstruction often results in Kerley A lines (straight, dense lines up to 4 cm in length running toward the hilum) as well as the findings of pulmonary hemosiderosis and rarely of parenchymal ossification. Pulmonary edema is seldom evident.

ANGIOGRAPHY.

Angiograms exposed in the right and left anterior oblique projections afford the best views of the mitral valve. Although contrast material should ideally be injected into the left atrium, it is often possible to achieve good visualization of the left side of the heart by injecting a large volume of contrast material into the main pulmonary artery. Such angiograms provide an assessment of left atrial size, may demonstrate thickening and reduced motion of the valve leaflets, and outline large intraluminal thrombi.[46] Left ventriculography makes possible simultaneous assessment of left ventricular contractile function and of the subvalvular mitral apparatus. However, echocardiography has largely superseded angiography in the evaluation of patients with MS or suspected MS.

ECHOCARDIOGRAPHY (See also Chap. 7) .

This is now the cornerstone of the diagnostic assessment of patients with MS. Two-dimensional transthoracic or transesophageal

Figure 46-4 Two-dimensional transthoracic parasternal short-axis view of the mitral valve orifice during diastole, demonstrating the echocardiographic method of mitral valve area calculation. The innermost border of the mitral orifice was planimetered with the use of a light-pen system to obtain the area (in cm^2). *(Reproduced with permission from Smith MD et al: Comparative accuracy of two-dimensional echocardiography and Doppler pressure half-time methods in assessing severity of mitral stenosis in patients with and without prior commissurotomy. Circulation 73:100, 1986. Copyright 1986 American Heart Association.)*

echocardiograms of a thickened, calcified, stenotic rheumatic valve demonstrate increased acoustic impedance and fusion of the mitral valve leaflets and poor leaflet separation in diastole (Fig. 46-4) . The leaflets fail to close normally in mid-diastole and may not reopen widely during atrial contraction when sinus rhythm is present. The left atrium is usually enlarged, and in isolated MS the left ventricular cavity is normal or reduced in size. Two-dimensional echocardiography (see Figs. 7-47 , 7-48 , 7-49 , 7-50 , 7-51 , and 7-52) may be helpful in recognizing left atrial thrombus preoperatively and in assessing mitral valve calcification and left ventricular contractility.[47] With progressive thickening and fibrosis of the leaflets, the orifice becomes fixed and can then often be imaged directly and measured. Two-dimensional echocardiography also provides information on the pliability of the leaflets, the extent of valvular calcification, thickening of the subvalvular apparatus, and fusion and

retraction of the chordae tendineae, as well as calcification of the mitral annulus. This technique allows determination of left ventricular size and function and can also evaluate the aortic valve. The two-dimensional echocardiogram is helpful in determining whether the patient with MS is a suitable candidate for balloon mitral valvuloplasty (see p. 1651). Transesophageal two-dimensional echocardiography provides images of the mitral valve that are superior to those obtained by transthoracic imaging and is more sensitive in detecting left atrial thrombus. Pedunculated and free-floating thrombi are also usually readily detected by this technique. Transesophageal echocardiography is necessary when the transthoracic signal is inadequate.

Doppler echocardiography is the most accurate noninvasive technique available for quantifying the severity of MS[47] (see Fig. 7-51) and for estimating pulmonary arterial pressure.[48] [49] Color flow Doppler imaging can enhance the accuracy of the Doppler data by determining whether MR, aortic regurgitation, and other valvular abnormalities coexist. The pulmonary arterial pressure also can be estimated from the tricuspid regurgitation velocity signal.

In a patient with MS, a detailed echocardiographic examination, including two-dimensional echocardiography (transthoracic or transesophageal), a Doppler study, and color flow Doppler imaging, can usually provide sufficient information to develop a therapeutic plan without the need for cardiac catheterization (see below).[50]

MANAGEMENT

Medical Treatment

Patients with MS due to rheumatic heart disease should receive penicillin prophylaxis for beta-hemolytic streptococcal infections and prophylaxis for infective endocarditis (see Chaps. 47 and 66) . Anemia and infections should be treated promptly and aggressively in patients with valvular heart disease. Adolescents and young adults with severe valvular heart disease should be advised to avoid entering occupations requiring strenuous exertion. Asymptomatic patients with moderate MS should be reevaluated yearly.[51] Heavy exertion is contraindicated in symptomatic patients.

In symptomatic patients with mitral valve disease, considerable improvement occurs with the administration of oral diuretics and the restriction of sodium intake. Digitalis glycosides do not alter the hemodynamics and usually do not benefit patients with MS and sinus rhythm,[52] but these drugs are of value in slowing the ventricular rate in patients with atrial fibrillation and in treating patients with right-sided heart failure. Hemoptysis is managed by measures designed to reduce pulmonary venous pressure, including sedation, assumption of the upright position, and aggressive diuresis. Beta-blocking agents and rate-slowing calcium antagonists may increase exercise capacity by reducing heart rate in patients with sinus rhythm[53] and especially in patients with atrial fibrillation.

Anticoagulant therapy is helpful in preventing venous thrombosis and pulmonary embolism in patients who have experienced one or more previous pulmonary embolic episodes; in patients who are at high risk of systemic embolization, i.e., with persistent or transient atrial fibrillation (especially elderly patients > 70 years of age); and in those with previous systemic emboli. Treatment with warfarin, to maintain the international normalized ratio (INR) between 2.0 and 3.0, is indicated.[54] However, no firm evidence exists that anticoagulant therapy reduces the incidence of pulmonary or systemic embolism in patients in sinus rhythm in whom such episodes have not previously occurred.

TREATMENT OF ARRHYTHMIAS.

Frequent premature atrial contractions often presage atrial fibrillation. The administration of antiarrhythmic agents (see Chap. 23) may be effective in preventing this complication. However, once atrial fibrillation has developed, these agents may be ineffective in restoring sinus rhythm because of the pathological changes that occur in the atrium secondary to the arrhythmia itself. After electrical cardioversion, sinus rhythm can often be maintained with antiarrhythmic agents, especially in young patients with mild MS but without marked left atrial enlargement who have been in atrial fibrillation less than 6 months and who are maintained on adequate doses of quinidine.

Immediate treatment of atrial fibrillation should include intravenous heparin followed by oral warfarin. The ventricular rate should be slowed with intravenous digoxin and a beta-blocking agent or rate-slowing calcium antagonist. An effort should be made to reestablish sinus rhythm by a combination of pharmacological treatment and cardioversion. If cardioversion is planned in a patient who has had atrial fibrillation for more than 24 hours before the procedure, anticoagulation with warfarin for more than three weeks is indicated. Alternatively, if a transesophageal echocardiogram shows no atrial thrombus, immediate cardioversion can be carried out using intravenous heparin.[55] Paroxysmal atrial fibrillation and repeated conversions, spontaneous or induced, carry the risk of embolization. In patients who cannot be converted or maintained in sinus rhythm, digitalis should be used to maintain the ventricular rate at rest at approximately 60 beats/min. If this is not possible, small doses of a beta-blocking agent, such as atenolol (25 mg daily), may be added. Multiple repeat cardioversions are *not* indicated if the patient fails to sustain sinus rhythm while on adequate doses of an antiarrhythmic. Patients with chronic atrial fibrillation who undergo open mitral valve repair or replacement may undergo the Cox maze procedure (atrial compartment operation). More than 80 percent of patients undergoing this procedure can be maintained in sinus rhythm postoperatively[56] and can regain normal atrial function.[57]

NEED FOR CATHETERIZATION.

There has been considerable debate concerning the need for routine cardiac catheterization in determining whether valvotomy is indicated.[51] A careful clinical evaluation and noninvasive assessment, particularly using two-dimensional and Doppler echocardiography, can provide sufficient information to permit an informed decision in the majority of patients. Preoperative catheterization is recommended for the following patients with MS: (1) patients who have a discrepancy between clinical and echocardiographic findings; hemodynamic measurements during exercise are often useful in these patients; (2) patients who have associated chronic obstructive pulmonary disease in whom it is important to determine the contribution of MS to the symptoms; (3) patients in whom left atrial myxoma should be excluded; (4) patients who have angina pectoris or angina-like chest pain in whom associated coronary artery disease must be excluded; and (5) men over 40 years of age and women over 50 years of age who have risk factors for coronary artery disease or a positive stress test and in whom surgery is planned; it is important to ascertain whether or not bypass grafting is indicated for those patients at risk of having coexisting coronary artery disease. Critical narrowing of one or more coronary vessels occurs in approximately 25 percent of all adults with severe MS. This finding is more common in men over 45 years of age who have angina and risk factors for coronary artery disease.[28]

Natural History

The development of effective surgical treatment has obscured our understanding of the natural history of MS (Fig. 46-5) and, for that matter, of all valvular lesions. Although few meaningful data are available, it appears that in temperate zones, such as the United States and Western Europe, patients who develop acute rheumatic fever have an asymptomatic period of approximately 15 to 20 years before symptoms of MS develop. It then takes approximately 5 to 10 years for most patients to progress from mild disability (i.e., early NYHA Class II) to severe disability (i.e., NYHA Class III or IV). The progression is much more rapid in patients in tropical and subtropical areas,[58] in Polynesians, and in Alaskan Inuit. Both economic and genetic conditions may play a role. In India, critical MS may be present in children as young as 6 to 12 years old. In North America and Western Europe, however, symptoms develop

Figure 46-5 Schematic representation of the subsequent life history after the initial development of symptoms in a large group of patients with mitral stenosis. The colored solid circles and colored lines indicate a surgical procedure. The dashed lines represent estimated survival of patients who are not receiving the surgical procedure. MC = mitral commissurotomy; MVR = mitral valve replacement; TA = tricuspid annuloplasty; AVR = aortic valve replacement. *(From Kirklin JW, Barratt-Boyes BG [eds]: Cardiac Surgery. New York, John Wiley and Sons, 1986, p 328.)*

more slowly and occur most commonly between the ages of 45 and 65.[51] Two echocardiographic studies have reported hemodynamic progression in patients with MS who had not undergone surgery[59] [60] ; there was considerable interpatient variability, but on average the mitral valve area decreased by 0.09 cm^2 /yr.

In the *presurgical era,* Olesen found 62 percent 5-year survival rates and 38 percent 10-year survival rates among medically treated patients with MS in NYHA Class III but only 15 percent 5-year survival rates among patients in Class IV.[61] Among asymptomatic patients with MS treated medically, 40 percent deteriorated or died within 10 years. Among mildly symptomatic patients (NYHA Class II), the comparable number was 80 percent.[62] In medically treated patients with MS or with combined MS and MR, Munoz and associates found a 45 percent 5-year survival rate.[63] In a comparable group of patients who underwent mitral valvotomy, the 5-year survival rate

was substantially better. Horstkotte et al. reported a 5-year survival rate of 44 percent in patients with symptomatic MS who refused valvotomy (Fig. 46-6) . [64]

Valvotomy

Indications

Patients with MS who are asymptomatic or minimally symptomatic frequently remain so for years. However, once moderate symptoms develop (NYHA Class II), if the stenosis is not relieved mechanically, the disease may progress relatively rapidly, as already discussed (Table 46-1) . Valvotomy (percutaneous balloon mitral valvuloplasty [BMV] or surgical valvotomy) should therefore be carried out in symptomatic patients with moderate to severe MS (i.e., a mitral valve orifice area < approximately 1.0 cm^2 /m^2 body surface area [BSA] or <1.5 to 1.7 cm^2 in normal-sized adults). It is also indicated in patients with mild stenosis (orifice area 1.0 to 1.5 cm^2 /m^2 who are symptomatic during ordinary activity and who develop pulmonary arterial systolic pressures exceeding 60 mm Hg or mean pulmonary capillary wedge pressures exceeding 25 mm Hg during exercise.[51]

Treatment must be individualized. For instance, mechanical relief of obstruction might well be deferred in a retired, mildly symptomatic, sedentary septuagenarian with a mitral valve orifice of 0.8 cm^2 /m^2 BSA. On the other hand, a 30-year-old laborer whose family's economic well-being depends on his continued physical exertion might be an excellent candidate for mechanical relief of obstruction, although his mitral valve orifice size is 1.2 cm^2 /m^2 BSA. Some years ago, I saw a 33-year-old woman with MS who

Figure 46-6 Natural history of 159 patients with isolated mitral stenosis (open circles) or mitral regurgitation (open triangles) who were not operated upon (even though the operation was indicated) compared with patients treated with valve replacement for mitral stenosis (solid circles) or mitral regurgitation (solid triangles). The expected survival rate in the absence of mitral valve disease is indicated by the upper curve (dashed line). *(From Horstkotte D, Niehues R, Strauer BE: Pathomorphological aspects, aetiology, and natural history of acquired mitral valve stenosis. Eur Heart J 12(Suppl):55-60, 1991.)*

had had hemoptysis and pulmonary edema during the second trimester of a pregnancy 2 years previously. She then became asymptomatic but wished to have another child. Hemodynamic study showed a pulmonary artery wedge pressure of 17 mm Hg and a mitral orifice area of 1.7 cm^2 /m^2 BSA. This patient underwent prophylactic BMV

TABLE 46-1 -- APPROACHES TO MECHANICAL RELIEF OF MITRAL STENOSIS

APPROACH	ADVANTAGES	DISADVANTAGES
Closed surgical valvotomy	Inexpensive	No direct visualization of valve
	Relatively simple	Only feasible with flexible, noncalcified valves
	Good hemodynamic results in selected patients	
		Contraindicated if MR>2+
	Good long-term outcome	Surgical procedure with general anesthesia
Open surgical valvotomy	Visualization of valve allows directed valvotomy	Best results with flexible, noncalcified valves
	Concurrent annuloplasty for MR is feasible	Surgical procedure with general anesthesia
Valve replacement	Feasible in all patients regardless of extent of valve calcification or severity of MR	Surgical procedure with general anesthesia
		Effect of loss of annular-papillary muscle continuity on LV function
		Prosthetic valve
		Chronic anticoagulation
Balloon mitral valvotomy	Percutaneous approach	No direct visualization of valve
	Local anesthesia	Only feasible with flexible, noncalcified valves
	Good hemodynamic results in selected patients	
		Contraindicated if MR>2+
	Good long-term outcome	

LV=left ventricular; MR=mitral regurgitation.

From Otto CM: Valvular Heart Disease. Philadelphia, WB Saunders, 1999, p 261.

because it was deemed that another pregnancy would have resulted in serious symptoms. However, there is no evidence that valvotomy improves the prognosis of patients with no or only slight functional impairment. Therefore, valvotomy is *not* ordinarily indicated in patients who are entirely asymptomatic. Because of the high rate of recurrence, mechanical relief of obstruction is also indicated in patients with MS who have had a previous systemic embolism, even if they are otherwise asymptomatic and even though there is no *definitive* evidence that the incidence of recurrent emboli will be significantly reduced. Anticoagulants should be administered to such patients up to the time of the procedure.

Balloon Mitral Valvotomy (See also Chap. 38)

This percutaneous technique consists of advancing a small balloon flotation catheter across the interatrial septum (after transseptal puncture), enlarging the opening, advancing a large (23 to 25 mm) hourglass-shaped balloon (the Inoue balloon), and inflating it within the orifice. Alternatively, two smaller (12 to 18 mm) balloons may be employed.[65] Commissural separation and fracture of nodular calcium appear to be the mechanisms responsible for improvement in valvular function. In several series, the hemodynamic results of BMV have been quite favorable (Fig. 46-7) , with reduction of the transmitral pressure gradient from an average of approximately 18 mm Hg to 6 mm Hg, a small (average 20 percent) increase in cardiac output, and an average doubling of the calculated mitral valve area from 1.0 to 2.0 cm^2 . Although the double-balloon technique may result in a slightly greater valve opening, the clinical outcomes of the two approaches are similar.[66] Improvement in exercise tolerance has paralleled the favorable hemodynamic changes.

Results are especially impressive in younger patients without valvular thickening or calcification. Elevated pulmonary vascular resistance declines rapidly, although usually not completely.[67] [67A] The reported mortality rate has ranged from 1 to 2 percent. Complications include cerebral emboli and cardiac perforation, each in approximately 1

Figure 46-7 Simultaneous left atrial (LA) and left ventricular (LV) pressure before and after balloon mitral valvotomy in a patient with severe mitral stenosis. *(Courtesy of Raymond G. McKay, M.D.)*

Figure 46-8 Determination of echocardiographic score. Leaflet rigidity, thickening, calcification, and the amount of subvalvular disease are graded 0 to 4, depending on the severity of the abnormality. The sum of the four factors equals the echocardiographic score. *(From Block PC: Mitral balloon valvotomy: Why, when and how? Cardiol Rev 2:19, 1994.)*

percent of patients, and the development of MR severe enough to require operation in another 2 percent (approximately 15 percent develop lesser, but still undesirable, degrees of MR). Approximately 5 percent of patients are left with a small residual atrial septal defect, but this closes or decreases in size in the majority. Rarely, the defect is large enough to cause right-sided heart failure. Results are surgeon-dependent and patients should be referred to experienced teams.[68] [69] [69A]

The indications for BMV are the same as those for valvotomy (discussed below). A combination of significant symptoms and documented MS generally serves as the indication. Detailed two-dimensional and Doppler echocardiographic studies are indicated before a decision is made. Left atrial thrombus must be excluded by echocardiography.

An echocardiographic scoring system developed by Wilkins and colleagues[70] has been found to be particularly valuable in patient selection and has been widely adopted. Leaflet rigidity, leaflet thickening, valvular calcification, and subvalvular disease are each scored from 0 to 4 (Fig. 46-8) . Rigid, thickened valves with extensive subvalvular fibrosis and calcification lead to suboptimal results. A score of 8 or less is usually associated with an excellent immediate and long-term result, whereas scores exceeding 8 are associated with less impressive results (Fig. 46-9) , including the risk of development of MR.[71] Fluoroscopically visible calcium[72] and coexisting MR[73] are additional important predictors of an adverse outcome.[72] Transesophageal echocardiography provides a precise assessment of mitral valve structure and function and evaluation of accompanying MR and left atrial thrombus (a contraindication to BMV).[74] It also provides an accurate assessment of outcome. Three-dimensional echocardiography has also been found to be useful in assessing indications for BMV.[75] The findings on echocardiography affect the outcome of both open and closed surgical valvotomy in a similar manner. A trial in which patients with severe MS were randomized to undergo either BMV or open surgical valvotomy resulted in similar clinical results from the two techniques. Indeed, after 3 years, mitral valve area was greater in the balloon catheter-treated group.[76] In patients with favorable anatomical findings, survival without functional disability or need for surgery or repeat BMV

Figure 46-9 Event-free survival after balloon mitral valvotomy for 736 patients enrolled in the Balloon Valvuloplasty Registry who were stratified by baseline echocardiographic morphology score: less than 8 (solid line), 8 to 12 (short-dashed line), or more than 12 (long-dashed line); P < 0.0001. *(From Dean LS, Mickel MC, Bonan R, et al: Four-year follow-up of patients undergoing percutaneous balloon mitral commissurotomy: A report from the National Heart, Lung and Blood Institute Balloon Valvuloplasty Registry. J Am Coll Cardiol 28:1452, 1996.)*

is 70 percent at 7 years.[77] [78] [79] Excellent results have also been reported in children[80] and adolescents[81] in developing nations, where patients tend to be younger. These young patients usually have quite pliable valves, which are ideal for BMV.[82]

Percutaneous BMV is the procedure of choice in patients who have symptomatic, hemodynamically severe stenosis with an echocardiographic score of 8 or less and without left atrial thrombus.[69] The lower cost and morbidity are obvious advantages. BMV can also be the initial procedure in patients with symptomatic, severe MS and less favorable valves (echocardiographic score > 8 and/or dense calcification on fluoroscopic examination).[65] [72] However, the failure rate is considerable in these patients, and they may require surgical treatment, most often mitral valve replacement. BMV also has acceptable results in patients with accompanying mild or moderate aortic regurgitation[74] [83] and in those with mitral restenosis after surgical valvotomy.[84] It may also be used in patients with less favorable valves who are unsuitable for surgery because of very high risk.[85] These include very elderly, frail patients; patients with associated severe ischemic heart disease; patients in whom MS is complicated by pulmonary, renal, or neoplastic disease; women of childbearing age in whom valve replacement is undesirable; and pregnant women with MS.[86] [87] BMV is contraindicated in patients with severe mitral or aortic regurgitation and should probably not be used in patients with stenotic bioprosthetic valves.[85]

Because the cost of the balloon catheter is deemed high in countries with restricted financial resources, a reusable metallic valvulotome has been devised. Early results are at least as good as those achieved with balloon catheters.[88]

Surgical Valvotomy

Three operative approaches are available for the treatment of rheumatic MS: (1) closed mitral valvotomy using a transatrial or transventricular approach[89] [90] [91] ; (2) open valvotomy, i.e., valvotomy carried out under direct vision with the aid of cardiopulmonary bypass; and (3) mitral valve replacement (see Table 46-1) .

CLOSED MITRAL VALVOTOMY.

This procedure is performed without cardiopulmonary bypass but with the aid of a transventricular dilator. It is an effective operation, provided that MR, atrial thrombosis, or valvular calcification is not serious and that chordal fusion and shortening are not severe. Echocardiography is useful in selecting suitable candidates for this procedure by identifying patients without valvular calcification or dense fibrosis. If possible, closed mitral valvotomy should be carried out with "pump standby"; if the surgeon is unable to achieve a satisfactory result, the patient can be placed on cardiopulmonary bypass and the valvotomy carried out under direct vision or the valve replaced.

On average, the mitral valve area is increased by 1.0 cm^2 , with only 20 to 30 percent of patients requiring mitral valve replacement within 15 years.[92] In one large series,[90] the hospital mortality rate was 1.5 percent, and 0.3 percent of patients developed severe MR. Marked symptomatic improvement occurred in 86 percent of survivors. The actuarial survival rate was 89.5 percent after 18 years. Patients undergoing closed valvotomy for restenosis had a 6.7 percent mortality rate. Long-term follow-up has shown that the results are best if the operation is carried out before chronic atrial fibrillation and/or heart failure has occurred, but complication rates are higher when valves are calcified and/or severely thickened.[89]

Closed mitral valvotomy is rarely used in the United States today, having been replaced by BMV, which is of similar effectiveness in patients who are candidates for closed mitral valvotomy. Closed mitral valvotomy is more popular in developing nations, where the expense of open-heart surgery and even of balloon catheters for BMV is an important factor and where patients with mitral valve disease are younger and therefore have more pliable valves. But even in these nations, closed mitral valvotomy is being displaced by BMV.

OPEN VALVOTOMY.

Most surgeons in North America and Western Europe now prefer to carry out *direct-vision* or *open valvotomy.*[92] [93] [94] This operation is most frequently performed in patients with MS whose mitral valves are too distorted or calcified for BMV. Cardiopulmonary bypass is established, and in order to obtain a dry, quiet heart, body temperature is usually lowered, the heart is arrested, and the aorta is occluded intermittently. Thrombi are removed from the left atrium and its appendage, and the latter is often amputated in order to remove a potential source of postoperative emboli. The commissures are incised, and, when necessary, fused chordae tendineae are separated, the underlying papillary muscle is split, and the valve leaflets are debrided of calcium. Mild or even moderate MR may be corrected. Left atrial and ventricular pressures are measured after bypass has been discontinued to confirm that the valvotomy has, in fact, been effective. When it has not been effective, another attempt can be made. When repair is not possible--most commonly owing to severe distortion and calcification of the valve and subvalvular apparatus with accompanying regurgitation that cannot be corrected--mitral valve replacement should be carried out (see p. 1653).[95] In patients with atrial fibrillation, conversion to sinus rhythm is done at the completion of the operation. In a series of open mitral valve reconstructive procedures for MS at Brigham and Women's Hospital, the actuarial probability of survival at 10 years was 95 percent. The annual reoperation rate was 1.7 percent.[93] A survival rate of 75 percent over 20 years after surgical repair of MS has been reported.[96]

The mortality rate after mitral valvotomy, whether open or closed, ranges from 1 to 3 percent, depending on the condition of the patient and the skill and experience of the surgical team.[93] Five-year survival rates are 90 to 96 percent, and event-free survival rates are 72 to 94 percent.[96] [97] In general, open valvotomy provides better hemodynamic relief of mitral valve obstruction than does the closed procedure,[94] [98] and the risk of dislodging thrombi from the atrium or calcium from the mitral valve is also less.[93] Left atrial size, the need for mitral or tricuspid annuloplasty, and the presence of left atrial thrombus are all "risk factors" for a less than optimal outcome after open mitral

valvotomy. [95] Although a contemporary control series of medically and surgically treated patients is not available (nor is it likely ever to be), valvotomy appears to prolong survival substantially in patients with MS (see Fig. 46-6) .

MITRAL RESTENOSIS.

Mitral valvotomy, whether percutaneous or operative and whether open or closed, is *palliative* rather than curative, and even when successful, this procedure merely "turns the clock back." (The generally more effective open valvotomy turns the clock back further than does the closed valvotomy or BMV.) Thus, successful valvotomy does not result in a normal mitral valve but rather in one resembling the valve as it existed perhaps a decade earlier. Because the valve is not normal postoperatively,

turbulent flow usually persists in the paravalvular region, and the resultant trauma may well play a role in restenosis. These changes are analogous to the gradual development of obstruction in a congenitally bicuspid aortic valve and are *not* usually the result of recurrent rheumatic fever.

On clinical grounds alone, i.e., based on the reappearance of symptoms, the incidence of "restenosis" has been estimated to range widely (from 2 to 60 percent).[99] Approximately 10 percent of patients who have undergone surgical mitral valvotomy require reoperation within 5 years, but that number increases to 60 percent by 10 years.[100] Recurrence of symptoms is usually *not* due to restenosis but may be due to one or more of the following conditions: (1) an inadequate first operation with residual stenosis; (2) the presence or development of MR, either at operation or as a consequence of infective endocarditis; (3) the progression of aortic valve disease; and (4) the development of coronary artery disease. True restenosis occurs in less than 20 percent of patients who are followed for 10 years.[51] In a study of 18 patients who had undergone successful surgical valvotomy in whom the size of the mitral orifice was estimated using two-dimensional echocardiography, no change in the mitral valve area occurred over a 10- to 14-year period in 13 patients (72 percent), whereas in true restenosis developed in 5 patients (28 percent).[100] Others have estimated the rate of true restenosis to be approximately 10 percent within 6 years.[101]

Thus, in properly selected patients, mitral valvotomy, however performed--balloon angioplasty, closed or open valvotomy--is a low-risk procedure that results in a significant increase in the size of the mitral orifice and favorably alters the clinical course of an otherwise progressive disease. Pulmonary arterial pressure falls promptly and decisively when mitral obstruction is effectively relieved.[102] [103] The majority of patients maintain clinical improvement for 10 to 15 years of follow-up. When a second procedure is required because of symptomatic deterioration, the valve is usually calcified and more seriously deformed than at the time of the first operation, and adequate reconstruction may not be possible. Accordingly, mitral valve replacement (MVR) is often necessary at that time.

INDICATIONS FOR MITRAL VALVE REPLACEMENT.

This procedure is often required in patients with combined MS and moderate or severe MR; in those with extensive commissural calcification, severe fibrosis, and subvalvular fusion; and in those who have undergone previous valvotomy. The operative mortality rate following isolated MVR ranges from 3 to 8 percent in most centers and averaged 6.4 percent in the large database of 13,936 such operations for patients with MS and/or MR reported in the Society of Thoracic Surgeons National Database[104] (Table 46-2) . As described later (see p. 1701), mechanical deterioration of bioprosthetic valves may occur. Also, the hazards of lifelong anticoagulant treatment in patients with mechanical prostheses must be considered. Therefore, the threshold for operation should be higher in patients in whom preoperative evaluation suggests that valve replacement may be required than in patients in whom valvotomy alone appears to be indicated.

TABLE 46-2 -- OPERATIVE MORTALITY RATES FOLLOWING VALVE REPLACEMENT AND REPAIR

OPERATIVE CATEGORY	NUMBER	OPERATIVE MORTALITY (%)
AVR (isolated)	26,317	4.3
MVR (isolated)	13,936	6.4
Multiple valve replacement	3,840	9.6
AVR+CAB	22,713	8.0
MVR+CAB	8,788	15.3
Multiple valve replacement+CAB	1,424	18.8
AVR+any valve repair	938	7.4
MVR+any valve repair	1,266	12.5
Aortic valve repair	26,597	5.9
Mitral valve repair	4,167	3.0
Tricuspid valve repair	144	13.9
AVR+aortic aneurysm repair	1,723	9.7

AVR=aortic valve replacement; CAB=coronary artery bypass; MVR=mitral valve replacement.

Modified from Jamieson WRE, Edwards FH, Schwartz M, et al: Risk stratification for cardiac valve replacement. National Cardiac Surgery Database. Ann Thorac Surg 67:943, 1999.

MVR is indicated in two groups of patients with MS whose valves are not suitable for valvotomy: (1) those with a mitral valve area less than 1.5 cm^2 in NYHA Class III or IV; and (2) those with severe MS (mitral valve area <1.0 cm^2), NYHA Class II, and severe pulmonary hypertension (pulmonary artery systolic pressure >70 mm Hg).[51] Since the operative mortality risk may be quite high (10 to 20 percent) in patients in NYHA Class IV, operation should be carried out before patients reach this stage if possible. On the other hand, such patients should not be denied operation unless they have comorbid conditions that preclude surgery or a satisfactory outcome. (The results of MVR are discussed on p. 1663).

Mitral Regurgitation

ETIOLOGY AND PATHOLOGY

The mitral valve apparatus involves the mitral leaflets *per se,* chordae tendineae, papillary muscles, and mitral annulus. Abnormalities of any of these structures may cause MR.[104A] The major causes of MR include rheumatic heart disease, infective endocarditis, collagen-vascular disease, cardiomyopathy, and ischemic heart disease (Table 46-3) . The mitral valve prolapse syndrome, an important cause of MR, is discussed in a separate section (see p. 1665). A less common cause is use of certain appetite suppressant drugs.

ABNORMALITIES OF VALVE LEAFLETS.

MR due to predominant involvement of the valve leaflets occurs in patients with chronic rheumatic heart disease. However, in contrast to MS, this lesion is more frequent in men than in women. It is a consequence of shortening, rigidity, deformity, and retraction of one or both mitral valve cusps and is associated with shortening and fusion of the chordae tendineae and papillary muscles. Infective endocarditis can cause MR by perforating valve leaflets (see Chap. 47) ; vegetations can prevent leaflet coaptation, and valvular retraction during the healing phase of endocarditis can cause MR. Destruction of the mitral valve leaflets can also occur

TABLE 46-3 -- CAUSES OF ACUTE AND CHRONIC MITRAL REGURGITATION

ACUTE
Mitral Annulus Disorders
Infective endocarditis (abscess formation)
Trauma (valvular heart surgery)
Paravalvular leak due to suture interruption (surgical technical problems or infective endocarditis)
Mitral Leaflet Disorders
Mitral Leaflet Disorders
Infective endocarditis (perforation or interfering with valve closure by vegetation)
Trauma (tear during percutaneous balloon mitral valvotomy or penetrating chest injury)
Tumors (atrial myxoma)
Myxomatous degeneration
Systemic lupus erythematosus (Libman-Sacks lesion)
Rupture of Chordae Tendineae
Idiopathic, e.g., spontaneous
Myxomatous degeneration (mitral valve prolapse, Marfan syndrome, Ehlers-Danlos syndrome)
Infective endocarditis
Acute rheumatic fever
Trauma (percutaneous balloon valvotomy, blunt chest trauma)
Papillary Muscle Disorders
Coronary artery disease (causing dysfunction and rarely rupture)
Acute global left ventricular dysfunction
Infiltrative diseases (amyloidosis, sarcoidosis)
Trauma
Primary Mitral Valve Prosthetic Disorders
Porcine cusp perforation (endocarditis)
Porcine cusp degeneration
Mechanical failure (strut fracture)
Immobilized disc or ball of the mechanical prosthesis
CHRONIC
Inflammatory
Rheumatic heart disease
Systemic lupus erythematosus
Scleroderma
Degenerative
Myxomatous degeneration of mitral valve leaflets (Barlow click-murmur syndrome, prolapsing leaflet, mitral valve prolapse)
Marfan syndrome
Ehlers-Danlos syndrome
Pseudoxanthoma elasticum
Calcification of mitral valve annulus
Infective

Infective endocarditis affecting normal, abnormal, or prosthetic mitral valves

Structural

Ruptured chordae tendineae (spontaneous or secondary to myocardial infarction, trauma, mitral valve prolapse, endocarditis)

Rupture or dysfunction of papillary muscle (ischemia or myocardial infarction)

Dilatation of mitral valve annulus and left ventricular cavity (congestive cardiomyopathies, aneurysmal dilatation of the left ventricle)

Hypertrophic cardiomyopathy

Paravalvular prosthetic leak

Congenital

Mitral valve clefts or fenestrations

Parachute mitral valve abnormality in association with:

Endocardial cushion defects

Endocardial fibroelastosis

Transposition of the great arteries

Anomalous origin of the left coronary artery

Data from Jutzy KR, Al-Zaibag M: Acute mitral and aortic valve regurgitation. In Al-Zaibag M, Duran CMG (eds): Valvular Heart Disease. New York, Marcel Dekker, 1994, pp 345-382 (top portion); and Haffajee CI: Chronic mitral regurgitation. In Dalen JE, Alpert JS (eds): Valvular Heart Disease. 2nd ed. Boston, Little, Brown and Co, 1987, p 112 (lower portion).

in patients with penetrating and nonpenetrating trauma (see Chap. 51) .

ABNORMALITIES OF THE MITRAL ANNULUS

Dilatation.

In a normal adult, the mitral annulus measures approximately 10 cm in circumference. It is soft and flexible, and contraction of the surrounding left ventricular muscle during systole causes the annular constriction that contributes importantly to valve closure. MR secondary to dilatation of the mitral annulus can occur in any form of heart disease characterized by dilatation of the left ventricle, especially dilated cardiomyopathy. Left ventricular submitral aneurysm has been reported as a cause of annular MR in sub-Saharan Africa. It appears to be due to a congenital defect in the posterior portion of the annulus. Diagnosis by transesophageal echocardiography[105] and surgical repair have been reported.

Calcification.

Idiopathic (degenerative) calcification of the mitral annulus is one of the most common cardiac abnormalities found at autopsy; in most hearts it is of little functional consequence. However, when severe, it may be an important cause of MR,[106] and, in contrast to MR secondary to rheumatic fever, it is more common in women than in men. The development of degenerative calcification of the mitral annulus is accelerated by systemic hypertension, aortic stenosis, and diabetes, as well as by an intrinsic defect in the fibrous skeleton of the heart, as occurs in the Marfan and Hurler syndromes. In these two syndromes, the mitral annulus is not only calcified but also dilated, further contributing to MR. The incidence of mitral annular calcification is also increased in patients who have chronic renal failure with secondary hyperparathyroidism.[107] The annulus may also become thick, rigid, and calcified secondary to rheumatic involvement; when this process is severe, it also can interfere with valve closure.

With severe annular calcification, a rigid, curved bar or ring of calcium encircles the mitral orifice (see Fig. 8-20) , and calcific spurs may project into the adjacent left ventricular myocardium.[108] The calcification may immobilize the basal portion of the mitral leaflets, preventing their normal excursion in diastole and coaptation in systole, and aggravating the MR that results from loss of the normal sphincteric action of the mitral ring. Rarely, obstruction to left ventricular filling may occur when severe calcification encroaches on or protrudes into the mitral orifice. In patients with severe calcification, the conduction system may be invaded by calcium, leading to atrioventricular and/or intraventricular conduction defects.[108] Calcification of the aortic valve cusps is an associated finding in approximately 50 percent of patients with severe mitral annular calcification, but this rarely causes aortic stenosis. Occasionally, calcific deposits extend into the coronary arteries.

ABNORMALITIES OF THE CHORDAE TENDINEAE.

Such abnormalities are important causes of MR. Lengthening and rupture of the chordae tendineae are cardinal features of the mitral valve prolapse syndrome (see p. 1666). The chordae may be congenitally abnormal; rupture may be spontaneous ("primary")[109] or may occur as a consequence of infective endocarditis, trauma, rheumatic fever, or, rarely, osteogenesis imperfecta or relapsing polychondritis.[110] In most patients, no cause for chordal rupture is apparent other than increased mechanical strain. Chordae to the posterior leaflet rupture more frequently than those to the anterior leaflet. Patients with idiopathic rupture of mitral chordae tendineae frequently exhibit pathological fibrosis of the papillary muscles. It is possible that the dysfunction of the papillary muscles may cause stretching and ultimately rupture of the chordae tendineae. Chordal rupture may also result from acute left ventricular dilatation, regardless of the cause. Depending on the number of chordae involved in rupture and the rate at which rupture occurs, the resultant MR may be mild, moderate, or severe and acute, subacute, or chronic.

INVOLVEMENT OF THE PAPILLARY MUSCLES.

Diseases of the left ventricular papillary muscles are a frequent cause of MR.[111] Because these muscles are perfused by the terminal portion of the coronary vascular bed, they are particularly vulnerable to ischemia, and any disturbance in coronary perfusion may result in papillary muscle dysfunction. When ischemia is transient, it results in temporary papillary muscle dysfunction and may cause transient episodes of MR that are sometimes associated with attacks of angina pectoris. When ischemia of papillary muscles is severe and prolonged, it causes papillary muscle dysfunction and scarring, as well as chronic MR. The posterior papillary muscle, which is supplied by the posterior descending branch of the right coronary artery, becomes ischemic and infarcted more frequently than does the anterolateral papillary muscle; the latter is supplied by diagonal branches of the left anterior descending coronary artery and often by marginal branches from the left circumflex artery as well. Ischemia of the papillary muscles is caused most commonly by coronary atherosclerosis, but it may also occur in patients with severe anemia, shock, coronary arteritis of any cause, or an anomalous left coronary artery. MR occurs frequently in patients with healed myocardial infarcts[112] and is caused by dyskinesis of the left ventricular myocardium at the base of a papillary muscle. MR has been reported in patients who are taking certain appetite suppressant drugs.[112A]

Left ventricular dilatation of any cause, including ischemia, can alter the spatial relationships between the papillary muscles and the chordae tendineae and thereby result in MR.[113] Although *necrosis of a papillary muscle* is a frequent complication of myocardial infarction, [114] frank rupture is far less common; the latter is usually fatal because of the extremely severe MR that it produces (see Chap. 35) . However, rupture of one or two of the apical heads of a papillary muscle results in a lesser degree of MR and thus makes survival possible, usually following surgical therapy (see Chap. 35) .

Some degree of MR is found in approximately 30 percent of patients with coronary artery disease who are being considered for coronary artery bypass surgery. In these patients, MR is secondary to ischemic damage to the papillary muscles and/or dilatation of the mitral valve ring. In most of these patients, MR is mild; however, in the small percentage with severe MR (3 percent in one large series of patients with coronary artery disease proved by coronary arteriography), it is associated with a poor prognosis.[115] The incidence and severity of regurgitation vary inversely with the left ventricular ejection fraction and directly with the left ventricular end-diastolic pressure. MR occurs in approximately 20 percent of patients following acute myocardial infarction and, even when mild, is associated with a higher risk of adverse outcomes.[112]

Various other disorders of the papillary muscles may also be responsible for the development of MR (see Table 46-3) . These include congenital malposition of the muscles; absence of one papillary muscle, resulting in the so-called parachute mitral valve syndrome; and involvement or infiltration of the papillary muscles by a variety of processes, including abscesses, granulomas, neoplasms, amyloidosis, and sarcoidosis.

Other causes of MR, discussed in greater detail elsewhere, include mitral valve prolapse (see p. 1665), obstructive cardiomyopathy (see Chap. 48) , the

hypereosinophilic syndrome,[116] endomyocardial fibrosis,[117] trauma affecting the leaflets[118] and/or papillary muscles[119] (see Chap. 51) , Kawasaki disease[120] (see Chap. 45) , left atrial myxoma (see Chap. 49) , and various congenital anomalies, including cleft anterior leaflet[121] and ostium secundum atrial septal defect (see Chap. 43) .[122]

PATHOPHYSIOLOGY

Because the regurgitant mitral orifice is functionally in parallel with the aortic valve, the impedance to ventricular emptying is reduced in patients with MR. Consequently, MR enhances left ventricular emptying. Almost 50 percent of the regurgitant volume is ejected into the left atrium before the aortic valve opens. The volume of MR flow depends on a combination of the instantaneous size of the regurgitant orifice and the (reverse) pressure gradient between the left ventricle and the left atrium.[19] [123] [124] [125] Both the orifice size and the pressure gradient are labile. Left ventricular systolic pressure, and therefore the left ventricular-left atrial gradient, depends on systemic vascular resistance,[123] and in patients in whom the mitral annulus has normal flexibility, the cross-sectional area of the mitral annulus may be altered by many interventions. Thus, increase of both preload and afterload and depression of contractility increase left ventricular size and enlarge the mitral annulus and thereby the regurgitant orifice.[125] When ventricular size is reduced by treatment with positive inotropic agents, diuretics, and particularly vasodilators, the volume of regurgitant flow declines, as reflected in the height of the *v* wave in the left atrial pressure pulse and in the intensity and duration of the systolic murmur. Pharmacological reductions of systemic vascular resistance and left ventricular filling pressure reduce the volume of regurgitant flow by means of a reduction in the regurgitant orifice area.[126] Conversely, left ventricular dilatation, regardless of cause, may increase MR.

LEFT VENTRICULAR COMPENSATION.

The left ventricle initially compensates for the development of *acute* MR in part by emptying more completely and in part by increasing preload, i.e., by use of the Frank-Starling principle. As regurgitation, particularly severe regurgitation, becomes chronic, the left ventricular end-diastolic volume increases and the end-systolic volume returns to normal. By means of the Laplace principle (which states that myocardial wall tension is related to the product of intraventricular pressure and radius), the increased ventricular end-diastolic volume increases wall tension to normal or supranormal levels in the so-called chronic compensated stage of severe MR.[127] The resultant increase in left ventricular end-diastolic volume and mitral annular diameter may create a vicious circle in which "MR begets more MR." In patients with chronic MR, both left ventricular end-diastolic volume and mass are increased; i.e., typical volume overload (eccentric) hypertrophy develops. The degree of hypertrophy is usually proportionate to the degree of left ventricular dilatation, so that the ratio of left ventricular mass to end-diastolic volume is normal (see Fig. 16-5) . The eccentric ventricular hypertrophy that accompanies the elevated end-diastolic volume of chronic MR is secondary to new sarcomeres laid down in parallel. A shift to the right (greater volume at any pressure) occurs in the left ventricular diastolic pressure-volume curve in patients with chronic MR (Fig. 46-10 *C*). With decompensation chamber stiffness increases, raising the diastolic pressure at any volume[128] (see Fig. 46-10 *D*).

In most patients with severe primary MR, compensation is maintained for years, but ultimately the prolonged hemodynamic overload leads to myocardial decompensation. End-systolic volume, preload, and afterload all rise, whereas ejection fraction and stroke volume decline. A depressed ratio of phosphocreatine/adenosine triphosphate has been reported in patients with MR and severe decompensation.[129] It is not clear whether this is the cause or a marker of heart failure in these patients.

In canine experiments which compared the *acute* effects of equally severe MR and aortic regurgitation (AR) on the left ventricle, left ventricular end-diastolic pressure, volume, and radius increased with

Figure 46-10 Left ventricular diastolic pressure-volume relationships in volume overload. *A,* A moderate acutely applied volume overload from MR. There is modest chamber enlargement at end-diastole with little increase in end-diastolic pressure and a leftward shift of the diastolic pressure-volume relationship due to a smaller end-systolic chamber size achieved from the hyperdynamic chamber performance. *B,* A major upward shift represents a higher pressure for a wide range of chamber volumes. This is acute pericardial restraint and a right-left ventricular interaction effect. These two mechanisms come into play when the acute MR is so severe that the total intrapericardial volume increases to the point of stretching the noncompliant pericardial sac. *C,* This is the classic rightward shift of compensated volume overload lesions--mitral, tricuspid, and aortic regurgitation being the most common (red line). With little change in wall thickness, the chamber is greatly enlarged, with myocardial cell slippage allowing a reduction in chamber stiffness and growth of the pericardium allowing increased intracavitary volumes to exist with a normal low pericardial pressure. *D,* Chamber stiffness increases when decompensation occurs in volume overload (red line). Often the myocardium has become myopathic and fibrotic. End-diastolic pressure volume and end-systolic volume have risen. ×1 = end-systolic pressure and volume; ×2 = end-diastolic pressure and volume in the normal subject.

both lesions, but far *less so* with MR.[130] Peak left ventricular wall tension rose markedly when AR was induced but either did not change greatly or actually declined with MR. Because *acute* MR reduces both late systolic ventricular pressure and radius, left ventricular wall tension declines markedly (and proportionately to a greater extent than left ventricular pressure), permitting a reciprocal increase in both the extent and the velocity of myocardial fiber shortening. The ratio of wall thickness to ventricular radius is lower and the fractional shortening of myocardium is greater in patients with MR than in those with AR.[131] Thus, the reduced left ventricular afterload allows a greater proportion of the contractile energy of the myocardium to be expended in shortening than in tension development and explains how the left ventricle can adapt to the load imposed by MR.

A large volume of induced experimentally MR produces only slightly increased myocardial oxygen consumption (MV_{O_2}) because myocardial fiber shortening, which is elevated in patients with MR, is not one of the principal determinants of MV_{O_2} .[132] One of these determinants, mean left ventricular wall tension, may actually be reduced in patients with MR, whereas the other two, contractility and heart rate, may be little affected. These experimental observations correlate with the low incidence of clinical manifestations of myocardial ischemia in patients with severe MR compared with the much higher incidence occurring in those with aortic stenosis and AR, conditions in which MV_{O_2} is augmented.

ASSESSMENT OF MYOCARDIAL CONTRACTILITY IN MITRAL REGURGITATION.

Because the ejection phase indices of myocardial contractility are inversely correlated with afterload, patients with early MR (with reduced left ventricular afterload) often exhibit elevations in ejection phase indices of myocardial contractility, such as ejection fraction (EF), fractional fiber shortening (FS), and velocity of circumferential fiber shortening (VCF).[133] However, by the time patients become seriously symptomatic, EF, FS, and mean VCF have usually declined to *normal* or *below normal* levels. As MR persists, the reduction in afterload, which increases myocardial fiber shortening and the earlier-mentioned ejection phase indices, is opposed by the impairment of myocardial function characteristic of severe chronic diastolic overload. However, even in patients with overt heart failure secondary to MR, the EF and FS may be only modestly reduced.[133A] Therefore, *normal* values for the ejection phase indices of myocardial performance in patients with acute MR may actually reflect impaired myocardial function,[134] whereas moderately reduced values (e.g., EF of 40 to 50 percent) generally signify severe, often irreversible, impairment of contractility. An EF of less than 35 percent in patients with severe MR usually represents advanced myocardial dysfunction; such patients are high operative risks and may not experience marked improvement following mitral valve replacement (see p. 1663).[127]

END-SYSTOLIC VOLUME.

Preoperative myocardial contractility is an important determinant of the risk of operative death, of cardiac failure perioperatively, and of the level of left ventricular function postoperatively. Therefore, it is not surprising that the end-systolic pressure/volume (or stress/dimension) relation has emerged as a useful index for evaluating left ventricular function in patients with MR.[135] Indeed, the simple measurement of end-systolic volume has been found to be more useful as a predictor of outcome than the EF, end-diastolic volume, or end-diastolic pressure.[136] Patients with severe MR who had a normal preoperative end-systolic volume (<40 ml/m^2) retained normal left ventricular function postoperatively, whereas a marked increase in the end-systolic volume (>80 ml/m^2) signified a high perioperative mortality rate and residual left ventricular dysfunction. An end-systolic volume of 55 ml/m^2 appears to discriminate between patients who do well after surgical correction (<55 ml/m^2) and those who are at risk of irreversible dysfunction (>55 ml/m^2). Patients with MR and a modest increase in end-systolic volume (40 to 80 ml/m^2) usually tolerate operation satisfactorily but may have reduced left ventricular function postoperatively.

A closely related variable, the end-systolic diameter, determined by echocardiography, is a reliable noninvasive predictor of outcome (survival without severe heart failure) following mitral valve replacement. The outcome is excellent until the end-systolic diameter exceeds approximately 45 mm or 26 mm/m^2 (Fig. 46-11) .[137]

HEMODYNAMICS.

Effective (forward) *cardiac output* is usually depressed in severely symptomatic patients with MR, whereas *total* left ventricular output (the sum of forward and regurgitant flow) is usually elevated until quite late in the patient's course. The cardiac output achieved during exercise, not the regurgitant volume, is the principal determinant of functional capacity.[138] The atrial contraction (*a*) wave in the left atrial pressure pulse is usually not as prominent in MR as in MS, but the *v* wave is often

much taller (see Fig. 11-5) because it is inscribed during ventricular systole, when the left atrium is being filled with blood from the pulmonary veins as well as from the left ventricle. Occasionally, backward transmission of the tall *v* wave into

Figure 46-11 The probability of postoperative death or persistence of severe heart failure in patients with mitral regurgitation plotted against preoperative echocardiographic end-systolic diameter. As end-systolic diameter exceeded 45 mm, the incidence of a poor postoperative outcome increased abruptly. *(Reproduced with permission from Wisenbaugh T, et al: Prediction of outcome after valve replacement for rheumatic mitral regurgitation in the era of chordal preservation. Circulation 89:191, 1994. Copyright 1994 American Heart Association.)*

the pulmonary arterial bed may result in an early diastolic "pulmonary arterial *v* wave."[139] In patients with pure MR, the *y* descent in the pulmonary capillary pressure pulse is particularly rapid as the distended left atrium empties rapidly during early diastole. However, in patients with combined MS and MR, the *y* descent is gradual. Although a left atrioventricular pressure gradient persisting throughout diastole signifies the presence of significant associated MS, a brief early diastolic gradient may occur in patients with isolated, severe MR as a result of the rapid flow of blood across a normal-sized mitral orifice early in diastole.[140]

LEFT ATRIAL COMPLIANCE

The compliance of the left atrium (and pulmonary venous bed) is an important determinant of the hemodynamic[141] and clinical picture in patients with severe MR. Three major subgroups of patients with severe MR based on left atrial compliance have been identified[130] [142] [143] (Fig. 46-12) and are characterized as follows:

NORMAL OR REDUCED COMPLIANCE.

In this subgroup, there is little enlargement of the left atrium but marked elevation of the mean left atrial pressure, particularly of the *v* wave,[144] [145] and pulmonary congestion is a prominent symptom. Severe MR usually develops acutely, as occurs with rupture of the chordae tendineae, infarction of one of the heads of a papillary muscle, or perforation of a mitral leaflet as a consequence of trauma or endocarditis. In patients with acute MR, the left atrium initially operates on the steep portion of its pressure-volume curve with a marked rise in pressure for a small increase in volume. Sinus rhythm is usually present; after the passage of weeks or a few months, the left atrial wall becomes hypertrophied, is capable of contracting vigorously, and facilitates left ventricular filling. The thicker atrium is less compliant than normal, which further increases the height of the *v* wave. Thickening of the walls of the pulmonary veins and proliferative changes in the pulmonary arteries, as well as marked elevations of pulmonary vascular resistance and pulmonary artery pressure, usually develop over the course of 6 to 12 months after the onset of acute, severe MR.

MARKEDLY INCREASED COMPLIANCE.

At the opposite end of the spectrum from patients in the first group are those with severe, longstanding MR with massive enlargement of the left atrium and normal or only slightly elevated left atrial pressure.[143] The atrial wall contains only a small remnant of muscle surrounded by fibrous tissue. Longstanding MR in these patients has altered the physical properties of the left atrial wall and thereby displaced the atrial pressure-volume curve to the right, allowing a normal or almost normal pressure to exist in a greatly enlarged left atrium. Pulmonary arterial pressure and pulmonary vascular resistance may be normal or only slightly elevated at rest. Atrial fibrillation and a low cardiac output are almost invariably present.[143]

MODERATELY INCREASED COMPLIANCE.

This, the most common subgroup, consists of patients between the ends of the spectrum represented by the first and second groups. These patients have severe, chronic MR and exhibit variable degrees of enlargement of the left atrium, associated with significant elevation of the left atrial pressure.

CLINICAL MANIFESTATIONS

History

The nature and severity of symptoms in patients with chronic MR are functions of its severity, rate of progression, the level of pulmonary arterial pressure, and the presence of associated valvular, myocardial, or coronary artery disease.

Figure 46-12 Diagram depicting the two extremes of the spectrum in pure mitral regurgitation. When severe mitral regurgitation appears suddenly in individuals with previously normal or near-normal hearts (top), the left atrium (LA) is relatively small and the high pressure within it is reflected back into the pulmonary vessels and right ventricle (RV). The anatomical indicator of this latter physiological event is severe hypertrophy of the left atrial and right ventricular walls and marked intimal proliferation and medial hypertrophy of the pulmonary arteries (PA), arterioles, and veins (PV). At the other extreme, in patients with severe chronic mitral regurgitation (bottom), the left atrial cavity is of giant size and its wall is thin. It is thus able to "absorb" the left ventricular (LV) pressure without reflecting it back into the pulmonary vessels or right ventricle. As a consequence, pulmonary vessels remain normal, and the right ventricular wall does not thicken. PT = pulmonary trunk; RA = right atrium. *(From Roberts WC, et al: Nonrheumatic valvular cardiac disease. A clinicopathologic survey of 27 different conditions causing valvular dysfunction. In Likoff W [ed]: Cardiovascular Clinics. Vol. 5, No. 2, Valvular Heart Disease. Philadelphia, F.A. Davis Co, 1973, p 403.)*

Because symptoms usually do not develop in patients with chronic MR until left ventricular decompensation occurs, the time interval between the initial attack of rheumatic fever (if one has occurred) and the development of symptoms tends to be longer in these patients than in those with MS and often exceeds two decades. Hemoptysis and systemic embolization are less common in patients with isolated or predominant MR than in those with MS. The development of atrial fibrillation affects the course adversely but perhaps not as dramatically as in MS. On the other hand, chronic weakness and fatigue secondary to a low cardiac output are more prominent features in MR.

The majority of patients with MR of rheumatic origin have only mild disability, unless regurgitation progresses as a result of chronic rheumatic activity, infective endocarditis, or rupture of the chordae tendineae. However, the indolent course of MR may be deceptive. By the time that symptoms secondary to a reduced cardiac output and/or pulmonary congestion become apparent, serious and sometimes even irreversible left ventricular dysfunction may have developed.

In patients with severe, chronic MR who have a greatly enlarged left atrium and relatively mild left atrial hypertension (patients with increased left atrial compliance [second subgroup], described earlier), pulmonary vascular resistance does not usually rise markedly. Instead, the major symptoms, fatigue and exhaustion, are related to the depressed cardiac output. Right-sided heart failure, characterized by congestive hepatomegaly, edema, and ascites, is prominent in patients with acute MR, elevated pulmonary vascular resistance, and pulmonary hypertension. Angina pectoris is rare unless coronary artery disease coexists.

NATURAL HISTORY.

This is variable and depends on a combination of the volume of regurgitation, the state of the myocardium, and the cause of the underlying disorder. Asymptomatic patients with mild primary MR usually remain in a stable state for many years.[146] Severe regurgitation develops in only a small percentage of these patients, most commonly because of intervening infective endocarditis or rupture of the chordae tendineae. Regurgitation tends to progress more rapidly in patients with connective tissue diseases, such as the Marfan syndrome, than in those with chronic MR of rheumatic origin. Acute rheumatic fever is a frequent cause of isolated, severe MR in adolescents in developing nations, and these patients often have a rapidly progressive course.

Because the natural history of severe MR has been altered greatly by surgical intervention, it is difficult now to predict the course of patients who receive medical therapy alone. However, in an unselected group of patients with MR who were treated medically before surgical treatment of severe MR became commonplace, approximately 80 percent survived 5 years and almost 60 percent survived 10 years after the diagnosis was established.[147] Patients with combined MS and MR had a poorer prognosis, with only 67 percent surviving 5 years and 30 percent surviving 10 years after diagnosis. Munoz and colleagues[63] found that medically treated patients with severe MR had a 5-year survival rate of 45 percent, whereas Horstkotte and associates[64] reported a 5-year survival of only 30 percent in patients who were candidates for but who declined operation (see Fig. 46-6) .

Physical Examination

Palpation of the arterial pulse is helpful in differentiating aortic stenosis from MR, both of which may produce a prominent systolic murmur at the base of the heart. The carotid arterial upstroke is sharp in severe MR[148] and delayed in aortic stenosis; the volume of the pulse may be normal or reduced in the presence of heart failure. The cardiac impulse, like the arterial pulse, is brisk and hyperdynamic. It is displaced to the left, and a prominent left ventricular filling wave is frequently palpable. Systolic expansion of the enlarged left atrium may result in a late systolic thrust in the parasternal region, which may be confused with right ventricular enlargement.

AUSCULTATION.

With severe, chronic MR due to defective valve cusps, S_1 , produced by mitral valve closure, is usually diminished. Wide splitting of S_2 is common and results from the shortening of left ventricular ejection and an earlier A_2 as a consequence of reduced resistance to left ventricular outflow. In patients with MR who have severe pulmonary hypertension, P_2 is louder than A_2 . The abnormal increase in the flow rate across the mitral orifice during the rapid filling phase is often associated with an S_3 , which should not be interpreted as a feature of heart failure in these patients.

The *systolic murmur* is the most prominent physical finding; it must be differentiated from the systolic murmur of aortic stenosis, tricuspid regurgitation, and ventricular septal defect. In most patients with severe MR, the systolic murmur commences immediately after the soft S_1 and continues beyond and may obscure the A_2 because of the persisting pressure difference between the left ventricle and left atrium after aortic valve closure. The holosystolic murmur of chronic MR is usually constant in intensity, blowing, high-pitched, and loudest at the apex with radiation to the left axilla and left infrascapular area; however, radiation toward the sternum or the aortic area may occur with abnormalities of the posterior leaflet. The murmur shows little change even in the presence of large beat-to-beat variations of left ventricular stroke volume, as occur in atrial fibrillation. This contrasts with most midsystolic (ejection) murmurs, such as in aortic stenosis, which vary greatly in intensity with stroke volume and therefore with the duration of diastole.[149] There is little correlation between the intensity of the systolic murmur and the severity of MR. Indeed, in patients with severe MR due to left ventricular dilatation, acute myocardial infarction, or paraprosthetic valvular regurgitation, or in those who have marked emphysema, obesity, chest deformity, or a prosthetic heart valve, the systolic murmur may be barely audible or even absent, a condition referred to as "silent MR."[150]

The murmur of MR may be holosystolic, late systolic, or early systolic. When the murmur is confined to late systole, the regurgitation is usually mild and may be secondary to prolapse of the mitral valve or to papillary muscle dysfunction. These causes of MR are frequently associated with a normal S_1 because initial closure of the mitral valve cusps may be unimpaired. The late systolic murmur of papillary muscle dysfunction is particularly variable; it may become accentuated or holosystolic during acute myocardial ischemia and often disappears when ischemia is relieved. The response of a mid- to late systolic murmur to a number of maneuvers, as described on page 1668 , helps to establish the diagnosis of mitral valve prolapse. When the left atrial *v* wave is markedly elevated in acute MR, the murmur may diminish or disappear in late systole as the reverse pressure gradient declines (see Fig. 4-29) . A short, low-pitched diastolic murmur following S_3 may be audible in patients with severe MR, even without accompanying MS.

DYNAMIC AUSCULTATION.

The holosystolic murmur of rheumatic MR varies little during respiration. However, sudden standing and amyl nitrite inhalation usually diminish the murmur (Table 46-4) , whereas squatting augments it. The murmur is reduced during the strain of the Valsalva maneuver and shows a left-sided response (i.e., a transient overshoot that occurs six to eight beats following release of the strain). The murmur of MR is usually intensified by isometric exercise, differentiating it from the systolic murmurs of valvular aortic stenosis and hypertrophic obstructive cardiomyopathy, both of which are reduced by this intervention. The murmur of MR caused by left ventricular dilatation *decreases* in intensity and duration following

TABLE 46-4 -- EFFECT OF VARIOUS INTERVENTIONS ON SYSTOLIC MURMURS

effective therapy with cardiac glycosides, diuretics, rest, and particularly vasodilators.

DIFFERENTIAL DIAGNOSIS.

The holosystolic murmur of MR resembles that produced by a ventricular septal defect. However, the latter is usually loudest at the sternal border rather than the apex and is usually accompanied by a parasternal, rather than an apical, thrill. The murmur of MR may also be confused with that of tricuspid regurgitation, which is usually heard best along the left sternal border, is augmented during inspiration, and is accompanied by a prominent *v* wave and *y* descent in the jugular venous pulse.

When the chordae tendineae to the posterior leaflet of the mitral valve rupture, the regurgitant jet is often directed anteriorly, so that it impinges on the atrial septum adjacent to the aortic root and causes a systolic murmur that is most prominent at the base of the heart. This murmur can be confused with that of aortic stenosis. On the other hand, when the chordae tendineae to the anterior leaflet rupture, the jet is usually directed to the posterior wall of the left atrium, and the murmur may be transmitted to the spine or even to the top of the head.[151]

Patients with rheumatic disease of the mitral valve exhibit a spectrum of abnormalities, ranging from pure MS to pure MR. The presence of an S_3 , a rapid left ventricular filling wave and left ventricular impulse on palpation, and a soft S_1 all favor predominant MR. In contrast, an accentuated S_1 , a prominent opening snap (OS) with a short A_2 -OS interval, and a soft, short systolic murmur all point to predominant MS. Elucidation of the predominant valvular lesion may be complicated by the presence of a holosystolic murmur of tricuspid regurgitation in patients with pure MS and pulmonary hypertension; this murmur may sometimes be heard at the apex when the right ventricle is greatly enlarged and may therefore be mistaken for the murmur of MR.

LABORATORY EXAMINATION

ELECTROCARDIOGRAPHY.

The principal ECG findings are left atrial enlargement[44] [152] and atrial fibrillation. ECG evidence of left ventricular enlargement occurs in about one-third of patients with severe MR. Approximately 15 percent of patients exhibit ECG evidence of right ventricular hypertrophy, a change that reflects the presence of pulmonary hypertension of sufficient severity to counterbalance the hypertrophied left ventricle of MR.

RADIOLOGICAL FINDINGS (see Fig. 8-18 *D*).

Cardiomegaly with left ventricular enlargement, and particularly with left atrial enlargement, is a common finding in patients with chronic, severe MR.[153] However, there is little correlation between left atrial size and pressure. Interstitial edema with Kerley B lines is frequently seen in patients with acute MR or with progressive left ventricular failure.

In patients with combined MS and MR, overall cardiac enlargement and particularly left atrial dilatation are prominent findings. However, it is often difficult to determine which lesion is predominant from the plain chest roentgenogram because distinguishing between right and left ventricular enlargement may not be possible. Predominant MS is suggested by relatively mild cardiomegaly (principally straightening of the left cardiac border) and significant changes in the lung fields, whereas predominant MR is more likely when the heart is greatly enlarged and the changes in the lungs are relatively inconspicuous. Chronic MR is almost always the dominant lesion when the left atrium is aneurysmally dilated. *Calcification of the mitral annulus,* an important cause of MR in the elderly, is most prominent in the posterior third of the cardiac silhouette. The lesion is best visualized on chest films exposed in the lateral or right anterior oblique projections, in which it appears as a dense, coarse, C-shaped opacity (see Fig. 8-20) .

ECHOCARDIOGRAPHY (See also Chap. 7) .

In patients with severe MR, *two-dimensional echocardiography* shows enlargement of the left atrium and left ventricle, with increased systolic motion of both chambers. The underlying cause of the regurgitation, e.g., rupture of chordae tendineae, mitral valve prolapse (see Fig. 7-57) , a flail leaflet[154] (see Figs. 7-55 and 7-56) , vegetations (see Chap. 47) , and left ventricular dilatation (see Fig. 7-54) can often be determined on the transthoracic echocardiogram. It may also show calcification of the mitral annulus as a band of dense echoes between the mitral apparatus and the posterior wall of the heart.[155] This technique is also useful for estimating the hemodynamic consequences of MR[155A] [155B] ; in patients with left ventricular dysfunction, end-diastolic and end-systolic volumes are increased and the ejection fraction and shortening rate may decline.

Doppler echocardiography in MR characteristically reveals a high-velocity jet in the left atrium during systole. The severity of the regurgitation is a function of the distance from the valve that the jet can be detected (see Fig. 7-53) and the size of the left atrium. Both color flow Doppler imaging and pulsed techniques correlate well with angiographic methods in estimating the severity of MR.[156] Other methods of assessing the severity of MR include measurement of the area of the mitral jet (8 cm^2 indicates severe MR). However, color flow jet areas are significantly influenced by the cause of the regurgitation and jet eccentricity, thus limiting the accuracy of this approach.[157] The vena contracta, defined as the narrowest cross-sectional areas of the regurgitant jet as mapped by color flow Doppler echocardiography, predicts the severity of MR[158] [159] [160] (Fig. 46-13) . Reversal of flow in the pulmonary veins during systole[161] and a high peak mitral inflow velocity[162] are also useful signs of severe MR.

Transesophageal echocardiography (see Fig. 7-55) is superior to transthoracic echocardiography in assessing the detailed anatomy of the regurgitant mitral valve. Therefore, this technique is useful when the transthoracic image is suboptimal and when determining whether valve repair is feasible or whether MVR is necessary.[163] [164] Also, angiographic grading of MR correlates better with color flow mapping obtained by the transesophageal than by the transthoracic technique.[165] Three-dimensional transthoracic echocardiography and three-dimensional color Doppler[166] have also been reported to help elucidate the mechanism of MR.

RADIONUCLIDE ANGIOGRAPHY (see also Chap. 9) .

Gated blood pool nuclear imaging or first-pass angiography may reveal an increased end-diastolic volume; the regurgitant fraction can be estimated from the ratio of left ventricular to right ventricular stroke volume. In patients with MR and impaired left ventricular function, the ejection fraction fails to rise normally during exercise. Radionuclide angiograms are useful for interval follow-up. Progressive increases in ventricular end-diastolic and/or end-systolic volume often suggest that surgical treatment is necessary (discussed later).

Figure 46-13 Linear regression plot showing good correlation between biplane vena contracta width and regurgitant volume. *(From Hall SA, Brickner E, Willen DL, et al: Assessment of mitral regurgitation severity by Doppler color flow mapping of the vena contracta. Circulation 95:636, 1997.)*

LEFT VENTRICULAR ANGIOCARDIOGRAPHY.

The prompt appearance of contrast material in the left atrium following its injection into the left ventricle indicates the presence of MR.[167] The injection should be rapid enough to permit left ventricular opacification but slow enough to avoid the development of premature ventricular contractions, which can induce spurious regurgitation.

The regurgitant volume can be determined from the difference between the total left ventricular stroke volume, estimated by angiocardiography, and the simultaneous measurement of the effective forward stroke volume by the Fick method. In patients with severe MR, the regurgitant volume may approach, and in rare instances may even exceed, the effective forward stroke volume. Qualitative but clinically useful estimates of the severity of MR may be made by cineangiographic observation of the degree of opacification of the left atrium and pulmonary veins following the injection of contrast material into the left ventricle.

The cause of the regurgitation (e.g., prolapse of the mitral valve) and a flail leaflet can often be distinguished by angiography. MR secondary to rheumatic heart disease is characterized angiographically by a central regurgitant jet and by thickened leaflets that exhibit reduced motion. In regurgitation due to other causes, particularly dilatation or calcification of the mitral annulus or ruptured chordae tendineae and papillary muscles, the systolic jet may be eccentric, and the valves consist of thin filaments that display excessive motion.

MAGNETIC RESONANCE IMAGING.

This study (see Fig. 10-24) is the most accurate technique for measuring regurgitant flow and provides measurements that correlate well with quantitative Doppler imaging.[168] [169] It is also the most accurate noninvasive technique that can provide measurement of ventricular end-diastolic and end-systolic volumes and ventricular mass.

Acute Mitral Regurgitation

The causes of acute MR are shown at the top of Table 46-3 . They are diverse and represent acute manifestations of disease processes that may, under other circumstances, cause chronic MR. Especially important causes of acute MR are infective endocarditis with disruption of valve leaflets or rupture of chordae tendineae, ischemic dysfunction or rupture of a papillary muscle, and malfunction of a prosthetic valve.

One major hemodynamic difference between acute and chronic MR derives from the differences in left atrial compliance, as discussed on page 1657 and as illustrated in Figure 46-12 . Acute, severe MR causes a marked reduction of forward stroke volume, a slight reduction of end-systolic volume, and an increase in end-diastolic volume. Patients who develop acute, severe MR usually have a normal-sized left atrium (normal or reduced left atrial compliance [first subgroup], see p. 1657). The left atrial pressure rises abruptly, which often leads to pulmonary edema, marked elevation of pulmonary vascular resistance, and right-sided heart failure.

Because the *v* wave is markedly elevated in patients with acute, severe MR, the reverse pressure gradient between the left ventricle and left atrium declines at the end

of systole, and the murmur may be decrescendo rather than holosystolic, ending well before A_2 (see Fig. 4-29) . It is usually lower pitched and softer than the murmur of chronic MR. A left-sided S_4 is frequently found.[130] Pulmonary hypertension, which is common in patients with acute MR, may increase the intensity of P_2 and the murmurs of pulmonary and tricuspid regurgitation, and a right-sided S_4 may also develop. In patients with severe, acute MR, a *v* wave (late systolic pressure rise) in the pulmonary artery pressure pulse (see Fig. 11-5) may rarely cause premature closure of the pulmonary valve, an early P_2 , and paradoxical splitting of S_2 . Acute MR, even if severe, often does not increase overall cardiac size, as seen on the chest roentgenogram, and may produce only mild left atrial enlargement despite marked elevation of left atrial pressure. In addition, the echocardiogram may show little increase in the internal diameter of either the left atrium or the left ventricle, but increased systolic motion of the left ventricle is prominent.

MANAGEMENT

Medical Treatment

This includes all of the measures used in the treatment of cardiac dysfunction, as outlined in Chapter 18 . Afterload reduction is of particular benefit in the management of both the acute and the chronic forms of MR.[170] [171] By reducing the impedance to ejection into the aorta, the volume of blood regurgitating into the left atrium is reduced. In addition, decreasing left ventricular volume reduces the regurgitant orifice.[172] Mean left atrial pressure and, in particular, the elevated *v* wave both decline. Afterload reduction with intravenous nitroprusside may be lifesaving in patients with acute MR due to rupture of the head of a papillary muscle that occurs during an acute myocardial infarction. It may permit stabilization of the patient's condition and thereby allow coronary arteriography and surgery to be performed with the patient in optimal condition. In patients with acute MR who are hypotensive, an inotropic agent such as dobutamine should be administered with the nitroprusside. Intraaortic balloon counterpulsation may be necessary to stabilize the patient as preparations for surgery are made.

When surgical treatment is contraindicated in patients with severe, chronic MR, chronic afterload reduction with an angiotensin converting enzyme inhibitor[170] [171] [173] [173A] or oral hydralazine may improve the clinical status. However, definitive randomized trials documenting the efficacy of these agents are not available. In addition to diuretics, digitalis glycosides are indicated in patients with severe MR

Figure 46-14 Schematic representation of the concept of optimal timing of valve replacement surgery. Early surgery yields low operative mortality and preservation of ventricular function. However, because of a finite postoperative risk of prosthesis-associated complications (the major determinant of the slope of the postoperative survival curve in either early or optimally timed surgery), postoperative risk exceeds that of pure medical treatment at this early phase of the disease. In contrast, if surgery is done too late, operative mortality is increased and ventricular function may progressively deteriorate after surgery. Thus, following late surgery, postoperative survival is primarily determined by both prosthesis-associated complications and congestive heart failure. Optimal timing of surgery balances the risks of maintaining medical management with the new risks associated with postoperative complications. With optimally timed surgical intervention, operative mortality is relatively low, ventricular function is almost completely preserved, and postoperative risk is determined, as in early surgery, predominantly by the risk of prosthesis-associated complications. *(From Schoen FJ, St. John Sutton M: Contemporary issues in the pathology of valvular disease. Hum Pathol 18:568, 1987.)*

and clinical evidence of heart failure and are particularly helpful in patients with established atrial fibrillation. The latter should also receive anticoagulants. As do all patients with valvular lesions, patients with MR require appropriate prophylaxis to prevent infective endocarditis (see Chap. 47) .

Surgical treatment should be considered for patients with functional disability despite optimal medical management and/or for patients with only mild symptoms but with progressively deteriorating left ventricular function as documented by noninvasive studies. Two-dimensional or transesophageal echocardiography with Doppler echocardiography and color flow Doppler imaging provide detailed assessment of mitral valve structure and function. However, left heart catheterization, left ventricular angiocardiography, and coronary arteriography are indicated for the following: (1) in evaluating a discrepancy between echocardiographic findings and the clinical picture; (2) in detecting and assessing the severity of any associated valvular lesions; and (3) in determining the presence and assessing the extent of coronary artery disease.

Surgical Treatment

Without surgical treatment, the prognosis for patients with MR and heart failure is poor (see Fig. 46-6) . When operative treatment is being considered, the chronic and often slowly but relentlessly progressive nature of MR must be weighed against the immediate risks and long-term uncertainties attendant upon surgery, especially mitral valve replacement (MVR) (Fig. 46-14) . Surgical mortality depends on the patient's clinical and hemodynamic status (particularly the function of the left ventricle); on the presence of comorbid conditions such as renal, hepatic, or pulmonary disease; and on the skill and experience of the surgical team[104] (see Table 46-2) . The decision to replace or to reconstruct the valve (Fig. 46-15) is of critical importance. Replacement involves the operative risk, as well as the risks of thromboembolism and anticoagulation in patients receiving mechanical prostheses, of late valve deterioration in patients receiving bioprostheses (see p. 1696), and of late

Figure 46-15 Valve repair techniques for quadrilateral resection of the posterior leaflet of the mitral valve. *(From Cohn LH, DiSesa VJ, Couper GS, et al: Mitral valve repair for myxomatous degeneration and prolapse of the mitral valve. J Thorac Cardiovasc Surg 98:987, 1989.)*

mortality, especially in patients with associated coronary artery disease who require coronary artery bypass grafting (see Table 46-2) . Surgical mortality does not depend significantly on *which* of the currently used tissue or mechanical valve prostheses is selected.

The reconstructive procedure consists of annuloplasty, often with the use of a rigid (Carpentier) or a flexible prosthetic (Duran) ring (Fig. 46-16) or with reconstruction of the valve[174] [175] [176] [177] [177A] [178] [179] (see Fig. 46-15) . Prolapsed valves causing severe MR are usually treated with resection of the prolapsing segment and plication of the annulus (see p. 1671). Replacing,[180] reimplanting, elongating, or shortening of chordae tendineae; splitting the papillary muscles; and repairing the subvalvular apparatus have been successful in selected patients with pure or predominant MR.[175] Reconstruction of the mitral valve is most often successful in (1) children and adolescents with pliable valves; (2) adults with MR secondary to mitral valve prolapse[18] ; (3) annular dilatation; (4) papillary muscle secondary to ischemia, dysfunction, or rupture; or (5) chordal rupture and perforation of a mitral leaflet due to infective endocarditis. These procedures are less likely to be successful in older patients with the rigid, calcified, deformed valves of rheumatic heart disease or those with severe subvalvular chordal thickening and major loss of leaflet substance. Many of the latter patients require MVR, which is also usually the procedure of choice for patients with badly scarred mitral valves who have previously undergone MVR. Young patients in developing countries who have severe rheumatic MR in the absence of active carditis may undergo successful repair.

Ischemic MR following acute myocardial infarction may be managed by reattaching the papillary muscle to adjacent myocardium or by valve replacement. Ischemic MR secondary to severe annular dilatation may be treated by direct or ring annuloplasty.[176] [177] [177A] Episodic MR due to transient ischemia is often eliminated by coronary revascularization, whereas severe, chronic MR secondary to fibrotic infarcted papillary muscle usually requires valve replacement.

Although MVR with a mechanical or bioprosthesis has been used successfully in treating MR for almost four decades,[181] there has been some dissatisfaction with the results of this operation. First, left ventricular function often deteriorates following this procedure, contributing to early and late mortality and late disability. The increase in afterload

preservation in patients with chronic mitral regurgitation; mechanisms for differences in postoperative ejection performance. Circulation 86:1718, 1992.)

consequent to abolishing the low impedance leak was first believed to be responsible, but now it is clear that the loss of annular-chordal-papillary muscle continuity interferes with left ventricular function in patients who have undergone MVR. This does not occur after mitral valve reconstruction.[180] Indeed, animal experiments have shown convincingly that the normal function of the mitral valve apparatus "primes" the left ventricle for normal contraction and that contraction is prevented when operation causes discontinuity of this apparatus. There is evidence from animal experiments[182] and from human patients[183] [184] [185] that preservation of the papillary muscle and its chordal attachments to the mitral annulus is beneficial to postoperative left ventricular function, after both mitral valve reconstruction and in MVR (Fig. 46-17) . Thus, preservation of these tissues, whenever possible, is now considered a critical feature of MVR.[186]

A second disadvantage of MVR results from the prosthesis itself. This includes thromboembolism or hemorrhage associated with mechanical prostheses, late mechanical dysfunction of bioprostheses, and the risk of infective endocarditis with all prostheses (see p. 1697). For these reasons, increasing efforts are being made to reconstruct the mitral valve whenever possible, especially in patients with isolated or predominant MR.[187] [188] [189] [190] These procedures have been widely employed in Europe since the early 1960s and are now frequently being used by surgeons in the United States as well. The Society of Thoracic Surgeons National Database Committee reported a 3 percent mortality rate in 4167 patients undergoing isolated mitral valve repair[104] (see Table 46-2) .

Intraoperative transesophageal color flow Doppler mapping is extremely useful in assessing the adequacy of mitral valve repair. In the minority of patients with persistent severe MR in whom the operative results are unsatisfactory, the problem can usually be corrected immediately, or, if necessary, the valve can be replaced. Left ventricular outflow tract obstruction due to systolic anterior motion of the

mitral valve occurs in 5 to 10 percent of patients following mitral valve repair. The causes are not clear; but they may include excess valvular tissue with severe leaflet redundancy and/or an interventricular septum bulging into a small left ventricle.[191] [192] These complications may also be recognized intraoperatively by transesophageal echocardiography. Treatment with volume loading and beta-blocking agents is often helpful. The obstruction usually disappears with time; if it does not, reoperation and re-repair or MVR may be necessary.

Progressive decrease in the prevalence of rheumatic heart disease (involving severely damaged valves that often are not suitable for reconstructive surgery) and a simultaneous increase in degenerative causes of MR (including mitral valve prolapse and rupture of chordae tendineae) as well as in ischemic MR are increasing the number of patients in whom reconstruction is carried out.[193] In many centers in the United States, approximately two-thirds of all patients requiring operation for pure or predominant MR now receive reconstructive procedures, and the remainder undergo MVR. However, mitral valve repair is technically a more demanding procedure than is MVR, with a distinct learning curve for the surgeon. Furthermore, some regurgitant valves, particularly those that are thickened, severely deformed, calcified, and partly stenotic, are not suitable for reconstruction, and patients with these valves require MVR.[193A] [193B]

Minimally invasive surgical techniques (Fig. 46-18) utilizing a small, low, asymmetrical sternotomy or anterior thoracotomy[194] and percutaneous cardiopulmonary bypass,[195] [195A] although quite demanding technically, have been found to be less traumatic and can be employed for both valve repair and replacement. This approach has been reported to reduce cost, improve cosmetic results, and shorten the recovery time.[196] However, it also is technically difficult and is successfully performed by only a minority of cardiac surgeons.

SURGICAL RESULTS.

Mortality rates of 3 to 9 percent are now common in many centers for patients with pure or predominant MR (NYHA Class II or III) who undergo elective isolated MVR.[137] [197] [198] The Society of Thoracic Surgeons National Database Committee reported an overall operative mortality rate of 6.4 percent in 13,936 patients undergoing isolated MVR; this compares with 4.3 percent for isolated aortic valve replacement and 3 percent for isolated mitral valve repair. The combination of MVR and repair of another valve was associated with a mortality rate of 12.5 percent and of MVR with coronary artery bypass grafting of 8 percent. The mortality rate is higher (up to 25 percent) in older patients with severe left ventricular dysfunction, especially when MR is secondary to myocardial ischemia, when pulmonary or renal function is impaired, or when the operation must be carried out as an emergency. Age *per se* is no barrier to successful surgery; MVR can be performed in patients older than 75 years of age if their general health status is adequate; however, surgery in these patients has a higher risk than in younger patients.[184]

Surgical treatment substantially improves survival in patients with symptomatic MR. Preoperative factors such as age less than 60 years, NYHA Class II, a cardiac index exceeding 2.0 liters/min/m^2 , a left ventricular end-diastolic pressure less than 12 mm Hg, and a normal ejection fraction and end-systolic volume all correlate with excellent immediate and long-term survival rates. Both preoperative end-systolic diameter (see Fig. 46-11) and ejection fraction (Fig. 46-19) are important predictors of short-term and long-term outcome. Excellent survival is observed in patients with end-systolic diameters less than 45 mm and ejection fractions of 60 percent or more. Intermediate outcomes are seen in patients with end-systolic diameters between 45 and 52 mm and ejection fractions between 50 and 60 percent. Poor outcomes are associated with values beyond these limits.

A large proportion of operative survivors have improved clinical status, quality of life, and exercise tolerance following valve replacement or repair. Severe pulmonary hypertension is reduced, and left ventricular end-diastolic volume and mass decrease. Depressed contractile function improves, especially if the papillary muscles and chordal attachment to the annulus remain intact. However, patients with MR who have marked left ventricular dysfunction preoperatively sometimes remain symptomatic with a depressed ejection fraction despite a technically satisfactory surgical procedure. Indeed, progressive left ventricular dysfunction and death from heart failure may occur in adults. Recovery of left ventricular function is much better in children.[199] Long-term survival in patients with predominant MR who undergo MVR may be poorer than in those with pure MS or with mixed stenotic and regurgitant lesions, presumably because left ventricular dysfunction may be quite advanced and largely irreversible by the time patients with pure MR develop serious symptoms.[200] Ten-year survival was 76 percent in patients in NYHA-Class I or II versus 48 percent in patients in Class III or IV.[200] Thus, every effort should be made to operate on patients before they develop serious symptoms. However, even though operating on patients with MR is clearly desirable before they develop marked left ventricular dysfunction[201] and despite the limitations of the results of surgical treatment, operation is still indicated in the majority of these patients because conservative therapy has little to offer.

The cause of MR also plays an important role in the outcome following surgical treatment.[202] In patients in whom mitral dysfunction is secondary to ischemic heart disease, the 5-year survival rate is about 40 percent, whereas in patients with rheumatic MR it is approximately 75 percent. Occlusive coronary artery disease coexisting with, but not the primary cause of, mitral dysfunction requires simultaneous coronary artery bypass grafting and mitral valve repair or replacement and is associated with decreased perioperative and long-term postoperative survival (Fig. 46-20) . However, some improvement resulting from mitral valve repair or replacement can be expected even in patients with MR secondary to ischemic heart disease who did not respond to medical treatment and now have congestive heart failure, as long as the cardiac index exceeds 1.8 liters/min/m^2 and the ejection fraction is greater than 30 percent. When left ventricular dysfunction is more severe, however, the risk of perioperative death becomes very high.[203]

SURGICAL TREATMENT OF ACUTE MITRAL REGURGITATION.

Emergency surgical treatment may be required for patients with acute left ventricular failure caused by acute MR secondary to myocardial infarction and rupture of the head of a papillary muscle, by trauma to the mitral valve, or by infective endocarditis. Emergency surgery is associated with higher mortality rates than is elective surgery for chronic MR. However, unless patients with acute, severe MR and heart failure are treated aggressively, a fatal outcome is almost certain. If patients with MR secondary to acute myocardial infarction can be stabilized by medical treatment, it is preferable to defer operation until 4 to 6 weeks after the infarction. Vasodilator treatment may be useful during this period. However, medical management should not be prolonged if multisystem (renal and/or pulmonary) failure develops. Intraaortic balloon counterpulsation may be required to stabilize the patient preoperatively. Surgical mortality rates are also higher in patients with acute MR and refractory heart failure (NYHA Class IV), in those in whom a previously implanted prosthetic valve must be replaced because of thromboembolism or valve dysfunction, and in those with active infective endocarditis (of either a natural or a prosthetic valve). Despite the higher

Figure 46-18 *A,* Minimally invasive right parasternal incision: A 5- to 7-cm incision is made, resecting a small portion of the third and fourth costal cartilages. Cannulation of the groin vessels (femoral artery and vein) has been performed frequently but has been revised to allow for minimal wound and vascular complications. The groin incision is placed parallel to the groin crease and is only 5 cm long. The artery and vein are exposed, and, after heparinization, the vein is cannulated using a pursestring and a 25- to 27-French wire reinforced Biomedicus catheter over a wire and then a dilator. The arterial cannula may be introduced by a small transverse cut downward. *B,* With the minimally invasive approach, a right atrial incision is used after exclusion of both the inferior and the superior vena cava, and the valve is approached through the septum (insert). *C,* When the right atrium is incised, an incision is made in the atrial septum through the fossae ovalis. Retraction sutures, on both

the right atrium and the atrial septum, of 2-0 silk, are then used to elevate the septum and to keep the left atrium open. The mitral valve will then be exposed (insert). *(From Byrne JG, et al: Minimally invasive direct access mitral valve surgery. Semin Thorac Cardiovasc Surg 11:212, 1999.)*

surgical risks, the efficacy of early operation has been established in patients with infective endocarditis complicated by medically uncontrollable congestive heart failure and/or recurrent emboli (see Chap. 47) . Because fungal endocarditis responds poorly to medical management, the practice now is to recommend valve replacement in these patients *before* the onset of heart failure or embolization.

INDICATIONS FOR OPERATION.

The threshold for surgical treatment of MR is declining for several reasons. These include the reductions in operative mortality, the improvements in both mitral valve reconstructive procedures and procedures involving prosthetic valves, and the recognition of the poor long-term results in many patients whose MR is corrected only after a long history of impaired

Figure 46-19 Graph of the late survival of of patients who underwent surgical correction of MR according to preoperative echocardiographic ejection fraction (EF). *(Reproduced with permission from Enriquez-Sarano M, et al: Echocardiographic prediction of survival after surgical correction of organic mitral regurgitation. Circulation 90:833, 1994. Copyright 1994 American Heart Association.)*

left ventricular function, atrial fibrillation, or pulmonary hypertension.

A detailed echocardiographic examination should be carried out to assess the likelihood that mitral valve repair, rather than replacement, is possible. In addition, the difference in outcome between these procedures should be weighed when deciding whether or not to proceed. Asymptomatic patients (NYHA Class I) should be considered for mitral valve reconstruction only if they have left ventricular dysfunction (ejection fraction
60 percent and/or left ventricular end-systolic diameter
45 mm). Class I patients with normal left ventricular function should be followed clinically and by echocardiography every 6 to 12 months. Rarely, they *may* be considered for operation if atrial fibrillation or pulmonary hypertension is present. At times, a careful history and performance of an exercise test often reveal that these patients are not truly asymptomatic. [204] [205] Patients with severe MR who are asymptomatic, who perform well on an exercise test, and who have excellent ventricular function (ejection fraction > 70 percent, end-systolic diameter <40 mm, end-systolic volume <40 ml/m^2) can be followed by echocardiography every 6 to 12 months. However, operation may be considered even in asymptomatic patients if they are less than 70 years of age, if they are likely to be candidates for mitral valve repair, and if ventricular function (as reflected by end-systolic diameter and ejection fraction) shows *progressive* deterioration. If valve replacement is likely to be necessary, a higher threshold for clinical and hemodynamic impairment should be employed than if valve reconstruction is contemplated. Because of the higher operative mortality, older patients (>75 years of age) should, in general, undergo surgery only if they are symptomatic.

Patients with severe MR and moderate or severe symptoms (NYHA Classes II, III, and IV) should generally be considered for surgery. One exception is a patient in whom echocardiography suggests that MVR will be required and

Figure 46-20 Plots of overall survival compared for repair and replacement groups for patients who had (left) or did not have (right) associated coronary artery bypass grafting (CABG). Note that the outcome is better with repair than with replacement in both groups and that the outcome is worse in patients who underwent CABG and MVR. *(From Enriquez-Sarano M, Schaff HV, Orszulak TA, et al: Valve repair improves the outcome of surgery for mitral regurgitation: A multivariate analysis. Circulation 91:1022, 1995.)*

whose ejection fraction is less than 30 percent. Because of the high risk of operation in these patients, medical therapy is usually advised, but the outcome is poor in any event. However, when mitral valve repair appears possible, even patients with serious left ventricular dysfunction may be considered for operation.[206] [207] [208]

Mitral Valve Prolapse Syndrome

ETIOLOGY AND PATHOLOGY

DEFINITION.

The mitral valve prolapse (MVP) syndrome has been given many names, including the systolic click-murmur syndrome, Barlow syndrome, billowing mitral cusp syndrome, myxomatous mitral valve syndrome, floppy valve syndrome, and redundant cusp syndrome.[209] [210] [211] [212] [213] It is a variable clinical syndrome that results from diverse pathogenic mechanisms of one or more portions of the mitral valve apparatus, valve leaflets, chordae tendineae, papillary muscle, and valve annulus. The MVP syndrome is one of the most prevalent cardiac valvular abnormalities and was

previously thought to affect as much as 5 to 10 percent of the population.[212] It now appears likely that overdiagnosis occurred in many individuals, perhaps because of the absence of rigorous echocardiographic criteria. Using such criteria (to be discussed), a community-based study showed that MVP syndrome occurred in only 2.4 percent of the population.[202] The syndrome is twice as frequent in females as in males. However, serious MR occurs more frequently in elderly males with MVP than in young females with this disorder.

Normally, the mitral valve billows slightly into the left atrium, and an exaggerated finding should be termed "billowing mitral valve." A "floppy valve" is regarded as an extreme form of billowing. MR occurs when the leaflet edges of the valve do not coapt. With chordal rupture, the prolapsed mitral valve is "flail." Obviously, these conditions blend into one another, and it is often difficult to distinguish among them.

Perloff and coworkers have proposed specific clinical criteria for the diagnosis of MVP.[213] They have divided the findings into three groups (Table 46-5) : (1) major criteria, the presence of one or more of which establishes the diagnosis of MVP; (2) minor criteria, the presence of which cannot be discounted and should raise the suspicion of MVP but which by themselves are not sufficient to establish the diagnosis; and (3) other findings not shown in Table 46-5 , which, although often present in patients with MVP, are nonspecific. Superior displacement of the mitral valve leaflets by more than 2 mm above the annulus is an important diagnostic criterion.[202] In addition, Marks and colleagues emphasized the importance of systolic displacement of one or both mitral leaflets into the left atrium in

TABLE 46-5 -- DIAGNOSTIC CRITERIA IN MITRAL VALVE PROLAPSE

MAJOR CRITERIA
Auscultation
Mid- to late systolic clicks and late systolic murmur or "whoop" alone or in combination at the cardiac apex
Two-dimensional echocardiogram
Marked superior systolic displacement of mitral leaflets (2 mm above annulus) with coaptation point at or superior to annular plane
Mild to moderate superior systolic displacement of mitral leaflets with:
Chordal rupture
Doppler mitral regurgitation
Annular dilatation
Echocardiogram plus auscultation
Mild to moderate superior systolic displacement of mitral leaflets with:
Prominent mid- to late systolic clicks at the cardiac apex
Apical late systolic or holosystolic murmur in the young patient
Late systolic "whoop"
MINOR CRITERIA
Auscultation
Loud S_1 with an apical holosystolic murmur
Two-dimensional echocardiogram
Isolated mild to moderate superior systolic displacement of the posterior mitral leaflet
Moderate superior systolic displacement of both mitral leaflets
Echocardiogram plus history of:
Mild to moderate superior systolic displacement of mitral leaflets with:
Focal neurologic attacks or amaurosis fugax in the young patient
First-degree relatives with major criteria
Modified from Perloff JK, Child JS, Edwards JE: New guidelines for the clinical diagnosis of mitral valve prolapse. Am J Cardiol 57:1124, 1986.

the *parasternal view* in the two-dimensional echocardiogram in the diagnosis of MVP.[214] Such an approach avoids overdiagnosis, which may occur with posterior bowing of the mitral valve on M-mode echocardiography and even in the four-chamber view on two-dimensional echocardiography.

ETIOLOGY.

Most frequently, MVP occurs as a primary condition that is not associated with other diseases.[211] However, it has also been reported to be associated with many conditions.[212] [215] [216] [217] [218] [219] [220] [221] [222] [223] [224] [225] [226] [227] [227A] [228] [229] MVP occurs quite commonly in heritable disorders of connective tissue that increase the size of the mitral leaflets and apparatus, including Marfan syndrome (see Chap. 56) , Ehlers-Danlos syndrome [224] (see Chap. 56) , osteogenesis imperfecta, pseudoxanthoma elasticum,[225] periarteritis nodosa, myotonic dystrophy,[218] von Willebrand disease,[217] hyperthyroidism,[216] and congenital malformations such as Ebstein anomaly of the tricuspid valve, atrial septal defect of the ostium secundum variety, the Holt-Oram syndrome, and hypertrophic cardiomyopathy.[51] There may

be a higher incidence of MVP in patients with an asthenic habitus[226] and various congenital thoracic deformities, including "straight back syndrome," pectus excavatum, and a shallow chest.[220] [222] These associations have not been proved using rigorous echocardiographic criteria, and, with the exception of connective tissue disorders, it is not clear how many of these are chance associations.

PATHOLOGY (Fig. 46-21) .

Findings include myxomatous proliferation of the mitral valve, in which the spongiosa component of the valve (i.e., the middle layer of the leaflet composed of loose, myxomatous material) is unusually prominent,[227] [227A] and the quantity of acid mucopolysaccharide is increased. Electron microscopy shows a haphazard arrangement of cells with disruption and with fragmentation of collagen fibrils (Fig. 46-22) . The concordance between inadequate production of type III collagen and echocardiographic findings of MVP in patients with type IV Ehlers-Danlos syndrome suggests that this collagen abnormality may be responsible in patients with this syndrome.[228] Although the majority of patients with MVP exhibit myxomatous degeneration of the valve, postinflammatory changes may also be responsible for prolapse.[229]

In mild cases, the valvular myxoid stroma is enlarged on histological examination, but the leaflets are grossly normal. However, with increasing quantities of myxoid stroma, the leaflets become grossly abnormal, redundant, and prolapsed. Regions of endothelial disruption are common and are possible sites of endocarditis or thrombus formation.[230] The severity of MR depends on the extent of the prolapse. The cusps of the mitral valve, the chordae tendineae, and the annulus may all be affected by myxomatous proliferation. Degeneration of collagen within the central core of the chordae tendineae is primarily responsible for chordal rupture, which often occurs and may intensify the severity of MR. Increased chordal tension resulting from the enlarged area of the valve cusps may play a contributory role.[231] Myxomatous changes in the annulus may result in annular dilatation and calcification, contributing to the severity of MR.

Myxomatous proliferation, although most commonly affecting the mitral valve, has also been described in the tricuspid, aortic, and pulmonic valves, particularly in patients with the Marfan syndrome, and may lead to regurgitation of these valves as well as the mitral valve.

The MVP syndrome can coexist with rheumatic MS, and it may develop following mitral valvotomy. *Ischemic heart disease* and MVP are both common disorders and sometimes coexist. MVP may also occur secondary to papillary muscle dysfunction. In some patients, MVP has been documented to develop for the first time *following* myocardial infarction.[232] It has been proposed that MVP may *cause* myocardial ischemia by increasing tension on the base of the involved muscle. During systole, the tips of the papillary muscles move basally instead of apically.

CLINICAL MANIFESTATIONS

The MVP syndrome appears to exhibit a strong hereditary component[209] [232] and in some patients is transmitted as an

Figure 46-21 *A,* Myxomatous mitral valve, atrial view, from a patient with severe mitral regurgitation. The surface area of the valve is increased, with increased folding of the valve surface. The widths of the anterior leaflet (AL) and the posterior leaflet (PL) are almost equal. Individual scallops of the posterior leaflet are enlarged and redundant. *B,* Comparison of an excised myxomatous mitral valve from a patient who had severe mitral regurgitation (top) with a normal mitral valve from a patient who died of noncardiac causes (bottom), showing the increased surface area of both anterior leaflets (AL) and posterior leaflets (PL) of the myxomatous valve with enlarged and redundant posterior leaflet scallops, enlarged mitral annulus, and elongated chordae tendineae. PCS = posteromedial commissural scallops; MS = middle scallop; ACS = anterolateral commissural scallop. *(From Boudoulas H, Wooley CF: Mitral valve prolapse and the mitral valve prolapse syndrome. In Yu P, Goodwin J [eds]: Progress in Cardiology. Philadelphia, Lea and Febiger, 1986.)*

autosomal dominant trait with varying penetrance. The clinical presentations of the MVP syndrome are diverse.[213] The condition has been observed in patients of all ages and in both sexes. Despite the overestimation of the prevalence in the population referred to earlier, MVP is the most common cause of isolated MR requiring surgical treatment in the United States.[211] Echocardiographic evidence of MVP has been found in more than 90 percent of patients with the Marfan syndrome[233] and in many of their first-degree relatives.

History

A large majority of patients with MVP are asymptomatic and remain so throughout their lives[234] (Fig. 46-23) . In many cases, otherwise asymptomatic patients with MVP suffer from undue anxiety, perhaps precipitated by their having been informed of the presence of heart disease. Boudoulas and colleagues have called attention to an "MVP syndrome" with a characteristic systolic nonejection click and various nonspecific symptoms, such as fatigability, palpitations, postural orthostasis, and neuropsychiatric symptoms, as well as symptoms of autonomic dysfunction.[235] How, and even whether, these symptoms relate to the presence of MVP is not clear. It has been suggested that many of the symptoms are related to dysfunction of the autonomic nervous system, with increased excretion of catecholamines that occurs frequently in the MVP syndrome.[236] [237]

Patients may complain of syncope, presyncope, palpitations, chest discomfort, and, when MR is severe, symptoms of diminished cardiac reserve. Chest discomfort may be typical of angina pectoris but is more often atypical in that

Figure 46-22 Electron micrographs of mitral valve. *A,* Normal mitral valve: Elastic fiber is composed of amorphous component (A), associated with microfibrils (M) oriented in parallel. Collagen fibrils (C) are compactly arranged (Kajikawa stain; original magnification 22,000). *B,* Prolapsed mitral valve. Collagen fibrils show spiraling appearance in longitudinal section (arrow) and flower-like appearance (arrowhead) in transverse section (Kajikawa stain; original magnification 27,000). *(From Tamura K, Fukuda Y, Ishizaki M, et al: Abnormalities in elastic fibers and other connective-tissue components of floppy mitral valve. Am Heart J 129:1149, 1995.)*

it is prolonged, not clearly related to exertion, and punctuated by brief attacks or severe stabbing pain at the apex. The discomfort may be secondary to abnormal tension on papillary muscles. In patients with MVP and severe MR, the symptoms of the latter (fatigue, dyspnea, and exercise limitation, see p. 1658) are present. Patients with MVP and arrhythmias (to be discussed) may have symptoms related to the latter.

Physical Examination

The body weight is often low, and the habitus may be asthenic. Blood pressure is usually normal or low; orthostatic hypotension may be present. As already mentioned, patients with MVP have a higher than expected prevalence of "straight back syndrome," scoliosis, and pectus excavatum.[222] MR ranges from nonexistent to severe.

The auscultatory findings are best elicited with the diaphragm of the stethoscope. The patient should be examined in the supine, left decubitus, and sitting positions. The physical findings unique to the MVP syndrome are detected by auscultation and can be corroborated by phonocardiography. The most important is a nonejection systolic click at least 0.14 second after S_1 (see Fig. 4-30) . [237A] This can be differentiated from a systolic ejection click by phonocardiography because it occurs *after* the beginning of the carotid pulse upstroke. Occasionally, multiple mid- and late systolic clicks are audible, most readily along the lower left sternal border. The clicks are believed to be produced by sudden tensing of the elongated chordae tendineae and of the prolapsing leaflets. They are often, although not invariably, followed by a mid- to late crescendo systolic murmur that continues to A_2 . This murmur is similar to that produced by papillary muscle dysfunction, which is readily understandable because both result from mid- to late systolic

Figure 46-23 *Left panel,* The dynamic spectrum and progression of mitral valve prolapse (MVP) are shown. A subtle gradation exists between the normal mitral valve and valves that produce mild MVP without mitral regurgitation (no MR). Progression from the level MVP-no MR to another level may or may not occur. Most of the MVP syndrome cases occupy the area above the dotted line, whereas progressive mitral valve dysfunction cases occupy the area below the dotted line. *Right panel,* The large circle represents the total number of patients with MVP. Patients with MVP may be symptomatic or asymptomatic. Symptoms may be directly related to mitral valve dysfunction (black circle) or to autonomic dysfunction (pink circle). Certain patients with symptoms directly related to mitral valve dysfunction may present with and continue to have symptoms secondary to autonomic dysfunction. *(From Boudoulas H, Wooley CF: Mitral Valve Prolapse and the Mitral Valve Prolapse*

Syndrome. Mount Kisco, NY, Futura Publishing Co, Inc, 1988.)

Figure 46-24 Dynamic auscultation in MVP. Any maneuver that decreases left ventricular (LV) volume (e.g., decreased venous return, tachycardia, decreased outflow impedance, increased contractility) will worsen the mismatch in size between the enlarged mitral valve and LV chamber, resulting in prolapse earlier in systole and movement of the click (C) and murmur (M) toward the first heart sound (S_1). Conversely, maneuvers that increase LV volume (e.g., increased venous return, bradycardia, increased outflow impedence, decreased contractility) will delay the occurrence of prolapse, resulting in movement of the click and murmur toward the second heart sound. (S_2). Ao = aorta. *(From Prabhu SD, O'Rourke RA: Mitral valve prolapse. In Rahimtoola SH (ed): Valvular Heart Disease. Atlas of Heart Diseases. Vol. 11. Braunwald E, series ed. Philadelphia: Current Medicine, 1997, pp 10.1-10.18 Adapted from O'Rourke RA, Crawford MH: The systolic click-murmur syndrome: Clinical recognition and management. Curr Probl Cardiol 1:9, 1976.)*

MR. In general, the duration of the murmur is a function of the severity of the MR. When the murmur is confined to the latter portion of systole, MR usually is not severe. However, as MR becomes more severe, the murmur commences earlier and ultimately becomes holosystolic.

It is important to emphasize the variability of the physical findings in the MVP syndrome. Some patients exhibit both a midsystolic click and a mid- to late systolic murmur; others present with only one of these two findings; still others have only a click on one occasion and only a murmur on another, both on a third examination, and no abnormality at all on a fourth. Conditions other than MVP cause midsystolic clicks; these include tricuspid valve prolapse, atrial septal aneurysms, and extracardiac causes.

DYNAMIC AUSCULTATION.

The auscultatory (and phonocardiographic) findings are exquisitely sensitive to physiological and pharmacological interventions, and recognition of the changes induced by these interventions is of great value in the diagnosis of the MVP syndrome (Fig. 46-24 ; see also Tables 4-4 and 46-4) . The mitral valve begins to prolapse when the reduction of left ventricular volume during systole reaches a critical point at which the valve leaflets no longer coapt; at that instant, the click occurs and the murmur commences. Any maneuver that decreases left ventricular volume, such as a reduction of impedance to left ventricular outflow, a reduction in venous return, tachycardia, or an augmentation of myocardial contractility, results in an earlier occurrence of prolapse during systole. As a consequence, the click and onset of the murmur move closer to S_1 . When prolapse is severe and/or left ventricular size is markedly reduced, prolapse may begin with the onset of systole. As a consequence, the click may not be audible, and the murmur may be holosystolic. On the other hand, when left ventricular volume is augmented by an

increase in the impedance to left ventricular emptying, an increase in venous return, a reduction of myocardial contractility, or bradycardia, both the click and the onset of the murmur will be delayed.

During the straining phase of the Valsalva maneuver, upon sudden standing, and early during the inhalation of amyl nitrite, cardiac size decreases, and both the click and the onset of the murmur occur earlier in systole. In contrast, a sudden change from the standing to the supine position, leg-raising, squatting, maximal isometric exercise, and, to a lesser extent, expiration will delay the click and the onset of the murmur. During the overshoot phase of the Valsalva maneuver (i.e., six to eight cycles following release) and with prolongation of the R-R interval, either following a premature contraction or in atrial fibrillation, the click and onset of the murmur are usually delayed, and the intensity of the murmur is reduced. Maneuvers that elevate arterial pressure, such as isometric exercise, increase the intensity of the click and murmur. In general, when the onset of the murmur is delayed, both its duration and intensity are diminished, reflecting a reduction in the severity of MR.

The response to several interventions may be helpful in differentiating hypertrophic obstructive cardiomyopathy (HOCM) from MVP. During the strain of the Valsalva maneuver, the murmur of HCM increases in intensity, whereas the murmur of MVP becomes longer but usually not louder. The murmur of HCM becomes louder after amyl nitrite inhalation, whereas that of MVP does not. Following a premature beat, the murmur of HCM increases in intensity and duration, whereas that due to MVP usually remains unchanged or decreases.

LABORATORY EXAMINATION

ELECTROCARDIOGRAPHY

The ECG is usually normal in asymptomatic patients with MVP. In a minority of asymptomatic patients and in many symptomatic patients, the ECG shows inverted or biphasic T waves and nonspecific ST segment changes in leads II III, and a_{Vf} and occasionally in the anterolateral leads as well.

ARRHYTHMIAS.

A spectrum of arrhythmias have been observed. These include atrial and ventricular premature contractions and supraventricular and ventricular tachyarrhythmias,[238] [239] [239A] as well as bradyarrhythmias due to sinus node dysfunction or varying degrees of atrioventricular block. The mechanism of the arrhythmias is not clear. Diastolic depolarization of muscle fibers in the anterior mitral leaflet in response to stretch has been demonstrated experimentally, and the abnormal stretch of the prolapsed leaflet may be of pathogenetic significance. Wit and associates have shown that mitral valve leaflets contain atrium-like muscle fibers in continuity with left atrial myocardium.[240] It is possible that mechanical stimulation of these fibers generates slow-response action potentials and sustained rhythmic action that penetrates the cardiac chambers.[240]

Paroxysmal supraventricular tachycardia is the most common sustained tachyarrhythmia in patients with MVP and may be related to what may be an increased incidence of left atrioventricular bypass tracts.[238] The incidence of MVP among patients with the Wolff-Parkinson-White syndrome is increased.[241] There is also an increased association between MVP and prolongation of the QT interval, and this association may play a role in the pathogenesis of serious ventricular arrhythmias.[238] Patients with MVP have an increased incidence of abnormal late potentials on signal-averaged ECGs, as well as reduced heart rate variability.[239]

MITRAL VALVE PROLAPSE AND SUDDEN DEATH.

The relation between the MVP syndrome and sudden death is not clear. However, the best evidence suggests that MVP increases the risk of sudden death slightly,[209] [242] [243] [243A] especially in patients with severe MR or severe valvular deformity. The immediate cause of the sudden, unexpected death is probably ventricular fibrillation.[244] Kligfield and Devereux have identified the following as potential risks for sudden death in patients with MVP: the presence of severe MR, complex ventricular arrhythmias, QT interval prolongation, and a history of syncope and palpitations.[238]

ECHOCARDIOGRAPHY (See also Chap. 7) .

Echocardiography plays a key role in the diagnosis of MVP and has been most useful in the delineation of this syndrome[244A] (see Figs. 7-57 and 7-58) . The most common finding on M-mode echocardiography is abrupt posterior movement of the posterior leaflet or of both mitral leaflets in midsystole with the leaflet interface greater than 2 mm posterior to the C-D line. This movement occurs simultaneously with the systolic click. A second finding is pansystolic posterior prolapse of one or both leaflets, giving rise to a U- or hammock-shaped configuration 3 mm or more posterior to the C-D segment.

To establish the diagnosis, the two-dimensional echocardiogram must show that one or both mitral valve leaflets billow by at least 2 mm into the left atrium during systole in the long-axis view (Fig. 46-25) .[202] [245] [246] Thickening of the involved leaflet to greater than 5 mm supports the diagnosis. This finding is also helpful in identifying patients at significant risk for developing severe MR or infective endocarditis.[214] The mitral annular diameter is often abnormally increased.[245] [247] Transesophageal echocardiography provides additional details regarding the mitral valve apparatus, such as rupture of chordae tendineae. In MR secondary to MVP, the echocardiogram provides valuable information regarding left ventricular function.

The variability in physical findings in this syndrome, already commented upon, extends to the echocardiogram.[247] [248] Thus, some patients have a systolic click with or without a murmur and show no evidence of MVP on the echocardiogram. Conversely, the echocardiographic findings of MVP may be observed in patients without a click or murmur. Others have both the typical echocardiographic and auscultatory features. The echocardiographic findings of MVP have been reported to occur in a large number of first-degree relatives of patients with established MVP. Two-dimensional echocardiography has also revealed prolapse of the tricuspid and aortic valves in approximately 20 percent of patients with MVP.[249] Conversely, however, prolapse of the tricuspid and aortic

Figure 46-25 Diagram of parasternal view of two-dimensional echocardiography in normal subject and in patient with MVP. *A,* Normal parasternal long-axis view at end-diastole immediately preceding mitral valve closure. Labeled are the anterior leaflet (AL), posterior leaflet (PL), ventricular septum (VS), posterior wall (PW), aorta (AO), left atrium (LA), and left ventricle (LV). Systolic prolapse may be predominantly anterior leaflet (*B,* arrows), predominantly posterior (*C,* arrow), or both (*D,* arrows). The presence of leaflet thickening, leaflet redundancy, chordal elongation, and annular dilatation should also be assessed on the two-dimensional study. Color flow and pulsed-wave Doppler studies are used to determine the presence and extent of mitral regurgitation, an important supporting finding in borderline cases. *(From Prabhu SD, O'Rourke RA: Mitral valve prolapse. In Rahimtoola SH (ed): Valvular Heart Disease. Atlas of Heart Diseases. Vol. 11. Braunwald E, series ed. Philadelphia: Current Medicine, 1997, pp 10.1-10.18.)*

valves occurs *uncommonly* in patients without prolapse of the mitral valve.[249]

Doppler echocardiography frequently reveals mild MR that is not always associated with an audible murmur. Color flow Doppler echocardiography is useful in identifying the location and severity of the regurgitant jets. MR is moderate or severe in about 10 percent of patients with MVP, most commonly in men over the age of 50.[247]

STRESS SCINTIGRAPHY.

The differential diagnosis between two common conditions--MVP associated with atypical chest pain and ECG abnormalities and primary coronary artery disease associated with MVP--may be aided by exercise electrocardiography. However, myocardial perfusion scintigraphy using thallium-201 or sestamibi during pharmacological exercise stress (see Chap. 9) is more specific. When findings are normal, i.e., when there is no evidence of stress-induced regional myocardial ischemia, the diagnosis of MVP unrelated to ischemic heart disease is favored.[250]

ANGIOGRAPHY.

The configuration of the left ventriculogram during systole is helpful in confirming the diagnosis of MVP. The right anterior oblique projection is most useful for defining the posterior leaflet of the mitral valve, and the left anterior oblique projection is most useful for studying the anterior leaflet. The most helpful sign is extension of the mitral leaflet tissue inferiorly and posteriorly to the point of attachment of the mitral leaflets to the mitral annulus.[251] Angiography may also reveal scalloped edges of the leaflets, reflecting redundancy of tissue. Other abnormalities noted on angiography of some patients with MVP include dilatation, decreased systolic contraction, and calcification of the mitral annulus and poor contraction of the basal portion of the left ventricle.[252]

NATURAL HISTORY

The outlook for children with MVP is excellent; a large majority remain asymptomatic for many years without any change in clinical or laboratory findings[209] [234] [253] [253A] (see Fig. 46-23) . Zuppiroli and associates monitored 316 patients with MVP for an average of more than 8 years; 70 percent were women and 29 percent had familial MVP.[234] Serious complications (cardiac death, need for cardiac surgery, acute infective endocarditis, or cerebral embolic events) occurred at a rate of only 1 per 100 patient years.[234]

Progressive MR with gradual increase in left atrial and left ventricular size, atrial fibrillation, pulmonary hypertension, and the development of congestive heart failure is the most frequent serious complication,[234] [254] occurring in about 15 percent of patients over a 10- to 15-year period. The incidence of this complication is significantly greater in patients with both murmurs and clicks than in those with an isolated click. In many patients, rupture of chordae tendineae is responsible for the precipitation and/or intensification of the MR. Severe MR occurs more frequently in men older than 50 years of age with MVP and in patients with thickened (>5 mm diameter) mitral valve leaflets.[243] [254] [255] [256] Patients with the MVP syndrome are also at risk of developing infective endocarditis.[257] [257A] Although the incidence of infective endocarditis appears to be extremely low in patients with only a midsystolic click, it increases in patients with a systolic murmur. The incidence is higher in men than in women and in those more than 50 years of age. Infective endocarditis often aggravates the severity of MR and therefore the need for surgical treatment.

Acute hemiplegia, transient ischemic attacks, cerebellar infarcts, amaurosis fugax, and retinal arteriolar occlusions have been reported to occur more frequently in patients with the MVP syndrome, suggesting that cerebral emboli are unusually common in this condition.[258] [259] [259A] It has been proposed that these neurological complications are associated with loss of endothelial continuity and tearing of the endocardium overlying the myxomatous valve, which initiates platelet aggregation and the formation of mural platelet-fibrin complexes.[258] Although it has been proposed that embolization secondary to MVP may be a significant cause for unexplained strokes in young people without cerebrovascular disease, a large case-controlled study showed no association between MVP and ischemic neurological events in persons under 45 years of age.[260]

MANAGEMENT (Table 46-6)

Patients with the physical findings of MVP (and those without such findings who have been given the diagnosis) should have two-dimensional and color flow Doppler echocardiography. This procedure should also be performed in first-degree relatives of patients with MVP.[51] The diagnosis of MVP requires definitive echocardiographic findings, and overdiagnosis and incorrect "labeling" have been a major problem with this condition. *Asymptomatic patients* (or those whose principal complaint is anxiety), with no arrhythmias evident on a routine extended ECG tracing and without evidence of MR, have an excellent prognosis. They should be reassured about the favorable prognosis and be encouraged to engage in normal life styles, but should have follow-up examinations every every 3 to 5 years. This should include a two-dimensional echocardiogram and a color flow Doppler study.

Patients with a long systolic murmur may show progression of MR and should be evaluated more frequently, at intervals of approximately 12 months. *Endocarditis prophylaxis* is advisable for patients with a typical click and systolic murmur and in those with only a click and characteristic echocardiographic features of MVP. Prophylaxis does *not* appear to be necessary for patients with a midsystolic

TABLE 46-6 -- MATCHING RISK AND MANAGEMENT IN PATIENTS WITH MITRAL VALVE PROLAPSE

RISK LEVEL	PATIENTS	MANAGEMENT
Lowest	Patients without mitral regurgitant murmurs or regurgitation revealed by Doppler echocardiography, especially women younger than age 45	Reassurance; prophylactic antibiotics not clearly necessary and if used should not include medication with risk of allergic reactions; reevaluation and echocardiography at moderate intervals (5 years)
Moderate	Patients with intermittent or persistent mitral murmurs and mild regurgitation revealed by Doppler echocardiography	Antibiotic prophylaxis with erythromycin or amoxicillin; treatment of even mild established hypertension; reevaluation and echocardiography more frequently (2 to 3 years)
High	Patients with moderate or severe mitral regurgitation	Antibiotic prophylaxis with amoxicillin (unless allergic); optimization of afterload (arterial pressure); reevaluation with Doppler echocardiography and other tests if needed annually; consider valve repair or replacement for exertional dyspnea or decline of left ventricular function into low-normal range

From Devereux RB: Recent developments in the diagnosis and management of mitral valve prolapse. Curr Opin Cardio 10:107, 1995. Modified from Devereux RB, Kligfield P: Mitral valve prolapse. In Rakel R: Current Therapy. Philadelphia, WB Saunders, 1992, pp 237, 241.

click without a systolic murmur or without typical echocardiographic findings (see also Chap. 47) .[261]

Patients with a history of palpitations, lightheadedness, dizziness, or syncope or those who have ventricular arrhythmias or QT prolongation on a routine ECG should undergo ambulatory (24-hour) ECG monitoring and/or exercise ECG to detect arrhythmias. Because of the risk, albeit very low, of sudden death,[238] electrophysiologic studies may be carried out to characterize arrhythmias if they exist. Beta-adrenergic blockers are useful in the treatment of palpitations secondary to frequent

premature ventricular contractions and for self-terminating episodes of supraventricular tachycardia. These drugs may also be useful in the treatment of chest discomfort, both in patients with associated coronary artery disease and in those with normal coronary vessels in whom the symptoms may be due to regional ischemia secondary to MVP. Radiofrequency ablation of atrioventricular bypass tracts is useful for frequent or prolonged episodes of supraventricular tachycardia.

Aspirin should be given to patients with MVP who have had a documented focal neurological event and in whom no other cause, such as a left atrial thrombus or atrial fibrillation, is apparent. Treatment with an angiotensin-converting enzyme inhibitor has been reported to reduce the severity of MR in patients with MVP.[171]

Patients with MVP and severe MR should be treated similarly to other patients with severe MR (see p. 1661) and may require mitral valve surgery. Reconstructive surgery without valve replacement is usually possible (see Fig. 46-15) .[179A] [211] [261A] Therefore, the threshold for surgical treatment in these patients is lower than in patients with MR in whom MVR may be necessary. Approximately 50 percent of all mitral valve reconstructions for MR are now carried out in patients with MVP. Among 252 such patients operated upon at the Brigham and Women's Hospital, resection of the most deformed leaflet segment and insertion of an annuloplasty ring to reduce the dilated annulus was the most commonly employed procedure. Rupture of the chordae tendineae to the anterior leaflet could sometimes be treated by chordal transfer from the posterior leaflet. In other patients, shortening of the chordae tendineae and/or papillary muscle was necessary. The operative mortality was 2 percent; structural valve degeneration occurred in 15 percent of patients at 5 years. Chordal replacement with polytetrafluoroethylene sutures has been reported to enhance mitral valve repair in patients with MVP.[210]

Coronary arteriography should be performed in patients with angina pectoris on effort and/or ischemic ECG changes or those with abnormalities on a stress myocardial perfusion scan. Treatment should take into account both the responsiveness of symptoms to medical management and the coronary anatomy.

Although this discussion has focused attention on complications of the MVP syndrome, it should not be forgotten that, on the whole, this is a benign condition and that the *vast majority* of patients with this syndrome remain asymptomatic for their entire lives and require, at most, observation every few years and reassurance.

Aortic Stenosis

ETIOLOGY AND PATHOLOGY

Obstruction to left ventricular outflow is localized most commonly at the aortic valve and is discussed in this section. However, obstruction may also occur above the valve (supravalvular stenosis) or below the valve (discrete subvalvular aortic stenosis [see Chap. 43]), or it may be caused by hypertrophic obstructive cardiomyopathy (see Chap. 48) . Valvular aortic stenosis (AS) *without accompanying mitral valve disease* is more common in men than in women and very rarely occurs on a rheumatic basis. Instead, isolated AS is usually either congenital or degenerative in origin[262] [263] (Figs. 46-26 and 46-27) .

CONGENITAL AORTIC STENOSIS (See also Chaps. 43 and 44) .

Congenital malformations of the aortic valve may be unicuspid, bicuspid, or tricuspid, or there may be a dome-shaped diaphragm. *Unicuspid valves* produce severe obstruction in infancy and are the most frequent malformations found in fatal valvular AS in children under the age of 1 year. Congenitally *bicuspid valves* may be stenotic with commissural fusion at birth, but more often they are not responsible for serious narrowing of the aortic orifice during childhood. Their abnormal architecture induces turbulent flow, which traumatizes the leaflets and leads to fibrosis, increased rigidity, calcification of the leaflets, and narrowing of the aortic orifice in adulthood[264] (Fig. 46-28) . Infective endocarditis may develop on a congenitally bicuspid valve, which then becomes regurgitant. Rarely, a congenitally bicuspid valve is purely regurgitant in the absence of antecedent infection.

A third form of a congenitally malformed valve is *tricuspid,* with the cusps of unequal size and some commissural fusion. Although many of these valves retain normal function throughout life, it has been postulated that the turbulent flow produced by the mild congenital architectural

Figure 46-26 Types of aortic valve stenosis. *A,* Normal aortic valve. *B,* Congenital aortic stenosis. *C,* Rheumatic aortic stenosis. *D,* Calcific aortic stenosis. *E,* Calcific senile aortic stenosis. *(From Brandenburg RO, et al: Valvular heart disease--When should the patient be referred? Pract Cardiol 5:50, 1979.)*

Figure 46-27 Causes of aortic stenosis, shown for two age groups. Among patients younger than 70 years (*top*), calcification of congenitally bicuspid valves accounted for half of the surgical cases. In contrast, in those 70 years of age or older (*bottom*), degenerative calcification accounted for almost half of the cases. *(From Passik CS, et al: Temporal changes in the causes of aortic stenosis: A surgical pathologic study of 646 cases. Mayo Clin Proc 62:119, 1987.)*

abnormality may lead to fibrosis and ultimately to calcification and stenosis. Tricuspid stenotic aortic valves in adults may be congenital, rheumatic, or degenerative in origin.

ACQUIRED AORTIC STENOSIS.

Rheumatic AS results from adhesions and fusions of the commissures and cusps and vascularization of the leaflets of the valve ring, leading to retraction and stiffening of the free borders of the cusps. Calcific nodules develop on both surfaces, and the orifice is reduced to a small round or triangular opening. As a consequence, the rheumatic valve is often regurgitant as well as stenotic.[262] The heart frequently exhibits other stigmata of rheumatic disease, especially mitral valve involvement. With the decline in rheumatic fever in industrialized nations, rheumatic AS is decreasing in frequency.

Age-related degenerative calcific (formerly termed senile) AS is now the most common cause of AS in adults and the most frequent reason for aortic valve replacement in patients with AS.[265] It appears to result from years of normal mechanical stress on a valve that sometimes exhibits inflammatory changes with infiltration of macrophages and T lymphocytes. The cusps are immobilized, and the stenosis is caused by deposits of calcium along the flexion lines at their bases. Immunohistochemical evidence of *Chlamydia pneumoniae* has been found in early lesions of age-related degenerative AS.[266] In a population-based echocardiographic study, 2 percent of persons 65 years of age or older had frank calcific AS, whereas 29 percent exhibited age-related aortic valve sclerosis without stenosis, defined by Otto and colleagues as irregular thickening of the aortic valve leaflets detected by echocardiography without significant obstruction and believed to represent a milder and/or earlier disease process.[265] This form of AS may be accompanied by calcifications of the mitral annulus and coronary arteries but rarely by aortic regurgitation. Both diabetes mellitus and hypercholesterolemia are risk factors for the development of age-related AS or degenerative calcific AS.[267] [268] It has been suggested that the hypercholesterolemia accelerates age-related degenerative changes in the aortic root and valve.[269] In turn, it has been noted that age-related aortic valve sclerosis and calcific AS are associated with traditional risk factors for atherosclerosis such as cigarette smoking, a history of hypertension, and low high-density-lipoprotein cholesterol values.[270] Not surprisingly, age-related aortic valve sclerosis is associated with an increased risk of cardiovascular death and mycoardial infarction.[265] In *atherosclerotic* aortic valve stenosis, severe atherosclerosis involves the aorta and other major arteries; this form of AS occurs most frequently in patients with severe hypercholesterolemia and is observed in children with homozygous type II hyperlipoproteinemia.[271]

Calcific AS is observed in a number of other conditions, including Paget disease of bone[272] and end-stage renal disease.[273] *Rheumatoid involvement* of the valve is a rare cause of AS and results in nodular thickening of the valve leaflets and involvement of the proximal portion of the aorta. *Ochronosis* with alkaptonuria is another rare cause of AS.[274]

Roberts studied hearts with AS obtained at autopsy from patients between 15 and 65 years of age and found that almost 40 percent had tricuspid aortic valves.[275] Because thickening of the mitral valve and a history of acute rheumatic fever were present in 50 percent of these patients, it is likely that the AS was rheumatic in etiology; in the remainder, it was either congenital or degenerative in origin. In 90 percent of hearts examined at autopsy in patients with AS who were older than 65 years of age, the valves were tricuspid, with nodular calcific deposits on the aortic aspects of the cusps, but without commissural fusion,[275] indicative of age-related degenerative calcific AS.

Hemodynamically significant AS leads to severe concentric left ventricular hypertrophy,[276] with heart weights as great as 1000 gm. The interventricular septum often bulges into and encroaches on the right ventricular cavity. When left ventricular failure supervenes, the ventricle dilates, the left atrium enlarges, and changes secondary to backward failure occur in the pulmonary vascular bed, the right side of the heart, and the systemic venous bed.

PATHOPHYSIOLOGY (Fig. 46-29)

The left ventricle responds to *sudden* severe obstruction to outflow by dilatation and reduction of stroke volume.[277] However, in adults with AS, the obstruction usually develops and increases gradually over a prolonged period. In infants and children with congenital AS, the valve orifice shows little change as the child grows, thereby intensifying the relative obstruction quite gradually. Left ventricular function can be well maintained in experimentally produced, gradually developing subcoronary AS in

animals. In the experimental model, as well as in children and adults

Figure 46-28 Calcific aortic stenosis. *A,* Congenitally bicuspid aortic valve, characterized by two equal cusps with basal mineralization. *B,* Congenitally bicuspid aortic valve having two unequal cusps, the larger with a central raphe (arrow). *C,* Otherwise anatomically normal tricuspid aortic valve in an elderly patient, characterized by isolated cusps with calcification localized to basilar aspect; cuspal free edges are not involved. *D* and *E,* Photomicrographs of calcific deposits in calcific aortic stenosis; deposits are rimmed by arrows (hematoxylin and eosin, original magnification ×15). *D,* Deposits with underlying cusp largely intact; transmural calcific deposits are shown in *E. (A and C from Schoen FJ, St. John Sutton M: Contemporary issues in the pathology of valvular heart disease. Hum Pathol 18:568, 1987.)*

with chronic, severe AS, left ventricular output is maintained by the presence of left ventricular hypertrophy, which may sustain a large pressure gradient across the aortic valve for many years without a reduction in cardiac output, left ventricular dilatation, or the development of symptoms. Critical obstruction to left ventricular outflow is usually characterized by (1) a peak systolic pressure gradient exceeding 50 mm Hg in the presence of a normal cardiac output or (2) an effective aortic orifice (calculated by the Gorlin formula [see Chap. 11]) less than about 0.8 cm^2 in an average-sized adult, i.e., 0.5 cm^2 /m^2 of body surface area (less than approximately one-fourth of the normal aortic orifice of 3.0 to 4.0 cm^2). An aortic valve orifice of 1.0 to 1.5 cm^2 is considered moderate stenosis, and an orifice of 1.5 to 2.0 cm^2 is referred to as mild stenosis (see Fig. 11-13) .

As contraction of the left ventricle becomes progressively more isometric, the left ventricular pressure pulse exhibits a rounded, rather than flattened, summit. The elevated left ventricular end-diastolic pressure, which is characteristic of severe AS, often reflects diminished compliance of the hypertrophied left ventricular wall.[278] [279]

In patients with severe AS, large *a* waves usually appear in the left atrial pressure pulse because of the combination of enhanced contraction of a hypertrophied left atrium and diminished left ventricular compliance. Atrial contraction plays a particularly important role in filling of the left ventricle in AS. It raises left ventricular end-diastolic pressure

Figure 46-29 Pathophysiology of aortic stenosis. Left ventricular (LV) outflow obstruction results in an increased LV systolic pressure, increased left ventricular ejection time (LVET), increased left ventricular diastolic pressure, and decreased aortic (Ao) pressure. Increased LV systolic pressure with LV volume overload increases LV mass, which may lead to LV dysfunction and failure. Increased LV systolic pressure, LV mass, and LVET increase myocardial oxygen (O_2) consumption. Increased LVET results in a decrease of diastolic time (myocardial perfusion time). Increased LV diastolic pressure and decreased Ao diastolic pressure decrease coronary perfusion pressure. Decreased diastolic time and coronary perfusion pressure decrease myocardial O_2 supply. Increased myocardial O_2 consumption and decreased myocardial O_2 supply produce myocardial ischemia, which further deteriorates LV function (
= increased,
= decreased). *(From Boudoulas H, Gravanis MB: Valvular heart disease. In Gravanis MB: Cardiovascular Disorders: Pathogenesis and Pathophysiology. St. Louis, CV Mosby Co, 1993, p 64.)*

without causing a concomitant elevation of mean left atrial pressure.[280] This "booster pump" function of the left atrium prevents the pulmonary venous and capillary pressures from rising to levels that would produce pulmonary congestion, while at the same time maintaining left ventricular end-diastolic pressure at the elevated level necessary for effective contraction of the hypertrophied left ventricle. Loss of appropriately timed, vigorous atrial contraction, as occurs in atrial fibrillation or atrioventricular dissociation, may result in rapid clinical deterioration in patients with severe AS.

Although the *cardiac output* at rest is within normal limits in the majority of patients with severe AS, it often fails to rise normally during exertion. Late in the course of the disease, the cardiac output, stroke volume, and therefore the left ventricular-aortic pressure gradient all decline, whereas the mean left atrial, pulmonary capillary, pulmonary arterial, right ventricular systolic and diastolic, and right atrial pressures rise, often sequentially. As a consequence of pulmonary hypertension and/or bulging of the hypertrophied septum into the right ventricular cavity, the *a* wave in the right atrial pressure pulse becomes prominent.

Left ventricular end-diastolic volume usually remains normal until late in the course of severe AS, but left ventricular mass increases in response to the chronic pressure overload, resulting in an increase in the mass/volume ratio. However, the increase in mass may not be as great as that seen with aortic regurgitation (AR) or combined AS and AR.

Gender differences in the response of the left ventricle to AS have been reported.[281] [282] [283] Women more frequently exhibit normal or even supernormal ventricular performance and a smaller, thicker-walled, concentrically hypertrophied left ventricle with diastolic dysfunction (to be discussed) and normal or even subnormal systolic wall stress. Men more frequently have eccentric left ventricular hypertrophy, excessive systolic wall stress, systolic dysfunction, and ventricular dilatation[284] [285] [286] (Fig. 46-30) .

MYOCARDIAL FUNCTION IN AORTIC STENOSIS

When the aorta is suddenly constricted in experimental animals, left ventricular pressure rises, wall stress increases significantly, and both the extent and the velocity of shortening decline. As pointed out in Chapter 16 , the development of ventricular hypertrophy is one of the principal mechanisms by which the heart adapts to such an increased hemodynamic burden. The increased systolic wall stress induced by AS leads to parallel replication of sarcomeres and concentric hypertrophy (see Fig. 16-4) . The increase in left ventricular wall thickness is often sufficient to counterbalance the increased pressure, so that peak systolic wall tension returns to normal or remains normal if the obstruction develops slowly.[287] An inverse correlation between wall stress and ejection fraction has been described in patients with AS.[288] This suggests that the depressed ejection fraction and velocity of fiber shortening that occur in *some* patients are a consequence of inadequate wall thickening,[289] resulting in "afterload mismatch."[290] In others, the lower ejection fraction is secondary to a true depression of contractility; in this group, surgical treatment is less effective.[291] Thus, both increased afterload and altered contractility are operative to varying extents in depressing left ventricular performance.[281] [282] In order to evaluate myocardial function in patients with AS, the ejection

Figure 46-30 The difference in pressure-generating capabilities of the left ventricle in an 83-year-old woman and a 60-year-old man with a similar degree of aortic stenosis is shown. dP/dt = rate of pressure increase. *(Reproduced with permission from Carroll JD, Carroll EP, Felman T, et al: Sex-associated differences in left ventricular function in aortic stenosis of the elderly. Circulation 86:1099, 1992. Copyright 1992 American Heart Association.)*

phase indices, such as ejection fraction and myocardial fiber shortening, should be related to the existing wall tension.

DIASTOLIC PROPERTIES (see also Chap. 15) .

Although ventricular hypertrophy is a key adaptive mechanism to the pressure load imposed by AS, it has an adverse pathophysiological consequence; i.e., it increases diastolic stiffness. As a result, greater intracavitary pressure is required for ventricular filling.[278] [279] [292] Some patients with AS manifest an increase in stiffness of the left ventricle (increased *chamber* stiffness) due simply to increased muscle mass with no alteration in the diastolic properties of each unit of myocardium (normal *muscle* stiffness); others exhibit increases in both chamber and muscle stiffness. This increased stiffness, however produced, contributes to the elevation of ventricular diastolic filling pressure at any level of ventricular diastolic volume[293] [294] and may be responsible for flash pulmonary edema in patients with AS. Diastolic dysfunction may revert toward normal as hypertrophy regresses following relief of AS.[279]

CARDIAC STRUCTURE.

An increase in the total collagen volume of the myocardium and in the orthogonal collagen fiber network in AS has been reported.[295] [296] This likely contributes to the

altered diastolic properties just discussed. An inverse correlation between the left ventricular ejection fraction and myocardial fiber diameter has been reported.[297] Changes in the myocardial ultrastructure in patients with severe AS include unusually large nuclei, loss of myofibrils, accumulation of mitochondria, large cytoplasmic areas devoid of contractile material, and proliferation of fibroblasts and collagen fibers in the interstitial space. The depression of myocardial function that occurs late in the course of the disease may well be related to these morphological alterations. In adults with AS, both myocardial cellular hypertrophy and relative and absolute increases in connective tissue occur.

ISCHEMIA.

In patients with AS, coronary blood flow at rest is elevated in absolute terms but is normal when corrections are made for myocardial mass.[298] There may be inadequate myocardial oxygenation in patients with severe AS, even in the absence of coronary artery disease. The hypertrophied left ventricular muscle mass, the increased systolic pressure, and the prolongation of ejection all elevate myocardial oxygen consumption. The abnormally heightened pressure compressing the coronary arteries may exceed the coronary perfusion pressure, and the shortening of diastole interferes with coronary blood flow,[299] [300] thus leading to an imbalance between myocardial oxygen supply and demand. Myocardial perfusion is also impaired by the relative decrease in myocardial capillary density as myocardial mass increases and by the elevation of left ventricular end-diastolic pressure, which lowers the aortic-left ventricular pressure gradient in diastole (i.e., the coronary perfusion pressure gradient). This underperfusion may be responsible for the development of subendocardial ischemia, especially during tachycardia. Marcus and associates have demonstrated a reduction in the velocity of coronary blood flow during reactive hyperemia in patients with severe AS,[301] and this may correlate with the angina pectoris commonly observed in these patients.

Myocardial ischemia in patients with severe AS and normal coronary arteries may be secondary to high systolic and diastolic stresses caused by inadequate ventricular hypertrophy and the reduced coronary flow reserve just described.[302] [303] Metabolic evidence of myocardial ischemia, i.e., lactate production, can be demonstrated when myocardial oxygen needs are stimulated by exercise or by isoproterenol in patients with AS, even in the absence of coronary artery narrowing.

CLINICAL MANIFESTATIONS

History

In the natural history of adults with AS, a long latent period exists during which there is gradually increasing obstruction and an increase in the pressure load on the myocardium while the patient remains asymptomatic.[304] The cardinal manifestations of acquired AS, which commence most commonly in the fifth or sixth decades of life, are angina pectoris, syncope, exertional dyspnea, and ultimately heart failure.[305]

Angina occurs in approximately two-thirds of patients with critical AS (about half of whom have associated significant coronary artery obstruction).[306] It usually resembles the angina observed in patients with coronary artery disease, in that it is commonly precipitated by exertion and relieved by rest. In patients without coronary artery disease, angina results from the combination of the increased oxygen needs of the hypertrophied myocardium and the reduction of oxygen delivery secondary to the excessive compression of coronary vessels[298] [301] [302] [303] (see Ischemia, just discussed). In patients with coronary artery disease, angina is caused by a combination of the epicardial coronary artery obstruction and the earlier-described oxygen imbalance characteristic of AS. Rarely, angina results from calcium emboli to the coronary vascular bed.[307]

Syncope is most commonly due to the reduced cerebral perfusion that occurs during exertion when arterial pressure declines consequent to systemic vasodilation in the presence of a fixed cardiac output. Syncope has also been attributed to malfunction of the baroreceptor mechanism in severe AS[277] , as well as to a vasodepressor response to a greatly elevated left ventricular systolic pressure during exercise.[308] Premonitory symptoms of syncope are common. Exertional hypotension may also be manifested as "graying out" spells or dizziness on effort. Syncope at rest may be due to transient ventricular fibrillation,[309] from which the patient recovers spontaneously; to transient atrial fibrillation with loss of the atrial contribution to left ventricular filling, which causes a precipitous decline in cardiac output; or to transient atrioventricular block due to extension of the calcification of the valve into the conduction system. Exertional dyspnea with orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema reflect varying degrees of pulmonary venous hypertension. These are relatively late symptoms in patients with AS, and their presence for more than 5 years should suggest the possibility of associated mitral valvular disease.

Gastrointestinal bleeding, either idiopathic or due to angiodysplasia (most commonly of the right colon) or other vascular malformations, occurs more often in patients with calcific AS than in persons without this condition; it may cease after aortic valve replacement.[310] Infective endocarditis is a greater risk in younger patients with milder valvular deformity than in older patients with rocklike calcific aortic deformities. Cerebral emboli resulting in stroke or transient ischemic attacks may be due to microthrombi on thickened bicuspid valves.[311] Calcific AS may cause embolization of calcium to various organs, including the heart, kidneys, and brain. Abrupt loss of vision has been reported when calcific emboli occlude the central retinal artery.[307] [312]

Because cardiac output is usually well maintained for many years in patients with severe AS, marked fatigability, debilitation, peripheral cyanosis, and other clinical manifestations of a low cardiac output are usually not prominent until quite late in the course of the disease. Other late findings in patients with isolated AS include atrial fibrillation, pulmonary hypertension, and systemic venous hypertension. Although AS may be responsible for sudden death, this usually occurs in patients who had previously been symptomatic (see Chap. 26) .

In patients in whom the obstruction remains unrelieved, the prognosis is poor once these symptoms are manifested. Survival curves show that the interval from the onset of symptoms to the time of death is approximately 2 years in patients with heart failure, 3 years in those with syncope, and 5 years in those with angina (Fig. 46-31) .

Physical Examination (Table 46-7)

The arterial pulse characteristically rises slowly and is small and sustained (pulsus parvus et tardus) (see Fig. 4-8 *B*).[313] [314] In the late stage of AS, systolic and pulse pressures are both reduced. However, in patients with mild AS with associated AR and in older patients with an inelastic arterial bed, both systolic and pulse pressures may be normal or even increased. A systolic pressure exceeding 200 mm Hg is rare in patients with critical AS. The anacrotic notch and coarse systolic vibrations are felt most readily in the carotid arterial pulse, producing the so-called carotid shudder. Simultaneous palpation of the apex and carotid arteries reveals a lag in the latter in patients with

Figure 46-31 Natural history of aortic stenosis without operative treatment. *(Reproduced with permission from Ross J Jr, Braunwald E: Aortic stenosis. Circulation 38[Suppl V]:61, 1968. Copyright 1968 American Heart Association.)*

severe AS.[315] Although left ventricular alternans occurs commonly in patients who have AS with left ventricular dysfunction,[316] obstruction of the aortic valve may prevent its recognition in the peripheral arterial pulse. The jugular venous pulse usually shows prominent *a* waves, reflecting reduced right ventricular compliance consequent to hypertrophy of the ventricular septum.[317] With pulmonary hypertension and secondary right ventricular failure and tricuspid regurgitation, *v* or *c-v* waves may become prominent.

The cardiac impulse is sustained and becomes displaced inferiorly and laterally with left ventricular failure. Presystolic distention of the left ventricle (i.e., a prominent precordial *a* wave) is often both visible and palpable. A hyperdynamic left ventricle suggests concomitant aortic and/or mitral regurgitation. A systolic thrill is usually best appreciated when the patient leans forward during full expiration. It is palpated most readily in the second left intercostal space on either side of the sternum or in the suprasternal notch and is frequently transmitted along the carotid arteries. A systolic thrill is quite specific for severe AS.

Rarely, right ventricular failure with systemic venous congestion, hepatomegaly, and edema precedes left ventricular failure. This is probably caused by the so-called Bernheim effect, which results when the hypertrophied ventricular septum bulges into and encroaches on the right ventricular cavity and leads to impairment of right ventricular filling. In such cases, the jugular venous pressure is elevated, and the *a* wave is prominent.

AUSCULTATION (See Table 46-7) .

S_1 is normal or soft and S_4 is prominent, presumably because atrial contraction is vigorous and the mitral valve is partially closed during presystole.[318] S_2 may be single because calcification and immobility of the aortic valve make A_2 inaudible, because P_2 is buried in the prolonged aortic ejection murmur, or because prolongation of left

ventricular systole makes A_2 coincide with P_2 . Paradoxical splitting of S_2 , which suggests associated left ventricular dysfunction, may also occur. In patients with left ventricular failure and secondary pulmonary hypertension, P_2 may become accentuated. When the aortic valve is rigid, which is the usual finding in adults with severe AS, A_2 may be inaudible, but when the valve is flexible, as may occur in patients with congenital AS, A_2 may be snapping and accentuated.

An aortic ejection sound occurs simultaneous with the halting upward movement of the aortic valve (see Fig. 4-15) . Like an audible A_2 , this sound is dependent on mobility of the valve cusps and disappears when they become severely calcified. Thus, it is common in children with congenital AS but is rare in adults with acquired calcific AS and rigid valves. The ejection sound occurs approximately 0.06 second after the onset of S_1 .

The *systolic murmur* of AS is usually late peaking and heard best at the base of the heart but is often well transmitted both along the carotid vessels and to the apex. Cessation of the murmur before A_2 is usually helpful in differentiating it from a pansystolic mitral murmur. However, the systolic murmur may be mistaken for a pansystolic murmur because it may end with S_2 , which represents pulmonic valve closure, whereas the pansystolic murmur is soft or even inaudible. In patients with calcified aortic valves, the systolic murmur is loudest at the base of the heart, but high-frequency components selectively radiate to the apex (the so-called Gallavardin phenomenon [see Fig. 4-24]), where it may actually be more prominent and where it may be mistaken for the murmur of MR. Frequently, there is a

TABLE 46-7 -- DIFFERENTIAL DIAGNOSIS OF AORTIC STENOSIS: PHYSICAL FINDINGS

TYPE OF STENOSIS	MAXIMUM MURMUR AND THRILL	AORTIC EJECTION SOUND	AORTIC COMPONENT OF SECOND SOUND	REGURGITANT DIASTOLIC MURMUR	ARTERIAL PULSE
Acquired nonrheumatic or rheumatic	Second right sternal border to neck; may be at apex in the aged	Uncommon	Decreased or absent	Common	Delayed upstroke; anacrotic notch; ± small amplitude
Hypertrophic subaortic	Fourth left sternal border to apex (± regurgitant systolic murmur at apex)	Rare	Normal or decreased	Very rare	Brisk upstroke, sometimes bisferiens
Congenital valvular	Second right sternal border to neck (along left sternal border in some infants)	Very common in children, disappearing with decrease in valve mobility with age	Normal or increased in children; decreased with decrease in valve mobility with age	Uncommon in children; not uncommon in adults	Delayed upstroke; anacrotic notch; ± small amplitude
Congenital subvalvular	Discrete: like valvular; tunnel: left sternal border	Rare	Not helpful (normal, increased, decreased, or absent)	Almost all	
Congenital supravalvular	First right sternal border to neck and sometimes to medial aspect of right arm; occasionally greater in neck than in chest	Rare	Normal or decreased	Uncommon	Rapid upstroke in right carotid, delayed in left carotid; right arm pulse pressure greater than left

"quiet area" between the base and apex where the murmur is diminished in intensity, supporting the erroneous impression that the apical and basal murmurs have different origins. In general, the more severe the stenosis, the longer the duration of the murmur and the more likely that it peaks later in systole.[320]

Patients with degenerative aortic sclerosis may have severe valvular calcification; however, obstruction may be mild or absent because the commissural fusion characteristic of congenital and rheumatic AS is not present.[92] The nonfused, calcified cusps vibrate freely, resulting in a softer and more musical murmur that is more prominent at the apex than the murmur of congenital or rheumatic AS. High-pitched decrescendo diastolic murmurs secondary to aortic regurgitation are common in many patients with dominant AS.

When the left ventricle fails and the stroke volume falls, the systolic murmur of AS becomes softer; rarely, it disappears altogether. The slow rise in the arterial pulse is more difficult to recognize. Stated simply, with left ventricular failure, the clinical picture changes from typical AS to that of severe left ventricular failure with a low cardiac output. Thus, occult AS may be a cause of intractable heart failure, and critical AS should be ruled out by echocardiography in patients with severe heart failure of unknown cause because operative treatment may be life-saving and may result in substantial clinical improvement.[321]

DYNAMIC AUSCULTATION (see Table 46-4) .

The intensity of the systolic murmur varies from beat to beat when the duration of diastolic filling varies, as in atrial fibrillation or following a premature contraction. This characteristic is helpful in differentiating AS from MR, in which the murmur is usually unaffected. The murmur of valvular AS is augmented by squatting, which increases stroke volume. It is reduced in intensity during the strain of the Valsalva maneuver and when standing, which reduce transvalvular flow.[322] Findings on physical examination including a delay in the carotid upstroke, a loud, long systolic murmur, and a single S_2 all correlate with severe stenosis.[323]

LABORATORY EXAMINATION

ELECTROCARDIOGRAPHY.

The principal ECG change is left ventricular hypertrophy (Fig. 5-19) , which is found in approximately 85 percent of patients with severe AS. The absence of left ventricular hypertrophy does not exclude the presence of critical AS, and the correlation between the absolute ECG voltages in precordial leads and the severity of obstruction is poor in adults but is quite good in children with congenital AS. T wave inversion and ST segment depression in leads with upright QRS complexes are common. ST segment depressions greater than 0.2 mV in patients with AS (left ventricular "strain") suggest that severe ventricular hypertrophy is present. Occasionally, a "pseudoinfarction" pattern is present, characterized by a loss of r waves in the right precordial leads. There is evidence of left atrial enlargement in more than 80 percent of patients with severe, isolated AS. The principal manifestation is prominent late negativity of the P wave in lead V_1 rather than an increased duration in lead II, suggesting hypertrophy rather than dilatation. Atrial fibrillation is an uncommon and late sign of pure AS, and its presence in a patient who does not appear to have end-stage aortic disease should suggest coexisting mitral valvular disease.

The extension of calcific infiltrates from the aortic valve into the conduction system may cause various forms and degrees of atrioventricular and intraventricular block in 5 percent of patients with calcific AS.[324] Such conduction defects are more common in patients who have associated mitral annular calcification.

RADIOLOGICAL FINDINGS.

(See Figs. 8-8 , 8-19 , and 8-20) . Routine radiological examination may be normal in patients with critical AS. The heart is usually of normal size or slightly enlarged, with a rounding of the left ventricular border and apex, unless regurgitation or left ventricular failure is present and causes substantial cardiomegaly. Poststenotic dilatation of the ascending aorta is a common finding. Calcification of the aortic valve is found in almost all adults with hemodynamically significant AS.[325] It is more readily detected on fluoroscopy or echocardiography than on roentgenography. The absence of calcium in the aortic valve region on careful fluoroscopic examination in a patient older than 35 years of age essentially rules out severe valvular AS. The converse is not true, however, and in patients over the age of 65 with degenerative AS, severe calcification of the aortic valve may occur with no or only mild obstruction. The left atrium may be slightly enlarged in patients with severe AS, and there may be radiological signs of pulmonary venous hypertension. However, when left atrial enlargement is marked, the presence of associated mitral valvular disease should be suspected.

ANGIOGRAPHY.

There is some hazard associated with the rapid injection of a large volume of contrast material into a high-pressure left ventricle, and therefore this procedure is usually

not advisable in patients with AS and critical obstruction. Angiographic studies of the left ventricle and aortic valve in these patients are best performed by injecting contrast material into the pulmonary artery and filming in the 30-degree right anterior oblique and 60-degree left anterior oblique projections. These examinations often make it possible to ascertain the number of cusps of the stenotic valve and to demonstrate doming of a thickened valve and a systolic jet.

ECHOCARDIOGRAPHY (see also Chap. 7 and Figs. 7-60 to 7-63) .

The normal range of opening of the aortic valve is 1.6 to 2.6 cm. Two-dimensional transthoracic echocardiography is helpful in detecting valvular calcification, in outlining the valve leaflets, and sometimes in determining the severity of the stenosis by imaging the orifice.[326] The orifice may be more clearly defined by transesophageal echocardiography, which offers a precise short-axis view of the aortic valve.[327] Multiplanar transesophageal echocardiography is particularly useful.[328] Two-dimensional echocardiography is invaluable in detecting associated mitral valve disease and in assessing left ventricular systolic performance, diastolic function, dilatation, and hypertrophy. Doppler echocardiography allows calculation of the left ventricular-aortic pressure gradient[329] using a modified Bernoulli (continuity) equation (see Fig 7-25) . The gradients noninvasively determined by this method correlate well with those determined by left-heart catheterization.[329] [330] Color flow Doppler imaging is helpful in detecting and determining the severity of aortic regurgitation (which coexists in approximately 75 percent of patients with predominant AS) and in estimating pulmonary artery pressure.[331] Indeed, in a large majority of patients the echocardiographic examination provides the information obtained by cardiac catheterization (except for the status of the coronary arteries).[329] Echocardiography has become the most important laboratory technique for evaluating and following patients with AS and selecting them for operation.

NATURAL HISTORY

In contrast to MS, which leads to symptoms almost immediately after its development, patients with severe AS may be asymptomatic for many years despite the presence of severe obstruction.[304] [306] The systolic pressure gradient may exceed 150 mm Hg, and the peak left ventricular systolic pressure may reach approximately 300 mm Hg with relatively little increase in overall heart size on radiological examination and with normal left ventricular end-diastolic and end-systolic volumes.

Patients with severe, chronic AS tend to be free of cardiovascular symptoms until relatively late in the course of the disease. Thus, there is a long latent period during which mortality and morbidity are very low.[51] In Rapaport's report, 40 percent of patients treated medically survived for 5 years and 20 percent for 10 years after diagnosis.[147] In another series of patients with hemodynamically significant valvular AS treated medically, the 5-year survival rate was 64 percent. However, obstruction is progressive and often insidious, with the aortic valve area decreasing by an average of 0.12 cm^2 /year in one study.[331] When symptoms develop, the valve area is, on average, 0.6 cm^2 .[332] Once patients with AS develop angina pectoris or syncope, the average survival is 1 to 3 years[333] [334] [335] (see Fig. 46-31) . In an analysis of elderly patients with severe AS and symptoms of heart failure who declined surgery, 50 percent had died by 18 months of follow-up; the ejection fraction correlated

inversely with survival.[336] Among symptomatic patients with severe AS, the outlook is poorest when the left ventricle has failed and the cardiac output and transvalvular gradient are both low.

Asymptomatic patients have an excellent prognosis.[92] [337] [338] Sudden death, like syncope, in patients with severe AS may be due to cerebral hypoperfusion followed by arrhythmia. Although severe AS is a potentially lethal disease, death (even when sudden) usually occurs in *symptomatic* patients. A number of authors who have followed asymptomatic patients with critical AS have found that sudden death is extremely rare in this group. Of 229 asymptomatic patients with critical AS, only 5 (2 percent) died suddenly (certainly not higher than the mortality from operation).[51] [337]

MANAGEMENT

Medical Treatment

Patients with known severe AS who are asymptomatic should be advised to report promptly the development of any symptoms possibly related to AS. Patients with critical obstruction should be cautioned to avoid vigorous athletic and physical activity. However, such restrictions do not apply to patients with mild obstruction. The need for infective endocarditis prophylaxis should be explained (see Chap 47) . Because of the gradual increase in the severity of obstruction, noninvasive assessment of this finding by Doppler echocardiography should be carried out at intervals. Doppler-derived gradients have been shown to increase by 4 to 8 mm Hg per year.[92] In patients with mild obstruction, this measurement should be repeated every 2 years. In asymptomatic patients with severe obstruction, repeat echocardiography should be carried out every 6 to 12 months, with particular attention to detecting changes in left ventricular function. Exercise stress testing should be avoided in symptomatic patients, but may be carried out in asymptomatic patients to detect limited exercise capacity.

Symptomatic patients with severe AS are usually operative candidates, as medical therapy has little to offer. However, medical therapy may be necessary in patients who are considered to be inoperable (usually because of comorbid conditions that preclude surgery.) Digitalis glycosides are indicated if the ventricular volume is increased or the ejection fraction is reduced. Although diuretics are beneficial when there is abnormal accumulation of fluid, they must be used with caution because hypovolemia may reduce the elevated left ventricular end-diastolic pressure, lower cardiac output, and produce orthostatic hypotension. Betaadrenergic blockers can depress myocardial function and induce left ventricular failure and should be avoided in patients with AS.

Atrial flutter or fibrillation occurs in fewer than 10 percent of patients with severe AS, perhaps because of the late occurrence of left atrial enlargement in this condition. When such an arrhythmia is observed in a patient with AS, the possibility of associated mitral valvular disease should be considered. When atrial fibrillation occurs, the rapid ventricular rate may cause angina pectoris. The loss of the atrial contribution to ventricular filling and a sudden fall in cardiac output may cause serious hypotension. Therefore, atrial fibrillation should be treated promptly, usually with cardioversion, and a search for previously unrecognized mitral valvular disease should be undertaken. Adults with severe AS who are being considered for surgical therapy should undergo coronary arteriography. Left-heart catheterization is also indicated if there is a discrepancy between the clinical picture and the echocardiographic findings.[50]

Surgical Treatment

INDICATIONS FOR OPERATION.

Children.

The indications for surgery, as well as the techniques and results of operation, depend on the patient's age, the type of valvular deformity, and the function of the left ventricle. In children and adolescents with noncalcific congenital AS, who most commonly have bicuspid aortic valves, simple commissural incision under direct vision usually leads to substantial hemodynamic improvement with low risk (i.e., a mortality rate of less than 1 percent) (see Chap. 43) .[339] Therefore, this procedure (or now, more commonly, balloon aortic valvuloplasty) is indicated not only in symptomatic patients but also in asymptomatic children and adolescents with severe AS, which is often defined as a calculated effective orifice less than 0.8 cm^2 or 0.5 cm^2/m^2 body surface area (BSA). Despite the salutary hemodynamic results following this procedure, the valve is not rendered entirely normal anatomically. The turbulent blood flow through the valve may subsequently lead to further deformation, calcification, the development of regurgitation, and restenosis after 10 to 20 years, probably requiring reoperation and valve replacement later.

Adults.

In most adults with calcific AS, satisfactory long-term valvular function cannot usually be restored even by careful sculpturing procedures under direct vision, and valve replacement is the surgical treatment of choice. Aortic valve replacement (AVR) (Fig. 46-32) should, in general, be performed in adults who have hemodynamic evidence of severe obstruction (aortic valve orifice <0.8 to 0.9 cm^2 or <0.5 to 0.6 cm^2/m^2 BSA) and whose symptoms are believed to result from AS. AVR should also be carried out in asymptomatic patients with *progressive* left ventricular dysfunction or a hypotensive response to exercise.[340] Although a prospective randomized controlled study has not been done, the long-term mortality in asymptomatic patients with critical AS and left ventricular dysfunction who undergo operation appears to be lower than that in medically treated patients who do not undergo operation.[51] As prosthetic valves and surgical skills continue to improve, it is likely that patients with severe AS will become candidates for operation at progressively earlier stages in the natural history of their disease.[340A] At the present time, however, I do *not* recommend prophylactic replacement of a critically narrow calcific aortic valve in *asymptomatic* adults unless they have progressive left ventricular dysfunction.

AVR is also indicated in patients with severe stenosis who are undergoing another cardiovascular operation (e.g., coronary artery bypass grafting or surgery on the aorta or another heart valve).[51] Surgical risk is higher in patients with impaired left ventricular function[340] (EF < 35 percent). However, since their prognosis is very poor without operation and some patients even in this group have clinical and functional recovery following AVR,[341] [341A] the procedure should generally be offered to

these patients. Even octogenarians with left ventricular dysfunction can have improved survival after AVR.[342] [343] [343A] Exceptions are patients with advanced congestive heart failure or left ventricular dysfunction that can be related to previous myocardial infarction.

RESULTS.

Successful replacement of the aortic valve results in substantial clinical and hemodynamic improvement in patients with AS, aortic regurgitation, or combined lesions.[343] In patients without frank left ventricular failure, the operative risk ranges from 2 to 5 percent in most centers, and in patients under 70 years of age, the operative risk has been reported to be as low as 1 percent.[344] The Society of Thoracic Surgeons National Database Committee reported an overall operative mortality rate of 4.3 percent in 26, 317 patients undergoing isolated AVR, 8.0 percent in 22,713 patients undergoing AVR and coronary artery bypass

Figure 46-32 Interrupted suture technique for aortic valve replacement. *A,* The aortic valve is excised, leaving 1 or 2 mm of annular tissue as a sewing cuff. *B,* Pledgetted Tyeron mattress sutures (2-0) are placed with the pledget on the aortic side. Sutures are placed in the aortic ring and passed directly onto the prosthetic valve sewing ring held at a distance. *C,* After all sutures are placed, the valve is lowered in place and the sutures tied. The valve is then inspected for proper function and fit. *(From Albertucci M, Karp RB: Prosthetic valve replacement. In Al-Zaibag M, Duran CMG [eds]: Valvular Heart Disease. New York, Marcel Dekker, 1994, pp 601-634.)*

grafting, 7.4 percent in 938 patients undergoing AVR and repair of another valve, and 9.7 percent in 1723 patients undergoing AVR and aortic aneurysm repair[104] (see Table 46-2) .

Risk factors causing a higher mortality rate include a high NYHA class, impairment of left ventricular function, advanced age, and the presence of associated coronary artery disease. The 10-year actuarial survival rate of hospital survivors in surgically treated patients is approximately 85 percent.[345] [345A] Risk factors for late death include higher preoperative NYHA class, advanced age, concomitant untreated coronary artery disease, preoperative impaired left ventricular function, preoperative ventricular arrhythmias, and associated significant aortic regurgitation.

Symptoms of pulmonary congestion (exertional dyspnea) and of myocardial ischemia (angina pectoris) are relieved in almost every patient. Hemodynamic results of AVR are also impressive; elevated end-diastolic and end-systolic volumes show significant reduction. Impaired ventricular performance returns to normal more frequently in patients with AS than in those with aortic or mitral regurgitation. Diastolic function is improved as well.[278] [279] However, the finding that the strongest predictor of postoperative left ventricular dysfunction is preoperative dysfunction[346] [347] suggests that patients should, if possible, be operated on *before* left ventricular function becomes seriously impaired. The increased left ventricular mass is reduced toward (but not to) normal within 18 months after AVR in patients with AS.[348] [349] When patients were restudied 5 years postoperatively, left ventricular mass usually had returned to normal.[350] [350A] Myocyte hypertrophy regresses as well. Diastolic dysfunction returns to normal long after systolic dysfunction.[351]

When operation is carried out in patients with critical AS, frank left ventricular failure, a depressed ejection fraction, or a low cardiac output (and hence a reduced transaortic pressure gradient[351A] [351B]), the operative risk is higher, and the mortality rate ranges from 8 to 20 percent, depending on the skill of the surgical team and the severity of heart failure.[341A] Obviously, performing surgery before heart failure develops is desirable, but emergency operation, even in patients with heart failure, is sometimes life-saving. In view of the extremely poor prognosis of such patients who are treated medically, unless serious comorbid conditions exist that preclude surgery, there is usually little choice but to advise immediate mechanical relief of obstruction, i.e., balloon angioplasty (see below) or urgent AVR. Since many symptomatic patients with calcific AS are elderly, particular attention must be directed to the adequacy of hepatic, renal, and pulmonary functions. However, the results of AVR are often quite satisfactory in patients older than 70 or even 80 years of age.[352] Therefore, advanced age per se, while adding to the risk, should not be considered a contraindication to operation.

In patients with AS and obstructive coronary artery disease (a relatively common combination), AVR and myocardial revascularization should be performed together.[353] [353A] Although the risk of AVR is increased when accompanied by coronary artery bypass grafting (see Table 46-2) ,[104] the surgical risk increases even more when severe coronary artery disease is left untreated. The ability to avoid serious myocardial ischemia in the perioperative period is a major factor that has served to reduce operative mortality in these patients. Characteristics of patients that have been shown to increase the risk of AVR, as reported in different series, are shown in Table 46-8 .

There has been increasing interest in performing AVR through a very small incision, generally a transverse sternotomy, so-called "minimally invasive surgery." Although the advantages (shorter hospital stay, less tissue damage, better cosmetic results) are clear, the procedure is technically demanding and the mortality rate may actually be higher than when a standard approach is employed.[354] [354A]

BALLOON AORTIC VALVULOPLASTY (See alsoChap. 38)

Balloon aortic valvuloplasty (BAV) represents an increasingly attractive alternative to aortic valvotomy in children, adolescents, and young adults with congenital noncalcific AS (see Chap. 43) ,[355] [356] but its value is limited in adults with calcific AS. A series of balloon dilation catheters are advanced along a guidewire positioned at the left ventricular apex. Fracture of calcified nodules, separation of fused commissures, and stretching of the aortic valve ring are responsible for the relief of obstruction.[355] [357] [358] Although the response of adult patients with calcific AS varies considerably, BAV initially results in relief of obstruction in most patients[359] [360] [361] [362] (Fig. 46-33) . The valve area in these patients initially increased from 0.5 to 0.8 cm^2 , and the mean transvalvular gradient declined from approximately 55 to 29 mm Hg. Left ventricular ejection fraction tends to rise in patients with depressed left ventricular function who undergo BAV. In a report of a multicenter registry involving 674 seriously ill, elderly patients (average age 78

years) treated at 24 centers, the procedural mortality rate was 3 percent, the 30-day mortality rate was 14 percent, and the one-year mortality rate was 45 percent. Better survival was seen in patients with higher preoperative pressure gradients, in those with better preserved left ventricular systolic function, and in women. In addition to the procedural mortality, another 6 percent of patients developed serious complications such as myocardial perforation, myocardial infarction, and severe aortic regurgitation.[363]

The major disadvantage of BAV in adults with critical calcified AS is restenosis due to scarring, which occurs in about 50 percent of patients within 6 months.

Symptoms lessen in severity in the majority of patients but recur in approximately 30 percent by 6 months.

Although the overall intermediate-term results (6 to 12 months) of BAV have been disappointing, largely because of restenosis, the procedure does have a role in the management of severe calcific AS in patients who are not surgical candidates. Indications include: (1) patients with cardiogenic shock due to critical AS,[364] (2) patients with critical AS who require an urgent noncardiac operation, (3) patients with severe heart failure who are at extremely high operative risk as a "bridge" to AVR, (4) pregnant women with critical AS,[365] (5) patients with severe comorbid conditions that preclude surgery, and (6) patients with critical AS who refuse surgical treatment. However, in adults with calcified AS, BAV is *not* a substitute for surgery (as balloon mitral valvuloplasty may be in patients with MS [see p. 1651]).

Aortic Regurgitation

ETIOLOGY AND PATHOLOGY

Aortic regurgitation (AR) may be caused by primary disease of the aortic valve leaflets and/or the wall of the aortic root (Fig. 46-34) . Among patients with *pure* AR who undergo valve replacement, the percentage with aortic root disease has been increasing steadily during the past few decades and now accounts for more than 50 percent of all such patients.[262]

Valvular Disease

Rheumatic fever is a common cause of primary disease of the aortic valve that leads to regurgitation[92] [366] (Fig. 46-35) . The cusps become infiltrated with fibrous tissues and retract, a process that prevents cusp apposition during diastole and usually leads to regurgitation into the left ventricle through a defect in the center of the valve.[5] The associated fusion of the commissures may restrict the opening of the valve, resulting in combined AS and AR; some associated mitral valve involvement is also common. Other primary valvular causes of AR include calcific AS in the elderly, in which some degree (usually mild) of AR is present in 75 percent of patients; *infective endocarditis* (see Chap. 47) , in which the infection may destroy or cause perforation of a leaflet, or the vegetations may interfere with proper coaptation of the cusps; and *trauma* that results in a tear of the ascending aorta, in which loss of commissural support can cause prolapse of an aortic cusp. Although the most common complication of a congenitally *bicuspid valve* in adults is stenosis, incomplete closure and/or prolapse of a bicuspid valve may also cause isolated regurgitation or a combination of stenosis and regurgitation.[367] [368] [369] Progressive AR may occur in patients with a large ventricular septal defect as well as in patients with membranous subaortic stenosis (see Chap. 43) and as a complication of radiofrequency catheter ablation.[370] Progressive regurgitation may also occur in patients with myxomatous proliferation of the aortic valve.[371] An increasingly common cause of valvular AR is structural deterioration of a bioprosthetic valve (see p. 1701).

Less common causes of AR include various forms of congenital AR, such as unicommissural and quadricuspid valves, or rupture of a congenitally fenestrated valve,[372] particularly in the presence of hypertension.[373] Other less common

Figure 46-34 Diagram of various causes of pure aortic regurgitation. *(From Waller BF: Rheumatic and nonrheumatic conditions producing valvular heart disease. In Frankl WS, Brest AN [eds]: Cardiovascular Clinics. Valvular Heart Disease: Comprehensive Evaluation and Management. Philadelphia, FA Davis Co, 1986, pp 30-31.)*

causes of AR occur in association with systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis,[374] Jaccoud arthropathy, Takayasu disease, Whipple disease,[375] Crohn disease, [376] and, in the past, use of certain anorectic drugs. Isolated congenital AR is an uncommon lesion on necropsy studies, but, when present, is usually associated with a bicuspid valve.[377]

Aortic Root Disease (See also Chap. 40)

AR secondary to marked dilatation of the ascending aorta is now more common than primary valve disease in patients undergoing AVR for pure AR.[262] The conditions responsible for aortic root disease include age-related (degenerative) aortic dilatation, cystic medial necrosis of the aorta (either isolated or associated with classic Marfan syndrome), aortic dissection, osteogenesis imperfecta, syphilitic aortitis, ankylosing spondylitis, the Behcet syndrome, psoriatic arthritis, arthritis associated with ulcerative colitis, relapsing polychondritis, the Reiter syndrome, giant cell arteritis, and systemic hypertension,[378] [379] [380] [381] as well as the ingestion of some appetite suppressant drugs.[381A]

When the aortic annulus becomes greatly dilated, the aortic leaflets separate, and AR may ensue. Dissection of the diseased aortic wall may occur and aggravate the AR. Dilatation of the aortic root may also have secondary effects on the aortic valve because dilatation causes tension and bowing of the individual cusps, which may thicken, retract, and become too short to close the aortic orifice. This leads to intensification of the AR, further dilating the ascending aorta and thus leading to a vicious circle in which, as is the case for MR, "regurgitation begets regurgitation."

AR, regardless of its cause, produces dilatation and hypertrophy of the left ventricle, dilatation of the mitral valve ring, and sometimes hypertrophy and dilatation of the left atrium. Endocardial pockets frequently develop in the left ventricular cavity at sites of impact of the regurgitant jet.

Figure 46-35 Chronic rheumatic aortic regurgitation with cuspal fibrosis, thickening, and retraction, with a jet lesion consisting of endocardial fibrosis (large arrow) and a "pocket" (small arrow) below the valve. Warty, small vegetations resulting from acute rheumatic fever are on the aortic valve edge, the aortic and mitral valve leaflets, and the chordae tendinae (open arrow). *(From Rozich JD, et al: Mitral valve replacement with and without chordal preservation in patients with chronic mitral regurgitation: Mechanisms for differences in postoperative ejection performance. Circulation 86:7718, 1992.)*

PATHOPHYSIOLOGY (Fig. 46-36)

In contrast to MR, in which a fraction of the left ventricular stroke volume is ejected into the low-pressure left atrium, in AR the entire left ventricular stroke volume is ejected

Figure 46-36 Pathophysiology of aortic regurgitation. Aortic regurgitation results in an increased left ventricular (LV) volume, increased stroke volume, increased aortic (Ao) systolic pressure, and decreased effective stroke volume. Increased LV volume results in an increased LV mass, which may lead to LV dysfunction and failure. Increased LV stroke volume increases systolic pressure and prolongation of left ventricular ejection time (LVET). Increased LV systolic pressure results in a decrease in diastolic time. Decreased diastolic time (myocardial perfusion time), diastolic aortic pressure, and effective stroke volume reduce myocardial O_2 supply. Increased myocardial O_2 consumption and decreased myocardial O_2 supply produce myocardial ischemia, which further deteriorates LV function (
= increased,
= decreased). *(From Boudoulas H, Gravanis MB: Valvular heart disease. In Gravanis MB: Cardiovascular Disorders: Pathogenesis and Pathophysiology. St. Louis, CV Mosby Co, 1993, p 64.)*

Figure 46-37 Pressure curves obtained from a 63-year-old man with symptoms of left ventricular failure and a loud decrescendo diastolic murmur. The femoral arterial (FA) pressure tracing demonstrates a widened pulse pressure of 115 mm Hg and equalization with left ventricular (LV) pressure late in diastole. The LV pressure curve exhibits a steady pressure increase throughout diastole, culminating in a markedly elevated end-diastolic pressure of 45 mm Hg. These findings are indicative of severe aortic regurgitation.

into a high-pressure chamber, i.e., the aorta (although the low aortic diastolic pressure does facilitate ventricular emptying during early systole). In MR, especially acute MR, the reduction of wall tension (i.e., reduced afterload) allows more complete systolic emptying; in AR the increase in left ventricular end-diastolic volume (i.e., increased preload) provides hemodynamic compensation.[382] [383]

Figure 46-38 Left ventricular (LV) diastolic pressure-volume (P-V) curve relationships: effects of chronic valve regurgitation. When the AR is mild to moderate, the LV end-diastolic volume (LVEDV) is increased moderately, the LV diastolic P-V curve is moved to the right (curve B) of normal (curve A) and the LV end-diastolic pressure (LVEDP) is usually normal. In severe AR, the LV diastolic P-V curves are moved to the right (curves C and D). If the LV systolic pump function is normal, the LVEDV can be quite large without significant elevation of LVEDP (curve C). However, if the LVEDV increases further, the LVEDP will be increased. If LV systolic pump dysfunction supervenes, the LV diastolic P-V curve relationships are moved even further to the right (curve D) with quite marked LV dilatation and increases in LVEDP. *(From Rahimtoola SH: Aortic valve regurgitation. In Rahimtoola SH (ed): Valvular Heart Disease. Atlas of Heart Diseases. Vol. 11. Braunwald E, series ed. Philadelphia, Current Medicine, 1997, pp 7.1-7.26 Adapted from Rahimtoola SH: Management of heart failure in valve regurgitation. Clin Cardiol 15(Suppl I):322-327, 1992.)*

Severe AR may occur with a normal effective forward stroke volume and a normal ejection fraction (forward plus regurgitant stroke volume/end-diastolic volume), together with an elevated left ventricular end-diastolic volume, pressure, and stress[384] (Fig. 46-37) . In accord with Laplace's law (which indicates that wall tension is related to the product of the intraventricular pressure and radius divided by wall thickness), left ventricular dilatation also increases the left ventricular systolic tension required to develop any level of systolic pressure. The volume overload leads to eccentric hypertrophy, with replication of sarcomeres in series and elongation of myocytes and myocardial fibers. In compensated AR, there is sufficient wall thickening so that the ratio of ventricular wall thickness to cavity radius remains normal. This maintains or returns end-diastolic wall stress to normal levels.[385] AR contrasts with AS, in which there is pressure overload (concentric) hypertrophy with replication of sarcomeres largely in parallel and an increased ratio of wall thickness to radius. In AR, left ventricular mass is usually greatly increased, often to levels even higher than in isolated AS,[276] and sometimes exceeding 1000 g. As AR persists and increases in severity over time, wall thickening fails to keep pace with the hemodynamic load and end-systolic wall stress rises.[386] [387] At this point, the ejection fraction falls.

Patients with severe chronic AR have the largest end-diastolic volumes of those with any form of heart disease (resulting in so-called cor bovinum). However, end-diastolic pressure is not uniformly elevated (i.e., left ventricular compliance is often increased Fig. 46-38).[388]

In the more severe cases of AR, the regurgitant flow may exceed 20 liters/min, so that the total left ventricular output at rest approaches 25 liters/min, a level that can be achieved acutely only by a trained endurance runner during maximal exercise. Thus, the adaptive response to gradually increasing, chronic AR permits the ventricle to function as an effective high-compliance pump, handling a large stroke volume, often with little increase in filling pressure. During exercise, peripheral vascular resistance declines, and with an increase in heart rate, diastole shortens and the regurgitation per beat decreases,[389] [390] facilitating an increment in effective (forward) cardiac output without substantial increases in end-diastolic volume and pressure. The ejection fraction and related ejection phase indices are often within normal limits, both at rest and during exercise, even though myocardial function, as reflected in the slope of the end-systolic pressure-volume relationship, is depressed.

LEFT VENTRICULAR FUNCTION.

As the left ventricle decompensates, interstitial fibrosis increases, compliance declines, and left ventricular end-diastolic pressure and volume rise (Fig. 46-39) . In advanced stages of decompensation, left atrial, pulmonary artery wedge, pulmonary arterial, right ventricular, and right atrial pressures rise and the effective (forward) cardiac output falls, at first during exercise[390] and then at rest. The normal decline in end-systolic volume or the rise in ejection fraction fails to occur during exercise. Symptoms of heart failure, particularly those secondary to pulmonary congestion, develop.

MYOCARDIAL ISCHEMIA.

When *acute* AR is induced experimentally, myocardial oxygen requirements rise substantially,[132] secondary to an increase in wall tension. In patients with chronic, severe AR, total myocardial oxygen requirements are also augmented by the increase in left ventricular mass. Because the major portion of coronary blood flow occurs during diastole, when arterial pressure is lower than normal

Figure 46-39 Hemodynamics of aortic regurgitation. *A,* Normal conditions. *B,* The hemodynamic changes that occur in severe acute aortic regurgitation. Although total stroke volume is increased, forward stroke volume is reduced. Left ventricular end-diastolic pressure rises dramatically. *C,* Hemodynamic changes occurring in chronic compensated aortic regurgitation are shown. Eccentric hypertrophy produces increased end-diastolic volume, which permits an increase in total as well as forward stroke volume. The volume overload is accommodated and left ventricular filling pressure is normalized. Ventricular emptying and end-systolic volume remain normal. *D,* In chronic decompensated aortic regurgitation, impaired left ventricular emptying produces an increase in end-systolic volume and a fall in ejection fraction, total stroke volume, and forward stroke volume. There is further cardiac dilatation and re-elevation of left ventricular filling pressure. *E,* Immediately following valve replacement, preload estimated by end-diastolic volume decreases, as does filling pressure. End-systolic volume also is decreased, but to a lesser extent. The result is an initial fall in ejection fraction. Despite these changes, elimination of regurgitation leads to an increase in forward stroke volume. AoP = aortic pressure; EDV = end-diastolic volume; ESV = end-systolic volume; EF = ejection fraction; LVEDP = left ventricular end-diastolic pressure; RF = regurgitant fraction. *(From Carabello BA: Aortic regurgitation: Hemodynamic determinants of prognosis. In Cohn LH and DiSesa VJ [eds]: Aortic Regurgitation: Medical and Surgical Management. New York, Marcel Dekker, Inc, 1986.)*

in AR, coronary perfusion pressure is reduced. Studies in experimentally induced AR have shown a reduction in coronary flow reserve with a change in forward coronary flow from diastole to systole.[391] The result--a combination of increased oxygen demand and reduced supply--sets the stage for the development of myocardial ischemia, especially during exercise.[392] Thus, patients with severe AR exhibit a reduction of coronary reserve,[393] which may be responsible for myocardial ischemia, which in turn may play a role in the deterioration of left ventricular function.

Acute Aortic Regurgitation

Acute AR is caused most commonly by infective endocarditis, aortic dissection, or trauma. In contrast to the pathophysiological events in chronic AR just described, in which the left ventricle is able to adapt to the increased hemodynamic load, in acute AR the regurgitant volume fills a ventricle of normal size that cannot accommodate the combined large regurgitant volume and inflow from the left atrium.[394] Because the ability of total stroke volume to rise acutely is limited, forward stroke volume declines. The sudden increase in left ventricular filling causes the left ventricular diastolic pressure to rise rapidly above left atrial pressure during early diastole,[382] causing the mitral valve to close prematurely in diastole (Fig. 46-40) . [395] Premature closure of the mitral valve protects the pulmonary venous bed from backward transmission of the greatly elevated end-diastolic pressure unless it is accompanied by diastolic mitral regurgitation.[396] Premature closure of the mitral valve, together with tachycardia that also shortens diastole, reduces the time interval during which the mitral valve is open. Left ventricular and aortic *systolic* pressures exhibit little change. Because aortic diastolic pressure cannot decline below the elevated left ventricular end-diastolic pressure, the systemic arterial pulse pressure widens relatively little.

CLINICAL MANIFESTATIONS

History

CHRONIC AORTIC REGURGITATION.

In patients with chronic, severe AR, the left ventricle gradually enlarges while the patient remains asymptomatic or almost so.[397] Symptoms of reduced cardiac reserve or myocardial ischemia develop, most often in the fourth or fifth decade and usually only *after* considerable cardiomegaly and myocardial dysfunction have occurred. The principal complaints of exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea usually develop gradually. Angina pectoris is prominent late in the course; nocturnal angina may be troublesome and is often accompanied by diaphoresis that occurs when the heart rate slows and arterial diastolic pressure falls to extremely low levels. Patients with severe AR often complain of an uncomfortable awareness of the heartbeat, especially on lying down, and disagreeable thoracic pain

due to pounding of the heart against the chest wall. Tachycardia, occurring with emotional stress or exertion, may cause troubling palpitations and head pounding. Premature ventricular contractions are particularly distressing because of the great heave of the volume-loaded left ventricle during the postpremature beat. These complaints may be present for many years before symptoms of overt left ventricular dysfunction develop.

ACUTE AORTIC REGURGITATION.

In light of the limited ability of the left ventricle to tolerate acute, severe AR, patients with this valvular lesion often develop clinical manifestations of sudden cardiovascular collapse, including weakness, severe dyspnea, and hypotension secondary to the reduced stroke volume and elevated left atrial pressure.

Figure 46-40 Schematic representations contrasting the hemodynamic, echocardiographic (ECHO), and phonocardiographic (PCG) manifestations of acute severe (*A*) and chronic severe (*B*) aortic regurgitation. Ao = aorta; LV = left ventricle; LA = left atrium; EDP = end-diastolic pressure; f = flutter of anterior mitral valve leaflet; AML = anterior mitral valve leaflet; PML = posterior mitral valve leaflet; SM = systolic murmur; DM = diastolic murmur; C = closure point of mitral valve. *(From Morganroth J et al: Acute severe aortic regurgitation. Ann Intern Med 87:225, 1977.)*

Physical Examination (See also Chap. 4)

In patients with chronic, severe AR, the head frequently bobs with each heartbeat (*de Musset sign*), [398] and the pulses are of the "water-hammer" or collapsing type with abrupt distention and quick collapse (*Corrigan pulse*). The arterial pulse is often prominent and can be best appreciated by palpation of the radial artery with the patient's arm elevated. A *bisferiens pulse* may be present (see Fig. 4-8 *C*) and is more readily recognized in the brachial and femoral arteries than in the carotid arteries. A variety of auscultatory findings provide confirmation of a wide pulse pressure. *Traube sign* (also known as "pistol shot sounds"[399]) refers to booming systolic and diastolic sounds heard over the femoral artery, *Muller sign* consists of systolic pulsations of the uvula, and *Duroziez sign* consists of a systolic murmur heard over the femoral artery when it is compressed proximally and a diastolic murmur when it is compressed distally. Capillary pulsations, i.e., *Quincke sign,* can be detected by pressing a glass slide on the patient's lip or by transmitting a light through the patient's fingertips.

Systolic arterial pressure is elevated, and diastolic pressure is abnormally low. *Hill sign* refers to popliteal cuff systolic pressure exceeding brachial cuff pressure by more than 60 mm Hg. Korotkoff sounds often persist to zero even though intraarterial pressure rarely falls below 30 mm Hg. The point of change in Korotkoff sounds, i.e., the muffling of these sounds in phase IV, correlates with the diastolic pressure. As heart failure develops, peripheral vasoconstriction may occur and arterial diastolic pressure may rise. This finding should not be interpreted as the presence of mild AR.

The apical impulse is diffuse and hyperdynamic and is displaced laterally and inferiorly; there may be systolic retraction over the parasternal region. A rapid ventricular filling wave is often palpable at the apex (as is a *systolic* thrill), at the base of the heart or suprasternal notch, and over the carotid arteries, resulting from the augmented stroke volume. In many patients, a carotid shudder is palpable or may be recorded.[400]

CHRONIC AORTIC REGURGITATION.

The PR interval may be prolonged, causing a soft S_1 . A_2 may be normal or accentuated when AR is due to disease of the aortic root, but is soft or absent when the valve is causing AR. P_2 may be obscured by the early diastolic murmur. Thus, S_2 may be absent or single or exhibit narrow or paradoxical splitting. A systolic ejection sound, presumably related to abrupt distention of the aorta by the augmented stroke volume, is frequently audible. An S_3 gallop correlates with an increased left ventricular end-diastolic volume. Its development may be a sign of impaired left ventricular function, which is useful in identifying patients with severe regurgitation who are candidates for surgical treatment.

The aortic regurgitant murmur, the principal physical finding of AR,[401] is one of high frequency that begins immediately after A_2 . It may be distinguished from the murmur of pulmonic regurgitation by its earlier onset, i.e., immediately after A_2 rather than after P_2 , and usually by the presence of a widened pulse pressure. The murmur is heard best with the diaphragm of the stethoscope while the patient is sitting up and leaning forward, with the breath held in deep exhalation. In severe AR, the murmur reaches an early peak and then has a dominant decrescendo pattern throughout diastole.

The severity of the regurgitation correlates better with the *duration* than with the *intensity* of the murmur. In mild AR, the murmur may be limited to early diastole and is typically high pitched and blowing. In severe AR, the murmur is holodiastolic and may have a rough quality. When the murmur is musical ("cooing dove" murmur), it usually signifies eversion or perforation of an aortic cusp. In patients with severe AR and left ventricular decompensation, equilibration of aortic and left ventricular pressures in late diastole (see Fig. 46-40) abolishes this component of the regurgitant murmur. When regurgitation is caused by primary valvular disease, the diastolic murmur is heard best along the left sternal border in the 3rd and 4th intercostal spaces. However, when it is due mainly to dilatation of the ascending aorta, the murmur is often more readily audible along the right sternal border.

A mid- and late diastolic apical rumble, the *Austin Flint murmur,* is common in severe AR and may occur in the presence of a normal mitral valve. This murmur appears to be created by rapid antegrade flow across a mitral orifice that is narrowed by the rapidly rising left ventricular diastolic pressure caused by severe aortic reflux impinging on the anterior leaflet of the mitral valve.[402] The Austin Flint murmur may be difficult to differentiate from that due to MS, but the presence of an opening snap and a loud S_1 in MS and the absence of these findings in AR are helpful clues. As the left ventricular end-diastolic pressure rises, the Austin Flint murmur commences and terminates earlier, and in acute AR with premature diastolic closure of the mitral valve, the presystolic portion of the Austin Flint murmur is eliminated. A short midsystolic murmur, caused by the increased ejection rate and stroke volume, may be audible at the base of the heart and transmitted to the carotid vessels. It may be higher pitched and less rasping than the murmur of AS but is often accompanied by a systolic thrill.

DYNAMIC AUSCULTATION.

The diastolic murmur of AR may be accentuated when the patient sits up and leans forward or by interventions that raise the arterial pressure, such as squatting or isometric exercise. The intensity of the murmur is reduced by interventions that lower the systolic pressure, such as inhalation of amyl nitrite or the strain of the Valsalva maneuver. The Austin Flint murmur, like the murmur of AR, is augmented by isometric exercise and administration of vasopressors and is reduced by amyl nitrite inhalation.[403]

ACUTE AORTIC REGURGITATION.

Patients with acute, severe AR appear gravely ill, with tachycardia, severe peripheral vasoconstriction and cyanosis, and sometimes pulmonary congestion and edema.[394] [404] The peripheral signs of AR are often not impressive and certainly not as dramatic as in patients with chronic AR. Duroziez murmur, Traube sign over the peripheral arteries, and bisferiens pulses are usually *absent* in acute AR. The normal or only slightly widened pulse pressure may lead to serious underestimation of the severity of the valvular lesion. The left ventricular impulse is normal or nearly so, and the rocking motion of the chest characteristic of chronic AR is not apparent. S_1 may be soft or absent because of premature closure of the mitral valve,[405] and the sound of mitral valve closure in mid- or late diastole is occasionally audible. However, closure of the mitral valve may be incomplete, and diastolic mitral regurgitation may occur.[395] Evidence of pulmonary hypertension, with an accentuated P_2 , S_3 , and S_4 , is frequently present. The early diastolic murmur of acute AR is lower pitched and shorter than that of chronic AR, because as left ventricular diastolic pressure rises, the (reverse) pressure gradient between the aorta and the left ventricle is rapidly reduced. A systolic murmur is common, resulting in "to and fro" sounds. The Austin Flint murmur, if present, is brief and ceases when left ventricular pressure exceeds left atrial pressure in diastole.

LABORATORY EXAMINATION

ELECTROCARDIOGRAM.

Chronic, severe AR results in left axis deviation and a pattern of left ventricular diastolic volume overload, characterized by an increase in initial forces (prominent Q waves in leads I, aVL, and V_3 through V_6) and a relatively small *r* wave in lead V_1 (Fig. 46-41) . With the passage of time, these initial forces diminish, but the

Figure 46-41 Atrial fibrillation and left ventricular hypertrophy in a patient with chronic AR. The most prominent features are the gross increase in precordial voltage (RV_5 +SV_2 =70 mm) and the marked anterolateral ST/T wave changes (leads I, aVL, and V_4 through V_6). The patient had aortic regurgitation and normal coronary arteries and was not taking digitalis. (Normal standardization, i.e., 1 mV=10 mm.) *(From Hall RJ, Julian DG: Diseases of the Cardiac Valves. New York, Churchill Livingstone, 1989, p 39.)*

total QRS amplitude increases (Fig. 5-20) . The T waves may be tall and upright in the left precordial leads early in the course, but, more commonly they are inverted, with ST segment depressions. A left ventricular "strain" pattern correlates with the presence of dilatation and hypertrophy.[92] [406] Left intraventricular conduction defects occur late in the course and are usually associated with left ventricular dysfunction. The ECG is not an accurate predictor of the severity of AR or cardiac weight. When AR is caused by an inflammatory process, prolongation of the PR interval may be present.[407]

In *acute* AR, the ECG may or may not show left ventricular hypertrophy, depending upon the severity and duration of the regurgitation. However, nonspecific ST segment and T wave changes are common.

RADIOLOGICAL FINDINGS (See Figs. 8-4 , 8-8 , and 8-24.)

Cardiac size is a function of the duration and severity of regurgitation and the state of left ventricular function. In acute AR, there may be minimal cardiac enlargement, but marked enlargement is a common finding in chronic AR. Typically, the left ventricle enlarges in an inferior and leftward direction, causing a significant increase in the long axis (see Fig. 8-24) but sometimes causing little or no increase in the transverse diameter of the heart. Calcification of the aortic valve is uncommon in patients with pure AR but is often present in patients with combined AS and AR. Distinct left atrial enlargement in the absence of heart failure suggests associated mitral valve disease. Dilatation of the ascending aorta is usually more marked than in AS and may involve the entire aortic arch, including the aortic knob. Severe aneurysmal dilatation of the aorta suggests that aortic root disease (e.g., the Marfan syndrome, cystic medial necrosis, or annuloaortic ectasia) is responsible for the AR. Linear calcifications in the wall of the ascending aorta are seen in syphilitic aortitis but are nonspecific and are observed in degenerative disease as well.

For angiographic assessment of AR, contrast material should be injected rapidly (i.e., 25 to 35 ml/sec) into the aortic root, and filming should be carried out in the right and left anterior oblique projections. Opacification may be improved by filming during a Valsalva maneuver. In acute AR, there is only a slight increase in ventricular end-diastolic volume, but with the passage of time both the end-diastolic volume and the thickness of the ventricular wall increase, usually in parallel.

ECHOCARDIOGRAPHY (See Figs. 7-64 to 7-67).

This technique is helpful in identifying the cause of AR. The echocardiogram may show thickening of the valve cusps, prolapse of the valve, a flail leaflet, vegetations, or dilatation of the aortic root.[379] Two-dimensional studies are useful for the measurement of left ventricular end-diastolic and end-systolic dimensions, volumes, shortening fraction, ejection fraction, and mass. These measurements, when made serially, are of great value in selecting the optimal time for surgical intervention (see p. 1688). Although transthoracic imaging is usually satisfactory, transesophageal echocardiography often provides more detail.

In acute AR, the echocardiogram reveals a reduction in amplitude of the opening movement, premature closure and delayed opening of the mitral valve.[408] Left ventricular end-diastolic dimensions are not markedly increased, and fractional shortening is normal. This contrasts with the findings in chronic AR, in which end-diastolic dimensions and wall motion are increased. Occasionally, with equilibration of aortic and left ventricular pressures in diastole, premature opening of the aortic valve may be detected.[409]

High-frequency fluttering of the anterior leaflet of the mitral valve during diastole is an important echocardiographic finding in both acute and chronic AR; however, it does not develop when the mitral valve is rigid, as occurs with rheumatic involvement. This sign, which, unlike the Austin Flint murmur, occurs even in mild AR, results from the movement imparted to the anterior leaflet of the mitral valve by the jet of blood regurgitating from the aorta.

Doppler echocardiography and color flow Doppler imaging are the most sensitive and accurate noninvasive techniques in the assessment of AR.[410] [411] [412] [413] [413A] They readily detect mild degrees of AR that may be inaudible on physical examination. Both the aortic regurgitant orifice size and the aortic regurgitant flow can be estimated. Serial studies permit determination of the progression of regurgitation and its effect on the left ventricle.

RADIONUCLIDE IMAGING (See Chap. 9) .

Radionuclide angiography provides an accurate noninvasive assessment of the severity of AR by allowing determination of the regurgitant fraction and of the left ventricular/right ventricular stroke volume ratio.[414] This technique is nonspecific because the ratio is increased by the presence of associated MR and reduced by tricuspid or pulmonary regurgitation. However, in the absence of these complicating lesions, a left ventricular/right ventricular stroke volume ratio of 2.0

---

or more denotes severe AR. Radionuclide angiography is also of value in the assessment of left ventricular function in patients with AR.[415] Serial measurements are useful in the early detection of deterioration of left ventricular function.

MAGNETIC RESONANCE IMAGING (see Fig. 10-23) .

This technique provides accurate measurements of regurgitant volumes and of ventricular end-systolic and diastolic volumes and allows calculation of the regurgitant orifice and of ventricular mass.[416] Although expensive, nuclear magnetic resonance imaging is the most accurate noninvasive technique for assessing the patient with AR (see Chap. 10) .

MANAGEMENT

The management of severe AR must take account of the natural history. Since this differs in patients with chronic and acute AR, the two disorders are presented separately.

NATURAL HISTORY OF CHRONIC AORTIC REGURGITATION.

Moderately severe or even severe chronic AR may be associated with a generally favorable prognosis for many years. Approximately 75 percent of patients survive for 5 years and 50 percent for 10 years after diagnosis.[147] However, as is the case for AS, once the patient becomes symptomatic, the downhill course becomes progressive. Congestive heart failure, punctuated by episodes of acute pulmonary edema, and sudden death may occur, usually in previously symptomatic patients who have considerable left ventricular dilatation. Without surgical treatment, death usually occurs within 4 years after the development of angina pectoris and within 2 years after the onset of heart failure. In a multivariate analysis of patients with severe or moderately severe AR diagnosed by Doppler echocardiography, Dujardin and colleagues found that the following were associated with a poor outcome: advanced age, progressive symptoms, atrial fibrillation, and end-systolic diameter >25 mm/m^2 BSA.[417] Gradual deterioration of left ventricular function may occur even during the asymptomatic period; it is therefore important to intervene surgically before these changes have become irreversible.[418] A review of multiple studies on the natural history of chronic AR has been described by Bonow and associates[51] (Table 46-9) .

ACUTE AORTIC REGURGITATION.

Since early death due to left ventricular failure is frequent in patients with *acute, severe* AR despite intensive medical management, prompt surgical intervention is indicated. Even a normal ventricle cannot sustain the burden of acute, severe volume overload; therefore, the risk of *acute* AR is much greater than that of chronic AR.[394] [404] While the patient is being prepared for surgery, treatment with an intravenous positive

inotropic agent (dopamine or dobutamine) and/or a vasodilator (nitroprusside) may be necessary. The agent and dosage should be selected on the basis of arterial pressure (see Chap. 21) . Beta-blocking agents and intraaortic balloon counterpulsation are contraindicated. In hemodynamically stable patients with acute AR secondary to active infective endocarditis, operation may be deferred to allow 5 to 7 days of intensive antibiotic therapy. However, AVR should be undertaken at the earliest sign of hemodynamic instability or if echocardiographic evidence of diastolic closure of the mitral valve develops.[419]

Medical Treatment

Patients with mild or moderate AR who are asymptomatic with normal or only minimally increased cardiac size require no therapy but should be followed clinically and by echocardiography every 12 or 24 months. These patients should also receive antibiotic prophylaxis for infective endocarditis. Asymptomatic patients with chronic, severe AR and normal left ventricular function should be examined at intervals of approximately 6 months. In addition to clinical examination, serial echocardiographic assessments of left ventricular size and ejection fraction should be made. Left-heart catheterization and aortography are useful in patients whose noninvasive test results are inconclusive or discordant with clinical findings.[51] As is the case for patients with other valvular lesions, adult surgical candidates who may need coronary artery bypass grafting should undergo coronary arteriography.

Patients with limitations of cardiac reserve and/or left ventricular dysfunction secondary to AR should not engage in vigorous sports or heavy exertion. Systemic arterial diastolic hypertension, if present, should be treated because it increases the regurgitant flow; however, beta-blocking agents should be used with great caution. Atrial fibrillation and bradyarrhythmias are poorly tolerated and should be prevented if possible. If these arrhythmias occur, they must be treated promptly and vigorously. Even though nitroglycerin and other nitrates are not as helpful in relieving anginal pain in patients with AR as they are in patients with coronary artery disease or AS, they are worth a trial. Although patients with left ventricular failure secondary to AR require prompt surgical treatment, they respond, at least temporarily, to treatment with digitalis glycosides, salt restriction, and diuretics.

The response to vasodilator therapy is often impressive. Hemodynamic studies have shown beneficial effects of intravenous hydralazine,[420] sublingual nifedipine,[421] felodipine,[421A] as well as oral prazosin. [422] Vasodilator therapy may be particularly helpful in stabilizing patients with acute lesions or those with decompensated chronic AR who are awaiting operation. However, because of the high incidence of side effects of hydralazine, attention has focused on calcium antagonists and angiotensin-converting enzyme (ACE) inhibitors.[423] In a comparison of digoxin with nifedipine in asymptomatic patients with severe AR, nifedipine delayed the need for operation as the result of development of symptoms or of left ventricular dysfunction.[424] In children with severe AR, therapy with an ACE inhibitor for one year has been reported to reverse ventricular dilatation and left ventricular wall stress.[425]

Thus, vasodilator therapy is indicated for patients with chronic, severe AR under the following circumstances: (1) as short-term therapy to improve the hemodynamic profile in the presence of heart failure while preparing for AVR; (2) as chronic therapy for patients in whom AVR is not possible; (3) as therapy for asymptomatic patients; and (4) as therapy for patients with left ventricular dysfunction after AVR.[51]

Surgical Treatment

INDICATIONS FOR OPERATION.

Because of their excellent prognosis in the short and medium term, operative correction should be deferred in patients with chronic, severe AR who are asymptomatic, have good exercise tolerance, *and* have an ejection fraction greater than 50 percent *without* severe left ventricular dilatation (i.e., an enddiastolic diameter <70 mm and an end-systolic diameter <50 mm). Similarly, in the absence of obvious contraindications or serious comorbidity, surgical treatment is advisable for symptomatic patients with severe AR. Between these two ends of the clinical-hemodynamic spectrum are many patients in whom it may be quite difficult to balance the immediate risks of operation and the continuing risks of an implanted prosthetic valve on the one hand against the hazards of allowing a severe volume overload to damage the left ventricle on the other.[426] [427] [428]

Since severe symptoms (NYHA Class III or IV) and left ventricular dysfunction with an ejection fraction less than 40 percent are independent risk factors for poor postoperative survival, surgery should be carried out in NYHA Class II patients before severe left ventricular dysfunction has developed.[51] Even after successful correction of AR, patients with severe left ventricular dysfunction may have persistent cardiomegaly and depressed left ventricular function.[429] [430] [431] Such patients often exhibit histological changes in the left ventricle, including massive fiber hypertrophy and increased interstitial fibrous tissue. Therefore, it is highly desirable to operate on patients *before* irreversible left ventricular changes have occurred.

Because AR has complex effects on both preload and afterload, the selection of appropriate indices of ventricular contractility to identify patients for operation is challenging. The relationship between end-systolic wall stress and ejection fraction or percent fractional shortening is a useful measurement.[136] However, in the absence of such measurements, *serial* changes in ventricular end-diastolic and end-systolic volumes or dimensions can be used to detect *relative* deterioration of ventricular function. Although left ventricular end-diastolic volume and the ejection phase indices such as ejection fraction and ventricular fraction shortening are strongly influenced by loading conditions, they are nonetheless useful empirical predictors of postoperative function.

Serial echocardiograms or radionuclide ventriculograms should be obtained to detect changes in left ventricular size and function in asymptomatic patients with severe AR. Both techniques allow repeated evaluation of ejection fraction and end-systolic volume (or dimensions) both at rest and during exercise. Impaired left ventricular function at *rest* is the basis for selecting patients for operation; normal left ventricular function at rest with failure of the ejection fraction to rise normally with *exercise* is not considered an indication for surgery *per se,* but is an early warning sign that portends impaired function at rest.[432]

Bonow and colleagues have reported that asymptomatic patients with severe AR but normal left ventricular function have an excellent prognosis and do not warrant prophylactic operation (see Table 46-9) . [427] Less than 4 percent of patients per year require operation because of the development of symptoms of left ventricular dysfunction. The end-systolic diameter determined by two-dimensional echocardiography is valuable in predicting outcome in asymptomatic patients. Patients with severe AR and an end-systolic diameter less than 40 mm almost invariably remain stable and can be followed without immediate surgery. However, patients with an end-systolic diameter greater than 55 mm (see Fig. 46-43) , an end-systolic volume greater than 55 ml/m^2 , an end-diastolic volume greater than 200 ml/m^2 , or an ejection fraction less than 50 percent have an increased risk of death secondary to left ventricular dysfunction if they are not operated upon. Furthermore, Bonow and coworkers found that patients with *prolonged* left ventricular dysfunction had poor postoperative survival.[430]

In *summary,* the following considerations apply to the selection of patients with chronic AR for surgical treatment. Operation should be *deferred* in asymptomatic patients with normal and stable left ventricular function and should be *recommended* in symptomatic patients. In asymptomatic patients with left ventricular dysfunction, a decision should be based not on a single abnormal measurement but rather on several observations of depressed performance and impaired exercise tolerance, carried out at intervals of 2 to 4 months. If evidence of left ventricular dysfunction is borderline or is not consistent, continued close follow-up is indicated. If

abnormalities are progressive or consistent (i.e., the left ventricular ejection fraction declines to 50 to 55 percent, the left ventricular end-systolic diameter rises to >55 mm, or the left ventricular end-systolic volume increases to >55 ml/m^2 [the "55 rule"[124]]), operation should be strongly considered even in asymptomatic patients. The threshold for operation may be lower when the surgeon believes that AVR will not be necessary (to be discussed), but this prediction may be difficult. Symptomatic patients with severe AR who have normal, mildly depressed, or moderately depressed left ventricular function should be operated upon. Patients with severely impaired left ventricular function (ejection fraction < 25 percent) are at high surgical risk and have a guarded prognosis even after successful

Figure 46-42 Repair of the aortic valve in patient with severe AR. Conduit tailoring in the supravalvular position. The conduit is cut to replace three (*left*), two (*middle*), or one (*right*) individual sinuses. The aortic aneurysm is replaced and the valve is spared. *(From David TE, Feindel CM, Bos J: Repair of the aortic valve in patients with aortic insufficiency and aortic root aneurysm. J Thorac Cardiovasc Surg 109:345, 1995.)*

Figure 46-43 Relation of preoperative ventricular function to postoperative survival. Data of Greves and colleagues (*left*) and those of Bonow and associates (*right*) show remarkable agreement: Both groups incorporated limits clearly in the abnormal range. Cunha and coworkers (*center*) selected a limit that was well within normal range. These and other published data indicate that preoperative ventricular function is an important determinant of postoperative survival. SEF = systolic ejection fraction; ESD = echocardiographically measured dimension at end-systole; angio = angiography; echo = echocardiography. *(From Errichetti A et al: Is valve replacement indicated in asymptomatic patients with aortic stenosis or aortic regurgitation? In Cheitlin M [ed]: Dilemmas in Clinical Cardiology. Philadelphia, FA Davis Co, 1990, p 204.)*

AVR. Their outlook is also poor when they receive medical therapy, and their management should be considered on an individual basis.

The indications for surgery in patients with severe AR secondary to aortic root disease are similar to those in patients with primary valvular disease. However, progressive expansion of the aortic root and/or a diameter greater than 50 mm by echocardiography with any degree of regurgitation is also an indication for surgery in patients with aortic root disease.

OPERATIVE PROCEDURES.

Because an increasing proportion of patients with severe, isolated AR coming to operation now have primary aortic root rather than primary valvular disease, an increasing number can be treated surgically by correcting the dilated aortic root.[433] One of two annuloplasty procedures may be employed--an encircling suture of the aorta or a subcommissural annuloplasty. Aneurysmal dilatation of the ascending aorta requires excision, replacement with a graft that includes a prosthetic valve, and reimplantation of the coronary arteries.[434]

AVR is required for a large majority of patients with severe AR due to primary valve disease (as opposed to aortic root disease) and for many patients with combined AS and AR. In some patients with aortic root disease, the native valve can be spared when the aortic root is replaced (Fig. 46-42) . Because the aortic annulus in patients with severe AR is usually not as narrow as it is in patients with AS, a larger prosthetic valve can be inserted, and mild postoperative obstruction to left ventricular outflow is less of a problem than it is in some patients with AS (to be discussed). Occasionally, when a leaflet has been torn from its attachments to the aortic annulus by trauma, surgical replacement without repair may be possible. In patients with AR secondary to prolapse of an aortic leaflet, aortic cusp resuspension or cusp resection may be employed. When AR is caused by leaflet perforation resulting from healed infective endocarditis, a pericardial patch can be used for repair.[435] [436]

In general, the risks and results of AVR in patients with AR are similar to those in patients with AS (see p. 1679), with a large percentage of patients exhibiting striking improvement in symptoms. Reductions in heart size and in left ventricular diastolic volume and mass occur in the majority of patients. Exceptions are patients who are in Class NYHA III or IV heart failure and/or patients who have severe left ventricular dysfunction preoperatively.[433] As is true for patients with AS, the operative risk of AVR for patients with AR depends on the general condition of the patient, the state of left ventricular function, and the skill and experience of the surgical team.[437] The mortality rate ranges from 3 to 8 percent in most medical centers (see Table 46-2) . A late mortality of approximately 5 to 10 percent per year is observed in survivors who had marked cardiac enlargement and/or prolonged left ventricular dysfunction preoperatively (Fig. 46-43) . Follow-up studies have shown both early rapid and then slower long-term reductions of ventricular mass, ejection fraction, myocyte hypertrophy, and ventricular fibrous content following relief of AR.[296] [350] By extending the indications for operation to symptomatic patients with normal left ventricular function as well as to asymptomatic patients with left ventricular dysfunction, both early and late results are improving.[437] With the continued improvement of surgical techniques and results, it will likely become possible to extend the recommendation for operative treatment to asymptomatic patients with severe regurgitation and normal cardiac function. However, given the risks of operation and the long-term complications of presently available prosthetic valves, I believe that the time for such a policy has not yet arrived.

Tricuspid, Pulmonic, and Multivalvular Disease

TRICUSPID STENOSIS

Etiology and Pathology

Tricuspid stenosis (TS) is almost always rheumatic in origin.[7] Other causes of obstruction to right atrial emptying are unusual and include congenital tricuspid atresia (see Chap. 43) ; right atrial tumors, which may produce a clinical picture suggesting rapidly progressive TS[438] (see Chap. 49) ; and the carcinoid syndrome (see Chap. 48) , which more frequently produces tricuspid regurgitation. Rarely, obstruction to right ventricular inflow can be due to endomyocardial fibrosis, tricuspid valve vegetations,[438A] a pacemaker lead,[438B] or extracardiac tumors.

The majority of patients with rheumatic tricuspid valve disease present with tricuspid regurgitation or a combination of stenosis and regurgitation. Isolated rheumatic TS is uncommon and *almost* never occurs as an isolated lesion but generally accompanies mitral valve disease.[51] [439] In many patients with TS, the aortic valve is also involved

(i.e., trivalvular stenosis is present). TS is found at autopsy in about 15 percent of patients with rheumatic heart disease but is of clinical significance in only about 5 percent.[92] Organic tricuspid valve disease is more common in India, Pakistan, and other developing nations near the equator than in North America or Western Europe; it has been reported to occur in the hearts of more than one-third of patients with rheumatic heart disease studied at autopsy on the Indian subcontinent.[440]

The anatomical changes of rheumatic TS resemble those of MS, with fusion and shortening of the chordae tendineae and fusion of the leaflets at their edges, producing a diaphragm with a fixed central aperture. However, valvular calcification is rare. As is the case with MS, TS is more common in women. The right atrium is often greatly dilated in TS, and its walls are thickened. There may be evidence of severe passive congestion, with enlargement of the liver and spleen.

Pathophysiology

A diastolic pressure gradient between the right atrium and ventricle--the hemodynamic expression of TS--is augmented when the transvalvular blood flow increases during inspiration or exercise and is reduced when the blood flow declines during expiration. A relatively modest diastolic pressure gradient (i.e., a mean gradient of only 5 mm Hg) is usually sufficient to elevate mean right atrial pressure to levels that result in systemic venous congestion and, unless sodium intake has been restricted or diuretics have been given, is associated with jugular venous distention, ascites, and edema.

In patients with sinus rhythm, the right atrial *a* wave may be very tall and may even approach the level of the right ventricular systolic pressure. Resting cardiac output is usually markedly reduced and fails to rise during exercise. This accounts for the normal or only slightly elevated left atrial, pulmonary arterial, and right ventricular systolic pressures, despite the presence of accompanying mitral valvular disease.

A *mean* diastolic pressure gradient across the tricuspid valve as low as 2 mm Hg is sufficient to establish the diagnosis of TS. However, exercise, deep inspiration, and the rapid infusion of fluids or the administration of atropine may greatly enhance a borderline pressure gradient in a patient with TS. Therefore, when this diagnosis is suspected, right atrial and ventricular pressures should be recorded simultaneously, using two catheters or a single catheter with a double lumen, with one lumen opening on either side of the tricuspid valve. The effects of respiration on any pressure difference should be examined.

Clinical Manifestations (Table 46-10)

HISTORY.

The low cardiac output characteristic of TS causes fatigue, and patients often complain of discomfort due to hepatomegaly, swelling of the abdomen, and anasarca. The severity of these symptoms, which are secondary to an elevated systemic venous pressure, is out of proportion to the degree of dyspnea. Some patients complain of a fluttering discomfort in the neck, caused by giant *a* waves in the jugular venous pulse. Despite the coexistence of MS, the symptoms characteristic of this valvular lesion (i.e., severe dyspnea, orthopnea, and paroxysmal nocturnal dyspnea) are usually mild or absent in the presence of severe TS because the latter prevents surges of blood into the pulmonary circulation behind the stenotic mitral valve. Indeed, the *absence* of symptoms of pulmonary congestion in a patient with obvious MS should suggest the possibility of TS.

TABLE 46-10 -- CLINICAL AND LABORATORY FEATURES OF RHEUMATIC TRICUSPID STENOSIS

HISTORY
Long history
Progressive fatigue, edema, anorexia
Minimal orthopnea, paroxysmal nocturnal dyspnea
Rheumatic fever in two-thirds of patients
Female preponderance
Pulmonary edema and hemoptysis are rare
PHYSICAL FINDINGS
Signs of multivalvular involvement
Wasting
Peripheral cyanosis
Neck vein distention, with prominent *v* waves
Right ventricular lift
Associated murmurs of mitral and aortic valve disease
Holosystolic murmur maximal at lower left sternal border, accentuating with inspiration
Hepatic pulsation

Ascites, peripheral edema
LABORATORY FINDINGS
Normal sinus rhythm is frequently present with large *a* waves in the neck veins
Absent right ventricular lift
Auscultation reveals a diastolic rumble at lower left sternal border, increasing in intensity with inspiration
Electrocardiogram shows tall right atrial P waves and no right ventricular hypertrophy
Chest roentgenogram shows a dilated right atrium without an enlarged pulmonary artery segment
Modified from Ockene IS: Tricuspid valve disease. In Dalen JE, Alpert JS (eds): Valvular Heart Disease. 2nd ed. Boston, Little, Brown and Co, 1987, pp 356, 390.Ebstein's anomaly /Normal Circumference Abnormal

PHYSICAL EXAMINATION.

Because of the high frequency with which MS occurs in patients with TS and the similarity in the physical findings between the two valvular lesions, the diagnosis of TS is commonly missed. The physical findings are mistakenly attributed to MS, which is more common and may be more obvious. Therefore, a high index of suspicion is required to detect the tricuspid valvular lesion. In the presence of sinus rhythm, the *a* wave in the jugular venous pulse is tall, and a presystolic hepatic pulsation is often palpable. The *y* descent is slow and barely appreciable. The lung fields are clear, and despite engorged neck veins and the presence of ascites and anasarca, the patient may be comfortable while lying flat. Thus, the diagnosis of TS may be suspected from inspection of the jugular venous pulse in a patient with MS but without clinical evidence of pulmonary hypertension. This suspicion is strengthened when a diastolic thrill is palpable at the lower left sternal border, particularly if the thrill appears or becomes more prominent during inspiration.

The auscultatory findings of the accompanying MS are usually prominent and often overshadow the more subtle signs of TS. A tricuspid opening snap (OS) may be audible but is often difficult to distinguish from a mitral OS. However, the tricuspid OS usually follows the mitral OS and is localized to the lower left sternal border, whereas the mitral OS is usually most prominent at the apex and radiates more widely. The diastolic murmur of TS is also commonly heard best along the lower left parasternal border in the 4th intercostal space and is usually softer, higher pitched, and shorter in duration than the murmur of MS. The presystolic component of the TS murmur has a scratchy quality and a crescendo-decrescendo configuration that diminishes before S_1 .[439] The diastolic murmur and OS of TS are both augmented by maneuvers that increase transtricuspid valve flow, including inspiration, the Mueller maneuver, assumption of the right lateral decubitus position, leg raising, inhalation of amyl nitrite, squatting, and isotonic exercise. They

are reduced during expiration or the strain of the Valsalva maneuver and return to control levels immediately (i.e., within two to three beats) after Valsalva release.

Laboratory Examination

ELECTROCARDIOGRAM.

In the absence of atrial fibrillation in a patient with valvular heart disease, TS is suggested by the presence of ECG evidence of right atrial enlargement (see Chap. 5) . The P wave amplitude in leads II and V_1 exceeds 0.25 mV. Because most patients with TS have mitral valvular disease, the EGG signs of biatrial enlargement are commonly found. The amplitude of the QRS complex in lead V_1 may be reduced by the dilated right atrium.

RADIOLOGICAL FINDINGS.

The key radiological finding is marked cardiomegaly with conspicuous enlargement of the right atrium (i.e., prominence of the right heart border), which extends into a dilated superior vena cava and azygos vein, but without conspicuous dilatation of the pulmonary artery. The vascular changes in the lungs characteristic of mitral valvular disease may be masked, with little or no interstitial edema or vascular redistribution, but left atrial enlargement may be present.

Angiography carried out following injection of contrast material into the right atrium and filming in the 30-degree right anterior oblique projection characteristically shows thickening and decreased mobility of the leaflets, a diastolic jet through the constricted orifice, and thickening of the normal atrial wall.

ECHOCARDIOGRAM (See also Chap. 7) .

The echocardiographic changes of the tricuspid valve in TS resemble those observed in the mitral valve in MS (see pp. 1648 and 1695). Two-dimensional echocardiography characteristically shows diastolic doming of the leaflets (especially the anterior tricuspid valve leaflet), thickening and restricted motion of the other leaflets, reduced separation of the tips of the leaflets,[441] and a reduction in diameter of the tricuspid orifice (Fig. 46-44) . Transesophageal echocardiography allows added delineation of the details of valve structure.[442] Doppler echocardiography shows a prolonged slope of antegrade flow and compares well with cardiac catheterization in the quantification of TS and in the assessment of associated tricuspid regurgitation.[443] [443A]

Management

Although the fundamental approach to the management of severe TS is surgical treatment, intensive sodium restriction and diuretic therapy may diminish the symptoms secondary to the accumulation of excess salt and water. A preparatory period of diuresis may diminish hepatic congestion and thereby improve hepatic function sufficiently to diminish the risks of subsequent operation.

Most patients with TS have coexisting valvular disease that requires surgery. In patients with combined TS and MS, the former must *not* be corrected alone because pulmonary congestion or edema may ensue. Surgical treatment of TS should be carried out at the time of mitral valve repair or replacement in patients with TS in whom the mean diastolic pressure gradient exceeds 5 mm Hg and the tricuspid orifice is less than approximately 2.0 cm^2 . The final decision concerning surgical treatment is often made at the operating table.[444]

Because TS is almost always accompanied by some TR, simple finger fracture valvotomy may not result in significant hemodynamic improvement but may merely substitute severe regurgitation for stenosis. However, open valvotomy in which the stenotic tricuspid valve is converted into a functionally bicuspid valve may result in substantial improvement. The commissures between the anterior and septal leaflets and between the posterior and septal leaflets are opened. It is not advisable to open the commissure between the anterior and posterior leaflets for fear of producing severe regurgitation. If open valvotomy does not restore reasonably normal valve function, the tricuspid valve may have to be replaced.[445] [446] [447] [447A] A large porcine bioprosthesis

Figure 46-44 Two-dimensional echocardiograms in the long-axis view in a patient with tricuspid stenosis. *Top,* Systolic frame. *Bottom,* Diastolic frame that shows doming of both leaflets of the tricuspid valve (TV) (arrows). RA = right atrium; RV = right ventricle. *(From Shimada R et al: Diagnosis of tricuspid stenosis by M-mode and two-dimensional echocardiography. Am J Cardiol 53:164, 1984.)*

(see p. 1704) is preferred to a mechanical prosthesis in the tricuspid position because of the high risk of thrombosis of the latter[447] and the longer durability of bioprostheses in the tricuspid than in the mitral or aortic positions.[448] [449] [450] [451] The feasibility of tricuspid balloon valvuloplasty has been demonstrated, and this procedure may be combined with mitral balloon valvuloplasty.[452]

TRICUSPID REGURGITATION

Etiology and Pathology (Table 46-11)

The most common cause of tricuspid regurgitation (TR) is not intrinsic involvement of the valve itself (i.e., primary TR) but rather *dilatation of the right ventricle* and of the tricuspid annulus causing secondary (functional) TR. This may be a complication of right ventricular failure of any cause. It is observed in patients with right ventricular hypertension secondary to any form of cardiac or pulmonary vascular disease, most commonly mitral valve disease.[452] [453] [454] [455] In general, a systolic right ventricular systolic pressure greater than 55 mm Hg will cause functional TR.[51] TR can also occur secondary to right ventricular infarction,[456] congenital heart disease (see Chap. 43) (e.g., pulmonic stenosis and pulmonary hypertension secondary to Eisenmenger syndrome), primary pulmonary hypertension, and, rarely, cor pulmonale. In infants, TR may complicate right ventricular failure secondary to neonatal pulmonary diseases and pulmonary hypertension with persistence of

the fetal pulmonary circulation. [457] In all of these cases, TR reflects the presence of, and in turn aggravates, severe right ventricular failure. Functional TR may diminish or disappear as the right ventricle decreases in size with the treatment of heart failure. TR can also occur as a consequence of dilatation of the annulus in the Marfan syndrome, in which right ventricular dilatation secondary to pulmonary hypertension is not present.

A variety of disease processes can affect the tricuspid valve apparatus *directly* and lead to regurgitation (primary TR).[457] Thus, organic TR may occur on a congenital basis, as part of *Ebstein anomaly,* in atrioventricular canal, and when the tricuspid valve is involved in the formation of an aneurysm of the ventricular septum,[458] or in corrected transposition of the great arteries,[459] or it may occur as an isolated congenital lesion.[457] Rheumatic fever may involve the tricuspid valve directly.[92] When this occurs, it usually causes scarring of the valve leaflets and/or chordae tendineae, leading to limited leaflet mobility and either isolated TR or a combination of TR and TS. Rheumatic involvement of the mitral, and often aortic, valves coexist.

TR or the combination of TR and TS is an important feature of the *carcinoid syndrome* (Fig. 46-45) , which leads to focal or diffuse deposits of fibrous tissue on the endocardium of the valvular cusps and cardiac chambers and on the intima of the great veins and coronary sinus[460] [461] [462] [463] (see Chap. 48) . The white, fibrous carcinoid plaques are most extensive on the right side of the heart, where they are usually deposited on the ventricular surfaces of the tricuspid valve and cause the cusps to adhere to the underlying right ventricular wall, thereby producing TR. Endomyocardial fibrosis with shortening of the tricuspid leaflets and chordae tendineae is an important cause of TR in tropical Africa (see Chap. 48) . TR may result from prolapse of the tricuspid valve caused by myxomatous changes in the valve and chordae tendineae; prolapse of the mitral valve is usually present in these patients as well.[464] [465] Prolapse of the tricuspid valve occurs in about 20 percent of all patients with mitral valve prolapse. Tricuspid valve prolapse may also be associated with atrial septal defect. Other causes of TR include penetrating and nonpenetrating trauma,[460] dilated cardiomyopathy, [467] infective endocarditis[468] (particularly staphylococcal endocarditis in narcotics addicts), and following surgical excision of the tricuspid valve in patients with infective endocarditis that is unresponsive to medical management.[469] Less common causes of TR[470] include cardiac tumors (particularly right atrial myxoma), transvenous pacemaker leads, repeated endomyocardial biopsy in a transplanted heart,[471] endomyocardial fibrosis, methysergide-induced valvular disease,[472] administration of fenfluramine-phentermine,[473] and systemic lupus erythematosus involving the tricuspid valve.[474]

Clinical Manifestations

HISTORY.

In the absence of pulmonary hypertension, TR is generally well tolerated. However, when pulmonary hypertension and TR coexist, cardiac output declines, and the manifestations of right-sided heart failure become intensified.[475] Thus, the symptoms of TR result from a reduced cardiac output and from ascites, painful congestive hepatomegaly, and massive edema. Occasionally, patients have throbbing pulsations in the neck, which intensify on effort and are due to jugular venous distention; and systolic pulsations of the eyeballs have also been described.[476] In the many patients with TR who have mitral valve disease, the symptoms of the latter usually predominate. Symptoms of pulmonary congestion may abate as TR develops, but they are replaced by weakness, fatigue, and other manifestations of a depressed cardiac output.

PHYSICAL EXAMINATION.

Evidence of weight loss and cachexia, cyanosis, and jaundice are often present on inspection in patients with severe TR. Atrial fibrillation is common. There is jugular

venous distention,[477] the normal

Figure 46-45 Septal tricuspid leaflet thickened by carcinoid plaques and fused to underlying ventricular septum.*(From Callahan JA et al: Echocardiographic features of carcinoid heart disease. Am J Cardiol 50:766, 1982.)*

x and *x*
descents disappear, and a prominent systolic wave, i.e., a *c-v* wave (or *s* wave), is apparent (see Fig. 4-5) . The descent of this wave, the *y* descent, is sharp and becomes the most prominent feature of the venous pulse (unless there is coexisting TS, in which case it is slowed). A venous systolic thrill and murmur in the neck may be present in patients with severe TR.[478] The right ventricular impulse is hyperdynamic and thrusting in quality. Systolic pulsations of an enlarged, tender liver are commonly present initially. However, in patients with chronic TR and congestive cirrhosis, the liver may become firm and nontender. Ascites and edema are frequent.

Auscultation.

This usually reveals an S_3 originating from the right ventricle, which is accentuated by inspiration. When TR is associated with and secondary to pulmonary hypertension, P_2 is accentuated as well. When TR occurs in the presence of pulmonary hypertension, the systolic murmur is usually high-pitched, pansystolic, and loudest in the 4th intercostal space in the parasternal region but occasionally is loudest in the subxiphoid area. When TR is mild, the murmur may be short. When TR occurs in the absence of pulmonary hypertension (e.g., in infective endocarditis or following trauma), the murmur is usually of low intensity and limited to the first half of systole. When the right ventricle is greatly dilated and occupies the anterior surface of the heart, the murmur may be prominent at the apex and difficult to distinguish from that produced by MR.

The response of the systolic murmur to respiration and other maneuvers is of considerable aid in establishing the diagnosis of TR (see Table 4-4) . The murmur is characteristically augmented during inspiration (Carvallo sign). However, when the failing ventricle can no longer increase its stroke volume in the recumbent or sitting positions, the inspiratory augmentation may be elicited by standing. The murmur also increases during the Mueller maneuver (forced inspiration against a closed glottis), exercise, leg-raising, and hepatic compression. It demonstrates an immediate overshoot after release of the Valsalva strain but is reduced in intensity and duration in the standing position and during the strain of the Valsalva maneuver. Increased atrioventricular flow across the tricuspid orifice in diastole may cause a short early diastolic flow rumble in the left parasternal region following S_3 . Tricuspid valve prolapse, like mitral valve prolapse, causes nonejection systolic clicks and late systolic murmurs. However, in tricuspid valve prolapse, these findings are more prominent at the lower left sternal border. With inspiration, the clicks occur later, and the murmurs intensify and become shorter in duration.

Laboratory Examination

ELECTROCARDIOGRAM.

This is usually nonspecific and characteristic of the lesion causing TR. Incomplete right bundle branch block, Q waves in lead V_1 , and atrial fibrillation are commonly found.

RADIOLOGICAL FINDINGS.

In patients with functional TR, marked cardiomegaly is usually evident, and the right atrium is prominent. Evidence of elevated right atrial pressure may include distention of the azygos vein and the presence of a pleural effusion. Ascites with upward displacement of the diaphragm may be present. Systolic pulsations of the right atrium may be present on fluoroscopy.

ECHOCARDIOGRAM (See Figs. 7-68 and 7-69) .

The goal of echocardiography is to detect TR, estimate its severity, and assess pulmonary arterial pressure and right ventricular function.[443A] In patients with TR secondary to dilation of the tricuspid annulus, the right atrium, right ventricle, and tricuspid annulus are all usually greatly dilated on echocardiography.[479] [480] There is evidence of right ventricular diastolic overload with paradoxical motion of the ventricular septum similar to that observed in atrial septal defect. Exaggerated motion and delayed closure of the tricuspid valve are evident in patients with Ebstein anomaly. Prolapse of the tricuspid valve due to myxomatous degeneration may be evident on echocardiography.[465] [466] Echocardiographic indications of tricuspid valve abnormalities, especially TR by Doppler examination, can be detected in the majority of patients with carcinoid heart disease.[463] In patients with TR due to endocarditis, echocardiography may reveal vegetations on the valve or a flail valve. Transesophageal echocardiography enhances detection of TR.

Contrast Echocardiography.

This involves rapid injection of saline indocyanine green dye or sanicated human albumin (Albunex)[481] into an antecubital vein while a two-dimensional echocardiogram is recorded[482] (see Chap. 7) . The injection produces microcavities that are readily visible on echocardiography and normally travel as a bolus through the circulation. In TR, these microcavities can be seen to travel back and forth across the tricuspid orifice and to pass into the inferior vena cava and hepatic veins during systole.

Pulsed Doppler Echocardiography.

This reveals systolic flow from the right ventricle to the right atrium and is a sensitive technique for detecting and quantifying[483] [484] TR. Reverse flow can also be recorded in the inferior vena cava and hepatic veins. The peak velocity of TR flow is useful in the noninvasive estimation of right ventricular (and pulmonary arterial) systolic pressure. Color flow Doppler imaging is a sensitive and specific method for assessing TR and is helpful in selecting patients for surgical treatment and in evaluating postoperative results.

HEMODYNAMIC FINDINGS.

The right atrial and right ventricular end-diastolic pressures are often elevated in TR, whether the condition is due to organic disease of the tricuspid valve or is secondary to right ventricular systolic overload. The right atrial pressure tracing usually reveals absence of the *x* descent and a prominent *v* or *c-v* wave ("ventricularization" of the atrial pressure). Absence of these findings essentially excludes moderate or severe TR.[485] As the severity of TR increases, the contour of the right atrial pressure pulse increasingly resembles that of the right ventricular pressure pulse (Fig. 46-46) . A rise or no change in right atrial pressure on deep inspiration, rather than the usual fall, is a characteristic finding. Determination of the pulmonary arterial (or right ventricular) systolic pressure may be helpful in deciding whether the TR is primary (i.e., due to disease of the valve or its supporting structures) or functional (i.e., secondary to right ventricular dilatation). A pulmonary arterial or right ventricular systolic pressure less than 40 mm Hg favors a primary cause, whereas a pressure greater than 55 mm Hg suggests that TR is secondary. Intermediate values are not helpful. Diagnosis and quantitative assessment of TR can be aided in many instances by right ventriculography.[486]

Management

TR in the absence of pulmonary hypertension usually is well tolerated and may not require surgical treatment. Indeed,

Figure 46-46 Appearance of right atrial (RA) pressure contour in patients with severe tricuspid regurgitation (TR), moderate TR, and no TR (normal). Note the regurgitant systolic ("s") wave that blends with the normal filling ("v") wave in severe TR. The resultant RA pressure waveform resembles a right ventricular (RV) pressure recording.*(From Grossman W [ed]: Cardiac Catheterization and Angiography. 5th ed. Philadelphia, Lea and Febiger, 1996.)*

both human patients and experimental animals with normal pulmonary arterial pressure may tolerate total excision of the tricuspid valve as long as right ventricular systolic pressure is normal. Dilatation of the right side of the heart usually occurs months or years after tricuspid valvectomy (usually carried out for acute infective endocarditis). *Surgical treatment* of acquired regurgitation secondary to annular dilatation was greatly improved when Carpentier introduced the concept of suturing the annulus to a prosthetic ring.[487] Annuloplasty without insertion of a prosthetic ring (the so-called DeVega annuloplasty) has also been found to be effective in patients with annular dilatation. This technique is now widely employed.[444] [475] [488] [489] [490]

At the time of mitral valve surgery in patients with TR secondary to pulmonary hypertension, the severity of the regurgitation should be assessed by palpation of the tricuspid valve. In addition, it should be determined whether the TR is secondary to pulmonary hypertension, in which case the valve is normal, or whether it is secondary to rheumatic fever. Patients with mild TR usually do not require surgical treatment[491] ; pulmonary vascular pressures decline following successful mitral valve surgery, and the mild TR tends to disappear. Excellent results have been reported in patients with moderate TR with the use of suture annuloplasty of the posterior (unsupported) portion of the annulus. Patients with severe TR and primary rheumatic tricuspid valve disease with commissural fusion require valvotomy and ring annuloplasty.[488] The latter is also employed for TR secondary to annular dilatation. A surgical mortality rate of 13.9 percent has been reported (see Table 46-2) .[104] If these procedures do not provide a good functional result at the operating table (as assessed by transesophageal echocardiography), valve replacement using a large porcine mitral heterograft may be required.

When organic disease of the tricuspid valve (Ebstein anomaly or carcinoid heart disease[449]) causes TR severe enough to require surgery, valve replacement is usually needed. The risk of thrombosis of mechanical prostheses is greater in the tricuspid than in the mitral or aortic positions, presumably because pressure and flow rates are lower in the right side of the heart. For this reason, the artificial valve of choice for the tricuspid position in adults is a large porcine heterograft.[450] [451] Anticoagulants are not required, and a graft durability of more than 10 years has been established.

In treating the difficult problem of tricuspid endocarditis in heroin addicts (see Chap. 47) , total excision of the tricuspid valve *without immediate replacement* can generally be tolerated by these patients, who usually do not have associated pulmonary hypertension. When antibiotic therapy is unsuccessful, valvular replacement frequently results in reinfection or continued infection. Therefore, diseased valvular tissue should be excised to eradicate the endocarditis, and antibiotic treatment can then be continued. Initially, most patients tolerate loss of the tricuspid valve without great difficulty. Later, right ventricular dysfunction usually occurs. A bioprosthetic valve may therefore be inserted 6 to 9 months after valve excision and control of the infection.

PULMONIC VALVE DISEASE

Etiology and Pathology

PULMONIC STENOSIS.

The *congenital* form is the most common cause of pulmonic stenosis (PS).[492] Manifestations in children are discussed in Chapter 43 and in adults in Chapter 44 . *Rheumatic* inflammation of the pulmonic valve is very uncommon, is usually associated with involvement of other valves, and rarely leads to serious deformity. However, in one study, a high incidence of significant pulmonic valve involvement secondary to rheumatic fever was reported in Mexico City, perhaps related to the pulmonary hypertension that occurs at high altitudes and the resultant greater stress on the pulmonic valve.[493] *Carcinoid* plaques, similar to those involving the tricuspid valve, are often present in the outflow tract of the right ventricle of patients with malignant carcinoid. The plaques result in constriction of the pulmonic valve ring, retraction and fusion of the valve cusps, and either PS or the combination of PS and pulmonic regurgitation (Fig. 46-47) . [494] [495] Obstruction in the region of the pulmonic valve may be extrinsic to the valve apparatus and may be produced by cardiac tumors or by aneurysm of the sinus of Valsalva.[496]

Management of congenital PS focuses on balloon dilation (see Chaps. 38 , 43 , and 44) .

PULMONIC REGURGITATION.

By far the most common cause of pulmonic regurgitation (PR) is dilatation of the valve ring secondary to pulmonary hypertension (of any etiology) or to dilatation of the pulmonary artery, either idiopathic[497] [498] or consequent to a connective tissue disorder such as the Marfan syndrome. The second most common cause of PR is infective endocarditis.[499] Less frequently, PR is iatrogenic and is induced at the time of surgical treatment of congenital PS or tetralogy of Fallot.[499A] PR may also result from various lesions that directly affect the pulmonic valve. These include congenital malformations, such as absent, malformed, fenestrated, or supernumerary leaflets. These anomalies may occur as isolated lesions[500] but more often are associated with other congenital anomalies,[501] particularly tetralogy of Fallot, ventricular septal defect, and pulmonic valvular stenosis. Less common causes include trauma, carcinoid syndrome,[494] rheumatic involvement, injury produced by a pulmonary artery flow-directed catheter,[502] syphilis, and chest trauma.[503]

Figure 46-47 Carcinoid heart disease; pulmonary valve viewed from above (*A*) and opened (*B*). The thickened and retracted cusps result in valvular incompetence. The constricted annulus results in valvular stenosis. Carcinoid plaques (arrows) extend onto the pulmonary trunk.*(From Callahan, JA et al: Echocardiographic features of carcinoid heart disease. Am J Cardiol 50:767, 1982.)*

Clinical Manifestations

Like TR, isolated PR causes right ventricular volume overload and may be tolerated for many years without difficulty unless it complicates, or is complicated by, pulmonary hypertension. In this case, PR is usually accompanied by and aggravates right ventricular failure. Patients with PR caused by infective endocarditis who develop septic pulmonary emboli and pulmonary hypertension often exhibit severe right ventricular failure.[503] In most patients, the clinical manifestations of the primary disease are severe and usually overshadow the PR, which often results only in incidental auscultatory findings. *Physical examination* reveals a hyperdynamic right ventricle that produces palpable systolic pulsations in the left parasternal area and an enlarged pulmonary artery that often results in systolic pulsations in the 2nd left intercostal space. Sometimes systolic and diastolic thrills are felt in the same area. A tap reflecting pulmonic valve closure is usually easily palpable in the 2nd intercostal space in patients with pulmonary hypertension and secondary PR.

AUSCULTATION.

P_2 is not audible in patients with congenital absence of the pulmonic valve; however, this sound is accentuated in patients with PR secondary to pulmonary hypertension. There may be wide splitting of S_2 caused by prolongation of right ventricular ejection accompanying the augmented right ventricular stroke volume.[501] A nonvalvular systolic ejection click due to the sudden expansion of the pulmonary artery by the augmented right ventricular stroke volume frequently initiates a midsystolic ejection murmur, most prominent in the 2nd left intercostal space. An S_3 and S_4 originating from the right ventricle are often audible, most readily in the 4th intercostal space at the left parasternal area, and are augmented by inspiration.

In the absence of pulmonary hypertension, the diastolic murmur of PR is low pitched and usually heard best at the 3rd and 4th left intercostal spaces adjacent to the sternum (see Fig. 4-37) .[504] The murmur commences when pressures in the pulmonary artery and right ventricle diverge, approximately 0.04 second after P_2 . It is diamond-shaped in configuration and brief, reaching a peak intensity when the gradient between these pressures is maximal and ending with equilibration of the pressures. The murmur becomes louder during inspiration.

The Graham Steell Murmur.

When systolic pulmonary arterial pressure exceeds approximately 55 mm Hg, dilatation of the pulmonic annulus results in a high-velocity regurgitant jet that is responsible for the Graham Steell murmur of PR. (Doppler ultrasonography reveals pulmonary regurgitation at much lower pulmonary arterial pressures.) The Graham Steell murmur is a high-pitched, blowing, decrescendo murmur beginning immediately after P_2 and is most prominent in the left parasternal region in the 2nd to 4th intercostal spaces. Thus, although it resembles the murmur of AR, it is usually accompanied by severe pulmonary hypertension, i.e., an accentuated P_2 or fused S_2 , an ejection sound, and a systolic murmur of TR, and not by a widened arterial pulse pressure. Sometimes a low-frequency presystolic murmur is present, i.e., a right-sided

Austin Flint murmur originating from the mitral valve.[505]

The Graham Steell murmur of PR secondary to pulmonary hypertension usually increases in intensity with inspiration, exhibits little change after amyl nitrite inhalation or vasopressor administration, is diminished during the Valsalva strain, and returns to baseline intensity almost immediately after release of the Valsalva strain. This murmur resembles and may be confused with the diastolic blowing murmur of AR. However, indicator dilution studies[506] and aortography have established that a diastolic blowing murmur along the left sternal border in patients with rheumatic heart disease and pulmonary hypertension (even in the *absence* of peripheral signs of AR) is usually due to AR rather than PR.

Laboratory Examination

ELECTROCARDIOGRAM.

In the absence of pulmonary hypertension, PR often results in an ECG that reflects right ventricular diastolic overload, i.e., an rSr (or rsR) configuration in the right precordial leads. PR secondary to pulmonary hypertension is usually associated with ECG evidence of right ventricular hypertrophy.

RADIOLOGICAL FINDINGS.

Both the pulmonary artery and the right ventricle are usually enlarged, but these signs are nonspecific. Fluoroscopy may demonstrate pronounced pulsation of the main pulmonary artery. PR can be diagnosed by observing opacification of the right ventricle following injection of contrast material into the main pulmonary artery (Fig. 46-48) . The diagnosis is supported by noting

Figure 46-48 Pulmonic valvular regurgitation. Contrast material has been injected into the main pulmonary artery (PA) and regurgitates back into an enlarged right ventricle (RV).*(Reproduced with permission from Carlsson E et al: The radiological diagnosis of cardiac valvular insufficiency. Circulation 55:921, 1977. Copyright 1977, American Heart Association.)*

superimposition of the pulmonary arterial and right ventricular pressure curves during mid- and late diastole. Indicator dilution studies with injections into the pulmonary artery and sampling from the right ventricle,[507] as well as intracardiac phonocardiography, can also be helpful in establishing the diagnosis in mild cases.

ECHOCARDIOGRAM.

Two-dimensional echocardiography shows right ventricular dilatation and, in patients with pulmonary hypertension, right ventricular hypertrophy as well. Right ventricular function can be estimated. Abnormal motion of the septum characteristic of volume overload of the right ventricle in diastole and/or septal flutter[508] may be evident. The motion of the pulmonic valve may point to the cause of the PR. Absence of *a* waves and systolic notching of the posterior leaflet suggest pulmonary hypertension; large *a* waves indicate pulmonic stenosis. PR can be detected by contrast echocardiography. The pulsed Doppler technique is also extremely accurate in detecting PR and in helping to estimate its severity. Abnormal Doppler signals in the right ventricular outflow tract with velocity sustained throughout diastole are generally observed in patients in whom PR is caused by dilatation of the valve ring secondary to pulmonary hypertension. When the velocity falls during diastole, the pulmonary artery pressure is usually normal, and the regurgitation is caused by an abnormality of the valve itself.[509]

Management

PR alone is seldom severe enough to require specific treatment. Cardiac glycosides are useful in the management of right ventricular dilatation or failure. Treatment of the primary condition, such as infective endocarditis, or the lesion responsible for the pulmonary hypertension, such as surgery for mitral valvular disease, often ameliorates the PR. Surgical treatment directed specifically at the pulmonic valve (e.g., in patients in whom surgical correction of tetralogy of Fallot has caused severe PR[509A]) is required only occasionally because of intractable right heart failure. Under such circumstances, valve replacement may be carried out,[510] [510A] [510B] preferably with a porcine bioprosthesis or a pulmonary allograft.[499A]

MULTIVALVULAR DISEASE

Multivalvular involvement is caused most frequently by rheumatic fever, and various clinical and hemodynamic syndromes can be produced by different combinations of valvular abnormalities. The Marfan syndrome and other

connective tissue disorders may cause multivalve prolapse and dilatation, resulting in multivalvular regurgitation. Degenerative calcification of the aortic valve may be associated with degenerative mitral annular calcification and cause AS and MR. Different pathological conditions may affect two valves in the same patient, such as infective endocarditis on the aortic valve causing AR and ischemia causing MR. Development of PR and TR secondary to dilatation of the pulmonic valve ring and tricuspid annulus, as a consequence of pulmonary hypertension secondary to mitral and/or aortic valvular disease, was discussed previously, as was the combination of organic rheumatic tricuspid and mitral valvular disease.

In patients with multivalvular disease, the clinical manifestations depend on the relative severities of each of the lesions. When the valvular abnormalities are of approximately equal severity, clinical manifestations produced by the more proximal (upstream) of the two valvular lesions (i.e., the mitral valve in patients with combined mitral and aortic valvular disease and the tricuspid valve in patients with combined tricuspid and mitral valvular disease) are generally more prominent than those produced by the distal lesion. Thus, the proximal lesion tends to mask the distal lesion.

It is important to recognize multivalvular involvement preoperatively because failure to correct all significant valvular disease at the time of operation increases mortality considerably. In patients with multivalvular disease, the relative severity of each lesion may be difficult to estimate by clinical examination and noninvasive techniques because one lesion may mask the manifestations of the other. For this reason, patients suspected of having multivalvular involvement and who are being considered for surgical treatment should undergo right- and left-cardiac catheterization and angiography. These studies are in addition to careful clinical examination and a noninvasive workup, with emphasis on two-dimensional and Doppler echocardiography. If there is any question concerning the presence of significant AS in patients undergoing mitral valve surgery, the aortic valve should be inspected because overlooking this condition can lead to a high perioperative mortality. Similarly, it is useful to palpate the tricuspid valve at the time of mitral valve surgery.

MITRAL STENOSIS AND AORTIC REGURGITATION

Approximately two-thirds of patients with severe MS have an early blowing diastolic murmur along the left sternal border with a normal pulse pressure. In about 90 percent of these patients, the murmur is due to mild or moderate AR and is usually of little clinical importance. However, approximately 10 percent of patients with MS have severe rheumatic AR,[511] which can generally be recognized by the usual signs of AR (i.e., a widened pulse pressure, left ventricular dilatation and increased wall motion on echocardiography, and signs of left ventricular enlargement on radiological and ECG examinations).

In keeping with the general observation that a proximal lesion may mask a distal lesion, significant AR may be missed in patients with severe MS.[512] The widened pulse pressure, in particular, may be absent. On the other hand, MS may be missed or, conversely, may be falsely diagnosed on clinical examination of patients with obvious AR. An accentuated S_1 and an opening snap in a patient with AR should suggest the possibility of mitral valvular disease. However, an Austin Flint murmur is often inappropriately considered to be the diastolic rumbling murmur of MS. These two murmurs may be distinguished at the bedside by means of amyl nitrite inhalation, which diminishes the Austin Flint murmur but augments the murmur of MS; isometric handgrip and squatting augment both the diastolic murmur of AR and the Austin Flint murmur. Echocardiography, particularly pulsed Doppler echocardiography, is of decisive value in detecting MS and MR.

Since double-valve replacement is associated with increased short-term and long-term risk,[114] [512A] balloon mitral valvotomy can be the first procedure. If this causes left ventricular dilatation, aortic valve replacement can follow. Alternatively, open mitral valvotomy and aortic valve replacement can be performed at the same time.[51]

MITRAL STENOSIS AND AORTIC STENOSIS

The left ventricle of a patient with these two lesions is usually small, stiff, and hypertrophied. When severe MS and AS coexist, the former masks many of the

manifestations of the latter.[513] The cardiac output tends to be reduced more than in patients with isolated AS. The reduced cardiac output lowers both the transaortic valvular pressure gradient and the left ventricular systolic pressure, diminishes the incidence of angina pectoris, and retards the development of aortic valvular calcification and left ventricular hypertrophy.[514] On the other hand, clinical manifestations associated with MS, such as pulmonary congestion and hemoptysis, atrial fibrillation, and systemic embolization, occur more frequently in patients with coexisting MS and AS than in those with isolated AS.

On physical examination, an S_4 , (which is common in patients with pure AS) is usually not present. The midsystolic murmur characteristic of AS may be reduced in intensity and duration because the stroke volume is reduced by the MS. The ECG may fail to demonstrate left ventricular hypertrophy, but left atrial enlargement is common. The chest roentgenogram is usually typical of MS except that calcium may be present in the region of the aortic valve. The two-dimensional and Doppler echocardiograms are of the greatest value because stenosis of both valves may be evident. However, the low cardiac output characteristic of the combined lesions may reduce the transvalvular pressure gradients estimated by Doppler echocardiography.

It is vital to recognize the presence of hemodynamically significant aortic valvular disease (i.e., stenosis and/or regurgitation) preoperatively in patients who are to undergo mitral valvotomy. This procedure may be hazardous because it can impose a sudden hemodynamic load on the left ventricle that had previously been protected by the MS and may lead to acute pulmonary edema. Balloon mitral valvotomy and aortic valve replacement may be the treatment of choice.

AORTIC STENOSIS AND MITRAL REGURGITATION

This combination of lesions is usually caused by rheumatic heart disease, although AS may be congenital and MR may be due to mitral valve prolapse. The combination of severe AS and MR is a hazardous one, but fortunately it is relatively uncommon. Obstruction to left ventricular outflow augments the volume of MR flow,[123] whereas the presence of MR diminishes the ventricular preload necessary for maintenance of the left ventricular stroke volume in patients with AS. The result is a reduced forward cardiac output and marked left atrial and pulmonary venous hypertension. The development of atrial fibrillation (due to left atrial enlargement) has an adverse hemodynamic effect in the presence of AS. The physical findings may be confusing because it may be difficult to recognize two distinct systolic murmurs. On echocardiography and roentgenography, the left atrium and ventricle are usually larger than in isolated AS. In patients with severe AS and MR, both valves must usually be treated surgically by aortic valve replacement and, if possible, by mitral valve repair.

AORTIC REGURGITATION AND MITRAL REGURGITATION

This relatively frequent combination of lesions[515] may be caused by rheumatic heart disease, by prolapse of both the aortic and the mitral valves due to myxomatous degeneration,[516] or by dilatation of both annuli in patients with connective tissue disorders. The left ventricle is usually greatly dilated. The clinical features of AR usually predominate, and it is sometimes difficult to determine whether the MR is due to organic involvement of this valve or to dilatation of the mitral valve ring secondary to left ventricular enlargement. When both valvular leaks are severe, this combination of lesions is poorly tolerated. The normal mitral valve ordinarily serves as a "backup" to the aortic valve, and premature (diastolic) closure of the mitral valve limits the volume of reflux that occurs in patients with acute AR.[382] With severe combined regurgitant lesions, regardless of the cause of the mitral lesion, blood may reflux from the aorta through both chambers of the left side of the heart into the pulmonary veins. Physical and laboratory examinations usually show evidence of both lesions. An S_3 and a brisk arterial pulse are frequently present. The relative severity of each lesion can be assessed best by Doppler echocardiography and contrast angiography. This combination of lesions leads to severe left ventricular dilatation.

MR that occurs in patients with AR secondary to left ventricular dilatation often regresses following aortic valve replacement alone. If severe, the MR may be corrected by annuloplasty at the time of aortic valve replacement. An intrinsically normal mitral valve that is regurgitant because of a dilated annulus should not be replaced.

Surgical Treatment of Multivalvular Disease

Combined aortic and mitral valve replacement is usually associated with a higher risk and poorer survival than is replacement of either of the valves alone.[517] [517A] The operative risk of double-valve replacement is about 70 percent higher than it is for single-valve replacement. The Society of Thoracic Surgeons National Database Committee reported an overall operative mortality rate of 9.6 percent for

multiple (usually double) valve replacement in 3840 patients, compared with 4.3 percent and 6.4 percent for isolated aortic valve replacement and mitral valve replacement, respectively[104] (see Table 46-2) . Kirklin and Barrat-Boyes reported a 5-year survival rate of 63 percent after double-valve replacement compared with 80 percent for single-valve replacement.[517] The long-term survival depends strongly on the preoperative functional status. Patients operated on for combined AR and MR have poorer outcomes than patients receiving double-valve replacement for any of the other combinations of lesions, presumably because both AR and MR may produce irreversible left ventricular damage. Mitral repair or balloon valvotomy in combination with aortic valve replacement is preferable to double-valve replacement and should be carried out whenever possible. Risk factors that reduce long-term survival after double-valve replacement include advanced age, higher NYHA class, greater left ventricular enlargement, and accompanying ischemic heart disease requiring coronary artery bypass grafting.

Given the higher risks, a higher threshold is required for multivalvular versus single-valve surgery. Thus, patients are generally advised not to undergo multivalvular surgery until they reach late NYHA Class II or Class III. Despite a detailed noninvasive and invasive workup, the decision to treat more than one valve is often made by palpation or by direct inspection at the operating table.

THREE-VALVE DISEASE.

Hemodynamically significant disease involving the mitral, aortic, and tricuspid valves is uncommon. Patients with trivalvular disease may present in advanced heart failure with marked cardiomegaly, and surgical correction of all three valvular lesions is imperative. However, triple-valve replacement is a long and complex operation. Early in the experience with this procedure, the mortality rate was 20 percent for patients in NYHA Class III and 40 percent for patients in Class IV. More recently, the mortality rate has declined, but, nevertheless, triple-valve replacement should be avoided if possible. In many patients with trivalvular disease, it is possible to replace the aortic valve, repair the mitral valve, and perform a tricuspid annuloplasty or valvuloplasty.

Patients who survive triple-valve replacement surgery usually show substantial clinical improvement during the early postoperative period,[517B] [518] [518A] and postoperative catheterization studies show marked reductions in pulmonary arterial and capillary pressures. However, some patients die of arrhythmias or congestive heart failure in the late postoperative period despite three normally functioning prostheses.[519] The cause of cardiac failure in this situation is not known, but it may be related to intraoperative myocardial ischemia, microemboli from the multiple prostheses, or continued subclinical episodes of rheumatic myocarditis.

When multiple prosthetic valves must be inserted, it is logical to select either two bioprostheses or two mechanical prostheses for the left side of the heart. If the patient is to be exposed to the hazards of anticoagulants for one mechanical prosthesis, it seems unreasonable to add the potential risks of early failure of a bioprosthesis. However, if two mechanical prostheses are selected for the left side of the heart, the use of a bioprosthesis in the tricuspid position is suggested.

Prosthetic Cardiac Valves

The first successful replacements of cardiac valves in the human were accomplished by Nina Braunwald and colleagues,[520] Harken and coworkers,[521] and Starr and Edwards [522] in 1960. Two major groups of artificial (prosthetic) valves are currently available in models designed for both the atrioventricular (mitral and tricuspid) and the aortic positions: mechanical prostheses and bioprostheses (tissue valves).[523]

MECHANICAL PROSTHESES

Mechanical prosthetic valves are classified into two major groups: caged-ball and tilting-disc valves. The *StarrEdwards* caged-ball valve, the oldest prosthetic valve in continuous use (Figs. 46-49 and 46-50) (Figure Not Available) , has the longest record of predictable performance of any artificial valve.[523] [524] [525] The poppet is made of silicone rubber, the cage of Stellite alloy, and the sewing ring of Teflon/polypropylene cloth. A disadvantage is its bulky cage design. Therefore, the Starr-Edwards valve is not suitable for the mitral position in patients with a small left ventricular cavity or for the aortic position in those with a small aortic annulus or a valve-aortic arch composite graft. In a small number of patients, this valve induces hemolysis, which may be greatly exaggerated and become clinically important if a perivalvular leak develops. When they are of small size, the Starr-Edwards valve may cause mild obstruction, and the incidence of thromboembolism is slightly higher than with the tilting-disc valve.[526]

Several types of disc valves are widely employed; these are less bulky, have a lower profile than the caged-ball valve, and are therefore superior hemodynamically. The *St. Jude* bileaflet valve (see Fig. 46-49 *D*), currently the most widely used prosthesis worldwide (Table 46-12) , is coated with pyrolytic carbon and has two semicircular discs that pivot between open and closed positions without the need for supporting struts. It has favorable flow characteristics and causes a lower transvalvular pressure gradient at any outer diameter and cardiac output than the caged-ball or single-leaflet tilting valves.[527] The St. Jude valve appears to have particularly favorable hemodynamic characteristics in the smaller sizes; therefore, it is especially useful in children. Thrombogenicity in the mitral position *may* be less than that associated with other prosthetic valves. However, as with other mechanical prostheses, lifelong anticoagulation is needed.[528] A variation of the St. Jude valve, the *Carbomedics* prosthesis[529] (see Fig. 46-49 *E*), is also a bileaflet valve composed of pyrolytic carbon with a titanium housing that can be rotated so as to avoid interference with disc excursion by subvalvular tissue.

The *Omniscience* valve (see Fig. 46-49 *B*), the successor to the *Lillehei-Kaster* pivoting-disc valve, consists of a titanium valve housing with a polyester knit sewing ring in which a pyrolytic disc is suspended. In the open position, the disc swings to an angle of 80 degrees, providing a large central flow orifice.[530] A closely related valve is the *Medtronic-Hall* valve[531] (see Fig. 46-49 *C*), which has a Teflon sewing ring and titanium housing; its thin, carbon-coated pivoting disc has a central perforation that allows improved hemodynamics. Thrombogenicity appears to be quite low (less than one episode per 100 patient-years in the mitral position[532]), and mechanical performance is excellent over the long term. Both the bileaflet and the tilting-disc valves

Figure 46-49 *A,* The Starr-Edwards caged ball valve. *B,* The Omniscience valve. *C,* The Medtronic-Hall valve. *D,* The St. Jude bileaflet valve. *E,* The Carbomedics bileaflet valve.*(From Cohn, LH: Aortic valve prostheses. Cardiol Rev 2:219, 1995.)*

are associated with small (
5-10 ml/beat) obligatory (normal) regurgitation.[92] All have distinctive auscultatory features (Fig. 46-51) .

DURABILITY AND THROMBOGENICITY.

All mechanical prosthetic valves have an excellent record of durability, up to 40 years for the Starr-Edwards valve. In the mitral position, perivalvular regurgitation appears to occur more frequently with mechanical than with tissue valves.[533] However, patients with any *mechanical* prosthesis, regardless of design or site of placement, require long-term anticoagulation and aspirin administration because of the hazard of thromboembolism, which is greatest in the first postoperative year. Without anticoagulants and aspirin, the incidence of thromboembolism is three- to sixfold higher than when proper doses of these medications are administered. Very rarely, thrombosis of the mechanical valve occurs. This may be a fatal event, but when nonfatal, it interferes with prosthetic valve function.

Warfarin should begin about 2 days after operation, and the international normalized ratio (INR) should be in the range of 2.0 to 3.0 for patients with the bileaflet disc and the Medtronic-Hall valve in the aortic position. The INR should be between 2.5 and 3.5 for patients at higher risk for thrombosis (e.g., atrial fibrillation, previous thromboembolism) as well as for patients with other mechanical valves in the aortic position and for *all* valves in the mitral position (see also p. 1722 and Chap. 62) .[51] This relatively conservative approach reduces the risk of anticoagulant hemorrhage but does not appear to be associated with a greater frequency of thromboembolism than an INR of 3.0 to 4.0, which was used in the past.[534] [535] [536] Antiplatelet agents without anticoagulants do not provide adequate protection.

Figure 46-50 (Figure Not Available) Designs and flow patterns of major categories of prosthetic heart valves: caged-ball, caged-disc, tilting-disc, bileaflet tilting-disc, and bioprosthetic (tissue) valves. Whereas flow in mechanical valves must course along both sides of the occluder, bioprostheses have a central flow pattern.*(Reproduced by permission from Schoen FJ et al: Bioengineering aspects of heart valve replacement. *Approximate number of implants through part or all of 1994.

Discontinued in 1988.

Does not require FDA approval for clinical use.

However, the addition of aspirin, 80 to 150 mg daily, together with warfarin may reduce the risk of thromboembolism and should be given to all patients with prosthetic valves.

Prosthetic valve thrombosis should be suspected by the sudden appearance of dyspnea and muffled sounds or new murmurs on auscultation (see Fig. 46-51) . This serious complication is diagnosed by transesophageal two-dimensional and Doppler echocardiography. Treatment consists of infusion of a thrombolytic agent for 24 to 72 hours, heparin, and aspirin. Surgery is required for nonresponders and for patients with mobile thrombi.[537]

It must be recognized that (1) the administration of warfarin carries its own mortality and morbidity, i.e., serious hemorrhage, estimated at 0.2 and 2.2 episodes per 100 patient-years,

Figure 46-51 Auscultatory characteristics of various prosthetic valves in the aortic and mitral positions, with schematic diagrams of normal findings and descriptions of abnormal findings. N Engl J Med 335:407, 1996.)*

respectively; and (2) despite treatment with anticoagulants, the incidence of thromboembolic complications with the best mechanical prosthesis is still about 0.2 fatal complications and 1.0 to 2.0 nonfatal complications per 100 patient-years for aortic valves and 2.0 to 3.0 nonfatal complications for mitral valves.[538] Valve thrombosis, a particularly hazardous complication, occurs at an incidence of about 0.1 percent per year in the aortic position and 0.35 percent per year in the mitral position. Thrombosis of mechanical prostheses in the tricuspid position is quite high, and for this reason bioprostheses are preferred at this site. The incidence of embolization in patients who have experienced repeated emboli from a prosthetic valve despite anticoagulants may be reduced by replacement with a tissue valve.

Mechanical prostheses regularly cause mild hemolysis,[538] but this is not severe enough to be of clinical importance unless the patient develops periprosthetic regurgitation.

TISSUE VALVES

Tissue valves (bioprostheses) have been developed primarily to overcome the risk of thromboembolism that is inherent in all mechanical prosthetic valves and the attendant hazards and inconvenience of permanent anticoagulant therapy.[539A] The first tissue valves to be widely used were chemically sterilized aortic homografts (allografts) obtained from cadavers. However, these had a high incidence of breakdown within 3 years, and antibiotic-treated, cryopreserved, frozen, irradiated homografts were then developed. These homografts are more durable, but, although they have many desirable properties, their use has been restricted by the problems inherent in their procurement (to be discussed).

PORCINE HETEROGRAFTS.

Stented porcine aortic heterografts were developed for both the mitral and the aortic positions and have been in wide clinical use since 1965.[523] The semirigid stents facilitate implantation and maintain the three-dimensional relationship between the leaflets.[92] Three porcine heterografts are widely used today.[523] [540] [541] [542] [543] [543A] The *Hancock* valve (Fig. 46-52 *A*) is fixed and preserved in glutaraldehyde and is mounted on a Dacron cloth-covered flexible polypropylene strut. In the smaller aortic models, the right coronary cusp is replaced by a posterior cusp from another valve to reduce obstruction resulting from the septal shelf of the valve. The *Carpentier-Edwards* valve (Fig. 46-52 *B*) is pressure-fixed, preserved in glutaraldehyde, and mounted on a Teflon-covered Eljgiloy strut so as to minimize the septal shelf. The *Intact* valve is also glutaraldehyde-treated but at a fixation pressure of zero and with toluidine in an attempt to inhibit calcium deposition. The hemodynamic profiles of the porcine heterografts are similar to those of comparably sized low-profile mechanical prostheses.[541] [544]

During the first 3 postoperative months, while the sewing ring becomes endothelialized, the thromboembolic rate is high enough that anticoagulation is extremely desirable. Thereafter, anticoagulants are not required for porcine valves in the aortic position, and the thromboembolic rate is approximately 1 to 2 episodes per 100 patient-years

Figure 46-52 *A,* Hancock porcine valve. *B,* Carpentier-Edwards porcine valve. *C,* Carpentier pericardial valve. *D,* Cryopreserved homograft valve. *E,* Incisions for placement of pulmonary autograft valve into the aortic position.*(From Oury JH: Pulmonary autograft--past, present and future. J Heart Valve Dis 2:366, 1993.)*

without these drugs.[545] [546] When these valves have been placed in the mitral position in patients who are in sinus rhythm, who do not have heart failure or thrombus in the left atrium or the left atrial appendage, and who do not have a history of embolism preoperatively, anticoagulants are not needed after the first 3 postoperative months, and the thromboembolic rate is also approximately 1 to 2 episodes per 100 patient-years. This rate is comparable to that observed in patients with the St. Jude

or other mechanical valves who are receiving anticoagulants and are therefore subject to the risks of hemorrhage. It is unlikely that any mitral valve replacement can be associated with a thromboembolic rate much below 0.5 episode per 100 patient-years because some of the emboli in patients with longstanding mitral disease are derived from the left atrium rather than from the valve itself.[546] In patients undergoing mitral valve replacement (MVR) with a bioprosthesis who have experienced a previous embolism, in whom thrombus is found in the left atrium at operation, or who remain in atrial fibrillation postoperatively (approximately one-third of all patients receiving MVR), the hazard of thromboembolism and the need for anticoagulants persist. This negates the principal advantage of the tissue valves, and mechanical prostheses would appear to be preferable to bioprostheses in these patients.

The major problem with porcine bioprostheses is their limited durability (Fig. 46-53) . Cuspal tears, degeneration, fibrin deposition, disruption of the fibrocollagenous structure, perforation, fibrosis, and calcification sufficiently severe to require reoperation begin to appear in some patients in the fourth or fifth postoperative year, and by 10 years the rate of primary tissue failure averages 30 percent. It then accelerates, and by 15 years postoperatively the actuarial *freedom* from bioprosthetic primary tissue failure has ranged from 30 to 60 percent in several series. Structural valve deterioration is more frequent in patients with bioprostheses in the mitral than in the aortic position, presumably because of the higher closing pressure. With the passage of time, even more of these valves will likely fail, and essentially all valves implanted into patients less than 60 years of age may have to be replaced ultimately.[547] Fortunately, however, these valves usually do not fail suddenly (as is often the case for structural failure or thrombosis of mechanical prostheses). Re-replacement of a bioprosthetic valve should be carried out when significant and/or progressive structural deterioration is evident but before operation becomes an emergency. The second operation, when carried out on an elective basis, may be associated with a surgical mortality rate of 10 to 15 percent.

Color Doppler echocardiography with two-dimensional imaging is extremely helpful in the early detection of bioprosthetic valve malfunction. Transesophageal echocardiography is more sensitive than transthoracic imaging in detecting bioprosthetic valve deterioration. Even patients without new murmurs or other physical findings of valve dysfunction should have routine echocardiographic studies to look for early bioprosthetic valve dysfunction every year for 5 to 6 years after valve replacement and every 6 months after that.

The time after implantation at which tissue valves fail varies inversely with age[543A] (Fig. 46-54) . Valve failure is prohibitively rapid in children and in adults under 35 to 40 years of age. Therefore, bioprostheses are *not* advisable in these age groups. On the other hand, degeneration is rare when these valves are implanted into patients over 70 years of age.[547] Bioprostheses also have extremely limited durability in patients with chronic renal failure and hypercalcemia related to secondary hyperparathyroidism.

Figure 46-53 Unified model for bioprosthetic heart valve failure relating isolated tissue processes of mineralization and collagen degeneration to gross clinical failures. Such failures have calcification with cuspal stiffening (1), cuspal defects without calcific deposits (2), or cuspal tears associated with mineralization (1 and 2). These processes may occur independently or they may be synergistic. Specifically, implant and host factors interact to induce the collagen-oriented and cell-oriented calcific deposits noted ultrastructurally. The deposits predominate in the central portions of valve cusps, particularly at flexion points such as the commissures (Pathway 1). Stress causes shear between and fracture of collagen fibers, which may create gross cuspal defects (Pathway 2). Although dynamic mechanical activity is not a prerequisite for calcification, stress may promote (i.e., accelerate) this process by means of unknown mechanisms. *(Amended from Schoen FJ, Levy RJ: Bioprosthetic heart valve failure: Pathology and pathogenesis. Cardiol Clin 2:717, 1984.)*

Figure 46-54 Estimates of freedom from structural valve deterioration (SVD) for patients undergoing porcine aortic valve replacement (AVR) are stratified according to age.*(From Fann JI, Miller DC, Moore KA, et al: Twenty-year clinical experience with porcine bioprostheses. Ann Thorac Surg 62:1301, 1996. Reprinted with permission from the Society of Thoracic Surgeons.)*

Prosthetic valve endocarditis is a serious, often grave illness (see Chap. 47) .

STENTLESS PORCINE XENOGRAFTS.

Since the stent adds to the obstruction and thereby increases stress on the leaflets, stentless valves have been developed for the aortic position[548] and are now being used increasingly, especially in patients with small aortic roots.[549] These include the Toronto SPV stentless valve (St. Jude Medical valve),[550] the Edwards stentless valve,[551] and the Medtronic freestyle valve.[548] It is hoped that the slightly improved hemodynamics provided by the stentless valves will translate into better long-term durability than that of valves mounted on stents.

HOMOGRAFT (ALLOGRAFT) AORTIC VALVES.

These are harvested from cadavers, often along with kidneys, usually within 24 hours of donor death. They are sterilized with antibiotics and cryopreserved for long periods at -196°C (see Fig. 46-52 *D*). They are inserted directly, usually in the aortic position, *without* being placed into a prosthetic stent. Their hemodynamics are superior to those of stented porcine valves. Like porcine xenografts, their thrombogenicity is low, but cryopreserved valves appear to have a similar rate of structural deterioration.[552] [552A] Perhaps this rate is reduced with the use of freshly harvested valves and approximate matching of donor's and patient's ages. Homograft aortic valves are indicated for patients with native or prosthetic valve endocarditis, but they are difficult to use when the aortic root and ascending aorta are greatly enlarged. Availability is often limited.[553]

PULMONARY AUTOGRAFTS.

In this operation, the Ross procedure, the patient's own pulmonary valve and adjacent main pulmonary artery are removed and used to replace the diseased aortic valve and often the neighboring aorta, with reimplantation of the coronary arteries into the graft[554] (see Fig. 46-52 *E*). A human pulmonary or aortic homograft is then inserted into the pulmonary position. The autograft is nonthrombogenic.[555] In children and adolescents, there is evidence that the autograft grows along with the patient. The risk of endocarditis is very low, anticoagulants are not required, and, perhaps most important, the long-term durability appears to be excellent.[556] Although the pulmonary autograft is the replacement valve of choice in children, adolescents, and younger adults who have a long (>20-year) life expectancy, its use has been limited because the operation is technically much more complex than a simple aortic valve replacement. The procedure should be carried out only by experienced surgeons.

PERICARDIAL AUTOGRAFTS.

The patient's own pericardium is inserted into a frame on the operating table (the Carpentier-Edwards Perimount pericardial bioprosthesis) and is inserted into either the aortic or the mitral position. Long-term durability appears to be excellent; in 267 patients undergoing isolated aortic valve replacement, the 14-year actuarial freedom of need for re-replacement because of structural valve dysfunction was 85 percent (94 percent in patients > 65 years of age).[557] Good results have also been reported for this valve in the mitral position, in which the results are also exceptional in older patients. However, there is a greater risk for the development of stenosis in the mitral position.[558]

HEMODYNAMICS OF VALVE REPLACEMENTS

The most commonly used prosthetic valves, i.e., mechanical prostheses and stented porcine xenografts, have an effective in vitro orifice size that is *smaller* than the normal valve at the same site. (Unstented, i.e., free, homografts and pulmonary autografts do not have this problem.) After implantation, tissue ingrowth and endothelialization reduce the size of the effective orifice even more. Therefore, the prosthetic valves that are currently available must be considered to be mildly stenotic. However, postoperative hemodynamic measurements of the mechanical prostheses show reasonably good function, with effective mitral valve orifice areas averaging 1.7 to 2.0 cm^2 and mitral valve gradients of 4 to 8 mm Hg at rest. The cloth-covered StarrEdwards valve appears to be intrinsically slightly more stenotic than the Medtronic-Hall or Omniscience tilting-disc valves. The bileaflet St. Jude and Carbomedics valves, in turn, may be slightly superior to the Medtronic-Hall or Omniscience valve. In hemodynamic studies, the stented porcine mitral valves behave in a manner similar to mechanical prosthetic valves of the same diameter. *Serious* hemodynamic obstruction of an artificial valve in the mitral position is quite uncommon, unless the valve (most commonly the Starr-Edwards valve) is placed into a small left ventricular cavity or into an unusually small mitral annulus or the prosthesis chosen is of inappropriate size.

The problem of prosthetic valve stenosis may be more serious in patients who undergo aortic valve replacement for AS. The annulus into which the prosthesis is inserted in these patients is usually smaller than it is in patients with AR, and the surgeon may be forced to select an artificial valve of relatively small size. As a consequence, aortic valve replacement, may not abolish obstruction in patients with AS but may merely convert severe to mild or moderate obstruction. When the smaller models of the stented porcine xenograft or mechanical prosthesis are placed into the aortic position, effective orifice areas of about 1.1 to 1.3 cm^2 are common.

In such patients, peak transvalvular gradients as high as 40 mm Hg during exercise have been recorded. The poor late results observed in a minority of patients undergoing replacement of stenotic aortic valves may possibly be related to the moderate stenosis of the prosthesis. In patients with AS who do not exhibit clinical improvement postoperatively, it is important to evaluate the function of both the prosthetic valve and the left ventricle. Rarely, reoperation to correct a malfunctioning prosthesis may be necessary.

SELECTION OF AN ARTIFICIAL VALVE (Table 46-13)

Most comparisons of mechanical and bioprosthetic valves indicate similar overall results in terms of early and late mortality, prosthetic valve endocarditis and other complications, and the need for reoperation, at least for the first 5 years postoperatively. As indicated, there appear to be no significant differences insofar as hemodynamics are concerned, except that patients with an unusually small left ventricular cavity or mitral or aortic annulus may have better results with the low-profile (tilting-disc) St. Jude or Carbomedics prosthesis or a tissue valve.[559] Patients with a small aortic annulus may be better candidates for unstented homografts, heterografts, or pulmonary autografts.

The major task in selecting an artificial valve is to weigh the advantage of durability and the disadvantages of the risks of thromboembolism and anticoagulant treatment inherent in mechanical prostheses on the one hand with the advantage of low thrombogenicity and the disadvantage of abbreviated durability of bioprostheses on the other. Hammermeister and associates[560] have compared the outcome in 575 men who were randomized to replacement of the mitral or the aortic valve with either mechanical or a bioprosthetic valve. There was no difference in survival or in the probability of developing a valve-related complication, including endocarditis, valve thrombosis, and systemic embolism, in patients receiving either a mechanical or a bioprosthetic valve. The rate of structurally related valve failure requiring reoperation (which is associated with about twice the mortality of the initial procedure) was much higher in patients receiving tissue as opposed to mechanical valves. As anticipated, anticoagulant-related bleeding was higher in patients receiving mechanical valves. Patients with mechanical valves also had a higher incidence of perivalvular regurgitation in the mitral position. In the Edinburgh randomized trial, which also compared a mechanical with a porcine xenograft valve,[561] actuarial survival rates tended to be better and the freedom from all valve-related adverse events was significantly better with mechanical valves. Retrospective cohort analyses are in agreement with the results of these trials.[562] [563] [564] Therefore, mechanical prostheses, usually of the bileaflet variety, are the valves of choice in the majority of patients under 65 years of age.

However, the following groups of patients should receive bioprostheses: (1) patients with coexisting disease who are prone to hemorrhage and who therefore tolerate anticoagulants poorly, such as those with bleeding disorders, intestinal polyposis, and angiodysplasia; (2) patients who are likely to be noncompliant with permanent anticoagulant treatment, who are unwilling to take anticoagulants on a regular basis, or who live in developing nations and cannot be monitored; (3) patients over the age of 65 years in whom bioprosthetic valves deteriorate very slowly, who are unlikely to outlive their bioprostheses, and who because of their age may also be at greater risk of hemorrhage while taking anticoagulants; (4) patients with a small aortic annulus in whom an unstented (free) bioprosthetic graft may provide superior hemodynamics; and (5) younger patients (< 40 years of age), especially women wishing to bear children, who require aortic valve replacement and in whom a pulmonary autograft may be preferable. However, the technical difficulties associated with the last procedure must be taken into account.

TABLE 46-13 -- VALVE SELECTION FOR AN INDIVIDUAL PATIENT

RELATIVE INDICATIONS FOR A MECHANICAL VALVE
Long expected lifetime (age<40 years)
Previous dysfunctional tissue valve
Anticoagulation required anyway
Double valve replacement
Composite graft (aortic root+valve) needed
Renal failure, dialysis
RELATIVE INDICATIONS FOR A BIOPROSTHESIS
Short expected lifetime (age 65 years)
Unreliable anticoagulant risk
Previous thrombosed valve
Anticoagulant intolerance
Pregnancy anticipated
From Grunkemeier GL, Rahimtoola SH, Starr A: Prosthetic heart valves. In Rahimtoola SH (ed): Valvular Heart Disease. Atlas of Heart Diseases. Vol 11. Braunwald E, series ed. Philadelphia, Current Medicine, 1977, pp 13.1-13.27.

Special Situations

PREGNANCY (see also Chap. 65) .

Women with artificial valves can tolerate the hemodynamic burden of pregnancy well, but the hypercoagulable state of pregnancy increases the risk of thromboembolism in pregnant patients with mechanical prostheses. Anticoagulation must not be interrupted, although an increased risk of fatal fetal hemorrhage occurs in women in whom anticoagulants are continued. There is also a risk of fetal malformation caused by the probable teratogenic effect of warfarin. Although these problems represent rationales for the use of tissue valves in all women of childbearing age,[565] [566] their limited durability in young adults makes their use unacceptable. Therefore, unless a pulmonary autograft can be employed (for patients who require aortic valve replacement), every effort should be made to defer valve replacement until after childbirth. In pregnant women with critical MS or AS, balloon valvuloplasty should be considered, and, if at all possible, mitral valve repair instead of replacement should be undertaken for patients with MR. Women of childbearing potential who have a mechanical prosthesis should be counseled against pregnancy. When a woman who already has a mechanical prosthetic valve becomes pregnant, the risk to the fetus if the mother receives oral anticoagulants appears to be lower than the risk to the mother if anticoagulants are discontinued. Therefore, coumarin derivatives should be continued and the INR maintained between 2.0 and 3.0 until 2 weeks before expected delivery, at which time the patient should be switched to intravenous heparin.[564] Heparin should be discontinued at the onset of labor but may be restarted, along with coumarin, several hours after delivery. Alternatively, warfarin may be briefly interrpted at the 38th week of gestation and planned cesarean section carried out.[567]

NONCARDIAC SURGERY.

When noncardiac surgery is required in patients with prosthetic valves who are receiving anticoagulants, the risk is minimal when the anticoagulant is stopped 1 to 3 days preoperatively and for a similar period postoperatively. It may be desirable, however, to protect the patient with low-molecular-weight dextran during the perioperative period and to resume anticoagulation rapidly with intravenous heparin.

PATIENTS DESTINED TO RECEIVE ANTICOAGULANTS.

Patients with earlier implantation of a mechanical prosthesis, chronic atrial fibrillation with an enlarged left atrium, a history of thromboembolism, or a thrombus in the left atrium at operation and who therefore are destined to receive anticoagulants should receive a mechanical valve prosthesis because the potential advantage of a tissue valve is negated.

CHILDREN AND PATIENTS RECEIVING CHRONIC HEMODIALYSIS.

The high incidence of bioprosthetic valve failure in children and adolescents[568] [569] and in patients on chronic hemodialysis virtually prohibits their use in these

groups. In young adults between the ages of 25 and 35 years, the failure of bioprosthetic valves is somewhat higher than it is in older adults; this serves as a relative, but not an absolute, contraindication to their use in this age group.

In children, a mechanical prosthesis (generally the St. Jude valve) with its favorable hemodynamics is preferred despite the disadvantages inherent in the need for anticoagulants in this age group.[570] Similarly, mechanical valve prostheses should be used in patients with chronic renal failure and/or hypercalcemia. Alternatively, if an experienced surgical team is available and the patient requires an aortic valve replacement, a pulmonary autograft may be employed.

TRICUSPID POSITION.

The risk of thrombosis for all valves is highest in the tricuspid position because of the lower pressures and velocity of blood flow. This complication appears to be highest for tilting-disc valves, intermediate for caged-ball valves, and lowest for bioprostheses, which are the valves of choice as tricuspid replacements. Fortunately, bioprostheses exhibit a much slower rate of mechanical deterioration in the tricuspid position than in the mitral or aortic positions.

GUIDELINES MANAGEMENT OF VALVULAR HEART DISEASE

Thomas H. Lee

Guidelines for management of patients with valvular heart disease were published by an American College of Cardiology/American Heart Association (ACC/AHA) committee in 1998.[1] As is the case for other ACC/AHA guidelines, the indications for various tests and procedures are divided into classes:

Class I:
Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.
Class II:
Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.
Class IIa:
Weight of evidence/opinion is in favor of usefulness/efficacy.
Class IIb:
Usefulness/efficacy is less well established by evidence/opinion.
Class III:
Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful.

Some material from these guidelines is presented elsewhere in this book. Guidelines for prevention and treatment of infective endocarditis are summarized in Chapter 47 and its guidelines. Guidelines for management of anticoagulation in pregnancy are included in the appendix to Chapter 65 . Recommendations for prevention of recurrence of rheumatic fever are included in the appendix to Chapter 66 .

The guidelines emphasize that the decision to use echocardiography to evaluate patients with cardiac murmurs should be influenced by the patient's symptomatic status and the physical examination. Additional reassurance that a murmur is clinically insignificant may be drawn from other clinical tests, such as the electrocardiogram and chest roentgenogram, if these tests are normal. Echocardiography is considered inappropriate (Class III) for evaluation of murmurs that experienced observers consider innocent or functional. In contrast, echocardiography is considered appropriate even in asymptomatic patients with murmurs suggesting significant valvular disease or in patients with other signs or symptoms of cardiovascular disease (Table 46-G-1) .

Mitral Stenosis

Transthoracic echocardiography is endorsed in the ACC/AHA guidelines as a valuable test for diagnosis and follow-up of patients with mitral stenosis. The ACC/AHA guidelines do not endorse routine use of transesophageal echocardiography for evaluation of mitral valve morphology, but do note a potential role (Class IIa) for detection of left atrial thrombus in patients being considered for percutaneous balloon mitral valvotomy or cardioversion.

Anticoagulation is endorsed for patients with mitral stenosis who have a history of atrial fibrillation or a prior embolic event. The ACC/AHA panel is not strongly supportive of anticoagulation on the basis of a left atrial dimension >55 mm in patients in sinus rhythm. Surgical therapy with valvotomy, valve repair, or valve replacement is indicated for patients with moderate or severe mitral stenosis (valve
1.5 cm^2) and NYHA functional class III or IV, with the choice of the procedure dictated by the anatomical findings. Balloon valvotomy is also endorsed for patients who are NYHA functional class II. For patients with mild or no symptoms of mitral stenosis, balloon valvotomy is considered appropriate (Class IIa) in the presence of pulmonary hypertension and in the absence of left atrial thrombus or moderate to severe mitral regurgitation.

Mitral Regurgitation

Echocardiography is considered appropriate for the diagnosis of acute or chronic mitral regurgitation, as well as in annual or semiannual surveillance of left ventricular function in patients with severe mitral regurgitation, even if the patients are asymptomatic. Serial use of chest roentgenograms and electrocardiograms is considered to be of less value. In asymptomatic patients with mild mitral regurgitation and no evidence of left ventricular enlargement or dysfunction, the guidelines recommend yearly evaluations to detect worsening symptomatic status, but do not support annual echocardiography. Transesophageal echocardiography is considered most appropriate for intraoperative guidance and when transthoracic studies are inadequate.

Cardiac catheterization is usually performed before surgery in patients with mitral regurgitation. Coronary angiography is not considered routinely necessary in the ACC/AHA guidelines for patients younger than age 35 years who have no clinical suspicion of coronary artery disease. Left ventriculography and hemodynamic assessment are appropriate when noninvasive studies do not provide definitive information about the severity of mitral regurgitation or left ventricular dysfunction or the need for surgery.

Surgery is considered appropriate for patients with acute symptomatic mitral regurgitation and for those with chronic severe mitral regurgitation and symptoms of congestive heart failure, even if they have normal left ventricular function. Even if patients are asymptomatic, surgery is appropriate when they have mild or more severe left ventricular dysfunction (i.e., ejection fraction 50 to 60 percent and end-systolic dimension 50 to 55 mm).

Mitral Valve Prolapse

Recommendations on use of echocardiography for patients with mitral valve prolapse were adopted from the recommendations of an earlier ACC/AHA task force on echocardiography.[2] These guidelines emphasize that the diagnosis of mitral valve prolapse should be made by physical examination and that echocardiography is primarily appropriate for evaluation of mitral regurgitation and ventricular compensation. Echocardiography is also appropriate for *excluding* the diagnosis of mitral valve prolapse in patients who have been given the diagnosis inappropriately. Serial use of echocardiography in stable patients with mild or no regurgitation is discouraged.

Antibiotic prophylaxis is considered appropriate for patients with the characteristic click-murmur complex or with echocardiographic evidence of mitral value prolapse with regurgitation. (Additional information on the use of antibiotic prophylaxis is included in the guidelines to Chapter 47.) Daily aspirin therapy is recommended for patients who have had cerebral transient ischemic attacks and for patients younger than age 65 years who have atrial fibrillation without other complicating factors. Warfarin therapy is recommended for poststroke patients and for older patients with atrial fibrillation.

Aortic Stenosis

Doppler echocardiography is considered a highly appropriate test for diagnosis and assessment of aortic stenosis and for evaluation of left

TABLE 46--G-1 -- MANAGEMENT OF VALVULAR HEART DISEASE IN ADULTS

Indication	Class I	Class IIa	Class IIb	Class III
Echocardiography in asymptomatic patients with cardiac murmurs	1. Diastolic or continuous murmurs 2. Holosystolic or late systolic murmurs 3. Grade 3 or greater midsystolic murmurs	1. Murmurs associated with abnormal physical findings on cardiac palpation or auscultation 2. Murmurs associated with an abnormal ECG or chest roentgenogram	--	1. Grade 2 or softer midsystolic murmur identified as innocent or functional by an experienced observer 2. To detect "silent" AR or MR in patients without cardiac murmurs; then recommend endocarditis prophylaxis
Echocardiography in symptomatic patients with cardiac murmurs	1. Symptoms or signs of congestive heart failure, myocardial ischemia or syncope 2. Symptoms or signs consistent with infective endocarditis or thromboembolism	Symptoms or signs likely due to noncardiac disease with cardiac disease not excluded by standard cardiovascular evaluation	--	Symptoms or signs of noncardiac disease with an isolated midsystolic "innocent" murmur
Transesophageal echocardiography in patients with MS	--	1. Assess for presence or absence of left atrial thrombus in patients being considered for percutaneous balloon mitral valvotomy or cardioversion 2. Evaluate mitral valve morphology and hemodynamics when transthoracic echocardiographic data are suboptimal	--	Routine evaluation of mitral valve morphology and hemodynamics when complete transthoracic echocardiographic data are satisfactory
Anticoagulation in patients with MS	1. Patients with paroxysmal or chronic atrial fibrillation 2. Patients with a prior embolic event	--	1. Patients with severe MS and left atrial dimension 55 mm by echocardiography	All other patients with MS
Cardiac catheterization in patients with MS	Perform percutaneous balloon mitral valvotomy in properly selected patients	1. Assess severity of MR in patients being considered for percutaneous balloon mitral valvotomy when clinical and echocardiographic data are discordant 2. Assess pulmonary artery, left atrial, and LV diastolic pressures when symptoms and/or estimated pulmonary arterial pressure is discordant with the severity of MS by 2-D and Doppler echocardiography 3. Assess hemodynamic response of pulmonary atrial and left atrial pressure to stress when clinical symptoms and resting hemodynamics are discordant.	--	1. Assess mitral valve hemodynamics when 2-D and Doppler echocardiographic data are concordant with clinical findings
Percutaneous balloon mitral valvotomy	1. Symptomatic patients (NYHA functional Class II, III, or IV), moderate or severe MS (mitral valve area 1.5 cm^2), and valve morphology favorable for percutaneous balloon valvotomy in the absence of left atrial thrombus or moderate to severe MR	1. Asymptomatic patients with moderate or severe MS (mitral valve area 1.5 cm^2) and valve morphology favorable for percutaneous balloon valvotomy who have pulmonary hypertension (pulmonary arterial systolic pressure >50 mm Hg at rest or 60 mm Hg with exercise) in the absence of left atrial thrombus or moderate to severe MR 2. Patients with NYHA functional Class III-IV symptoms, moderate or severe MS (mitral valve area 1.5 cm^2), and a nonpliable calcified valve who are at high risk for surgery in the absence of left atrial thrombus or moderate to severe MR	1. Asymptomatic patients with moderate to severe MS (mitral valve area 1.5 cm^2) and valve morphology favorable for percutaneous balloon valvotomy who have new onset of atrial fibrillation in the absence of left atrial thrombus or moderate to severe MR 2. Patients in NYHA function Class III-IV, moderate or severe MS (mitral valve area cm^2), and a nonpliable calcified valve who are low-risk candidates for surgery	Patients with mild MS.
Mitral valve repair for MS	Patients with NYHA functional Class III-IV symptoms, moderate or severe MS (mitral valve area 1.5 cm^2), and valve morphology favorable for repair if percutaneous balloon mitral valvotomy is not available	--	Patients with NYHA functional Class I symptoms, moderate or severe MS (mitral valve area 1.5 cm^2), and valve morphology favorable for repair who have had recurrent embolic events on adequate anticoagulation	1. Patients with NYHA functional Class I-IV symptoms and mild MS

Mitral valve replacement for MS	Patients with moderate or severe MS (mitral valve area 1.5 cm^2), and NYHA functional Class III-IV symptoms who are not considered candidates for percutaneous balloon valvotomy or mitral valve repair	1. Patients with severe MS (mitral valve area 1.0 cm^2) and severe pulmonary hypertension (pulmonary arterial systolic pressure >60 to 80 mm Hg) with NYHA functional Class I-II symptoms who are not considered candidates for percutaneous balloon valvotomy or mitral valve repair	--	--
Coronary angiography in patients with MR	1. When mitral valve surgery is contemplated in patients with angina or previous myocardial infarction 2. When mitral valve surgery is contemplated in patients with one or more risk factors of CAD 3. When eschemia is suspected as an etiologic factor in MR	--	To confirm noninvasive tests in patients not suspected of having CAD	When mitral valve surgery is contemplated in patients aged 35 years in whom there is no clinical suspicion of CAD
Left ventriculography and hemodynamic measures in patients with MR	1. When noninvasive tests are inconclusive regarding severity of MR, LV function, or the need for surgery 2. When there is a discrepancy between clinical and noninvasive findings regarding severity of MR	--	--	Patients in whom valve surgery is not contemplated
Mitral valve surgery in patients with nonischemic severe MR	1. Patients with acute symptomatic MR in whom repair is likely 2. Patients with NYHA functional Class II, III, or IV symptoms with normal LV function, defined as ejection fraction >60% and end-systolic dimension <45 mm 3. Symptomatic or asymptomatic patients with mild LV dysfunction, ejection fraction 50% to 60%, and end-systolic dimension 45 to 50 mm 4. Symptomatic or asymptomatic patients with moderate LV dysfunction, ejection fraction 30%, to 50%, and/or end-systolic dimension 50 to 55 mm	1. Asymptomatic patients with preserved LV function and atrial fibrillation 2. Asymptomatic patients with preserved LV function and pulmonary hypertension (pulmonary arterial systolic pressure >50 mm Hg at rest or >60 mm Hg with exercise) 3. Asymptomatic patients with ejection fraction 50% to 60% and end-systolic dimension <45 mm, and asymptomatic patients with ejection fraction >60% and end-systolic dimension 45 to 55 mm 4. Patients with severe LV dysfunction (ejection fraction <30% and/or end-systolic dimension >55 mm) in whom chordal preservation is highly unlikely	1. Asymptomatic patients with chronic MR with preserved LV function in whom mitral valve repair is highly likely 2. Patients with MVP and preserved LV function who have recurrent ventricular arrhythmias despite medical therapy	Asymptomatic patients with preserved LV function in whom significant doubt about the feasibility of repair exists
Antibiotic endocarditis prophylaxis for patients with MVP undergoing procedures associated with bacteremia	1. Patients with characteristic systolic click-murmur complex 2. Patients with isolated systolic click and echocardiographic evidence of MVP and MR	Patients with isolated systolic clock, echocardiographic evidence of high-risk MVP	--	Patients with isolated systolic clock and equivocal or no evidence of MVP
Aspirin and oral anticoagulants in patients with MVP	1. Aspirin therapy for transient ischemic attacks 2. Warfarin therapy for patients aged 65 years in atrial fibrillation with hypertension, MR, or history of heart failure 3. Aspirin therapy for patients aged <65 years in atrial fibrillation with no history or MR, hypertension, or heart failure 4. Warfarin therapy for poststroke patients	1. Warfarin therapy for patients with transient ischemic attacks despite aspirin therapy 2. Aspirin therapy for poststroke patients with contraindications to anticoagulants	1. Aspirin therapy for patients in sinus rhythm with echocardiographic evidence of high-risk MVP	
Cardiac catheterization in patients with aortic stenosis	1. Coronary angiography before aortic valve replacement in patients at risk for CAD 2. Assessment of severity of aortic stenosis in symptomatic patients when aortic valve replacement is planned, when noninvasive tests are inconclusive, or when there is a discrepancy with clinical findings regarding severity of aortic stenosis or need for surgery	--	Assessment of severity of aortic stenosis before aortic valve replacement when noninvasive tests are adequate and concordant with clinical findings and coronary angiography is not needed	Assessment of LV function and severity of aortic stenosis in asymptomatic patients when noninvasive tests are adequate

Aortic valve replacement in patients with aortic stenosis	1. Symptomatic patients with severe aortic stenosis 2. Patients with severe aortic stenosis undergoing coronary artery bypass surgery 3. Patients with severe aortic stenosis undergoing surgery on the aorta or other heart valves	1. Patients with moderate aortic stenosis undergoing coronary artery bypass surgery or surgery on the aorta or other heart valves 2. Asymptomatic patients with severe aortic stenosis and: a. LV systolic dysfunction, or b. Abnormal response to exercise (e.g., hypotension)	1. Asymptomatic patients with severe aortic stenosis and: a. Ventricular tachycardia, or b. Marked or excessive LV hypertrophy, or c. Valve area <0.6 cm^2	Prevention of sudden death in asymptomatic patients with none of the findings listed in Class II
Aortic balloon valvotomy in adults with aortic stenosis	--	A "bridge" to surgery in hemodynamically unstable patients who are at high risk for AVR	1. Palliation in patients with serious comorbid conditions 2. Patients who require urgent noncardiac surgery	An alternative to AVR
Vasodilator therapy for patients with chronic aortic regurgitation	1. Chronic therapy in patients with severe regurgitation who have symptoms and/or LV dysfunction, when surgery is not recommended because of additional cardiac or noncardiac factors 2. Long-term therapy in asymptomatic patients with severe regurgitation who have LV dilatation but normal systolic function 3. Long-term therapy in asymptomatic patients with hypertension and any degree of regurgitation 4. Long-term ACE inhibitor therapy in patients with persistent LV systolic dysfunction after AVR 5. Short-term therapy to improve hemodynamic profile of patients with severe heart failure symptoms and severe LV dysfunction before AVR	--	--	1. Long-term therapy in asymptomatic patients with mild to moderate aortic regurgitation and normal LV systolic function 2. Long-term therapy in asymptomatic patients with LV systolic dysfunction who are otherwise candidates for valve replacement 3. Long-term therapy in symptomatic patients with either normal LV function or mild to moderate LV systolic dysfunction who are otherwise candidates for valve replacement
Cardiac catheterization in patients with chronic AR	1. Coronary angiography before AVR in patients at risk for CAD 2. Assessing severity of regurgitation when noninvasive tests are inconclusive or discordant with clinical findings regarding severity of regurgitation or need for surgery 3. Assessing LV function noninvasive tests are inconclusive or discordant with clinical findings regarding LV dysfunction and need for surgery in patients with severe AR	--	Assessing LV function and severity of regurgitation before AVR when noninvasive tests are adequate and concordant with clinical findings and coronary angiography is not needed	Assessing LV function and severity of regurgitation in asymptomatic patients when noninvasive tests are adequate
Aortic valve replacement in patients with chronic severe AR	1. Patients with NYHA function Class III or IV symptoms and preserved LV systolic function, defined as normal ejection fraction at rest (ejection fraction 50%) 2. Patients with NYHA function Class II symptoms and preserved LV systolic function (ejection fraction 50% at rest) but with progressive LV dilatation or declining ejection fraction at rest on serial studies or declining effort tolerance on exercise testing 3. Patients with Canadian Heart Association functional Class II or greater angina with or without CAD 4. Asymptomatic or symptomatic patients with mild to moderate LV dysfunction at rest (ejection fraction 25% to 49%) 5. Patients undergoing coronary artery bypass surgery or surgery on the aorta or other heart valves	1. Patients with NYHA functional Class II symptoms and preserved LV systolic function (ejection fraction 50% at rest) with stable LV size and systolic function on serial studies and stable exercise tolerance 2. Asymptomatic patients with normal LV systolic function (ejection fraction >50%) but with severe LV dilatation (diastolic dimension >75 mm or end-systolic dimension >55 mm; consider lower threshold values for patients of small stature	1. Patients with severe LV dysfunction (ejection fraction <25%) 2. Asymptomatic patients with normal systolic function at rest (ejection fraction >50%) and progressive LV dilatation when the degree of dilatation is moderately severe (end-diastolic dimension 70 to 75 mm, end-systolic dimension 50 to 55 mm) 3. Asymptomatic patients with normal systolic function at rest (ejection fraction >50%) but with decline in ejection fraction during exercise radionuclide angiography	1. Asymptomatic patients with normal systolic function at rest (ejection fraction >50%) but with decline in ejection fraction during stress echocardiography 2. Asymptomatic patients with normal systolic function at rest (ejection fraction >50%) and LV dilatation when degree of dilatation when degree of dilatation is not severe (end-systolic dimension <70 mm, end-systolic dimension <50 mm)

Recommendations for surgery for patients with TR	Annuloplasty for severe TR and pulmonary hypertension in patients with mitral valve disease requiring mitral valve surgery	1. Valve replacement for severe TR secondary to diseased/abnormal tricuspid valve leaflets not amenable to annuloplasty or repair 2. Valve replacement or annuloplasty for severe TR with mean pulmonary arterial pressure <60 mm Hg when symptomatic	Annuloplasty for mild TR in patients with pulmonary hypertension secondary to mitral valve disease requiring mitral valve surgery	Valve replacement or annuloplasty for TR with pulmonary arterial systolic pressure <60 mm Hg with a normal mitral valve in asymptomatic patients or in symptomatic patients who have not had a trial of diuretic therapy
Follow-up strategy in patients with prosthetic heart valves	1. History, physical exam, ECG, chest roentgenogram, echocardiogram, CBC, serum chemistries, and INR (if indicated) at first postoperative outpatient evaluation (this evaluation should be performed 3 to 4 weeks after hospital discharge) 2. Radionuclide angiography or magnetic resonance imaging to evaluate LV function if echocardiography is unsatisfactory 3. Routine follow-up visits at yearly intervals with earlier reevaluations for change in clinical status		Routine serial echocardiograms at time of annual follow-up visit in absence of change in clinical status	Routine serial fluoroscopy
Valve replacement with a mechanical prosthesis	Patients with expected long life spans Patients with a mechanical prosthetic valve already in place in a different position that the valve to be replaced	1. Patients in renal failure, on hemodialysis, or with hypercalcemia (Class II rather than IIa) 2. Patients requiring warfarin therapy because of risk factors for thromboembolism 3. Patients 65 years for AVR and 70 years for MVR	Valve re-replacement for thrombosed biological valve	Patients who cannot or will not take warfarin therapy
Valve replacement with a bioprosthesis	1. Patients who cannot or will not take warfarin therapy 2. Patients >65 years needing AVR who do not have risk factors for thromboembolism	1. Patients considered to have possible compliance problems with warfarin therapy 2. Patients >70 years needing MVR who do not have risk factors for thromboembolism	1. Valve re-replacement for thrombosed mechanical valve 2. Patients <65 years	1. Patients in renal failure, on hemodialysis, or with hypercalcemia 2. Adolescent patients who are still growing

AR = atrial regurgitation; AVR = aortic valve replacement; CAD = coronary artery disease; CBC = complete blood count; 2-D = two-dimensional; ECG = electrocardiogram; INR = international normalized ratio; LV = left ventricle; MR = mitral regurgitation; MS = mitral stenosis; MVP = mitral valve prolapse; MVR = mitral valve replacement; NYHA = New York Heart Association; TR = tricuspid regurgitation.

*In centers with expertise in cardiac magnetic resonance imaging, cardiac MRI may be used in place of radionuclide angiography for these indications.

ventricular function in patients with this condition. The ACC/AHA guidelines note that yearly echocardiograms may be helpful for management of asymptomatic patients with severe aortic stenosis, but recommend an interval of 2 years for echocardiography in asymptomatic patients with moderate aortic stenosis and 5 years for asymptomatic patients with mild stenosis.

The guidelines indicate that exercise testing of asymptomatic patients can be performed safely and can provide useful information; however, the need for supervision by an experienced physician with close monitoring of blood pressure and electrocardiographic findings is emphasized. Recommendations from the Task Force on Acquired Valvular Heart Disease of the 26th Bethesda Conference address the issue of participation in competitive athletics.[3] These guidelines recommend that patients with severe aortic stenosis be advised to limit such activity to relatively low levels.

Coronary angiography is considered appropriate in the ACC/AHA guidelines for patients with possible coronary artery disease and may be needed to assess the severity of stenosis in symptomatic patients when other data are inconclusive. The guidelines discourage catheterization solely for the purpose of confirming information available from noninvasive tests.

Aortic valve replacement is indicated for virtually all symptomatic patients with severe aortic stenosis, and the ACC/AHA guidelines are generally supportive (Class IIa) of this procedure for asymptomatic patients with severe aortic stenosis, and left ventricular systolic dysfunction or exertional hypotension (see Table 46-G-1) . However, valve replacement for asymptomatic patients is otherwise discouraged. Aortic balloon valvotomy is given qualified support only as a "bridge" to surgery in hemodynamically unstable patients who cannot undergo immediate aortic valve replacement.

Aortic Regurgitation

Doppler echocardiography is a highly appropriate test for diagnosis and serial assessment of patients with aortic regurgitation. For new patients in whom the chronic nature of the lesion is uncertain, the guidelines support repeating the physical examination and echocardiogram 2 to 3 months after the initial evaluation to ensure that rapid progression is not underway. Asymptomatic patients with mild aortic regurgitation, normal left ventricular function, and little or no left ventricular dilatation can be seen on an annual basis, and echocardiography can be performed every 2 to 3 years in the absence of changes in symptoms. However, the guidelines support echocardiography every 6 to 12 months for patients with severe aortic regurgitation and significant left ventricular dilatation, such as an end-diastolic dimension greater than 60 mm. For patients with even more advanced left ventricular dilatation, echocardiography as often as every 4 to 6 months is endorsed.

Exercise testing is considered appropriate for assessment of functional capacity in patients in whom the history is not definitive, but the impact of this test on management is not otherwise strongly supported by the ACC/AHA guidelines. Radionuclide angiography is endorsed as an alternative to echocardiography for assessment of left ventricular volume and function. However, the ACC/AHA guidelines emphasize that there is no need for serial testing using both techniques.

The ACC/AHA guidelines consider vasodilator therapy appropriate for patients with aortic regurgitation who have hypertension or left ventricular dysfunction, even if the patients are asymptomatic. However, the guidelines do not endorse vasodilator therapy for normotensive patients with normal left ventricular function and mild aortic regurgitation. The guidelines emphasize that vasodilator therapy is *not* an alternative to surgery for patients who are appropriate candidates for valve replacement.

Cardiac catheterization is not routinely needed to confirm the diagnosis or assess the severity of aortic regurgitation when echocardiographic studies are adequate. The most common appropriate indication for cardiac catheterization is the performance of coronary angiography before surgery. Aortic valve replacement is considered clearly appropriate in patients with severe (NYHA functional Class III or IV) symptoms, progressive left ventricular dilatation, mild-to-moderate left ventricular dysfunction, or declining exercise tolerance. The guidelines are not supportive of surgery solely because of a decline in ejection fraction during exercise.

Other Valvular Diseases

Tricuspid valve annuloplasty is an appropriate procedure for patients with severe tricuspid regurgitation and pulmonary hypertension who are undergoing surgery for mitral valve disease, but is inappropriate for patients whose pulmonary arterial systolic pressure does not exceed 60 mm Hg or more.

Valvular Disease in Young Adults

For adolescents and young adults with aortic stenosis, ACC/AHA guidelines reflect a lower threshold for exercise testing and cardiac catheterization to assess the risk of participation in athletics (Table 46-G-2) (Table Not Available) . In this population, balloon valvotomy is an effective and appropriate option. Since this procedure has little morbidity and mortality, the indications for intervention are more liberal in younger patients than in older adults. The indications for management of chronic aortic regurgitation and mitral valvular disease are similar to those for older adult patients (see Table 46-G-1) . Pulmonic valvotomy is considered an appropriate intervention for patients who have symptomatic pulmonic stenosis and for asymptomatic patients with a peak valve gradient greater than 50 mm.

TABLE 46--G-2 -- GUIDELINES FOR MANAGEMENT OF VALVULAR HEART DISEASE IN ADOLESCENTS AND YOUNG ADULTS

(Not Available)

TABLE 46--G-3 -- AMERICAN COLLEGE OF CARDIOLOGY/AMERICAN HEART ASSOCIATION RECOMMENDATIONS FOR APPROPRIATE (CLASS I) ANTITHROMBOTIC THERAPY IN PATIENTS WITH PROSTHETIC HEART VALVES

Indication	Medication	Target	Class
1. First 3 months after valve replacement	Warfarin	INR 2.5 to 3.5	I
2.			
3 months after valve replacement:			
a. Mechanical valve:	Warfarin	INR 2.0 to 3.0	I
(1). AVR and no risk factors *	Warfarin	INR 2.5 to 3.5	I
Bileaflet valve or Medtronic-Hall valve			
(2). Other disc valves or Starr-Edwards valve	Warfarin	INR 2.5 to 3.5	I
(3). AVR plus risk factors*	Warfarin	INR 2.5 to 3.5	I
(4). MVR			
b. Bioprosthesis:	Aspirin	80 to 100 mg/day	I
(1). AVR and no risk factors*	Warfarin	INR 2.0 to 3.0	I
(2). AVR and risk factors*	Aspirin	80 to 100 mg/day	I
(3). MVR and no risk factors*	Warfarin	INR 2.5 to 3.5	I
(4). MVR and risk factors*			

AVR = aortic valve replacement; INR = international normalized ratio; MVR = mitral valve replacement.

*Risk factors: Atrial fibrillation, left ventricular dysfunction, previous thromboembolism, hypercoagulable conditions.

Patients with Prosthetic Heart Valves

The ACC/AHA guidelines recommend that INR be maintained between 2.0 and 3.0 for patients with bileaflet mechanical valves and Medtronic-Hall valves and between 2.5 and 3.5 for other disc valves and Starr-Edwards valves (Table 46-G-3) . Aspirin therapy is considered appropriate for patients with aortic or mitral valve bioprostheses and no risk factors for thromboembolism.

The guidelines indicate that hospital admission to administer heparin before noncardiac surgery or dental care is usually unnecessary. They recommend that heparin be reserved for patients who have had a recent thrombosis or embolism, those with demonstrated thrombotic problems when previously off therapy, those with a Bjork-Shiley valve, and those with three or more risk factors for thromboembolism.

After prosthetic valve implantation, asymptomatic patients need be seen only at 1-year intervals (see Table 46-G-1) . Routine serial echocardiograms are not strongly endorsed (Class IIb).

The ACC/AHA guidelines offer general recommendations to guide the selection of bioprosthetic versus mechanical valves. Bioprostheses are considered *inappropriate* for patients in renal failure, on hemodialysis, or with hypercalcemia, or for adolescent patients who are still growing.

Chapter 47 - Infective Endocarditis

ADOLF W. KARCHMER

DEFINITION

Infective endocarditis (IE) is a microbial infection of the endothelial surface of the heart. The characteristic lesion, the vegetation, is a variably sized amorphous mass of platelets and fibrin in which abundant microorganisms and scant inflammatory cells are enmeshed. Heart valves are most commonly involved; however, infection may occur at the site of a septal defect or on chordae tendineae or mural endocardium. Infection of arteriovenous shunts, arterioarterial shunts (patent ductus arteriosus), or coarctation of the aorta, although actually an endarteritis, is clinically and pathologically similar to IE. Many species of bacteria and fungi, mycobacteria, rickettsiae, chlamydiae, and mycoplasmas cause IE; nevertheless, streptococci, staphylococci, enterococci, and fastidious gram-negative coccobacilli cause the majority of cases of IE.

The terms *acute* and *subacute* are often used to describe IE. Acute IE presents with marked toxicity and progresses over days to several weeks to valvular destruction and metastatic infection. In contrast, subacute IE evolves over weeks to months with only modest toxicity and rarely causes metastatic infection. Acute IE is caused typically, although not exclusively, by *Staphylococcus aureus,* whereas the subacute syndrome is more likely caused by viridans streptococci, enterococci, coagulase-negative staphylococci, or gram-negative coccobacilli.

EPIDEMIOLOGY

The incidence of IE remained relatively stable from 1950 through 1987 at about 4.2 per 100,000 patient-years. During the early 1980s, the yearly incidence of IE per 100,000 population was 2.0 in the United Kingdom and Wales and 1.9 in the Netherlands.[1] A higher incidence was noted from 1984 through 1990; 5.9 and 11.6 episodes per 100,000 population were reported from Sweden and Metropolitan Philadelphia, respectively.[2] [3] Injection drug abuse accounted for approximately half of the cases in Philadelphia. Endocarditis usually occurred more frequently in men; gender-derived ratios range from 1.6 to 2.5. The age-specific incidence of endocarditis increased progressively after 30 years of age and exceeded 15 to 30 cases per 100,000 person-years in the sixth through eighth decades of life.[2] From 55 to 75 percent of patients with native valve endocarditis (NVE) have predisposing conditions: rheumatic heart disease, congenital heart disease, mitral valve prolapse, degenerative heart disease, asymmetrical septal hypertrophy, or intravenous drug abuse.[24] [5] From 7 to 25 percent of cases involve prosthetic valves.[2] [3] Predisposing conditions cannot be identified in 25 to 45 percent of patients. The nature of predisposing conditions and, in part, the microbiology of IE correlate with the age of patients (Table 47-1) .

CHANGE IN PATIENTS WITH IE.

Changes in the epidemiology of IE appear incontestable despite the hazard of referral bias in available data. As a consequence of changes in both the frequency of predisposing conditions encountered in patients with IE as well as the increasing age of the population at risk for IE, the median age of patients has gradually increased from 30 to 40 years of age in the preantibiotic and early antibiotic eras to 47 to 69 years in recent decades.[2] [4] [5] Rheumatic fever with subsequent rheumatic heart disease in children and young adults has been markedly reduced in developed countries. Acquired valvular disease emerges as a risk for IE as patients enjoy greater longevity. Additionally, during their later years, many of these patients require valve replacement, which places them at greater risk for endocarditis. The increasing life span of the general population results in the emergence of degenerative heart disease as a major substrate for IE. Finally, nosocomial endocarditis presents with increased frequency among the elderly, who experience high rates of hospitalization for underlying illnesses.[6] In recent decades, only the increasing role of intravenous (IV) drug abuse as predisposition for IE and the high IE risk in children and young adults surviving after correction of complex congenital heart disease favor the occurrence of infection in younger patients.[2] [7]

CHANGES IN THE MICROBIOLOGY OF IE.

Coagulase-negative staphylococci, previously a minor cause of NVE, are an important cause of prosthetic valve endocarditis (PVE) and nosocomial IE.[8] *S. aureus* is the predominant cause of IE among IV drug abusers, particularly of infection involving the tricuspid valve. In addition, *Pseudomonas aeruginosa,* other gram-negative bacilli, and *Candida* species, unusual causes of NVE in other settings, are important causes of IE in drug abusers. Even in series not biased by inclusion of large numbers of cases

Often tricuspid valve IE.

associated with drug abuse, *S. aureus* causes an increasing proportion of cases and rivals viridans streptococci.[2] [9] IE caused by enterococci, which are associated with genitourinary tract manipulations, and by *Streptococcus bovis,* which is associated with gastrointestinal malignancy and colonic polyps, occurs more frequently in the elderly, the population likely to experience these precipitating conditions.

PATIENT GROUPS

CHILDREN.

The incidence of IE among hospitalized children ranges from 1 in 4500 to 1 in 1280.[10] In the Netherlands, IE was noted in 1.7 and 1.2 per 100,000 male and female children younger than 10 years, respectively.[1] IE has been noted in neonates with increasing frequency. Among neonates, IE typically involves the tricuspid valve of structurally normal hearts and is associated with very high mortality rates. It is likely that many of these episodes arise as a consequence of infected IV and right-heart catheters as well as cardiac surgery.[10] [11]

The vast majority of children with IE occurring after the neonatal period have identifiable structural cardiac abnormalities (see Table 47-1) . In some series, rheumatic heart disease was an infrequent predisposition for IE (
4 percent).[11] [12] Congenital heart abnormalities, particularly those involving the aortic valve; ventricular septal defects; tetralogy of Fallot; and other complex structural anomalies associated with cyanosis are found in 75 to 90 percent of cases. Of children with IE on congenital defects, 50 percent develop infection after cardiac surgery; in these children, infection frequently involves prosthetic valves, valved conduits, or synthetic patches.[7] [11] [12] Secundum atrial septal defects are not associated with an increased risk for IE nor is patent ductus arteriosus or pulmonic stenosis after repair.[7] Since 1990, mitral valve prolapse has been recognized to predispose to IE in children; it, generally in association with a regurgitant murmur, was the predisposing cardiac abnormality in 15 percent and 5 percent of cases in two series.[12]

Endocarditis among neonates is caused primarily by *S. aureus,* coagulase-negative staphylococci, and group B streptococci.[10] Occasionally, infection is caused by gram-negative bacilli and *Candida* species.[10] [11] Among older children, streptococci, the predominant cause, account for at least 40 percent of cases, and *S. aureus* occurring as a nosocomial or community-acquired acute infection is the second most common cause of IE.[10] [11] [12] *Streptococcus pneumoniae,* a common cause of bacteremia in children, is nevertheless an uncommon cause of IE. *S. aureus* and *S. pneumoniae* may involve normal or abnormal valves, present as acute fulminant IE, cause rapid valve destruction and heart failure, and often result in death.[10]

The clinical features and echocardiographic findings of IE in children are similar to those noted among adults with NVE or PVE, respectively.[10] In contrast, IE among neonates is more cryptic; the clinical picture is dominated by bacteremia, and classical signs of IE are rare.[10]

ADULTS.

Mitral valve prolapse (MVP) has emerged as a prominent predisposing structural cardiac abnormality and in adults accounts for 7 to 30 percent of NVE in cases not related to drug abuse or nosocomial infection.[1] [4] [5] The frequency of MVP in IE is not entirely a direct reflection of risk but rather arises because of the high frequency of the lesion in the general population, 2 to 4 percent of healthy persons and 20 percent among young women.

The relative risk of endocarditis among patients with MVP ranges from 3.5 to 8.2. This increased risk of endocarditis is largely confined to patients with both prolapse and a mitral regurgitation murmur. Risk is also increased among men and patients older than 45 years. Valve redundancy and thickened leaflets (>5 mm) by echocardiography also identify a population at increased risk for IE (see Chap. 46) . Among patients with MVP and a systolic murmur, the incidence of IE is 52 per 100,000 person-years, compared with a rate of 4.6 per 100,000 person-years among those with prolapse and no murmur or among the general population. The microbiology of IE engrafted on MVP is similar to that of NVE that is not associated with drug abuse. Similarly, the mortality rate of 14 percent approximates that of NVE in general.

Rheumatic heart disease was the predisposing cardiac lesion for IE in 20 to 25 percent of cases in the 1970s and 1980s.[13] In reports from hospitals in North America and Europe in the 1980s, rheumatic heart disease predisposed to IE in only 7 and 18 percent of cases.[2] [4] [5] [9] In patients with rheumatic heart disease, endocarditis occurs most frequently on the mitral valve, a site at which women are more commonly infected. The aortic valve is the next most common site for IE; infection in this setting occurs more commonly in men.

Congenital heart disease is the substrate for IE in 10 to 20 percent of younger adults and 8 percent of older adults. Among adults, the common predisposing lesions are patent ductus arteriosus, ventricular septal defect, and bicuspid aortic valve, the latter particularly found among older men (>60 years).[2] [9]

In settings where NVE among adults is not skewed dramatically by infection occurring among IV drug abusers and nosocomial disease, the microbiology is notably similar to that shown in Table 47-1 . [2] [9] *Coxiella burnetii,* an uncommon cause of IE in the United States, caused 3 percent of all cases in the United Kingdom from 1976 to 1985 and is a prominent cause of IE in France.[14] *Bartonella* species have emerged as a significant cause of IE, accounting for 3 percent of cases in one report.[15]

INTRAVENOUS DRUG ABUSERS.

The risk for IE among IV drug abusers, 2 to 5 percent per patient-year, is estimated to be severalfold greater than that of patients with rheumatic heart disease or prosthetic valves.[16] In one study, IE was diagnosed in 74 (6.4 percent) of 1150 IV drug abusers who were hospitalized during 12 months. In metropolitan Philadelphia, 5.3 of a total of 11.6 cases of IE per 100,000 population was attributed to injection drug abuse.[3] From 65 to 80 percent of cases of IE in this population occurs in men, and the average age of patients ranges from 27 to 37 years.[17] [18] [19] [20]

Endocarditis occurring in IV drug abusers has a unique propensity to infect right heart valves.[16] [17] [20] On postmortem examination of 80 addicts with active or healed IE involving 103 valves, evidence of infection was seen on the tricuspid valve in 44 percent, the mitral valve in 43 percent, the aortic valve in 40 percent, and the pulmonic valve in 3 percent. Because mortality rates are higher in patients with left-sided versus right-sided IE, this distribution is undoubtedly skewed. In clinical series, distribution of valve involvement is tricuspid in 46 to 78 percent, mitral in 32 to 24 percent, and aortic in 8 to 19 percent (as many as 16 percent of patients have infection at multiple sites).[18] In IV drug abusers, the valves were normal before infection in 75 to 93 percent of patients.[16] [17] [18] The remaining patients have preexisting aortic or mitral valve abnormalities, resulting primarily from rheumatic heart disease, congenital heart disease, or prior episodes of IE. IV drug abuse is a risk factor for recurrent NVE.

The microbiology of IE occurring in IV drug abusers is unique in several respects (Table 47-2) . In contrast to NVE among adults in general, *S. aureus* causes more than 50 percent of these infections overall and 60 to 70 percent of those involving the tricuspid valve. The well-established predilection for *S. aureus* to infect normal as well as abnormal left heart valves is noted in addicts. Although the phenomenon of *S. aureus* infection of normal tricuspid valves is not unique to addicts, the high frequency is characteristic.[16] [21] Streptococcal and enterococcal infection of previously abnormal mitral or aortic valves in addicts is comparable to that noted generally

in NVE. In contrast, infection of right and left heart valves by *P. aeruginosa* and other gram-negative bacilli and left heart valves by fungi occurs with increased frequency among drug abusers. In addition, unusual organisms, some of which are likely related to injection of contaminated materials, cause endocarditis in these patients, e.g., *Corynebacterium* species, *Lactobacillus, Bacillus cereus,* and nonpathogenic *Neisseria* species. Polymicrobial endocarditis occurs with increased frequency in IV drug abusers.

The clinical manifestations of IE in IV drug abusers depend on the valve(s) involved and, to a lesser degree, on the infecting organism. Tricuspid valve endocarditis, particularly when caused by *S. aureus,* presents with pleuritic

chest pain, shortness of breath, cough, and hemoptysis. In 65 to 75 percent of patients, chest roentgenograms reveal abnormalities due to septic pulmonary emboli. Murmurs of tricuspid regurgitation are noted in less than half of these patients. Infection of the aortic or mitral valve in addicts clinically resembles IE seen in other patients. That caused by *S. aureus* generally presents as acute endocarditis with marked systemic toxicity. Symptoms and signs of left heart failure, neurologic injury, systemic emboli, metastatic infections, and the classical peripheral stigmata of IE are strongly associated with left-sided endocarditis.[16] [18]

Infection with human immunodeficiency virus (HIV) has been noted in 27 to 73 percent of IV drug abusers with IE[18] [19] [20] (see Chap. 68) . Among drug abusers with IE, HIV serostatus does not significantly modify the clinical presentation, microbiology, complications, and overall survival. However, among HIV-infected drug abusers with IE, the risk of death is increased among those with a CD4 count less than 200/mm^3 .[19] [20]

PROSTHETIC VALVE ENDOCARDITIS.

Epidemiologic studies suggest that prosthetic valve endocarditis (PVE) comprises 10 to 30 percent of all cases of IE in developed countries.[19] In metropolitan Philadelphia, 0.94 cases of IE per 100,000 population involved prosthetic valves.[3] The cumulative incidence of PVE estimated actuarially has ranged from 1.4 to 3.1 percent at 12 months and 3.2 to 5.7 percent at 5 years.[22] [23] [24] [25] [26] The risk of PVE over time, however, is not uniform. The risk is greatest during the initial 6 months after valve surgery (particularly during the initial 5 to 6 weeks) and thereafter declines to a lower but persistent risk (0.2 to 0.35 percent per year).[22] [23] [24] [25] [26] [27]

PVE has been called "early" when symptoms begin within 60 days of valve surgery and "late" with onset thereafter. These terms were established to distinguish early PVE that arose as a complication of valve surgery from late infection that was more likely community acquired. In fact, many cases with onset between 60 days and 1 year after surgery are likely to be nosocomial and, despite their delayed presentation, derive from events during the surgical admission.[28] Studies to identify risk factors for PVE have not resulted in a coherent picture. Data suggest that, during the initial months after valve implantation, mechanical prostheses are at greater risk of infection than bioprosthetic valves but that after 12 months the risk of infection of bioprostheses exceeds that of mechanical valves.[23] [24] [25] [26] [27] Patients with antecedent NVE, particularly if the disease is active, are at increased risk for PVE.[23] [24] [25] [26] [27]

Microbiology.

The microbiology of PVE is relatively predictable and reflects in part the presumed nosocomial or community acquisition of infection (Table 47-3) . Coagulase-negative staphylococci, which when speciated are primarily *Staphylococcus epidermidis,* are the predominant causes of PVE diagnosed within 60 days after surgery. *S. aureus,* gram-negative bacilli, diphtheroids (particularly *Corynebacterium jeikeium*), and fungi (particularly *Candida* species) are also common causes of PVE during this period.

Occasional cases of nosocomial PVE caused by *Legionella* species, atypical mycobacteria, mycoplasma, and fungi other than *Candida* have been reported. The spectrum and frequency of microorganisms causing PVE that occurs between 2 and 12 months after cardiac surgery and within the initial 60 postoperative days are similar. More than 80 percent of the coagulase-negative staphylococci from either of these periods are resistant to methicillin and all other beta-lactam antibiotics. In contrast, 30 percent or fewer of the coagulase-negative staphylococci causing PVE with onset more than 1 year after valve surgery are methicillin resistant.[25] [28] PVE with onset 1 year or more postoperatively presumably results from transient bacteremia arising from dental, gastrointestinal, and genitourinary manipulations; breaks in the skin barrier; and intercurrent infections.[27] [28] Consequently, the microbiology of these cases resembles that in community-acquired NVE in nonaddicts: streptococci, *S. aureus,* enterococci, and fastidious gram-negative coccobacilli (*Haemophilus* species, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella,* and *Kingella*-the so-called HACEK group). Coagulase-negative staphylococci cause about 10 percent of these cases of PVE.

Pathology.

The intracardiac pathology of PVE differs notably from the largely leaflet-confined pathology of NVE. Infection on mechanical prostheses commonly extends beyond the valve ring into the annulus and periannular tissue as well as the mitral-aortic intravalvular fibrosa, resulting in ring abscesses, septal abscesses, fistulous tracts, and dehiscence of the prosthesis with hemodynamically significant paravalvular regurgitation (Fig. 47-1) . In autopsy experience with 74 patients, which is clearly biased toward the

most severe pathology, annular invasion was noted in 85 percent, myocardial abscess in 32 percent, and valve obstruction by vegetation overgrowth, a phenomenon of PVE at the mitral site, in 19 percent.[28] Erosion through the aortic annulus to cause pericarditis occurred in 5 percent[28] (Fig. 47-2) . In clinical series encompassing 85 patients, the rate of annulus invasion was 42 percent, myocardial abscess 14 percent, valve obstruction 4 percent, and pericarditis 2 percent.[28] Bioprosthetic valve IE may result in invasive disease, comparable to that noted when PVE involves mechanical valves, as well as leaflet destruction (see Fig. 47-1) . Among 85 patients with bioprosthetic PVE, 29 (59 percent) of 49 with infection within a year after surgery had invasive disease, in contrast to only 9 (25 percent) of 36 patients with infection occurring more than 1 year postoperatively.[28] In surgically treated bioprosthetic IE, invasion was confirmed in 15 of 19 cases (79 percent), with onset in the initial 12 months after surgery but in only 22 of 71 bioprostheses (31 percent) when infection began more than 12 months after surgery.[29] Fernicola and Roberts, at surgery or autopsy, noted annular invasion in 4 of 5 bioprosthetic infections with onset within 60 days of surgery and in 17 of 32 infected bioprostheses with presentation occurring more than 60 days after surgery.[30] Aortic site and clinical onset within a year of valve surgery were significantly correlated with an increased risk of invasive infection.

Signs and symptoms in patients developing PVE within 60 days of cardiac surgery may be obscured by surgery or other postoperative complications. Peripheral signs of endocarditis (5 to 14 percent) and central nervous system emboli (10 percent) occur less frequently in these patients than in those with PVE occurring later after surgery. Among patients with later-onset PVE, congestive heart failure occurs in 40 percent, cerebrovascular complications in 26 to 28 percent, and peripheral signs in 15 to 28 percent.[28] [31] [32]

NOSOCOMIAL ENDOCARDITIS.

Hospital-acquired endocarditis unrelated to concurrent cardiac surgery comprises 5 to 29 percent of all cases of IE in various series.[4] [5] [6] [33] Nosocomial IE has involved abnomal native cardiac valves, normal valves including the tricuspid, and prosthetic valves and occurs with similar frequency among patients with NVE and PVE (unrelated to valve surgery).[1] [4] Infected intravascular devices and catheters give rise to 45 to 65 percent of the bacteremia that results in nosocomial IE.[6] [33] Other sources of bacteremia include genitourinary and gastrointestinal tract instrumentation or surgery. Right-sided endocarditis was found in 5 and 7 percent of patients with central venous catheters extending into or near the right atrium and those with flow-directed pulmonary artery catheters, respectively. The onset of nosocomial IE is usually acute, and although a changing murmur may be heard, other classical signs of endocarditis are infrequent.[33] Mortality rates among these patients, many of whom are elderly and have serious underlying diseases, are high (40 to 56 percent).[6] [33]

Microbiology.

Gram-positive cocci are the predominant cause of nosocomial IE. Among 45 episodes from two series, *S. aureus* caused 44 percent, coagulase-negative staphylococci 22 percent, enterococci 18 percent, and streptococci and *Candida* species and gram-negative bacilli each 4 percent. One patient (2 percent) had negative cultures.[6] In a meta-analysis, the mean rate of endocarditis or other deep-seated *S. aureus* infections after catheter-related bacteremia was 6.1 percent (95 percent confidence interval 2.0 to 10.2 percent).[34] When patients with *S. aureus* catheter-related bacteremia were studied with transesophageal echocardiography (TEE), 16 of 69 (23 percent) were found to have IE.[35] Accordingly, patients with catheter-related *S. aureus* bacteremia should be studied by transthoracic echocardiography (TTE) and, if IE is not diagnosed, should be evaluated by TEE.

Catheter-associated *S. aureus* bacteremia occurs with sufficient frequency to be the predominant predisposing factor for nosocomial IE.[6] [34] [35] [36] IE complicates 0.85 to 3.1 percent of cases of nosocomial enterococcal bacteremia; although the risk of nosocomial enterococcal IE is increased in patients with abnormal valves, it remains small, relative to that for nosocomial *S. aureus* bacteremia.[6] Among 115 patients who had prosthetic valves and who experienced a nosocomial bacteremia that was not indicative of PVE, 18 (15.6 percent) subsequently developed PVE that was the apparent consequence of the bacteremia. *S. aureus* and *S. epidermidis* were the most common organisms in these cases of PVE, although gram-negative bacilli and fungi also caused episodes of PVE.[37] Bacteremia persisting for days before treatment or for 72 hours or more after removal of an infected catheter and initiation of treatment, especially in patients with abnormal heart valves or prosthetic valves, suggests the diagnosis of IE.[6] [33] [36]

Figure 47-2 *A,* A large vegetation caused by *Candida albicans* partially occludes the orifice of a bioprosthetic valve removed from the mitral position.*(From Karchmer AW: Infections of prosthetic heart valves. In Korzeniowski OM [ed]: Cardiovascular Infection, vol. x, Atlas of Infectious Diseases. Philadelphia, Current Medicine; with permission.) B,* A Starr-Edwards prosthesis removed from the aortic position, where this large vegetation due to *Aspergillus* infection partially obstructed the outflow tract but also allowed regurgitation by preventing valve closure.

Etiological Microorganisms

VIRIDANS STREPTOCOCCI.

These streptococci, which cause 30 to 65 percent of NVE cases unrelated to drug abuse, are normal inhabitants of the oropharynx, characteristically produce alpha-hemolysis when grown on sheep blood agar, and are usually nontypable using Lancefield's system. Using earlier taxonomy, the species causing streptococcal NVE were distributed as follows: *Streptococcus mitior* (31 percent of cases), *Streptococcus sanguis* (24 percent), *S. bovis* (27 percent), *Streptococcus mutans* (7 percent), *Streptococcus milleri* (4 percent). *Streptococcus faecalis* (now *Enterococcus faecalis*) (7 percent), and *Streptococcus salivarius* and other species (2 percent). Another study, adjusted for the new taxonomy, has reported a similar distribution of streptococci causing IE.[38] Nutritional variant organisms that require media supplemented with either pyridoxal hydrochloride or L-cysteine for growth and were previously speciated as *Streptococcus adjacens* or *Streptococcus defectivus,* cause 5 percent of streptococcal NVE. These organisms have been reclassified into a new genus, *Abiotrophia.*[39]

The viridans streptococci, other than the nutritionally variant organisms, had been in general highly susceptible to penicillin (minimum inhibitory concentration [MIC] 0.1 mug/ml for 83 percent) and are killed in an enhanced manner (synergistically) by penicillin plus gentamicin.[39] Viridans streptococci isolated from blood, although not specifically from patients with IE, have demonstrated increased resistance to penicillin (penicillin MIC > 0.12 mug/mL).[40] This finding raises the concern that strains

causing IE may also be less susceptible to penicillin than in the past. *Abiotrophia* species, previously called *S. adjacens* and *S. defectivus,* appear more resistant to penicillin (MIC > 0.12 mug/ml in more than 30 percent of strains).[39] Although penicillin-aminoglycoside synergy was not demonstrated in vitro with *S. adjacens* and *S. defectivus,* in therapy of experimental endocarditis caused by these organisms, penicillin-aminoglycoside combinations were more effective than penicillin alone; also, therapy with vancomycin alone was comparable to that with the penicillin-aminoglycoside combination.[39]

STREPTOCOCCUS BOVIS AND OTHER STREPTOCOCCI.

S. bovis, part of the gastrointestinal tract normal flora, causes 27 percent of the episodes of streptococcal NVE. Although superficially resembling the enterococci, this species can be easily distinguished by its biochemical characteristics. The distinction is important because *S. bovis* is highly penicillin susceptible, in contrast to the relative penicillin resistance of enterococci. *S. bovis* NVE is frequently associated with coexistent colonic polyps or malignancy.[41]

Group A streptococci, which can infect normal valves, cause rare episodes of endocarditis. Among IV drug abusers, group A streptococci have caused tricuspid valve IE similar to that noted with *S. aureus.* Group B organisms, *Streptococcus agalactiae,* are part of the normal flora of the mouth, genital tract, and gastrointestinal tract. Group B streptococci infect normal and abnormal valves and cause a morbid NVE syndrome with a high incidence of systemic emboli and septic musculoskeletal complications (arthritis, diskitis, osteomyelitis).[42] The organisms' failure to produce fibrinolysin may result in large vegetations and a high rate of systemic emboli. Endocarditis caused by this organism may be associated with villous adenomas and colonic neoplasms. Group G streptococci also produce a destructive, highly morbid left-sided NVE. The *S. milleri* group, now divided into three species--*Streptococcus intermedius, Streptococcus constellatus,* and *Streptococcus anginosus*--are highly pyogenic organisms that cause destructive infections similar to those caused by *S. aureus* and accounted for 2 to 5 percent of streptococcal NVE cases.[38]

STREPTOCOCCUS PNEUMONIAE.

Although pneumococcal bacteremia occurs frequently, *S. pneumoniae* accounts for only 1 to 3 percent of NVE cases. When causing IE, *S. pneumoniae* frequently involves a previously normal aortic valve and progresses rapidly with valve destruction, myocardial abscess formation, and acute congestive heart failure (CHF).[43] The mortality rate among medically treated patients exceeded 60 percent but was 32 percent among those undergoing medical-surgical therapy.[43] Alcoholism is a risk factor for pneumococcal IE, and concurrent pneumonia or meningitis is common. Pneumococci that are resistant to penicillin and ceftriaxone are increasingly common causes of infection, particularly in children. These strains remain susceptible to vancomycin. In the future, these penicillin-resistant strains are likely to cause sporadic cases of IE; therefore, vancomycin might be included in the therapy of suspected pneumococcal IE until definitive susceptibility results for the isolate become available.[44]

ENTEROCOCCI.

E. faecalis and *Enterococcus faecium* cause 85 percent and 10 percent of cases of enterococcal IE, respectively. Enterococci are part of the normal gastrointestinal flora and cause genitourinary tract infection. Enterococci account for 5 to 15 percent of cases of NVE and a similar percentage of PVE cases (see Tables 47-2 and 47-3) .[9] [28] [45] Cases occur in young women as a consequence of genitourinary tract manipulation or infection and in older predominantly male patients, who have the urinary tract as a likely portal of entry. Enterococci infect either normal or previously abnormal valves and present as either acute or subacute IE.[45]

Enterococci are overtly resistant to cephalosporins, semisynthetic penicillinase-resistant penicillins (oxacillin and nafcillin), and therapeutic concentrations of aminoglycosides. Most enterococci are inhibited by modest concentrations of the cell wall-active antibiotics--penicillin, ampicillin, vancomycin, and teicoplanin (not licensed in the United States). Bactericidal antienterococcal activity can be achieved by combining an inhibitory cell wall-active agent and an appropriate aminoglycoside. This bactericidal activity called *synergy,* is essential for optimal treatment of enterococcal IE.[45] Strains of enterococci that are highly resistant to penicillin and ampicillin, resistant to vancomycin, and highly resistant to all aminoglycosides have been identified as causes of nosocomial infections.[45] [46]

STAPHYLOCOCCI.

The coagulase-positive staphylococci are a single species, *S. aureus.* Of the 13 species of coagulase-negative staphylococci that colonize humans, one, *S. epidermidis,* has emerged as an important pathogen in the setting of implanted devices and hospitalized patients. Coagulase-negative staphylococci on the surface of foreign devices have altered phenotypes, including increased resistance to the bactericidal effects of many antibiotics.[47] [48]

Antibiotic Resistance.

In excess of 90 percent of *S. aureus* cases, whether acquired in the hospital or community, produce beta-lactamase and thus are resistant to penicillin, ampicillin, and the ureidopenicillins. These organisms are, however, susceptible to the penicillinase-resistant beta-lactam antibiotics (oxacillin, nafcillin, cefazolin, and other first-generation cephalosporins). Methicillin-resistant strains of *S. aureus* are increasingly prevalent in nosocomial settings and among selected, nonhospitalized populations (IV drug abusers, nursing home residents) and must be considered when selecting initial empirical therapy for IE in patients from these groups.[17] [49] Coagulase-negative staphylococci frequently produce beta-lactamase; furthermore, strains causing community-acquired infections are frequently methicillin susceptible, whereas those causing nosocomial infections, including IE, are commonly methicillin resistant.[50] Coagulase-negative staphylococci may not always phenotypically express methicillin resistance (a property called *heteroresistance*). Consequently, special testing may be required to detect this resistance.[49] [50] Staphylococci, including most strains that are resistant to methicillin, remain susceptible to vancomycin and telcoplanin.[49]

Clinical Features.

S. aureus is a major cause of IE in all population groups (see Tables 47-1 and 47-2) . *S. aureus* IE is characterized by a highly toxic febrile illness, frequent focal metastatic infection, and a 30 to 50 percent rate of central nervous system complications.[49] A cerebrospinal fluid polymorphonuclear pleocytosis, with or without *S. aureus* cultured from the cerebrospinal fluid, is common.[49] Heart murmurs are heard in 30 to 45 percent of patients on initial evaluation and are ultimately heard in 75 to 85 percent as a consequence of intracardiac damage. The mortality rate in nonaddicts with left-sided *S. aureus* endocarditis ranges from 16 to 46 percent overall and increases in those over 50 years of age, in those with significant underlying diseases, and when IE is complicated by a major neurologic event valve dysfunction or CHF.[49] [51] [52] Among addicts, left-sided *S. aureus* IE resembles that in nonaddicts. In contrast, in patients with IE limited to the tricuspid valve, complications are rare and mortality rates are only 2 to 4 percent.[18] Tricuspid staphylococcal IE occasionally results in overwhelming septic pulmonary emboli, pyopneumothorax, and severe respiratory insufficiency.

Coagulase-Negative Staphylococci.

These are a major cause of PVE, particularly during the initial year after valve surgery, an important cause of nosocomial IE, and the cause of 3 to 8 percent of NVE cases, usually in the setting of prior valve abnormalities (see Tables 47-1 and 47-2 .[49] [50] The vast majority of coagulase-negative staphylococci causing PVE, when speciated, are *S. epidermidis.*[49] In contrast, when infection involves native valves, only 50 percent of isolates are *S. epidermidis.* [49] [50] *Staphylococcus lugdunensis,* a coagulase-negative species, has caused highly destructive, often fatal NVE and PVE.[53] *S. lugdunensis* IE is usually community acquired, and the organism is often susceptible to many antistaphylococcal antibiotics, including penicillin.[53]

GRAM-NEGATIVE BACTERIA.

Organisms of the so-called HACEK group, which are part of the upper respiratory tract and oropharyngeal flora, infect abnormal cardiac valves, causing subacute NVE, and cause PVE that occurs a year or more after valve surgery.[54] in NVE, the HACEK organisms have been associated with large vegetations and a high incidence of systemic emboli.[54] These organisms are fastidious and slow growing; when they are suspected, blood cultures should be incubated for 3 weeks. *Haemophilus* species, primarily *H. aphrophilus* followed by *H. parainfluenzae* and *H. Influenzae,* account for 0.5 to 1.0 percent of all IE.

P. aeruginosa is the gram-negative bacillus that most commonly causes endocarditis. The proclivity of *P. aeruginosa,* as opposed to Enterobacteriaceae, to cause IE correlates with its resistance to the bactericidal activity of human sera and its adherence to cardiac valves and platelet-fibrin thrombi. Pseudomonal IE involves normal and abnormal valves on both sides of the heart and often causes valve destruction and heart failure.[54]

The Enterobacteriaceae, despite causing frequent episodes of bacteremia, are implicated in only sporadic cases of IE.

Neisseria gonorrhoeae, a common cause of IE during the preantibiotic era, rarely causes endocarditis today.[55] [56] Gonococci, similar to pneumococci, infect the aortic valve of young patients, resulting in valve destruction abscess formation, and a probable need for valve replacement.[53] [54] [55] [56] Penicillinase production and intrinsic

to penicillin are common among gonococci; however, all strains remain susceptible to ceftriaxone.

OTHER ORGANISMS.

Corynebacterium species, often called diphtheroids, although often contaminants in blood cultures, cannot be ignored when isolated from multiple blood cultures. Prolonged incubation of blood cultures is often required to isolate these slow-growing, fastidious organisms from patients with IE. They are an important cause of PVE occurring during the initial year after valve surgery and a surprisingly common cause of endocarditis involving abnormal valves.[28] [56] [57] *Listeria monocytogenes,* a small gram-positive rod, causes occasional cases of IE involving abnormal left heart valves and prosthetic devices.[56] *Bartonella quintana, Bartonella elizabethae,* and *Bartonella henselae* have caused IE and can be isolated from blood cultures by prolonged incubation (2 weeks) followed by blind subculturing to fresh chocolate agar or sheep blood agar, which is in turn incubated for 2 to 3 weeks in 5 to 8 percent carbon dioxide.[58] [59] In the absence of special efforts in culturing, or serologic testing, many cases would have been "culture negative."[15] [58] [59] *Tropheryma whippelii,* the cause of Whipple's disease, has caused a cryptic afebrile form of IE with associated arthralgias but without diarrhea. The diagnosis has been established by examination of valve tissue by polymerase chain reaction and by microscopic identification of the organism in periodic acid-Schiff (PAS) or silver-stained vegetations.[60]

The rickettsia *C. burnetii* infects humans after inhalation of desiccated materials from infected animals or contact with infected parturient animals. At variable intervals after acute infection by *C. burnetii* (Q fever), persons with abnormal mitral or aortic valves who have not been able to eradicate the organism develop subacute IE with typical manifestations and often with valve dysfunction causing heart failure.[14] The diagnosis is typically based on high IgG and IgA antibody titers to phase I *C. burnetii* antigens. The organism can be demonstrated in excised cardiac valves by immunohistological or Gimenez staining.[14] *Chlamydia psittaci,* the agent of psittacosis, has caused occasional episodes of subacute IE and has resulted in hemodynamically significant valve damage.

FUNGI.

Candida albicans, nonalbicans *Candida* species, *Torulopsis glabrata,* and *Aspergillus* species are the most common of the many fungal organisms identified as causing IE. Fungal endocarditis arises in specific settings. Valve replacement cardiac surgery and IV drug abuse are major predispositions. The most frequent fungi causing PVE are *C. albicans, Aspergillus* species, and nonalbicans *Candida* species, whereas addiction-associated fungal IE is most commonly caused by non*albicans Candida* species, particularly *C. parapsilosis.*[61] [62] [63] [64] Fungal IE resulting from prolonged IV antimicrobial therapy and parenteral alimentation is caused predominantly by *C. albicans* and *T. glabrata.* Patients who are severely immunodepressed occasionally experience IE caused by *Candida* species, *Aspergillus* species, or opportunistic mycelia fungi. Blood cultures frequently are positive when *Candida* species or *T. glabrata* causes IE but rarely yield organisms when IE is caused by mycelial organisms. Bulky vegetations, which embolize frequently, are common in fungal IE. Removal and careful microbiological evaluation of an embolic vegetation may provide an etiological diagnosis in fungal IE.[61] [62]

PATHOGENESIS

The interactions between the human host and selected microorganisms that culminate in IE involve the vascular endothelium, hemostatic mechanisms, the host immune system, gross anatomic abnormalities in the heart, surface properties of microorganisms, and peripheral events that initiate bacteremia. Each component of these interactions is in itself complex, influenced by many factors and not fully elucidated. The rarity of endocarditis and endarteritis in the presence of frequent transient asymptomatic and symptomatic bacteremia indicates that the intact endothelium is resistant to infection. Endothelial damage results in platelet-fibrin deposition, which in turn is more receptive to colonization by bacteria than is the intact endothelium. It is hypothesized that platelet-fibrin deposition occurs spontaneously in persons vulnerable to endocarditis and that these deposits, called nonbacterial thrombotic endocarditis (NBTE), are the sites at which microorganisms adhere during bacteremia to initiate IE.[65] The relative uniformity of organisms causing IE, as contrasted with the variety of organisms causing overt and asymptomatic bacteremia, and the infectiousness of specific organisms in animal models of endocarditis indicate that certain microorganisms are advantaged in their ability to colonize and infect NBTE. The events after colonization that lead to IE entail survival and multiplication of microorganisms and the accrual of vegetation, as well as complex host-pathogen interactions.[66]

DEVELOPMENT OF NONBACTERIAL THROMBOTIC ENDOCARDITIS.

Two major mechanisms appear pivotal in the formation of NBTE: endothelial injury and a hypercoagulable state. NBTE has been found in 1.3 percent of patients at autopsy and is more common with increasing age. These lesions have also been noted frequently in patients with malignancy, disseminated intravascular coagulation, uremia, burns, systemic lupus erythematosus, valvular heart disease, and intracardiac catheters.[66] The platelet-thrombin deposits are found at the valve closure-contact line on the atrial surfaces of the mitral and tricuspid valves and on the ventricular surfaces of the aortic and pulmonic valves, the sites of infected vegetations in patients with IE.

Three hemodynamic circumstances may injure the endothelium, initiating NBTE: (1) a high-velocity jet impacting endothelium, (2) flow from a high- to a low-pressure chamber, and (3) flow across a narrow orifice at high velocity. Flow through a narrowed orifice, as a consequence of Venturi's effect, deposits bacteria maximally at the low-pressure sink immediately beyond an orifice or at the site where a jet stream impacts a surface. These are the same sites where NBTE forms as a result of hemodynamic circumstances. The superimposition of NBTE formation and preferential deposition of bacteria help to explain the distribution of infected vegetations. [67]

CONVERSION OF NBTE TO IE.

Bacteremia is the initiating event that ultimately converts NBTE to IE. The frequency and magnitude of bacteremia associated with daily activities and health care procedures appear related to specific mucosal surfaces and skin, the density of colonizing bacteria, the disease state of the surface, and the extent of the local trauma. Bacteremia rates are highest for events that traumatize the oral mucosa, particularly the gingiva, and progressively decrease with procedures involving the genitourinary tract and the gastrointestinal tract.[68] A diseased mucosal surface--particularly one that is infected--is associated with an increased risk of bacteremia.

Although IE develops when circulating microorganisms are deposited at a site of NBTE, the coincidence of bacteremia and NBTE does not uniformly result in IE. To cause IE, the organism must be able to persist and propagate on the endothelium. This requires resistance to host defenses. The complement-mediated bactericidal activity of serum limits the ability of susceptible aerobic gram-negative bacilli to cause IE. Only strains resistant to the bactericidal activity of serum, e.g., selected *E. coli, P. aeruginosa,* and *Serratia marcescens,* cause IE with significant frequency or are virulent in the rabbit model of endocarditis.[66] The precise role of granulocytes in eradicating early colonizing organisms is not clear. Platelet-released microbicidal material has been shown to eliminate recently adherent, susceptible viridans streptococci from valves in experimental endocarditis, and the resistance of *S. aureus* to these peptides correlates with ability of strains to cause endocarditis in animal models as well as IE and intravascular infection in patients.[68] [69] [70] [71]

The adherence of microorganisms to the NBTE is a pivotal early event in the development of IE. Those organisms that most frequently cause endocarditis adhere more vigorously in vitro to cardiac valves than do organisms that rarely cause IE. Many mechanisms promote this adherence, including the surface carbohydrates of bacteria. Bacteremic steptococci that produce extracellular dextran cause endocarditis more frequently than do strains that do not produce dextran. Dextran on the surface of streptococci can be shown to mediate adherence to platelet fibrin lattices and injured valves. Dextran production, however, is not universal among the major microbial causes of IE; thus, other mechanisms of adherence are likely.

Fibronectin has been identified as an important factor in this process. Fibronectin has been identified in lesions on heart valves and is produced by endothelial cells, platelets, and fibroblasts in response to vascular injury; a soluble form binds to exposed subendothelial collagen. Receptors for fibronectin are present on the surface of *S. aureus;* viridans streptococci; groups A, C, and G streptococci; enterococci;

S. pneumoniae; and *C. albicans.* Fibronectin has numerous binding domains and thus can bind simultaneously to fibrin, collagen, cells, and microorganisms and can serve to facilitate adherence of bacteria to the valve at the site of injury or NBTE. Clumping factor (or fibrinogen-binding surface protein) of *S. aureus* also mediates the binding of these organisms to platelet fibrin thrombin and to aortic valves in models of endocarditis.[72] The glycocalyx or slime on the surface of *S. epidermidis* does not appear to function as an adhesin but may render organisms more virulent by virtue of enhancing their ability to avoid eradication by host defenses.[73]

The mechanism by which virulent organisms colonize and infect intact valvular endothelium is less clearly understood. Endothelial cells in monolayers in vitro can phagocytize *S. aureus* and *Candida.* Multiplication of the organism intracellularly results in cell death, which in turn disrupts the endothelial surface and initiates formation of platelet-fibrin deposits. Alternatively, fibronectin may facilitate the adherence of *S. aureus* to intact endothelium.

After adherence to the NBTE or endothelium, persistence and multiplication result in a complex dynamic process during which the infected vegetation increases in size by platelet-fibrin aggregation, microorganisms are shed into the blood, and vegetation fragments embolize. Staphylococci and streptococci promote platelet aggregation and growth of the vegetation. Surface antigens that promote platelet adhesion (class I antigen) and aggregation (class II antigen that functionally mimics a platelet interactive domain of collagen) are expressed by *S. aureus.* Strains of *S. sanguis* with the aggregation antigen cause more severe endocarditis in the rabbit model than do antigen-negative strains.[74] Fibrin deposition is enhanced by tissue factor (a tissue thromboplastin that binds to factor VII) elaborated by endothelial cells, fibroblasts, or monocytes interacting with bacteria.[75] The persistence of this cycle results in the clinical syndrome of IE.

PATHOPHYSIOLOGY

Aside from the constitutional symptoms of infection, which are likely mediated by cytokines, the clinical manifestations of IE result from (1) the local destructive effects of intracardiac infection; (2) the embolization of bland or septic fragments of vegetations to distant sites, resulting in infarction or infection; (3) the hematogenous seeding of remote sites during continuous bacteremia; and (4) an antibody response to the infecting organism with subsequent tissue injury due to deposition of preformed immune complexes or antibody-complement interaction with antigens deposited in tissues.

The intracardiac consequences of IE range from trivial, characterized by an infected vegetation with no attendant tissue damage, to catastrophic, when infection is locally destructive or extends beyond the valve leaflet. Distortion or perforation of valve leaflets, rupture of chordae tendineae, and perforations or fistulas between major vessels and cardiac chambers or between chambers themselves as a consequence of burrowing infection may result in CHF that is progressive (Fig. 47-3) .[76] [77] Infection, particularly that involving the aortic valve or prosthetic valves, may extend into paravalvular tissue and result in abscesses and persistent fever due to antibiotic-unresponsive infection, disruption of the conduction system with electrocardiographic conduction abnormalities and clinically relevant arrhythmias, or purulent pericarditis.[78] Large vegetations, particularly at the mitral valve, can result in functional valvular stenosis and hemodynamic deterioration.[28] [79] In general, intracardiac complications involving the aortic valve evolve more rapidly than those associated with the mitral valve; nevertheless, the progression is highly variable and unpredictable in individual patients.

Embolization of fragments from vegetations is clinically evident in 11 to 43 percent of patients.[9] [67] [80] [81] However, pathologic evidence of emboli at autopsy is found more frequently (45 to 65 percent). Emboli from left-sided IE produce symptoms by infection or infarction at the site of lodgment. Although not demonstrated in all studies, pooled data suggest that larger vegetations (>10 mm) are associated with a higher frequency of emboli, as are hypermobile vegetations and those attached to the mitral valve, particularly the anterior leaflet.[82] [83] Pulmonary emboli, which are often

Figure 47-3 A normal valve with a large, bulky vegetation caused by *Staphylococcus aureus* infection. Clot is present centrally in the vegetation, obscuring a valve fenestration.

septic, occur in 66 to 75 percent of IV drug abusers with tricuspid valve IE (Fig. 47-4) .[16] [18]

The persistent bacteremia of IE, with or without septic emboli, may result in metastatic infection. These infections may present as local signs and symptoms or as persistent fever during therapy.[78] [84] IE caused by virulent organisms, particularly *S. aureus* or beta-hemolytic streptococci, is complicated more frequently by metastatic infection than is that due to avirulent bacteria, e.g., viridans streptococci. Virtually any organ or tissue may be hematogenously infected. Metastatic abscesses are often small and miliary. Metastatic infection assumes particular importance when the required therapy is more than the antibiotics indicated for IE or when these infections constitute a focus that engenders relapse.[84]

The humoral and cell-mediated arms of the immune system are stimulated in patients with IE. Antibodies to the infecting organism in the three major classes--IgM, IgG, and IgA--with functional capacity including opsonization, agglutination, and complement fixation have been noted. Additionally, hypergammaglobulinemia and cryoglobulinemia have been noted. Cellular responses are suggested by activated circulating macrophages and splenomegaly.

Circulating immune complexes in high titer have been detected in most patients with bacteremic IE and PVE. The frequency and titer of the circulating immune complexes are highest in IE of long duration, in the presence of extravalvular manifestation, and in right-sided IE. Although circulating immune complex titers fall with effective antibiotic therapy, titers are not widely used to monitor therapy. Immune complexes are clinically relevant when, with complement, they deposit

Figure 47-4 Infiltrates in the right and left midlung fields caused by septic pulmonary emboli arising from *Staphylococcus aureus* tricuspid valve infective endocarditis in an intravenous drug abuser.

subepithelially along the glomerular basement membrane to cause diffuse or focal glomerulonephritis.[67] Histological examination of affected glomeruli stained with fluorescent-labeled antibody to human globulin reveals a "lumpy-bumpy" pattern. The immunoglobulin eluted from the glomerular lesions reacts with bacterial antigens. Rheumatological manifestations of IE and some peripheral manifestations of IE, such as Osler's nodes, have been attributed to local deposition of immune complexes.[67] Osler's nodes, however, have also been associated with septic embolization in *S. aureus* IE.

Rheumatoid factor (an IgM antibody directed against IgG) is present in half of the patients with IE of greater than 6 weeks' duration.[67] The titer of rheumatoid factor decreases slowly with effective antimicrobial therapy.

CLINICAL FEATURES

The interval between the presumed initiating bacteremia and the onset of symptoms of IE is estimated to be less than 2 weeks in more than 80 percent of patients with NVE. Interestingly, in some patients with intraoperative or perioperative infection of prosthetic valves, the incubation period may be prolonged (2 to 5 or more months).[28]

Fever is the most common symptom and sign in patients with IE (Table 47-4) . Fever may be absent or minimal in the elderly or in those with CHF, severe debility, or chronic renal failure and occasionally in patients with NVE caused by coagulase-negative staphylococci.[50] [85]

Heart murmurs are noted in 80 to 85 percent of patients with NVE and are emblematic of the lesion predisposing to IE. Murmurs are commonly not audible in patients with tricuspid valve IE. Similarly, in acute NVE due to *S. aureus,* murmurs are heard in only 30 to 45 percent of patients on initial evaluation but are ultimately noted in 75 to 85 percent. The new or changing murmurs (alterations unrelated to heart rate or cardiac output but rather regurgitant murmurs indicative of valve dysfunction) are relatively infrequent

TABLE 47-4 -- CLINICAL FEATURES OF INFECTIVE ENDOCARDITIS

SYMPTOMS	PERCENT	SIGNS	PERCENT
Fever	80-85	Fever	80-90
Chills	42-75	Murmur	80-85
Sweats	25	Changing/new murmur	10-40
Anorexia	25-55		
Weight loss	25-35	Neurological abnormalities	30-40
Malaise	25-40		
Dyspnea	20-40	Embolic event	20-40

Cough	25	Splenomegaly	15-50
Stroke	13-20	Clubbing	10-20
Headache	15-40	Peripheral manifestation	
Nausea/vomiting	15-20

Central nervous system.
*More common in intravenous drug abusers.

in subacute NVE and are more prevalent in acute IE and PVE.[28] [86] They frequently are important harbingers of CHF.

Enlargement of the spleen is noted in 15 to 50 percent of patients and is more common in subacute IE of long duration.

The classical peripheral manifestations of IE are encountered less frequently today and are absent in IE restricted to the tricuspid valve.[4] [16] *Petechiae* (Fig. 47-5) , the most common of these manifestations, are found on the palpebral conjunctiva, the buccal and palatal mucosa, and the extremities. They are not specific for endocarditis even on the conjunctiva. *Splinter or subungual hemorrhages* (Fig. 47-6) are dark red, linear, or occasionally flame-shaped streaks in the nail bed of the fingers or toes. Distal lesions are likely due to trauma, whereas the more proximal ones are more likely related to IE. *Osler's nodes* are small, tender subcutaneous nodules that develop in the pulp of the digits or occasionally more proximally in the fingers and persist for hours to several days. These too are not pathognomonic for

Figure 47-5 Conjunctival petechiae in a patient with infective endocarditis. *(From Kaye D: Infective Endocarditis. Baltimore, University Park Press, 1976.)*

Figure 47-6 Subungual hemorrhages (splinter hemorrhages) and digital petechiae in a patient with infective endocarditis.*(From Korzeniowski OM, Kaye D: Infective endocarditis. In Braunwald E [ed]: Heart Disease. 4th ed. Philadelphia, WB Saunders, 1992.)*

IE. [86] Janeway's lesions are small erythematous or hemorrhagic macular nontender lesions on the palms and soles and are the consequence of septic embolic events. Roth's spots (Fig. 47-7) , oval retinal hemorrhages with pale centers, are infrequent findings in patients with IE. They have been noted in patients with collagen vascular disease and hematologic disorders, including severe anemia.

Musculoskeletal symptoms, unrelated to focal infection, are relatively common in patients with IE. These include arthralgias and myalgias, occasional true arthritis with nondiagnostic but inflammatory synovial fluid findings, and prominent back pain without evidence of vertebral body, disc space, or sacroiliac joint infection.[86] In patients with arthritis or back pain, focal infection must be precluded because additional therapy may be required.

Systemic emboli are among the most common clinical sequelae of IE, occurring in up to 40 percent of patients, and are frequent subclinical events found only at autopsy.[9] [67] [80] [81] Emboli often antedate diagnosis. Although embolic events may occur during or after antimicrobial therapy, the incidence decreases promptly during administration of effective

Figure 47-7 Roth spot (retinal hemorrhage with a clear center) in a patient with infective endocarditis.*(From Korzeniowski OM, Kaye D: Infective endocarditis. In Braunwald E [ed]: Heart Disease. 4th ed. Philadelphia, WB Saunders, 1992.)*

antibiotic therapy.[85] [87] Embolic splenic infarction may cause left upper quadrant abdominal pain and left shoulder pain. Renal emboli may occur asymptomatically or with flank pain and may cause gross or microscopic hematuria. Embolic stroke syndromes, predominantly involving the middle cerebral artery territory, occur in 15 to 20 percent of patients with NVE and PVE.[28] [88] Coronary artery emboli are common findings at autopsy but rarely result in transmural infarction. Emboli to the extremities may produce pain and overt ischemia, and those to mesenteric arteries may cause abdominal pain, ileus, and guaiac-positive stools.

Neurological symptoms and signs occur in 30 to 40 percent of patients with IE, are more frequent when IE is caused by *S. aureus,* and are associated with increased mortality rates.[80] [86] [89] [90] Embolic stroke is the most common and clinically important of the neurological manifestations. Intracranial hemorrhage occurs in 5 percent of patients with IE. Bleeding results from rupture of a mycotic aneurysm, rupture of an artery due to septic arteritis at the site of embolic occlusion, or hemorrhage into an infarct.[91] Mycotic aneurysms, with or without rupture, occur in 2 to 10 percent of patients with IE; approximately half of these involve intracranial arteries (Fig. 47-8) . Cerebritis with microabscesses complicates IE caused by invasive pathogens such as *S. aureus,* but large brain abscesses are rare.[88] Purulent meningitis complicates some episodes of IE caused by *S. aureus* or *S. pneumoniae,* but more typically the cerebrospinal fluid has an aseptic profile.[43] [89] Other neurological manifestations include severe headache (a potential clue to a mycotic aneurysm), seizure, and encephalopathy.

CHF complicating IE is primarily the result of valve destruction or distortion or rupture of chordae tendineae. Intracardiac fistulas, myocarditis, or coronary artery embolization may occasionally contribute to the genesis of CHF, as obviously can underlying cardiac disease. In the absence of surgery to correct valvular dysfunction, CHF, particularly that due to aortic insufficiency, is associated with very high mortality rates.[76]

Renal insufficiency as a result of immune complex-mediated glomerulonephritis occurs in less than 15 percent of patients with IE. Azotemia as a result of this process may develop or progress during initial therapy; it usually improves

Figure 47-8 An irregular mycotic aneurysm of the middle cerebral artery lies laterally on the cerebral cortex. A second aneurysm is projected just lateral to the anterior cerebral artery.

with continued administration of effective antibiotic therapy.[86] Focal glomerulonephritis and embolic renal infarcts cause hematuria but rarely result in azotemia. Renal dysfunction in patients with IE is most commonly a manifestation of impaired hemodynamics or toxicities associated with antimicrobial therapy (interstitial nephritis or aminoglycoside-induced injury).

DIAGNOSIS

The symptoms and signs of endocarditis are often constitutional and, when localized, often result from a complication of IE rather than reflect the intracardiac infection itself (see Table 47-4) . Consequently, if physicians are to avoid overlooking the diagnosis of IE, a high index of suspicion must be maintained. The diagnosis must be investigated when patients with fever present with one or more of the cardinal elements of IE: a predisposing cardiac lesion or behavior pattern, bacteremia, embolic phenomenon, and evidence of an active endocardial process. Because patients with prosthetic heart valves are always at risk for PVE, the presence of fever or new

prosthesis dysfunction at any time warrants considering this diagnosis. In patients at risk for endocarditis, concurrent illnesses or iatrogenic events may create clusters of symptoms and signs that superficially mimic IE and require careful consideration to arrive at a correct diagnosis. Even when the illness seems typical of endocarditis, the definitive diagnosis requires positive blood cultures or positive cultures (or histology or polymerase chain reaction recovery of a microorganism's DNA) from the vegetation or embolus. There are many culture-negative mimics of IE: atrial myxoma, acute rheumatic fever, systemic lupus erythematosus or other collagen-vascular disease, marantic endocarditis, the antiphospholipid syndrome, carcinoid syndrome, renal cell carcinoma with increased cardiac output, and thrombotic thrombocytopenic purpura.

When used judiciously over the entire evaluation sequence, i.e., not limited to initial findings, published criteria provide a sensitive and specific approach to the diagnosis of IE (Table 47-5) .[92] [94] Erroneous rejection of the diagnosis of endocarditis is unlikely. When using these diagnostic criteria to guide therapy, patients who are categorized with possible endocarditis should be treated as if they have IE. This management philosophy, however, may lead to the treatment of individuals as possible IE patients who are not likely to have the infection.[96] Requiring at least one major criterion or three minor criteria to designate possible endocarditis may reduce this potential for overdiagnosis.[94]

To use bacteremia due to coagulase-negative staphylococci or diphtheroids (organisms that may cause IE but more often contaminate blood cultures) to support the diagnosis of endocarditis, blood cultures must be persistently positive or the organisms recovered in several sporadically positive cultures must be proved to represent a single clone.[92]

Inclusion of echocardiographic evidence of endocardial infection in these criteria recognizes the high sensitivity of two-dimensional echocardiography with color Doppler, especially if multiplanar TEE and TTE are combined, and the relative infrequency of false-positive studies when experienced operators use specific definitions for vegetations.[94] [97] [98] Although the sensitivity of TEE to detect vegetations in patients with suspected infective endocarditis is 82 to 94 percent (or higher if a follow-up study is performed), a negative study result does not preclude the diagnosis or the need for therapy if the clinical suspicion is high.[98] The likelihood of a false-negative result can be reduced to 5 to 10 percent if TEE is repeated, especially if the study is biplanar or multiplanar.[94] [98] Thus, these studies help to preclude the diagnosis when the clinical suspicion is

TABLE 47-5 -- DIAGNOSIS OF INFECTIVE ENDOCARDITIS

Definitive Infective Endocarditis
Pathological criteria
Microorganisms: demonstrated by culture or histology in a vegetation, *or* in a vegetation that has embolized, *or* in an intracardiac abscess, *or*
Pathological lesions: vegetation or intracardiac abscess present, confirmed by histology showing active endocarditis
Clinical criteria, using specific definitions listed below
Two major criteria, *or*
One major and three minor criteria, *or*
Five minor criteria
Possible Infective Endocarditis
Findings consistent with infective endocarditis that fall short of definite endocarditis but are not rejected
Rejected
Firm alternative diagnosis for manifestations of endocarditis, *or*
Sustained resolution of manifestations of endocarditis, with antibiotic therapy for 4 days or less, *or*
No pathological evidence of infective endocarditis at surgery or autopsy, after antibiotic therapy for 4 days or less
Criteria for Diagnosis of Infective Endocarditis
Major Criteria
Positive blood culture
Typical microorganism for infective endocarditis from two separate blood cultures
Viridans streptococci, *Streptococcus bovis,* HACEK group *or*
Community-acquired *Staphylococcus aureus* or enterococci in the absence of a primary focus, *or*
Persistently positive blood culture, defined as recovery of a microorganism consistent with infective endocarditis from:
Blood cultures drawn more than 12 hr apart, *or*
All of three or a majority of four or more separate blood cultures, with first and last drawn at least 1 hr apart
Evidence of endocardial involvement
Positive echocardiogram
Oscillating intracardiac mass, on valve or supporting structures, *or* in the path of regurgitant jets, *or* on implanted material, in the absence of an alternative anatomical explanation, *or*
Abscess, *or*
New partial dehiscence of prosthetic valve, *or*
New valvular regurgitation (increase or change in preexisting murmur not sufficient)
Minor Criteria
Predisposition: predisposing heart condition *or* intravenous drug use
Fever 38.0°C (100.4°F)
Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway's lesions
Immunological phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor
Microbiological evidence: positive blood culture but not meeting major criterion as noted previously* *or* serologic evidence of active infection with organism consistent with infective endocarditis
Echocardiogram: consistent with infective endocarditis but not meeting major criterion
Adapted from Durack DT, Lukes AS, Bright DK: New criteria for diagnosis of infective endocarditis: Utilization of specific echocardiographic findings. Am J Med 96:200, 1994.

*Excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

low. [94] [98] Nevertheless, when the clinical suspicion is high, even these highly sensitive tests cannot preclude the diagnosis. These guidelines are vulnerable to misidentifying as culture-negative IE the vegetations that complicate marasmus, malignancy, cryptic collagen-vascular disease, or the antiphospholipid antibody syndrome.

A microbial cause of IE is established by recovering the infecting agent from the blood or by identifying it in surgically removed vegetations or embolic material. In detecting the bacteremia of IE there is no advantage to obtaining blood cultures in relationship to fever nor from arterial blood (as opposed to venous blood). In patients who have not received prior antibiotics and who will ultimately have blood culture-positive IE, it is likely that 95 to 100 percent of all cultures obtained will be positive

and that one of the first two cultures will be positive in at least 98 percent of patients. Prior antibiotic therapy is a major cause of blood culture-negative IE, particularly when the causative microorganism is highly antibiotic susceptible. At least 35 percent of cases of culture-negative IE can be attributed to prior antimicrobial therapy.[99] After subtherapeutic antibiotic exposure, the time required for reversion to positive cultures is directly related to the duration of antimicrobial therapy and the susceptibility of the causative agent; days to a week or more may be required.

OBTAINING BLOOD CULTURES.

Three separate sets of blood cultures, each from a separate venipuncture, obtained over 24 hours, are recommended to evaluate patients with suspected endocarditis.[94] Each set should include two flasks, one containing an aerobic medium and the other containing thioglycollate broth (anaerobic medium) into which at least 10 ml of blood should be placed. For optimal processing, the laboratory should be advised that endocarditis is a possible diagnosis and which, if any, unusual bacteria are suspected (*Legionella* species, *Bartonella* species, HACEK organisms). If a clinically stable patient has received an antimicrobial agent during the past several weeks, it is prudent to delay therapy so that repeat cultures can be obtained on successive days. If fungal endocarditis is suspected, blood cultures should be obtained using the lysis-centrifugation method. The laboratory should be asked to save the organism causing endocarditis until successful therapy has been completed. Serologic tests are occasionally used to make the presumptive etiological diagnosis of endocarditis caused by *Brucella* species, *Legionella* species, *Bartonella* species, *C. burnetii,* or *Chlamydia* species. By special techniques, including polymerase chain reaction, these agents and others that are difficult to recover in blood culture can be identified in or recovered from blood or vegetations.[14] [58] [59] [60] [94] [100] [101]

Laboratory Tests

Many other tests are inevitably performed in the evaluation of patients with suspected IE.[102] Hematological parameters are commonly abnormal. Anemia, with normochromic normocytic red blood cell indices, a low serum iron level, and low serum iron-binding capacity, is found in 70 to 90 percent of patients. Anemia worsens with increased duration of illness and thus in acute IE may be absent. In subacute IE, the white blood cell count is usually normal; in contrast, a leukocytosis with increased segmented granulocytes is common in acute IE. Thrombocytopenia occurs only rarely.

The *erythrocyte sedimentation rate* (ESR) is elevated (average approximately 55 mm/hr) in almost all patients with IE; the exceptions are those with CHF, renal failure, or disseminated intravascular coagulation. Other tests often indicate immune stimulation or inflammation (see Pathophysiology): circulating immune complexes, rheumatoid factor, quantitative immune globulin determinations, cryoglobulins, and C-reactive protein. Although the results of these tests parallel disease activity, the tests are costly and not efficient ways to diagnose IE or monitor response to therapy. Measurement of circulating immune complexes and complement may be useful in evaluating for azotemia due to diffuse immune complex glomerulonephritis.[102]

The *urinalysis* result is often abnormal, even when renal function remains normal. Proteinuria and microscopic hematuria are noted in 50 percent of patients. Urinalysis has a standard role in the evaluation of azotemia.

Serological tests are used to evaluate blood culture-negative IE (see Diagnosis). The presence or absence of antibodies to ribitol teichoic acids from staphylococci does not distinguish uncomplicated *S. aureus* bacteremia from that associated with IE or other deep-seated infection.

Echocardiography (See also Chap. 7)

Evaluation of patients with clinically suspected IE by this technique frequently allows morphological confirmation of infection and increasingly aids in decisions about management.[97] [98] Echocardiography should not be used as a screening test for IE in unselected patients with positive blood cultures or in patients with fevers of unknown origin when the clinical probability is low.[94] [95] Nevertheless, echocardiographic evaluation should be performed in all patients with clinically suspected IE, including those with negative blood cultures.[94] Although many patients with NVE involving the aortic or mitral valve can be imaged adequately by TEE using biplane or multiplane technology with incorporated color flow and continuous as well as pulsed Doppler is the state of the art.[94] [99] [103] TEE allows visualization of smaller vegetations and provides improved resolution compared with TTE. Not only is TEE the preferred approach in patients with clinically suspected IE in whom TTE is suboptimal, it is also the procedure of choice for imaging the pulmonic valve, patients with PVE (especially at the mitral site), and patients who are at high risk for intracardiac complications or those with signs of persistent or invasive infection despite adequate antimicrobial therapy.[94] [97] [103] [104] [105]

A decision analysis evaluation of echocardiography for diagnosis of IE involving native valves suggests that, assuming the diagnostic enhancement of TEE over TTE is 15 percent, the most cost-effective strategy (yielding optional quality adjusted life years) is 1) if prior probability of IE is less than 2 percent, treat for bacteremia without echocardiography; 2) if prior probability is 2 to 4 percent, use TTE; 3) if prior probability is 5 to 45 percent, use TEE in lieu of TTE, which would be followed by TEE if negative. If the prior probability of IE is greater than 45 percent, therapy without echocardiography is cost effective, although studies may still be desirable to evaluate for complications and other risks.[105A]

The sensitivity of TTE for the detection of vegetations in NVE is less than 65 percent, although its specificity is excellent. In contrast, in proven NVE, the sensitivity for vegetation detection of TEE was 100 and 90 percent, and in clinically suspected NVE, it ranged from 82 to 94 percent (see Diagnosis).[98] In patients with PVE, TTE is limited by the shadowing effect of mitral valve prostheses. The sensitivity of TEE for detecting vegetations in PVE involving mechanical or bioprosthetic devices ranged from 82 to 96 percent, whereas that of TTE was from 36 to 16 percent.[104] [105] [106]

Despite the sensitivity of TEE in detecting vegetations in patients with proven IE, echocardiography does not itself provide a definite diagnosis. Vegetations and valve dysfunction may be demonstrated, but determination of causality requires clinical or direct anatomical and microbiological confirmation. Infectious vegetations cannot be distinguished from marantic lesions, nor can vegetations be distinguished from thrombus or pannus on prostheses. Furthermore, it is usually not possible to distinguish active from healed vegetations in NVE.[97] [107] Thickened valves, ruptured chordae or valves, valve calcification, and nodules may be mistaken for vegetations, indicating the specificity limitations of echocardiography.[97]

Valve dysfunction due to tissue disruption or large obstructing vegetations can be visualized and quantitated by echocardiogram with Doppler.[82] [97] Some degree of regurgitation by Doppler is almost universal early in the course of NVE and PVE and does not necessarily predict subsequent hemodynamic deterioration.[97] Extension of infection beyond the valve leaflet into surrounding tissue is an ominous step in the progression of IE. It can result in abscesses in various areas of the annulus or adjacent structures, mycotic aneurysms of the sinus of Valsalva or mitral valve, intracardiac fistulas, and purulent pericarditis. Myocardial abscesses are more readily detected by TEE than TTE in patients with NVE or PVE.[104] [105] [106] The sensitivity and specificity for abscess detection were 28 percent and 98 percent for TTE, compared with 87 percent and 95 percent for TEE. Other studies have reported similar findings, especially in recognizing subaortic invasive disease.[108]

The natural history of vegetations during therapy is variable. On repeat echocardiogram 3 weeks to 3 months after initiation of ultimately effective antimicrobial therapy, 29 percent of 41 initial vegetations were no longer detectable. Of the 29 vegetations that remained detectable, 58 percent were unchanged, 24 percent were smaller, and 17 percent were larger. Mobility and extent (valves involved) of vegetations were unchanged in 86 and 65 percent, respectively. The evolution of these vegetations was not related to the duration of therapy or initial vegetation size, nor did it predict late complications of IE.[107] [108] In another study among patients, not all of whom were responding to therapy, persistence or increase in vegetation size during therapy was associated with an increased rate of complications. Accordingly, changes in vegetations must be interpreted in a clinical context and do not in themselves reflect the efficacy of therapy.

Stratification of patients into groups that are at high and low risk for CHF, systemic embolization, need for surgical intervention, and death based on the presence or absence of vegetations remains controversial.[82] [94] [97] The heterogeneous nature of the patients examined, the technologies used, and the lack of correlation with other features of IE, as well as the increasing ability to visualize vegetations in most patients with IE using TEE, undermine this debate. Although not demonstrated in all individual studies, pooled data from two-dimensional echocardiographic studies suggest that patients with larger vegetations (>10 mm in diameter) are at increased risk for embolic complications (20 percent versus 40 percent).[82] [97] This increased risk appears to be associated with large vegetations involving the mitral valve, particularly the anterior leaflet, and with the mobility of vegetations.[94] [97] The correlation of aortic or mitral valve vegetation size, extent, mobility, and site with CHF, need for surgical intervention, and mortality (other than that associated with embolic events) has not been fully established.[94] [97]

Among patients with right-sided IE, visualization of vegetations by TTE has been correlated with prolonged fever during therapy and increased right ventricular end-diastolic dimensions. These findings were not related to vegetation size, nor did the presence of vegetations or their size predict the failure of medical therapy and a need for surgical intervention.

MAGNETIC RESONANCE IMAGING.

This technique has identified paravalvular extension of infection, aortic root aneurysms, and fistulas; however, its utility relative to echocardiography has not been established.

SCINTIGRAPHY.

Efforts to identify vegetations and intracardiac abscess in patients with IE and in animal models have used scintigraphy with gallium-67 citrate, indium-111-labeled granulocytes, and indium-111-labeled platelets. These efforts have not been sufficiently sensitive or anatomically localizing to be useful clinically.[109]

TREATMENT

Two major objectives must be achieved to treat IE effectively. The infecting microorganism in the vegetation must be eradicated. Failure to accomplish this results in relapse of infection. Also, invasive, destructive intracardiac and focal extracardiac complications of infection must be resolved if morbidity and mortality are to be minimized. The second objective often exceeds the capacity of effective antimicrobial therapy and requires cardiac or other surgical intervention.

Bacteria in vegetations multiply to population densities approaching 10^{9} to 10^{10} organisms per gram of tissue, become metabolically dormant, and are difficult to eradicate. Clinical experience and animal model experiments suggest that optimal therapy should use bactericidal antibiotics or antibiotic combinations rather than bacteriostatic agents. Additionally, antibiotics reach the central areas of avascular vegetations by passive diffusion. To reach effective antibiotic concentrations in vegetations, high serum concentrations must be achieved, and penetration by some agents is limited even then. Parenteral antimicrobial therapy is used whenever feasible in order to achieve suitable serum antibiotic concentrations and to avoid the potentially erratic absorption of orally administered therapy. Treatment is continued for prolonged periods to ensure eradication of dormant microorganisms.

In selecting antimicrobial therapy for patients with IE, one must consider the ability of potential agents to kill the causative organism as well as the MIC and minimum bactericidal concentration (MBC) of these antibiotics for the organism. The MIC is the lowest concentration that inhibits growth, and the MBC is the lowest concentration that decreases a standard inoculum of organisms 99.9 percent during 24 hours. For the vast majority of streptococci and staphylococci, the MIC and MBC of penicillins, cephalosporins, or vancomycin are the same or differ by only a factor of two to four. Organisms for which the MBC for these antibiotics is 10-fold or greater than the MIC are occasionally encountered. This phenomenon has been termed *tolerance.*[110] Most of the tolerant strains are simply killed more slowly than nontolerant strains, and with prolonged incubation (48 hours) their MICs and MBCs are similar. Enterococci exhibit what superficially appears to be tolerance when tested against penicillins and vancomycin; however, these organisms are, in fact, not killed by these agents but are merely inhibited, even after longer incubation times. Enterococci can be killed by the combined activity of selected penicillins or vancomycin and an aminoglycoside. This enhanced antibiotic activity of the combination against enterococci, if of sufficient magnitude, is called *synergy* or a *synergistic bactericidal* effect.[45] [110] A similar effect can be seen with these combinations against streptococci and staphylococci; this effect overcomes tolerance.[110]

A synergistic bactericidal effect is required for optimal therapy of enterococcal endocarditis and has been used to achieve more effective therapy or effective short-course therapy of IE caused by other organisms. Tolerance in streptococci or staphylococci has been associated with reduced eradication of organisms from vegetations in animal model experiments.[111] [112] However, this finding in organisms causing endocarditis has not been correlated with decreased cure rates or delayed responses to treatment with penicillins, cephalosporins, or vancomycin. Accordingly, the presence of tolerance in streptococci or staphylococci has not required combination therapy, and, in fact, regimens are designed using the MICs of these organisms.[113]

The regimens recommended for the treatment of IE caused by specific organisms are designed to provide high concentrations of antibiotics in serum, also deep in vegetations. Concentrations that exceed the organism's MIC throughout most, if not all, of the interval between doses are recommended. Although antibiotic concentrations in vegetations of patients with IE have been measured infrequently, the success of the recommended regimens suggests that this goal has been achieved. Accordingly, for optimal therapy, it is important that the recommended regimens be followed carefully.

Antimicrobial Therapy for Specific Organisms

The antimicrobial therapy for endocarditis should not only eradicate the causative agent but should do so while causing little or no toxicity. Therapy for a given patient requires

modification to accommodate end-organ dysfunction, existing allergies, and other anticipated toxicities. With the exception of staphylococcal endocarditis, the antimicrobial regimens recommended for the treatment of NVE and PVE are similar, although more prolonged treatment is often advised for PVE.[28] [113]

PENICILLIN-SUSCEPTIBLE VIRIDANS STREPTOCOCCI OR *STREPTOCOCCUS BOVIS.*

Four regimens provide highly effective, comparable therapy for patients with endocarditis caused by penicillin-susceptible

TABLE 47-6 -- TREATMENT FOR NATIVE VALVE ENDOCARDITIS DUE TO PENICILLIN-SUSCEPTIBLE VIRIDANS STREPTOCOCCI AND *STREPTOCOCCUS BOVIS* (MINIMUM INHIBITORY CONCENTRATION 0.1 mug/ml)*

ANTIBIOTIC	DOSAGE AND ROUTE	DURATION (WK)
Aqueous penicillin G	12-18 million units/24 hr IV either continuously or every 4 hr in six equally divided doses	4
Ceftriaxone	2 gm once daily IV or IM	4
Aqueous penicillin G	12-18 million units/24 hr IV either continuously or every 4 hr in six equally divided doses	2
plus		
Gentamicin	1 mg/kg IM or IV every 8 hr	2
Vancomycin	30 mg/kg/24 hr IV in two equally divided doses, not to exceed 2 gm/24 hr unless serum levels are monitored	4

Modified from Wilson WR, Karchmer AW, Dajani AS, et al: Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, staphylococci, and HACEK microorganisms. JAMA 274:1706, 1995. Copyright 1995 American Medical Association.

*For nutritionally variant streptococci (*Streptococcus adjacens, Streptococcus defectivus*), see Table 47-8 .

Dosages given are for patients with normal renal function. Vancomycin and gentamicin doses must be reduced for treatment of patients with renal dysfunction. Vancomycin and gentamicin doses are calculated using ideal body weight (men=50 kg+2.3 kg per inch over 5 feet; women=45.5 kg+2.3 kg per inch over 5 feet).

TABLE 47-7 -- TREATMENT FOR NATIVE VALVE ENDOCARDITIS DUE TO STRAINS OF VIRIDANS STREPTOCOCCI AND *STREPTOCOCCUS BOVIS* RELATIVELY RESISTANT TO PENICILLIN G (MINIMUM INHIBITORY CONCENTRATION >0.1 mug/ml AND <0.5 mug/ml)

ANTIBIOTIC	DOSAGE AND ROUTE*	DURATION (WK)
Aqueous penicillin G	18 million units/24 hr IV either continuously or every 4 hr in 6 equally divided doses	4
plus		
Gentamicin	1 mg/kg IM or IV every 8 hr	2
Vancomycin	30 mg/kg/24 hr IV in two equally divided doses, not to exceed 2 gm/24 hr unless serum levels are monitored	4

Modified from Wilson WR, Karchmer AW, Dajani AS, et al: Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, staphylococci, and HACEK microorganisms. JAMA 274:1706, 1995. Copyright 1995 American Medical Association.

*Dosages are for patients with normal renal function. See Table 47-6 , footnote.

streptococci and *S. bovis* (Table 47-6) . The 4-week regimens yield bacteriologic cure rates of 98 percent among patients who complete therapy. Treatment with the synergistic combination of penicillin plus gentamicin for 2 weeks is as effective in selected cases as treatment with the 4-week regimens. The combination regimen is recommended for patients who have uncomplicated native valve endocarditis and who are not at increased risk for aminoglycoside toxicity. Patients with endocarditis caused by nutritionally variant streptococci, endocarditis involving a prosthetic valve, or endocarditis complicated by a mycotic aneurysm, myocardial abscess, perivalvular infection, or an extracardiac focus of infection should not be treated with this short-course regimen. From 2 to 8 percent of viridans streptococci and *S. bovis* causing endocarditis are highly resistant to streptomycin (MIC >2000 mug/ml) and are not killed synergistically by penicillin plus streptomycin. These highly streptomycin-resistant strains are, however, killed synergistically by penicillin plus gentamicin. Consequently, unless a causative streptococcus can be evaluated to preclude high-level resistance to streptomycin, gentamicin is recommended for use in the short-course combination regimen.[114] Ceftriaxone 2 gm once daily plus either gentamicin (3 mg/kg) or netilmicin (4 mg/kg) given as a single daily dose for 14 days has effectively treated endocarditis caused by penicillin-susceptible streptococci.[115] [116] Nevertheless, experience with single daily doses of aminoglycosides in the treatment of IE is limited, and these regimens are not currently recommended. The *Abiotrophia* species, previously called nutritionally variant streptococci, *S. adjacens* and *S. defectivus,* are generally more resistant to penicillin than are other viridans streptococci.[39] Patients with endocarditis caused by these organisms are treated with regimens recommended for enterococcal endocarditis (see Table 47-8) ; however, outcome remains unsatisfactory.

For the treatment of streptococcal endocarditis in patients with a history of immediate allergic reactions (urticarial or anaphylactic reactions) to a penicillin or cephalosporin antibiotic, vancomycin is recommended (see Table 47-6) . Patients with other forms of penicillin allergy (delayed maculopapular skin rash) may be treated cautiously with the ceftriaxone regimen (see Table 47-6) or with cefazolin, 2 gm IV every 8 hours for 4 weeks.

For patients with PVE caused by penicillin-susceptible streptococci, treatment with 6 weeks of penicillin is recommended, with gentamicin given during the initial 2 weeks.[28]

RELATIVELY PENICILLIN-RESISTANT STREPTOCOCCI.

Four weeks of high-dose parenteral penicillin plus an aminoglycoside (primarily gentamicin for the reasons noted previously) during the initial 2 weeks is recommended for treatment of patients with endocarditis caused by streptococci with MICs for penicillin between 0.2 and 0.5 mug/ml (Table 47-7) . Patients who cannot tolerate penicillin because of immediate hypersensitivity reactions can be treated with vancomycin alone. For those with nonimmediate penicillin hypersensitivity, effective treatment can be accomplished with either vancomycin alone or by adding gentamicin to the initial 2 weeks of the ceftriaxone regimen (see Table 47-6) . Patients with endocarditis caused by streptococci that are highly resistant to penicillin (MIC > 0.5 mug/ml) should be treated with one of the regimens recommended for enterococcal endocarditis (see Table 47-8) .

STREPTOCOCCUS PYOGENES, STREPTOCOCCUS PNEUMONIAE, AND GROUPS B, C, AND G STREPTOCOCCI.

Endocarditis caused by these streptococci has been either refractory to antibiotic therapy or associated with extensive valvular damage. Penicillin G in a dose of 3 million units IV every 4 hours for 4 weeks is recommended for the treatment of group A streptococcal and pneumococcal endocarditis. Pneumococci that are relatively resistant (MIC>0.1

mug/ml to 1.0 mug/ml) and highly resistant (MIC>1.0 mug/ml) to penicillin are widely distributed and likely to cause sporadic cases of endocarditis. Treatment with ceftriaxone plus vancomycin may be preferable until the penicillin susceptibility of the infecting strain is confirmed.[44] IE caused by group G, C, or B streptococci is more difficult to treat than that caused by penicillin-susceptible viridans streptococci. Consequently, the addition of gentamicin to the first 2 weeks of a 4-week regimen using high doses of penicillin is often advocated[42] (see Table 47-7) . Early cardiac surgery to correct intracardiac complications is needed in almost half of these cases; prompt intervention may improve outcome.[42]

BACTEREMIA.

Sustained bacteremia is typical of IE. In evaluating positive blood cultures, sustained bacteremia (persisting over >1 hour) should be distinguished from transient bacteremia. When several blood cultures obtained over 24 hours or more are positive, the diagnosis of IE must be considered. The identity of the organism is also helpful in determining the intensity with which the diagnosis is entertained. Organisms can be divided into those that commonly cause IE, those that rarely cause IE, and the intermediate-behaving organisms, e.g., enterococci and *S. aureus,* which, when in the blood, may or may not indicate IE. Finally, the presence or absence of alternative sources for the bacteremia aids in the assessment of bacteremia. These considerations are embodied in the diagnostic criteria for IE (see Table 47-5) .[90] [92]

Among patients with *S. aureus* bacteremia, the risk of IE has been greatest in those with community-acquired infection, those who lack a peripheral site of infection, those who are IV drug abusers, those who have evidence of valvular disease, and those who are diabetic with chronic cutaneous infections. Screening of patients with community-acquired *S. aureus* bacteremia using TTE demonstrated 20 percent of the patients to have either occult IE or valve lesions predisposing to IE.[93] Early studies have suggested that *S. aureus* catheter-associated bacteremia leads to IE in only 6.1 percent of patients.[34] IE was noted in 23 percent of 69 patients with catheter-associated *S. aureus* bacteremia. [35] In an additional study, 50 percent of patients with *S. aureus* IE had an intravascular catheter or a hemodialysis graft as the presumed source of infection.[52] In both of these studies, TTE was not sufficiently sensitive, and TEE was frequently required to diagnose IE. Thus, it is prudent to use TTE to evaluate patients with catheter-associated *S. aureus,* who appear to be at moderate clinical risk of having IE and to use TEE if that is negative or not diagnostic.[51] [94] [95] Patients with *S. aureus* bacteremia who have known underlying valvular heart disease, have a new significant heart murmur, or have persistent fever or bacteremia for 3 days or more after removal of the presumed primary focus of infection (intravascular catheter or drainage of an abscess) and initiation of therapy are at high risk for IE and require full echocardiographic evaluation.[36] [93]

ENTEROCOCCI.

Optimal therapy for enterococcal endocarditis requires synergistic bactericidal interaction of an antimicrobial targeted against the bacterial cell wall (penicillin, ampicillin, or vancomycin) and an aminoglycoside that is able to exert a lethal effect (primarily streptomycin or gentamicin). High-level resistance, defined as the inability of high concentrations of streptomycin (2000 mug/ml) or gentamicin (500 to 2000 mug/ml) to inhibit the growth of an enterococcus, is predictive of the agent's inability to exert this lethal effect and participate in the bactericidal synergistic interaction in vitro and in vivo.[45] [46] The standard regimens recommended for the treatment of enterococcal endocarditis (Table 47-8) are designed to achieve bactericidal synergy. Synergistic combination therapy has resulted in cure rates of approximately 85 percent, compared with 40 percent with single-agent, nonbactericidal treatment.[45]

TABLE 47-8 -- STANDARD THERAPY FOR ENDOCARDITIS DUE TO ENTEROCOCCI*

ANTIBIOTIC	DOSAGE AND ROUTE	DURATION (WK)
Aqueous penicillin G	18-30 million units/24 hr IV given continuously or every 4 hr in six equally divided doses	4-6
plus		
Gentamicin	1 mg/kg IM or IV every 8 hr	4-6
Ampicillin	12 gm/24 hr IV given continuously or every 4 hr in six equally divided doses	4-6
plus		
Gentamicin	1 mg/kg IM or IV every 8 hr	4-6
Vancomycin	30 mg/kg/24 hr IV in two equally divided doses not to exceed 2 gm/24 hr unless serum levels are monitored	4-6
plus		
Gentamicin	1 mg/kg IM or IV every 8 hr	4-6

Modified from Wilson WR, Karchmer AW, Dajani AS, et al: Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, staphylococci, and HACEK microorganisms. JAMA 274:1706, 1995. Copyright 1995 American Medical Association.

*All enterococci causing endocarditis must be tested for antimicrobial susceptibility in order to select optimal therapy. These regimens are for treatment of endocarditis caused by enterococci that are susceptible to vancomycin or ampicillin and not highly resistant to gentamicin. These may also be used for treatment of endocarditis caused by penicillin-resistant (MIC>0.5) viridans streptococci and nutritionally variant streptococci (*S. defectivus, S. adjacens*), or enterococcal PVE.

Dosages are for patients with normal renal function. See Table 47-6 , footnote.

Cephalosporins are not alternatives to penicillin/ampicillin in penicillin-allergic patients.

Some authorities prefer gentamicin doses of 1.5 mg/kg every 8 hours; however, because this dose may be associated with an increased frequency of nephrotoxicity, others advocate doses of 1 mg/kg every 8 hours. Peak serum gentamicin concentrations of approximately 5 mug/ml and 3.5 mug/ml are sought with these doses, respectively. In the absence of high-level resistance to streptomycin in a causative strain, streptomycin, 7.5 mg/kg intramuscularly (IM) or IV, every 12 hours, to achieve a peak serum concentration of approximately 20 mug/ml, can be substituted for gentamicin in the standard regimens. For patients allergic to penicillin, the vancomycin-aminoglycoside regimen (Table 47-8) is recommended; alternatively, patients can be desensitized to penicillin. Desensitization may be desirable when preexisting renal dysfunction favors avoiding the potentially more nephrotoxic vancomycin-aminoglycoside combination. Cephalosporins are not effective in the treatment of enterococcal endocarditis. Therapy is administered for 4 to 6 weeks, with the longer course used to treat patients with IE that was symptomatic for more than 3 months, with complicated disease, and with enterococcal PVE. During treatment, careful clinical follow-up of patients and aminoglycoside levels is required to prevent nephrotoxicity and ototoxicity.

Previously, 40 percent of enterococci demonstrated high-level resistance to streptomycin, and none was highly resistant to gentamicin. Furthermore, penicillin, ampicillin, and vancomycin inhibited all enterococci at concentrations achieved in the serum with standard IV doses. Accordingly, one of the standard regimens could be selected for treatment with confidence that bactericidal synergy would be achieved. Antimicrobial resistance among enterococci is now complex and cannot be predicted without in vitro testing. High-level resistance to gentamicin has been noted in 25 percent of *E. faecalis* and 50 percent of *E. faecium* infections, and resistance to penicillin, ampicillin, and vancomycin has become commonplace, especially in *E. faecium* infections. Resistance to these antibiotics is most common among enterococci isolated from hospitalized or previously hospitalized persons.

Nevertheless, all enterococci causing endocarditis must be evaluated carefully in order to select effective therapy (Table 47-9) . The strain causing endocarditis must be tested for high-level resistance to both streptomycin and gentamicin, as well as to determine its susceptibility to penicillin, ampicillin, and vancomycin. If the strain is either resistant to achievable serum concentrations of the cell wall-active agent or highly resistant to the aminoglycosides, synergy and optimal therapy cannot be obtain with a standard regimen that includes the inactive antimicrobial. Furthermore, high-level resistance to gentamicin predicts resistance to all other aminoglycosides except

TABLE 47-9 -- STRATEGY FOR SELECTING THERAPY FOR ENTEROCOCCAL ENDOCARDITIS CAUSED BY STRAINS RESISTANT TO COMPONENTS OF THE STANDARD REGIMEN 1

I. Ideal therapy includes a cell wall-active agent plus an effective aminoglycoside to achieve bactericidal synergy
II. Cell wall-active antimicrobial
A. Determine MIC for ampicillin and vancomycin; test for beta-lactamase production (nitrocefin test)
B. If ampicillin and vancomycin susceptible, use ampicillin
C. If ampicillin resistant (MIC 16 mug/ml) and vancomycin susceptible, use vancomycin
D. If beta-lactamase produced, use vancomycin or consider ampicillin-sulbactam
E. If ampicillin resistant and vancomycin resistant (MIC 16 mug/ml), consider teicoplanin*
F. If ampicillin resistant and highly resistant to vancomycin and teicoplanin (MIC 256 mug/ml), see IV C, D
III. Aminoglycoside to be used with cell wall-active antimicrobial
A. If no high level resistance to streptomycin (MIC<2000 mug/ml) or gentamicin (MIC<500-2000 mug/ml), use gentamicin or streptomycin
B. If high-level resistance to gentamicin (MIC>500-2000 mug/ml), test streptomycin. If no high-level resistance to streptomycin, use streptomycin
C. If high-level resistance to gentamicin and streptomycin, omit aminoglycoside therapy; use prolonged therapy (8-12 wk) with cell wall-active antimicrobial if the organism is susceptible (see II A-E) or alternative therapy (see IV C,D)
IV. Alternative regimens and approaches
A. Single drug therapy (see III C) and surgical intervention
B. Consider ampicillin, vancomycin (or teicoplanin), and gentamicin (or streptomycin) based on absence of high-level resistance
C. Consider quinupristin/dalfopristin therapy for infective endocarditis due to susceptible *Enterococcus faecium* and surgical intervention
D. Consider suppressive therapy with chloramphenicol or tetracycline and surgical intervention
E. Treatment with fluoroquinolones, rifampin, or trimethoprim-sulfamethoxazole of questionable efficacy
MIC=minimum inhibitory concentration.

*Not approved by the Food and Drug Administration for use in the United States; may be available by compassionate-use protocol.

streptomycin. These susceptibility data allow selection of a bactericidal synergistic regimen, if one is possible, or alternative treatment (see Table 47-9) . [46]

STAPHYLOCOCCI.

More than 90 percent of coagulase-positive and coagulase-negative staphylococci are penicillin resistant. Methicillin resistance is common among coagulase-negative staphylococci and is a less frequent but important characteristic among *S. aureus.* Methicillin-resistant strains are resistant to all beta-lactam antibiotics but usually remain susceptible to vancomycin. Although staphylococci are killed by cell wall-active antibiotics, the bactericidal effects of these agents can be enhanced by aminoglycosides. Combinations of semisynthetic penicillinase-resistant penicillins or vancomycin with rifampin do not result in predictable bactericidal synergism; nevertheless, rifampin has unique activity against staphylococcal infections that involve foreign material.[28] [117] Staphylococcal infections involving prosthetic heart valves are treated differently from native valve endocarditis caused by the same species (Table 47-10) .[28] [50] [113]

STAPHYLOCOCCAL NATIVE VALVE ENDOCARDITIS.

The semisynthetic penicillinase-resistant penicillins are the cornerstones of the treatment of endocarditis caused by methicillin-susceptible staphylococci. When patients have a penicillin allergy that does not induce urticaria or anaphylaxis, a first-generation cephalosporin can be used. The synergistic interaction of beta-lactam antibiotics with an aminoglycoside has not increased the cure rates for staphylococcal endocarditis; however, treatment with these combinations has modestly accelerated the eradication of staphylococci in vegetations and from the blood. To achieve this potential benefit, gentamicin may be added to beta-lactam antibiotic therapy for *S. aureus* during the initial 3 to 5 days of treatment.[113] More prolonged administration of gentamicin has been associated with nephrotoxicity and should be avoided. The role for combination therapy is less well defined in NVE caused by coagulase-negative staphylococci; pooled data suggest improved cure rates with

combination therapy.[50] In IV drug addicts, Methicillin-susceptible *S. aureus* endocarditis that is apparently uncomplicated and limited to the right heart valves has been effectively treated with 2 weeks of semisynthetic penicillinase-resistant penicillin (but not vancomycin) plus an aminoglycoside (doses as noted in Table 47-10) .[118] However, some patients with right-sided *S. aureus* endocarditis remain febrile and toxic for a significant portion or the entire 2 weeks of combination

TABLE 47-10 -- TREATMENT FOR STAPHYLOCOCCAL ENDOCARDITIS IN THE ABSENCE OF PROSTHETIC MATERIAL

ANTIBIOTIC	DOSAGE AND ROUTE*	DURATION (WK)
Methicillin-Susceptible Staphylococci		
Nafcillin or oxacillin	2 gm IV every 4 hr	4-6
With optional addition of gentamicin	1 mg/kg IM or IV every 8 hr	3-5 days
Cefazolin (or other first-generation cephalosporins in equivalent dosages)	2 gm IV every 8 hr	4-6
With optional addition of gentamicin	1 mg/kg IM or IV every 8 hr	3-5 days
Vancomycin	30 mg/kg/24 hr IV in two equally divided doses, not to exceed 2 gm/24 hr unless serum levels are monitored	4-6
Methicillin-Resistant Staphylococci		
Vancomycin	30 mg/kg/24 hr IV in two equally divided doses, not to exceed 2 gm/24 hr unless serum levels are monitored	4-6

Modified from Wilson WR, Karchmer AW, Dajani AS, et al: Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, staphylococci, and HACEK microorganisms. JAMA 274:1706, 1995. Copyright 1995 American Medical Association.

*Dosages are for patients with normal renal function; see Table 47-6 footnote.

For treatment of endocarditis due to penicillin-susceptible staphylococci (minimum inhibitory concentration 0.1 mug/ml), aqueous penicillin G (18-24 million units/24 hr) can be used for 4-6 wk instead of nafcillin or oxacillin.

Cefazolin, other first-generation cephalosporins, or vancomycin may be used in selected penicillin-allergic patients.

therapy. Hence, clinical judgment must be exercised when this abbreviated regimen is used. Therapy should be extended in those patients who remain febrile after 1 week of treatment or who develop signs suggesting left-sided infection.

Endocarditis caused by methicillin-resistant staphylococci requires treatment with vancomycin (see Table 47-10) . Trimethoprim-sulfamethoxazole treatment of right-sided endocarditis caused by *S. aureus* susceptible to this antimicrobial has been only moderately successful.[119] Truly suitable alternatives to vancomycin are not available. Teicoplanin, a glycopeptide antibiotic similar to vancomycin but not available in the United States, has been considered a possible alternative; however, some strains of *S. aureus* have become resistant to teicoplanin.[120] If the methicillin-resistant strain is susceptible to gentamicin, the aminoglycoside can be used in combination with vancomycin to enhance activity against these organisms. However, the frequency of renal toxicity may also be increased by this combination. The addition of rifampin to vancomycin for treatment of methicillin-resistant *S. aureus* NVE has not been beneficial. Right-sided endocarditis caused by methicillin-resistant *S. aureus* is not treated with a 2-week regimen.

STAPHYLOCOCCAL PROSTHETIC VALVE ENDOCARDITIS.

Staphylococcal infections of prosthetic heart valves should be treated with two or preferably three antibiotics in combination. Rifampin provides unique antistaphylococcal activity when infection involves foreign bodies.[117] However, rifampin-resistant staphylococci rapidly emerge when rifampin is used alone or in combination with vancomycin to treat staphylococcal PVE.[28] Consequently, staphylococcal PVE is treated with two antimicrobials plus rifampin.[28] I prefer to delay rifampin therapy briefly until treatment with two effective antistaphylococcal agents is begun.

For PVE caused by methicillin-resistant staphylococci, treatment is initiated with vancomycin plus gentamicin, with rifampin added if the organism is susceptible to gentamicin. If the organism is resistant to gentamicin, an alternative aminoglycoside to which the organism is susceptible should be sought. Alternatively, for treatment of PVE caused by an organism resistant to all aminoglycosides, a quinolone to which it is susceptible may be used in lieu of an aminoglycoside.[28] For treatment of PVE caused by methicillin-susceptible staphylococci, a semisynthetic penicillinase-resistant penicillin should be substituted for vancomycin in the combination regimen (Table 47-11) .

Patients with a nonimmediate penicillin allergy can be treated with a first-generation cephalosporin in lieu of the semisynthetic penicillin. PVE caused by coagulase-negative staphylococci that occurs within the initial year after valve placement is often complicated by perivalvular extension of infection, and valve replacement surgery is often required to eradicate infection and maintain suitable valve function.[28] Patients with *S. aureus* PVE have frequent intracardiac complications and exceptionally high mortality rates. Cure of *S. aureus* PVE is significantly more likely if early surgical intervention is combined with appropriate combination antimicrobial therapy.[121] [122]

***HAEMOPHILUS PARAINFLUENZAE, HAEMOPHILUS APHROPHILUS, ACTINOBACILLUS ACTINOMYCETEMCOMITANS, CARDIOBACTERIUM HOMINIS, EIKENELLA CORRODENS, AND KINGELLA KINGAE* (HACEK ORGANISMS).**

Endocarditis caused by the HACEK group has in the past been treated with ampicillin administered alone or in combination with gentamicin. Occasional HACEK organisms that are ampicillin resistant by virtue of beta-lactamase production have been isolated. Given the marked susceptibility of both beta-lactamase-producing and non-beta-lactamase-producing HACEK strains to third-generation cephalosporins, ceftriaxone or a comparable third-generation cephalosporin is recommended for treatment of NVE or PVE caused by these organisms (Table 47-12) .[113] For endocarditis caused by strains that do not produce beta-lactamase, ampicillin combined with gentamicin can be used in lieu of ceftriaxone (see Table 47-12) .

OTHER PATHOGENS.

Antimicrobial therapy for patients with IE caused by unusual organisms is based on limited clinical experience

TABLE 47-11 -- TREATMENT OF STAPHYLOCOCCAL ENDOCARDITIS IN THE PRESENCE OF A PROSTHETIC VALVE OR OTHER PROSTHETIC MATERIAL

ANTIBIOTIC	DOSAGE AND ROUTE*	DURATION (WK)
Regimen for Methicillin-Resistant Staphylococci		
Vancomycin	30 mg/kg/24 hr IV in two equally divided doses, not to exceed 2 gm/24 hr unless serum levels are monitored	6
plus		
Rifampin *and* gentamicin	300 mg PO every 8 hr	6
	1.0 mg/kg IM or IV every 8 hr	2
Regimen for Methicillin-Susceptible Staphylococci		
Nafcillin or oxacillin	2 gm IV every 4 hr	6

plus		
Rifampin *and* gentamicin	300 mg PO every 8 hr	6
	1.0 mg/kg IM or IV every 8 hr	2

*Dosages are for patients with normal renal function. See Table 47-6 , footnote.

Use during initial 2 wk of treatment. If strain is gentamicin resistant, see text for alternatives.

and data from animal models and in vitro studies. Therapeutic regimens for most of these infections are beyond the scope of this chapter: in fact, physicians are urged to review the published experience with a specific causative agent as well as to seek assistance from experienced infectious disease consultants when treating these infections. Among the more common of the unusual agents causing endocarditis are *P. aeruginosa, Candida* species, and *Corynebacterium* species. The preferred treatment for endocarditis caused by *P. aeruginosa* is an antipseudomonal penicillin (ticarcillin or piperacillin) plus high doses of tobramycin (8 mg/kg/d IM or IV in divided doses every 8 hours to achieve peak serum concentrations of 15 mug/ml). Endocarditis caused by *P. aeruginosa* is often both destructive and poorly responsive to antibiotic therapy. As a result, many patients with *P. aeruginosa* endocarditis require cardiac surgery.

Amphotericin at full doses, often combined with 5-fluorocytosine, is recommended for treatment of *Candida* endocarditis. Several patients with *Candida* NVE and PVE without intracardiac complications are reported to have been cured by prolonged treatment with fluconazole.[123] [124] Nevertheless, surgical intervention shortly after beginning amphotericin treatment remains the standard treatment for *Candida* endocarditis.[125] [126] Prolonged or indefinite finuconazole administration has been advocated for patients treated either medically or surgically [124] [125] [126]

TABLE 47-12 -- TREATMENT FOR ENDOCARDITIS DUE TO HACEK MICROORGANISMS*

ANTIBIOTIC	DOSAGE AND ROUTE	DURATION (WK)
Ceftriaxone	2 gm once daily IV or IM	4
Ampicillin	12 gm/24 hr IV given continuously or every 4 hr in six equally divided doses	4
plus		
Gentamicin	1 mg/kg IM or IV every 8 hr	4

Modified from Wilson WR, Karchmer AW, Dajani AS, et al: Antibiotic treatment of adults with infective endocarditis due to streptococci, enterococci, staphylococci, and HACEK microorganisms. JAMA 274:1706, 1995. Copyright 1995 American Medical Association.

*HACEK microorganisms are *Haemophilus parainfluenzae, Haemophilus aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae.*

Dosages are for those with normal renal function. See Table 47-6 , footnote.

Cefotaxime or ceftizoxime in comparable doses may be substituted for ceftriaxone.

The antimicrobial susceptibility of corynebacteria causing endocarditis must be carefully evaluated. Many remain susceptible to penicilin, vancomycin, and aminoglycosides. Strains susceptible to aminoglycosides are killed synergistically by penicillin in combination with an aminoglycoside. *C. jelkeium,* although often resistant to penicillin and aminoglycosides, is killed by vancomycin. NVE or PVE caused by *Corynebacterium* species can be treated with the combination of penicillin plus an aminoglycoside or vancomycin, contingent on the susceptibilities of the causative strain.[55]

The Enterobacteriaceae (*E. coli* and *Klebsiella, Enterobacter, Serratia,* and *Proteus* species) are highly susceptible to third-generation cephaloporins, imipenem, and aztreonam. One of these antimicrobial agents in high doses is combined with an aminoglycoside to treat IE caused by Enterobacteriaceae.

Coxiella burnetii IE is difficult to eradicate. Prolonged therapy (at least 4 years) using doxycycline (100 mg twice daily) or another tetracycline combined with a quinolone has been advocated. Treatment with doxycycline combined with hydroxychloroquine for 18 to 48 months (mean 31 months, median 26 months) may be as effective as longer courses of doxycycline plus a quinolone.[127] Surgery is important in effective treatment.

CULTURE-NEGATIVE ENDOCARDITIS.

Special studies to diagnose IE caused by fastidious bacteria and other organisms must be performed (see Diagnosis). Thereafter, unless clinical or epidemiologic clues suggest an etiological diagnosis, the recommended treatment for culture-negative NVE is ampicillin plus gentamicin (see standard regimen for enterococcal endocarditis, Table 47-8) ; because in the absence of confounding antibiotic therapy enterococci and staphyclococci are unlikely causes of culture-negative NVE, ceftriaxone could be used in this regimen instead of ampicillin. For patients with culture-negative PVE, vancomycin is added to this regimen.[28] [128] Mortality rates are lower for patients who have culture-negative endocarditis and who received antibiotics before obtaining blood cultures and those who become afebrile during the initial week of antimicrobial treatment.[96] [128] Marantic endocarditis should be carefully considered when treating patients for culture-negative IE. Surgical intervention should be considered for those who do not fully respond to empirical antimicrobial therapy. If surgical intervention is undertaken, a detailed microbiological and pathological examination of excised material must be performed to establish an etiologic diagnosis.

TIMING THE INITIATION OF ANTIMICROBIAL THERAPY.

Current cost-containment pressures frequently result in initiation of antimicrobial therapy for suspected endocarditis immediately after blood cultures have been obtained. This practice is appropriate in the treatment of patients with acute IE that is highly destructive and rapidly progressive and of patients presenting with hemodynamic decompensation requiring urgent or emergent surgical intervention. Immediate therapy may have a favorable impact on outcome in these patients. In contrast, precipitous initiation of therapy in hemodynamically stable patients with suspected subacute endocarditis does not prevent early complications and may, by compromising subsequent blood cultures, obscure the etiological diagnosis of endocarditis. In these latter patients, it is prudent to delay antibiotic therapy briefly pending the results of the initial blood cultures. If these cultures are not positive promptly, this delay provides an important opportunity to obtain additional blood cultures without the confounding effect of empirical treatment. This opportunity is particularly important when patients have received antibiotics recently.

MONITORING THERAPY FOR ENDOCARDITIS.

Patients must be carefully monitored during therapy and for several months thereafter. Failure of antimicrobial therapy, myocardial or metastatic abscess, emboli, hypersensitivity to antimicrobial agents, and other complications of therapy (catheter-related infection, thrombophlebitis) or intercurrent illness may be manifested by persistent or recurrent fever. Adverse reactions occur in 33 percent of patients treated for IE with beta-lactam antimicrobials, especially penicillin and ampicillin. The reactions include fever, rash, and neutropenia; they are increasingly frequent after 15 days of therapy.[129] Clinical events may indicate a need for potentially life-saving revision of antimicrobial therapy or adjunctive surgical therapy.

The serum bactericidal titer (SBT), the highest dilution of the patient's serum during therapy that in vitro kills 99.9 percent of a standard inoculum of the patient's infecting organism, has been used to assess the adequacy of antimicrobial therapy. The SBT has correlated poorly with outcome of therapy because it has been performed in a nonstandardized manner and because of the marked impact of complications on outcome. Peak and trough titers of at least 1:64 or 1:32 and 1:32, respectively, obtained with a standardized SBT method, correlate with bacteriological cure. When using regimens considered optimal on the basis of clinical experience, monitoring therapy with this test is not recommended.[113] The SBT may be useful when treating patients with endocarditis caused by organisms for which

optimal therapy is not established or when using unconventional antimicrobial regimens.

The serum concentration of vancomycin or aminoglycosides should be measured periodically. This allows dose adjustment to ensure optimal therapy and avoid adverse events. Additionally, renal function should be monitored in patients receiving these two antimicrobials, and the complete blood count should be checked at least weekly in patients receiving high-dose beta-lactam antibiotics or vancomycin.

Repeat blood cultures should be obtained during the initial days of therapy or if fever persists to determine if the bacteremia has been controlled. In patients with recrudescent fever after treatment, prompt cultures are essential to assess possible relapse of endocarditis.

OUTPATIENT ANTIMICROBIAL THERAPY.

Technical advances allowing safe administration of complex antimicrobial regimens, combined with well-developed home care systems that provide supplies and monitor outpatient treatment, make it feasible to treat patients with endocarditis on an outpatient basis. Doing so can significantly reduce the cost of therapy. However, only those patients who have responded to initial therapy and are free of fever, who are not experiencing threatening complications, who will be compliant with therapy, and who have a home situation that is physically suitable should be considered for outpatient treatment. Furthermore, patients being treated at home must be apprised of the potential complications of endocarditis, instructed to seek advice promptly when encountering unexpected or untoward clinical events, and have assiduous clinical and laboratory monitoring. Finally, outpatient therapy must not result in compromises of antimicrobial therapy leading to suboptimal treatment.

Surgical Treatment of Intracardiac Complications

Cardiac surgical intervention has an increasingly important role in the treatment of intracardiac complications of endocarditis. Retrospective data suggest that mortality is unacceptably high when these complications are treated with antibiotics alone, whereas mortality is reduced when treatment combines antibiotics and surgical intervention.[76] [130] [131] Accordingly, these complications have become indications for cardiac surgery (Table 47-13) .

VALVULAR DYSFUNCTION.

Medical therapy of NVE that is complicated by moderate to severe (New York Heart Association Class III and IV) CHF due to new or worsening valvular dysfunction results in mortality rates of 50 to 90 percent. Survival rates for a similar group of patients treated with antibiotics and cardiac surgery are 60 to 80 percent.[76] [130] [131] Although survival rates among surgically treated patients with PVE complicated by valvular dysfunction and CHF are 45 to 85 percent, few PVE patients with these complications are alive at 6 months when treated with antibiotics alone.[28] [29] Worsening aortic valve incompetence is associated with more severe and more rapidly progressive CHF than is mitral valve incompetence. Hence, patients with aortic valve endocarditis not only account for

TABLE 47-13 -- CARDIAC SURGERY IN PATIENTS WITH INFECTIVE ENDOCARDITIS

Indications
Moderate to severe congestive heart failure due to valve dysfunction
Unstable prosthesis
Uncontrolled infection despite optimal antimicrobial therapy
Unavailable effective antimicrobial therapy: endocarditis due to fungi, *Brucellae, Pseudomonas aeruginosa* (aortic or mitral valves)
Staphylococcus aureus PVE with an intracardiac complication
Relapse of PVE after optimal therapy
Relative Indications*
Perivalvular extension of infection, intracardiac fistula
Poorly responsive *S. aureus* NVE (aortic or mitral valves)
Relapse of NVE after optimal antimicrobial therapy
Culture-negative NVE or PVE with persistent fever (10 d)
Large (>10 mm diameter) hypermobile vegetation (with or without prior arterial embolus)
Endocarditis due to highly antibiotic-resistant enterococci
PVE=prosthetic valve endocarditis; NVE=native valve endocarditis.

*Surgery commonly required for optimal outcome.

the majority of surgically treated patients but also require surgery on a more urgent basis when heart failure supervenes. Severe mitral valve insufficiency, nevertheless, results in inexorable heart failure and ultimately requires surgical intervention. Doppler echocardiography and color flow mapping indicating significant valvular regurgitation during the initial week of endocarditis treatment do not reliably predict those patients who will require valve replacement during active endocarditis. Alternatively, despite the absence of significant valvular regurgitation on early echocardiography, marked CHF may still develop. Decisions about surgical intervention should not be made solely on the basis of echocardiographic findings but rather by integrating clinical data during careful serial monitoring. On occasion, very large vegetations on the mitral valve, particularly a mitral valve prosthesis, result in significant obstruction and require surgery.[28]

UNSTABLE PROSTHESES.

Dehiscence of an infected prosthetic valve is a manifestation of perivalvular infection and often results in hemodynamically significant valvular dysfunction. Surgical intervention is recommended for PVE patients with these complications.[28] [130] The risk of invasive infection is increased among patients with onset of PVE within the year after valve implantation and those with infection of an aortic valve prosthesis. Endocarditis in these patients is often caused by invasive antimicrobial-resistant organisms; consequently, the benefit of combined medical-surgical therapy is enhanced further. Patients who appear clinically stable but who have overtly unstable and hypermobile prostheses, a finding indicative of dehiscence in excess of 40 percent of the circumference, are likely to experience progressive valve instability and warrant surgical treatment. Occasional patients with PVE caused by noninvasive, highly antibiotic-susceptible organisms, e.g., streptococci, despite a favorable clinical course during antibiotic therapy, late in treatment experience minor valve dehiscence without prosthesis instability or hemodynamic deterioration. Surgical treatment of these patients can be deferred unless clear indications arise.

UNCONTROLLED INFECTION OR UNAVAILABLE EFFECTIVE ANTIMICROBIAL THERAPY.

Surgical intervention has improved the outcome of several forms of endocarditis when maximal antibiotic therapy fails to eradicate infection or, in some instances, even to suppress bacteremia. Amphotericin B is inadequate therapy for fungal endocarditis, including that caused by *Candida* species, and surgical intervention is recommended shortly after initiation of full doses of antifungal therapy. Endocarditis caused by some gram-negative bacilli, e.g., *P. aeruginosa, Achromobacter xylosoxidans,* may not be eradicated by maximum tolerable antibiotic therapy and may require surgical excision of the infected tissue to achieve cure. Similarly, standard therapy of endocarditis caused by *Brucella* species includes surgery because medical therapy is rarely successful.[94] Surgical intervention is recommended when patients with enterococcal endocarditis caused by a strain resistant to synergistic bactericidal therapy do not respond to initial therapy or relapse. Perivalvular invasive infection is in some instances a form of ineradicable infection. Relapse of PVE after optimal antimicrobial therapy reflects invasive disease or the difficulty in eradicating infection involving foreign devices. Patients with relapse of PVE are treated surgically.[28] In contrast, patients with NVE that relapses, unless it is associated with a highly resistant microorganism or demonstrable perivalvular infection, often are treated again with an intensified, prolonged course of antimicrobial therapy.[132]

S. AUREUS PROSTHETIC VALVE ENDOCARDITIS.

Among 129 patients who had *S. aureus* PVE and who were culled from large retrospective general series of PVE, the crude mortality rate for those treated with antibiotics alone and with antibiotics plus surgery was 73 and 25 percent, respectively.[51] [122] [133] [134] The overall mortality rate in 33 cases of *S. aureus* PVE treated at a single institution was 42 percent.[122] In these latter cases, when a multivariate model was used for analysis to adjust for confounding variables, the presence of intracardiac complications was associated with a 13.7-fold increased risk of death, and surgical intervention during active disease was accompanied by a 20-fold reduction in mortality. These data suggest that surgical treatment can improve outcome. Although the occurrence of central nervous system emboli is often considered to limit the opportunity for surgical intervention, in fact, appropriately timed surgery remains the preferred treatment. Thus, surgical intervention is recommended for *S. aureus* PVE with intracardiac complication and may benefit even those patients with uncomplicated *S. aureus* PVE.[122] [133]

PERIVALVULAR INVASIVE INFECTION.

NVE at the aortic site and PVE are most commonly associated with perivalvular invasion with abscess or intracardiac fistula formation.[28] Invasive infection occurs in 10 to 14 percent of patients with NVE and 45 to 60 percent of those with PVE.[28] Persistent, otherwise unexplained fever despite appropriate antimicrobial therapy or pericarditis in patients with aortic valve endocarditis suggests infection extending beyond the valve leaflet.[78] New-onset and persistent electrocardiographic conduction abnormalities, although not a sensitive indicator of perivalvular infection (28 percent), are relatively specific (85 to 90 percent).[135] TEE is superior to TTE for detecting invasive infection in patients with NVE and PVE. Doppler and color flow Doppler or contrast two-dimensional echocardiography optimally define fistulas. Patients who have IE and in whom an abscess is suspected but not detected by an initial and repeat TEE should undergo magnetic resonance imaging, including magnetic resonance angiography. Cardiac catheterization adds little to these imaging studies and is not recommended unless coronary angiography is needed.

In patients with endocarditis complicated by perivalvular extension of infection, cardiac surgery should be considered to debride invasive infection, ablate abscesses, and reconstruct anatomical damage. Surgery is warranted in patients with invasive disease that significantly disrupts cardiac structures, that is associated with CHF, that results in instability of a prosthetic valve, or that renders infection uncontrolled (persistent fever). However, it is likely that increasingly sensitive imaging techniques will elucidate invasive

infections that do not require immediate surgery. Sporadic case reports of medically treated invasive infection suggest that these infections will be small, structurally nonsignificant abscesses in which the cavity is open to the circulatory stream.

LEFT-SIDED *S. AUREUS* ENDOCARDITIS.

Because this infection is difficult to control, highly destructive, and associated with high mortality, some investigators have suggested that these patients should be considered for surgical treatment when the response to antimicrobial therapy is not prompt and complete. Additionally, patients with *S. aureus* NVE (aortic or mitral valve) and vegetations that are visible by TTE are at increased risk for arterial emboli and death and should be considered for surgery.[52] In contrast, IV drug abusers with *S. aureus* endocarditis limited to the tricuspid or pulmonary valves often experience prolonged fever during antimicrobial therapy; nevertheless, the vast majority of these patients respond to antimicrobial therapy and do not require surgery.[136]

UNRESPONSIVE CULTURE-NEGATIVE ENDOCARDITIS.

Patients who have culture-negative endocarditis and who experience unexplained persistent fever during empirical antimicrobial therapy, particularly those with PVE, should be considered for surgical intervention. If endocarditis is not marantic, persistent fever in these patients is likely to represent either unrecognized perivalvular infection or ineffective antimicrobial therapy.

LARGE VEGETATIONS (>10 mm) AND THE PREVENTION OF SYSTEMIC EMBOLI.

Systemic embolization was increased in patients with vegetations greater than 10 mm versus those with smaller or no detectable vegetations, 33 percent versus 19 percent.[82] Larger mitral valve vegetations (>10 mm), particularly those on the anterior mitral valve leaflet, are uniquely associated with systemic emboli. Although a relationship may exist between vegetation characteristics--including size, mobility, and extent (number of leaflets involved)--and embolic complications, the implications for surgical intervention are not clear. Yet to be performed are multivariate analyses examining the relationship between outcome or the need for surgical intervention and variables including not only vegetation characteristics but also valve dysfunction, perivalvular invasion by infection, organism, and infection site. Nevertheless, some researchers have concluded that vegetation characteristics alone might warrant surgery to prevent arterial emboli. This recommendation can be questioned, as can the recommendation for valve surgery after two major arterial emboli.[94]

In deciding to intervene in the therapy of IE with cardiac surgery to prevent arterial emboli, many factors must be considered carefully. The rate of systemic or cerebral emboli in patients with NVE and PVE decreases during the course of effective antibiotic therapy.[87] [137] Additionally, it is not clear that surgical intervention reduces the frequency of systemic emboli.[76] [130] Finally, the risks of morbidity and mortality caused by cerebral and coronary emboli, the major events to be prevented, must be compared with the immediate and long-term risks of valve replacement surgery. The latter include perioperative mortality, recrudescent endocarditis on the prosthesis, thromboembolic complications, early and late valve dysfunction requiring repeat valve replacement, the hazards of warfarin anticoagulation (including its contraindication during pregnancy), and the risk and morbidity of late-onset PVE.[128] Vegetation size alone is rarely an indication for surgery. The clinical findings and echocardiographic evidence for other intracardiac complications must be weighed against the immediate and remote hazards of cardiac surgery, including the possibility of valve preservation by vegetectomy and valve repair, when recommending therapy.[82] [94] Thus, the risk for systemic embolization as related to vegetation size or prior systemic embolus is not an independent indication for surgical intervention but is only one of many factors to be considered when planning treatment.[87] [94] [137]

TECHNIQUES FOR REPAIR OF INTRACARDIAC DEFECTS.

New surgical techniques to address severe tissue destruction in NVE and PVE have been developed. Although these are beyond the scope of this discussion, examples include valve composite graft replacement of the aortic root, use of sewing skirts attached to the prostheses, and homograft replacement of the aortic valve and root with coronary artery reimplantation.[138] [139] Furthermore, repair of the mitral valve in patients with acute or healed endocarditis avoids the need for insertion of prosthetic materials and the associated hazards.[140] Although tricuspid valvulectomy without valve replacement has been advocated for treatment of uncontrolled tricuspid valve infection in IV drug abusers at high risk of recidivism and recurrent endocarditis, the likelihood of refractory right-heart failure with time after valvulectomy makes tricuspid valve repair preferable. Cardiac transplantation has been used to salvage an occasional patient with refractory endocarditis.

TIMING OF SURGICAL INTERVENTION.

When endocarditis is complicated by valvular regurgitation and significant impairment of cardiac function, surgical intervention before the development of severe intractable hemodynamic dysfunction is recommended, regardless of the duration of antimicrobial therapy.[130] [141] Postoperative mortality correlates with the severity of preoperative hemodynamic dysfunction; consequently, this approach is justified.[94] In patients who have valvular dysfunction and in whom infection is controlled and cardiac function is compensated, surgery may be delayed until antimicrobial therapy has been completed. However, if infection is not controlled, surgery should be performed promptly. Similarly, if a patient who requires valve replacement in the near future has a large vegetation, indicating a high risk for systemic embolization, early cardiac surgery is appropriate.

To avoid worsening of neurological status or death in patients who have sustained recent neurological injury, the timing of surgical intervention may require modification. Among patients who have had a nonhemorrhagic embolic stroke, exacerbation of cerebral dysfunction occurs during cardiac surgery in 44 percent of cases when the interval between the stroke and surgery is 7 days or less, in 17 percent when the interval is 8 to 14 days, and in 10 percent or less when more than 2 weeks has elapsed. After hemorrhagic intracerebral events, the risk for neurological worsening or death with cardiac surgery persists at 20 percent even after 1 month.[142]

Thus, when the response of IE to antimicrobial therapy and hemodynamic status permit, delaying cardiac surgery for 2 to 3 weeks after a significant embolic infarct and at least a month after intracerebral hemorrhage (with prior repair of a mycotic aneurysm) has been recommended.[142] [143] In another study of patients with nonhemorrhagic focal cerebral lesions or encephalopathy, those undergoing cardiac surgery without delay experienced no greater mortality or neurological

deterioration than did those treated medically. This study suggests that the improved outcomes reported with delayed surgery may simply reflect selection of hardier patients and that more prompt cardiac surgery in patients with nonhemorrhagic cerebral complications, if required, is reasonable and potentially beneficial.[144] Contrast-enhanced cerebral tomography is recommended as the initial study of choice to detect intracerebral hemorrhage with subsequent magnetic resonance angiography or standard cerebral angiography to further evaluate hemorrhagic lesions for a leaking mycotic aneurysm.[143] [145] It is prudent to evaluate the cerebral vasculaturs in patients who have sustained an embolic infarct or who have persistent headaches before cardiac surgery. If a mycotic aneurysm is found, the timing of cardiac surgery should be reconsidered and prostheses that require postoperative anticoagulant therapy should be avoided.[94]

DURATION OF ANTIMICROBIAL THERAPY AFTER SURGICAL INTERVENTION.

Inflammatory changes and bacteria are commonly found in vegetations removed from patients who have received most or all of the standard antibiotic therapy recommended for endocarditis caused by the specific microorganism. If valve cultures are negative, this does not indicate that antimicrobial therapy has failed or that a full course of antibiotic therapy is needed postoperatively. The duration of antimicrobial therapy after surgery depends on the length of preoperative therapy, the antibiotic susceptibility of the causative organism, the presence of paravalvular

invasive infection, and the culture status of the vegetation. In general, for endocarditis caused by relatively antibiotic-resistant organisms with negative cultures of operative specimens, preoperative plus postoperative therapy should at least equal a full course of recommended therapy; for those patients with positive intraoperative cultures, a full course of therapy should be given postoperatively. Patients with PVE should receive a full course of antimicrobial therapy postoperatively when organisms are seen in resected material.[28]

Treatment of Extracardiac Complications

SPLENIC ABSCESS.

Three to 5 percent of patients with IE develop a splenic abscess.[80] Although splenic defects can be identified by ultrasonography and computed tomography, these tests usually cannot discriminate between abscess and infarct. Persistent fever and progressive enlargement of the lesion during antimicrobial therapy suggest that it is an abscess; this can be confirmed by percutaneous needle aspiration. Successful therapy of splenic abscesses generally requires drainage, which can often be accomplished by percutaneous placement of a catheter.[84] In patients with endocarditis complicated by numerous splenic abscesses or in whom percutaneous drainage is unsuccessful, splenectomy is required.[84] [94] Splenic abscesses should be effectively treated before valve replacement surgery. If they are not effectively treated before cardiac surgery, splenectomy should be performed as soon thereafter as surgical risks permit.[94]

MYCOTIC ANEURYSMS AND SEPTIC ARTERITIS.

From 2 to 10 percent of patients with endocarditis have mycotic aneurysms; in 1 to 5 percent, the aneurysms involve cerebral vessels.[88] Cerebral mycotic aneurysms occur at the branch points in cerebral vessels, are generally located distally over the cerebral cortex, and are found most commonly in branches of the middle cerebral artery. The aneurysms arise either from occlusion of vessels by septic emboli with secondary arteritis and vessel wall destruction or from bacteremic seeding of the vessel wall through the vasa vasorum. *S. aureus* is commonly implicated in the former and viridans streptococci in the latter.[91] Many patients with mycotic aneurysms or septic arteritis present with devastating intracranial hemorrhage. Focal deficits from embolic events, persistent focal headache, or sterile meningeal irritation (cerebrospinal fluid pleacytosis) may be premonitory symptoms. Cerebral angiography is required to evaluate patients with subarachnoid hemorrhage, and this or magnetic resonance angiography has been recommended for patients experiencing premonitory symptoms, especially if cardiac surgery or anticoagulant therapy is planned.[88] [94] Mycotic aneurysms may resolve during antimicrobial therapy[94] ; however, when anatomically feasible, aneurysms that have ruptured should be repaired surgically. Aneurysms that have not leaked should be monitored angiographically during antimicrobial therapy. Surgery should be considered for a single lesion that enlarges during or after antimicrobial therapy. Anticoagulant therapy should be avoided in patients with a persisting mycotic aneurysm. Although persistent stable aneurysms may rupture after completion of standard antimicrobial therapy, there is no accurate estimation of risk for late rupture, and recommendations for surgical intervention are arbitrary. Nevertheless, prevailing opinion favors, whenever possible without serious neurological injury, the resection of single aneurysms that persist after therapy. The potential existence of occult aneurysms in patients without neurological symptoms or in those who have had a nondiagnostic angiographic evaluation is not considered a contraindication to anticoagulant therapy after completion of antimicrobial therapy.

Extracranial mycotic aneurysms should be managed as outlined for cerebral aneurysms. Those that leak, are expanding during therapy, or persist after therapy should be repaired. Particular attention should be given to aneurysms that involve intraabdominal arteries, rupture of which could result in life-threatening hemorrhage.[94]

ANTICOAGULANT THERAPY.

Patients with PVE involving devices that would usually warrant maintenance anticoagulation are continued on anticoagulant therapy.[28] Prothrombin times should be maintained at 1.5 times the control (INR = 3.0). Anticoagulation is not initiated as prophylaxis against thromboembolism in patients with PVE involving devices that do not usually require this therapy. Among patients with NVE, no evidence shows that anticoagulant therapy prevents embolization, and in some instances it may contribute to intracranial hemorrhage, particularly in the presence of a recent cerebral infarct or a mycotic aneurysm.[88] Anticoagulant therapy in patients with NVE is limited to those patients for whom there is a clear indication for this therapy and for whom there is not a known increased risk for intracranial hemorrhage. If central nervous system complications occur in patients who have IE and who are receiving anticoagulant therapy, anticoagulation should be reversed immediately.[28]

Response to Therapy and Outcome

Within a week after initiation of effective antimicrobial therapy, almost 75 percent of patients with IE, including those with PVE, are afebrile and 90 percent have defervesced by the end of the second week of treatment.[47] [137] [28] [76] [146] The duration of fever during therapy is longer in patients with IE due to *S. aureus, P. aeruginosa,* and culture-negative IE as well as IE characterized by microvascular phenomena and major embolic complications.[76] [146] Persistence or recurrence of fever more than 7 to 10 days after initiation of antibiotic therapy identified patients with increased mortality rates and with complications of infection or therapy.[28] [78] [146] Those patients with prolonged or recurrent fever should be evaluated for intracardiac complications, focal extracardiac septic complications, intercurrent nosocomial infections, recurrent pulmonary emboli (patients with right-sided IE), drug-associated fever, additional underlying illnesses, and, if appropriate, in-hospital substance abuse.

Blood cultures should be repeated in search of persistent bacteremia or the presence of additional pathogens, e.g., previously unrecognized polymicrobial IE. The antimicrobial susceptibility of the causative organism should be reevaluated, as should the adequacy of antibiotic therapy. Drug reactions have accounted for fever in 17 to 28 percent of these patients.[78] [124] Drug fever attributed to the antimicrobial therapy itself may warrant revision of treatment if a suitable alternative is available. In the absence of effective alternative therapy, treatment can be continued despite drug fever if the antimicrobial is not causing significant end-organ toxicity. In 33 to 45 percent of patients, persistent fever was associated with significant intracardiac complications, many of which required surgical intervention.[76]

Many clinical and laboratory features of IE are slow to resolve despite effective antimicrobial therapy. Systemic emboli occur during the early weeks of treatment, although with decreasing frequency.[87] The increased ESR and anemia may not correct until after therapy has been completed.

Mortality rates for large series of NVE treated between 1975 and 1993 range from 16 to 27 percent.[1] [4] [5] [9] [134] Death due to IE has been associated with increased age (>65 to 70 years old), underlying diseases, infection involving the aortic valve, development of CHF, renal failure, and central nervous system complications.[1] [5] The treatment of heart failure due to valve dysfunction by early surgical intervention has decreased the mortality associated with CHF, but subsequently, neurological events and septic complications, e.g., uncontrolled infection and myocardial abscess, have accounted for a larger proportion of deaths and have been associated with high mortality rates.[80]

Mortality rates among patients with IE caused by viridans streptococci and *S. bovis* have ranged from 4 to 16 percent.[1] [4] [9] Higher mortality rates are reported with left-sided NVE caused by other organisms: enterococci, 15 to 25 percent[1] [4] [9] ; *S. aureus,* 25 to 47 percent[1] [4] [9] [50] [73] ; nonviridans streptococci (groups B, C, and G), 13 to 50 percent[42] [147] ; *C. burnetti,* 5 to 37 percent[31] [114] [124] ; *P. aeruginosa,* Enterobacteriaceae, and fungi, greater than 50 percent.[54] [61]

In a retrospective study of patients with NVE with either Class III or IV heart failure (New York Heart Association) or invasive uncontrolled infection, only 9 percent of patients treated surgically died, compared with 51 percent of those treated with antibiotics alone.[76] Mortality rates among patients who have NVE, particularly involving the aortic valve, and who were treated surgically have ranged from 5 to 26 percent, with rates toward the high end of this range reported more frequently.[148] [149] [150]

Severity of heart failure, abscess, *S. aureus* infection, and decreased renal function (possibly related to heart failure) have been associated with

increased postoperative mortality.[150] Nevertheless, survival rates of 85 percent can be achieved when patients with paravalvular abscesses undergo meticulous debridement and reconstructive cardiac surgery.[151]

Outcome for patients with PVE, as contrasted with NVE, has been less desirable. Before 1980, mortality rates among patients with onset less than 60 days after surgery and later-onset PVE averaged 70 and 45 percent, respectively. With the recognition that PVE was frequently complicated by invasive infection and that patients would benefit from surgical intervention, mortality rates have decreased to 33 to 45 percent, with lower rates in later-onset cases.[28] [151] Long-term survival was adversely affected by the presence of moderate or severe heart failure at discharge. Survival rates after aggressive surgery for PVE ranged from 75 to 85 percent and were not related to time of onset after cardiac surgery.[29] [139]

Among patients with NVE (nonaddicts) discharged after medical or medical-surgical therapy, long-term survival was 88 percent at 5 years and 81 percent at 10 years.[134] Among patients treated surgically for NVE, survival at 5 years ranged from 70 to 80 percent.[138] [149] Among patients with PVE treated surgically, survival rates at 4 to 6 years range from 50 to 82 percent.[29] [139]

RELAPSE AND RECURRENCE.

Relapse of IE usually occurs within 2 months of discontinuing antibiotic treatment. Of patients who have NVE caused by penicillin-susceptible viridans streptococci and who receive a recommended course of therapy, less than 2 percent suffer relapse. From 8 to 20 percent of patients with enterococcal IE experience relapse after standard therapy.[132] Patients with IE caused by *S. aureus,* Enterobacteriaceae, or fungi are more likely to experience overt failure of therapy rather than relapse; nevertheless, 4 percent of patients with *S. aureus* IE suffer relapse.[132] Relapse of fungal endocarditis at long intervals after treatment has been reported. Relapse occurs in 10 percent of patients with PVE overall and in 6 to 15 percent of those treated surgically. [131]

Among nonaddicts with an initial episode of NVE or PVE, 4.5 to 7 percent experience one or more additional episodes.[132] [134] Among these patients, recurrent IE shares the clinical, microbiological, and response to therapy noted in primary episodes of IE. IV drug abuse is now the most common predisposition for recurrent IE (43 percent of patients).

PREVENTION

During bacteremia provoked by daily activities, infections, or health care procedures, bacteria adhere to and colonize the platelet fibrin aggregates, NBTE, that have formed on the valve endothelium as a consequence of preexisting congenital or acquired cardiac disease. If the adherence and the subsequent multiplication of bacteria at this site exceed the capacity of host defenses for bacterial eradication, IE results. Although many bacteria enter the bloodstream, those uniquely suited to adhere to NBTE cause the majority of cases of endocarditis. These organisms and the cardiac abnormalities vulnerable to IE are evident from reported cases. Events that predispose to bacteremia by organisms causing endocarditis have been identified. By identifying the patients at risk, the causative bacteria, and the events that induce bacteremia, strategies for prevention of some episodes of IE have been formulated and are routinely recommended even in the absence of supporting clinical trials.[152] [153] [154]

Viridans streptococci, the most common cause of NVE and late-onset PVE, are the primary target for prophylaxis used in conjunction with procedures involving the oral cavity, respiratory tract, or esophagus. Procedures involving the genitourinary and gastrointestinal tracts commonly precede the development of enterococcal endocarditis. Accordingly, the prophylaxis for endocarditis used in conjunction with procedures involving these mucosal surfaces is targeted against enterococci. When incision and drainage of infected skin or soft tissue infections are undertaken, prophylaxis is focused on *S. aureus.*

Procedures for which IE prophylaxis is recommended or not recommended have been identified by the American Heart Association and others (Table 47-14) . [152] [153] [154] [155] Although prophylaxis is advised for all at-risk patients who undergo dental procedures that cause gingival bleeding, extractions

TABLE 47-14 -- PROCEDURES FOR WHICH PROPHYLAXIS AGAINST ENDOCARDITIS IS CONSIDERED

PROPHYLAXIS RECOMMENDED	PROPHYLAXIS NOT RECOMMENDED
Dental procedures known to induce gingival or mucosal bleeding, including professional cleaning and scaling	Dental procedures not likely to cause bleeding, such as adjustment of orthodontic appliances and simple fillings above the gum line
Tonsillectomy or adenoidectomy	
Surgery involving gastrointestinal or upper respiratory mucosa	Intraoral injection or local anesthetic (nonintraligamentary)
Bronchoscopy with rigid bronchoscope	Shedding of primary teeth
Sclerotherapy for esophageal varices	Tympanostomy tube insertion
Esophageal dilation	Endotracheal tube insertion
Endoscopic retrograde cholangiography with biliary obstruction	Bronchoscopy with flexible bronchoscope, with or without biopsy
Gallbladder surgery	
Cytoscopy, urethral dilation	Transesophageal echocardiography
Urethral catheterization if urinary infection is present	Cardiac catheterization, coronary angioplasty
Urinary tract surgery, including prostate surgery	Pacemaker implantation
Incision and drainage of infected tissue*	Gastrointestinal endoscopy, with or without biopsy
	Gastrointestinal endoscopy, with or without biopsy
	Incision or biopsy of scrubbed skin
	Cesarean section
	Vaginal hysterectomy
	Circumcision
	In the absence of infection: urethral catheterization, dilatation and curettage, uncomplicated vaginal delivery, therapeutic abortion, insertion or removal of intrauterine device, sterilization procedures, laparoscopy

In patients at highest risk, physicians may elect to use prophylaxis for these procedures.
*Antibiotic prophylaxis should be directed against the most likely endocarditis-associated pathogen(s), often staphylococci.

TABLE 47-15 -- RELATIVE RISK OF INFECTIVE ENDOCARDITIS ASSOCIATED WITH PREEXISTING CARDIAC DISORDERS

RELATIVELY HIGH RISK	INTERMEDIATE RISK	VERY LOW OR NEGLIGIBLE RISK*
Prosthetic heart valves	Mitral valve prolapse with regurgitation (murmur) or thickened valve leaflets	Mitral valve prolapse without regurgitation (murmur) or thickened valve leaflets
Previous infective endocarditis*		
Cyanotic congenital heart disease*	Pure mitral stenosis	
Patent ductus arteriosus	Tricuspid valve disease	Trivial valvular regurgitation on echocardiography without structural abnormality
Aortic regurgitation	Pulmonary stenosis	
Aortic stenosis	Asymmetrical septal hypertrophy	
Mitral regurgitation	Bicuspid aortic valve or calcific aortic sclerosis with minimal hemodynamic abnormality	Isolated atrial septal defect (secundum)
Mitral stenosis and regurgitation		Arteriosclerotic plaques
Ventricular septal defect		Coronary artery disease
Coarctation of the aorta	Degenerative valvular disease in elderly patients	Cardiac pacemaker, implanted defibrillators
Surgically repaired intracardiac lesion with residual hemodynamic abnormality or prosthetic device	Surgically repaired intracardiac lesions with minimal or no hemodynamic abnormality, less than 6 mo after operation	Surgically repaired intracardiac lesions, with minimal or no hemodynamic abnormality, more than 6 mo after operation (atrial septal defect, ventricular septal defect, patent ductus arteriosus, pulmonary stenosis)
Surgically constructed systemic-pulmonary shunts*		
		Prior coronary bypass graft surgery
		Prior Kawasaki's disease or rheumatic fever without valvular dysfunction

*Prophylaxis against endocarditis not recommended.

Lesions considered at highest risk for endocarditis.

are the most strongly associated with subsequent IE.[154] Because endocarditis has been reported only rarely in association with other gastrointestinal endoscopic procedures with or without biopsy, prophylaxis is not routinely recommended in this situation. Prophylaxis is not recommended with routine cardiac catheterization or TEE.[152] [155]

Based on the frequency of a lesion among patients with endocarditis compared with the general population, lesions have been assigned to high, intermediate, low, and negligible risk categories (Table 47-15) . [7] [13] [155] [156] [157] [157A] Rheumatic heart disease currently is a less common predisposition for IE in most of the developed countries; however, the attack rate of IE among persons with rheumatic valvular disease approaches that with prosthetic valves and suggests that these lesions entail a high risk also.[158]

The risk of IE for patients with mitral valve prolapse and the resulting role of prophylaxis among these patients have been controversial. Mitral valve prolapse has been identified frequently among patients with IE. However, the risk of endocarditis among patients with mitral valve prolapse and a murmur of mitral regurgitation is still relatively low. It is 5- to 10-fold higher than that in the general population but 100-fold less than that among patients with rheumatic valvular heart disease.[158] As a result, mitral valve prolapse with a murmur of mitral regurgitation or mitral valve thickening and prolapse defines a patient with an intermediate risk for IE and one for whom prophylaxis against endocarditis is recommended.

GENERAL METHODS.

The incidence of IE can be significantly reduced by total surgical correction of some congenital lesions that otherwise predispose patients to IE, e.g., patent ductus arteriosus, ventricular septal defect, and pulmonary stenosis.[7] [157] The incidence of IE remains high among patients who have undergone surgical correction of other major congenital defects, especially those involving a stenotic aortic valve.[7] Patients with persisting as well as many corrected congenital lesions and those with acquired valvular heart disease who remain at risk for IE should be given written material about their predisposing lesion, their risk for endocarditis, and the recommended antibiotic prophylaxis.

Maintenance of attentive oral hygiene which decreases the frequency of bacteremia that accompanies daily activities (chewing, brushing teeth), may be a more important preventive than procedure-focused chemoprophylaxis.[156] Oral hygiene should be addressed before prosthetic valves are placed electively.

Among patients at risk for IE, some activities or procedures likely to induce bacteremia should be avoided. Oral irrigating devices, which may produce bacteremia even in patients with normal gingiva, are not recommended. Similarly, the use of central intravascular catheters and urinary catheters should be minimized. Infections associated with bacteremia must be treated promptly and if possible eradicated before the involved tissues are incised or manipulated.[153]

CHEMOPROPHYLAXIS.

The widely promulgated recommendations of antimicrobial prophylaxis for endocarditis are based on circumstantial evidence supplemented by studies of prophylaxis using animal models. Studies suggest that prophylactic antibiotics prevent endocarditis by inhibiting growth of the bacteria adherent to NBTE sufficiently to allow their subsequent complete elimination by host defenses.[155] [159] Experimental studies that mimic single-dose amoxicillin prophylaxis in humans suggest adequate margins of efficacy are present after a single prophylactic dose. Nevertheless, because a more sustained inhibitory effect can be achieved through a postprocedure dose of antibiotics this is recommended for patients in the high-risk group.[152] [160]

Clinical studies supporting the efficacy of antibiotic prophylaxis for endocarditis are limited. A retrospective study of patients who had prosthetic valves and who underwent dental and surgical procedures suggested that antibiotic prophylaxis prevented PVE.[161] However, a large case-control study failed to identify dental procedures as a risk for IE among persons with valvular abnormalities and questioned the benefit of antibiotic prophylaxis for these procedures.[162] Additionally, failures of antibiotic prophylaxis unrelated to resistant bacteria have been noted.[155]

Risk-benefit and cost-benefit analyses have raised significant questions about antibiotic prophylaxis for patients with mitral valve prolapse. Unless both the cost and risks of prophylaxis are very low, the cost per case of IE prevented is high and mortality or morbidity may not be reduced. From a population perspective, prophylaxis in low-

TABLE 47-16 -- REGIMENS FOR PROPHYLAXIS AGAINST ENDOCARDITIS: USE WITH GENITOURINARY AND GASTROINTESTINAL (EXCEPT ESOPHAGEAL) PROCEDURES

SETTING	ANTIBIOTIC	REGIMEN*
High-risk patients	Ampicillin plus gentamicin	Ampicillin 2.0 gm IV/IM plus gentamicin 1.5 mg/kg within 30 min of procedure, repeat ampicillin 1.0 gm IV/IM or give amoxicillin 1.0 gm PO 6 hr later
High-risk, penicillin-allergic patients	Vancomycin plus gentamicin	Vancomycin 1.0 gm IV over 1-2 hr plus gentamicin 1.5 mg/kg IM/IV infused or injected 30 min before procedure. No second dose recommended
Moderate-risk patients	Amoxicillin or ampicillin	Amoxicillin 2.0 gm PO 1 hr before procedure or ampicillin 2.0 gm IM/IV 30 min before procedure
Moderate-risk, penicillin-allergic patients	Vancomycin	Vancomycin 1.0 gm IV infused over 1-2 hr and completed within 30 min of procedure

Adapted from Dajani AS, Taubert KA, Wilson W, et al: Prevention of bacterial endocarditis: Recommendations by the American Heart Association from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young. JAMA 277:1794-1801, 1997.

*Dosing for children: ampicillin 50 mg/kg IV/IM, vancomycin 20 mg/kg IV, gentamicin 1.5 mg/kg IV/IM (children's doses should not exceed adult doses).

to intermediate-risk settings may not be cost or risk beneficial, and prophylaxis might be reserved for patients who have high-risk cardiac lesions and who are undergoing high-risk procedures.[162]

Even if antibiotic prophylaxis is effective as well as safe and inexpensive, only a small percentage of the cases are preventable. For example, only 55 to 75 percent of patients with NVE have preexisting endocarditis-prone valvular disease, and many are not aware of the lesion before the onset of NVE.[4] [5] [155] [156] Additionally, among patients with IE, only a small fraction (5 percent) had both a known valve lesion and a procedure within 30 days of onset of IE that would have warranted prophylaxis.[156] Nevertheless, the morbidity and mortality associated with IE are used to justify prophylaxis (Table 47-16; see Table 43-4) in patients who have high- and intermediate-risk cardiac lesions (see Table 47-15) and who are to undergo bacteremia-inducing procedures (see Table 47-14) . Penicillin-resistant flora may emerge among patients who are receiving continuous penicillin for prevention of rheumatic fever or repetitive courses of antibiotics for serial dental procedures. Consequently, a nonpenicillin prophylaxis regimen is preferred for these patients. Initiation of prophylaxis several days before a procedure encourages the emergence of antibiotic-resistant organisms at the mucosal site and is not recommended.

GUIDELINES
PREVENTION, EVALUATION, AND MANAGEMENT OF INFECTIVE ENDOCARDITIS

THOMAS H. LEE

Guidelines for antibiotic prophylaxis were issued by the American Heart Association (AHA) in 1997.[1] These guidelines represented a major departure from prior recommendations by emphasizing that most cases are not attributable to an invasive procedure. According to these guidelines, patients with preexisting cardiac disease should be divided into high-, moderate-, and negligible-risk categories on the basis of their potential outcomes if endocarditis were to develop (see Table 47-15) . For dental work, for example, antibiotic prophylaxis is recommended only for patients who have high- and moderate-risk cardiac conditions and who are undergoing high-risk procedures (Table 47-G-1) . For nondental procedures, endocarditis prophylaxis is recommended only for high-risk patients undergoing high-risk procedures (see Table 47-15) ; this strategy is considered optional for medium-risk patients. Antibiotic regimens are described in Table 47-16 .

The 1998 American College of Cardiology/American Heart Association (ACC/AHA) guidelines for patients with valvular heart disease[2] endorse the earlier guidelines from the AHA, with a few caveats (Table 47-G-2) . The ACC/AHA guidelines recommend antibiotic prophylaxis for patients with hypertrophic cardiomyopathy only when latent or resting obstruction is a factor. In addition, the ACC/AHA committee expressed concern that an increased risk for endocarditis may exist for some patients with mitral valve prolapse without regurgitation; hence, this group was not willing to state that antibiotic prophylaxis was inappropriate for such patients. Instead, the ACC/AHA guidelines indicate that this issue must be addressed by using clinical judgment in individual cases. Finally, the ACC/AHA guidelines specified that antibiotic prophylaxis was not necessary for patients with physiological mitral regurgitation in the absence of a murmur.

INDICATIONS FOR ECHOCARDIOGRAPHY

Echocardiography is strongly supported in virtually all patients with suspected or known infective endocarditis, but the 1997 ACC/AHA guidelines on echocardiography[3] do *not* recommend transesophageal echocardiography (TEE) as the initial test of choice in the diagnosis of native valve endocarditis (see Table 47-G-2) . Instead, the guidelines urge use of TEE when specific questions are not adequately addressed by the initial transthoracic echocardiography (TTE) evaluation, such as when the TTE study is of poor quality, when the TTE is nondiagnostic despite a high clinical suspicion of endocarditis, when a prosthetic valve is involved, when there is a high suspicion such as in

TABLE 47--G-1 -- DENTAL PROCEDURES AND ENDOCARDITIS PROPHYLAXIS[1]

Endocarditis Prophylaxis Recommended for Patients with High- and Moderate-Risk Cardiac Conditions (see Table 47-1)
Dental extractions
Periodontal procedures including surgery, scaling and root planing, probing, and recall maintenance
Dental implant placement and reimplantation of avulsed teeth
Endodontic (root canal) instrumentation or surgery only beyond the apex
Subgingival placement of antibiotic fibers or strips
Initial placement of orthodontic bands but not brackets
Intraligamentary local anesthetic injections
Prophylactic cleaning of teeth or implants where bleeding is anticipated
Endocarditis Prophylaxis Not Recommended
Restorative dentistry* (operative and prosthodontic) with or without retraction cord
Local anesthetic injections (nonintraligamentary)
Intracanal endodontic treatment; post placement and buildup
Placement of rubber dams
Postoperative suture removal
Placement of removable prosthodontic or orthodontic appliances
Taking of oral impressions
Fluoride treatments
Taking of oral radiographs
Orthodontic appliance adjustment
Shedding of primary teeth
From Dajani AS, Taubert KA, Wilson W, et al: Prevention of bacterial endocarditis: Recommendations by the American Heart Association. Circulation 96:358-366, 1997.

*This includes restoration of decayed teeth (filling cavities) and replacement of missing teeth.

Clinical judgment may indicate antibiotic use in selected circumstances that may create significant bleeding.

TABLE 47--G-2 -- ACC/AHA GUIDELINES FOR PREVENTION, EVALUATION, AND TREATMENT OF ENDOCARDITIS[2] [3]

Indication	Class I*	Class IIa	Class IIb	Class III§

Antibiotic endocarditis prophylaxis for patients with mitral valve prolapse undergoing procedures associated with bacteremia	1. Patients with characteristic systolic click-murmur complex 2. Patients with isolated systolic click and echocardiographic evidence of MVP and MR	1. Patients with isolated systolic click, echocardiographic evidence of high-risk MVP		1. Patients with isolated systolic click and equivocal or no evidence of MVP
Echocardiography in infective endocarditis: Native valves (from 3)	1. Detection and characterization of valvular lesions, their hemodynamic severity, and/or ventricular compensation¶ 2. Detection of vegetations and characterization of lesions in patients with congenital heart disease in whom infective endocarditis is suspected 3. Detection of associated abnormalities (e.g., abscesses, shunts)¶ 4. Reevaluation studies in complex endocarditis (e.g., virulent organism, severe hemodynamic lesion, aortic valve involvement, persistent fever or bacteremia, clinical change, or symptomatic deterioration) 5. Evaluation of patients with high clinical suspicion of culture-negative endocarditis¶	1. Evaluation of bacteremia without a known source¶ 2. Risk stratification in established endocarditis¶	1. Routing reevaluation in uncomplicated endocarditis during antibiotic therapy	1. Evaluation of fever and nonpathological murmur without evidence of bacteremia
Echocardiography in infective endocarditis: Prosthetic valves (from 3)	1. Detection and characterization of valvular lesions, their hemodynamic severity, and/or ventricular compensation¶ 2. Detection of associated abnormalities (e.g., abscesses, shunts)¶ 3. Reevaluation in complex endocarditis (e.g., virulent organism, severe hemodynamic lesion, aortic valve involvement, persistent fever or bacteremia, clinical change, or symptomatic deterioration) 4. Evaluation of suspected endocarditis and negative cultures¶ 5. Evaluation of bacteremia without a known source¶	1. Evaluation of persistent fever without evidence of bacteremia or new murmur¶	1. Routine reevaluation in uncomplicated endocarditis during antibiotic therapy¶	1. Evaluation of transient fever without evidence of bacteremia or new murmur
Surgery for native valve endocarditis (criteria also apply to repaired mitral and aortic allograft or autograft valves)	1. Acute AF or MR with heart failure 2. Acute AF with tachycardia and early closure of the mitral valve 3. Fungal endocarditis 4. Evidence of annular or aortic abscess, sinus or aortic true or false aneurysm 5. Evidence of valve dysfunction and persistent infection after a prolonged period (7 to 10 days) of appropriate antibiotic therapy, as indicated by presence of fever, leukocytosis, and bacteremia, provided there are no noncardiac causes of infection	1. Recurrent emboli after appropriate antibiotic therapy 2. Infection with gram-negative organisms or organisms with a poor response to antibiotics in patients with evidence of valve dysfunction	1. Mobile vegetations >10 mm	1. Early infections of the mitral valve that can likely be repaired 2. Persistent pyrexia and leukocytosis with negative blood cultures
Surgery for prosthetic valve endocarditis (criteria exclude repaired mitral and aortic allograft or autograft valves)	1. Early prosthetic valve endocarditis (first 2 months or less after surgery) 2. Heart failure with prosthetic valve dysfunction 3. Fungal endocarditis 4. Staphylococcal endocarditis not responding to antibiotic therapy 5. Evidence of paravalvular leak, annular or aortic abscess, sinus or aortic true or false aneurysm, fistula formation, or new-onset conduction disturbances 6. Infection with gram-negative organisms or organisms with a poor response to antibiotics	1. Persistent bacteremia after a prolonged course (7 to 10 days) of appropriate antibiotic therapy without noncardiac causes of bacteremia 2. Recurrent peripheral embolus despite therapy	1. Vegetation of any size on or near the prosthesis	

AF=atrial fibrillation; MR=mitral regurgitation; MVP=mitral valve prolapse.

*Procedure or treatment is beneficial, useful, and effective.

Weight of evidence in favor of usefulness/efficacy.

Usefulness/efficacy less well established.
§Procedure or treatment not considered useful or effective.
¶Transesophageal echocardiography may provide incremental value in addition to information obtained by transthoracic imaging.

a patient with staphylococcus bacteremia, or in an elderly patient with valvular abnormalities that make diagnosis difficult.

Diagnosis of prosthetic valve endocarditis with TTE is more difficult than diagnosis of endocarditis of native valves. Thus, the ACC/AHA guidelines suggest a lower threshold for performance of TEE in patients with prosthetic valves and suspected endocarditis (see Table 47-G-2) .

SURGERY FOR ACTIVE ENDOCARDITIS

The ACC/AHA guidelines for valvular heart disease support performance of surgery for patients with life-threatening congestive heart failure or cardiogenic shock due to active endocarditis. Indications for surgery for patients with stable endocarditis are considered less clear (see Table 47-G-2) .

Chapter 48 - The Cardiomyopathies and Myocarditides

JOSHUA WYNNE
EUGENE BRAUNWALD

The cardiomyopathies constitute a group of diseases in which the dominant feature is direct involvement of the heart muscle itself. They are distinctive because they are *not* the result of pericardial, hypertensive, congenital, valvular, or ischemic diseases. Although the diagnosis of cardiomyopathy requires the exclusion of these etiological factors, the features of cardiomyopathy are often sufficiently distinctive--both clinically and hemodynamically--to allow a definitive diagnosis to be made.[1] With increasing awareness of this condition, along with improvements in diagnostic techniques, cardiomyopathy is being recognized as a significant cause of morbidity and mortality.[2] Whether the result of improved recognition or of other factors, the incidence and prevalence of cardiomyopathy appear to be increasing.[2] Although coronary artery disease is the most common cause of congestive heart failure (accounting for about two thirds of all cases), we avoid using the term *cardiomyopathy* in this setting, because the primary problem is in the coronary arteries and not the heart muscle itself.

TABLE 48-1 -- CLASSIFICATION OF THE CARDIOMYOPATHIES

DISORDER	DESCRIPTION
Dilated cardiomyopathy	Dilatation and impaired contraction of the left or both ventricles. Caused by familial/genetic, viral and/or immune, alcoholic/toxic, or unknown factors, or is associated with recognized cardiovascular disease.
Hypertrophic cardiomyopathy	Left and/or right ventricular hypertrophy, often asymmetrical, which usually involves the interventricular septum. Mutations in sarcoplasmic proteins cause the disease in many patients.
Restrictive cardiomyopathy	Restricted filling and reduced diastolic size of either or both ventricles with normal or near-normal systolic function. Is idiopathic or associated with other disease (e.g., amyloidosis, endomyocardial disease).
Arrhythmogenic right ventricular cardiomyopathy	Progressive fibrofatty replacement of the right, and to some degree left, ventricular myocardium. Familial disease is common.
Unclassified cardiomyopathy	Diseases that do not fit readily into any category. Examples include systolic dysfunction with minimal dilatation, mitochondrial disease, and fibroelastosis.
Specific Cardiomyopathies	
Ischemic cardiomyopathy	Presents as dilated cardiomyopathy with depressed ventricular function not explained by the extent of coronary artery obstructions or ischemic damage.
Valvular cardiomyopathy	Presents as ventricular dysfunction that is out of proportion to the abnormal loading conditions produced by the valvular stenosis and/or regurgitation.
Hypertensive cardiomyopathy	Presents with left ventricular hypertrophy with features of cardiac failure due to systolic or diastolic dysfunction.
Inflammatory cardiomyopathy	Cardiac dysfunction as a consequence of myocarditis.
Metabolic cardiomyopathy	Includes a wide variety of causes, including endocrine abnormalities, glycogen storage disease, deficiencies (such as hypokalemia), and nutritional disorders.
General systemic disease	Includes connective tissue disorders and infiltrative diseases such as sarcoidosis and leukemia.
Muscular dystrophies	Includes Duchenne, Becker-type, and myotonic dystrophies.
Neuromuscular disorders	Includes Friedreich ataxia, Noonan syndrome, and lentiginosis.
Sensitivity and toxic reactions	Includes reactions to alcohol, catecholamines, anthracyclines, irradiation, and others.
Peripartal cardiomyopathy	First becomes manifest in the peripartum period, but it is likely a heterogeneous group.

Figure 48-2 Gross pathology of dilated cardiomyopathy. Prominent ventricular dilatation is apparent in this heart, which has been opened so that the interior of the left ventricle can be seen. Wall thickness is normal, but the shape of the heart has become more globular. (From Kasper EK, Hruban RH, Baughman KL: Idiopathic dilated cardiomyopathy. \i\In\r\ Abelmann WH, Braunwald E ;obeds.;cb: Atlas of Heart Diseases. Vol 2. Cardiomyopathies, Myocarditis, and Pericardial Disease. Philadelphia, Current Medicine, 1995, pp 3.1-3.18.)

A variety of schemes have been proposed for classifying the cardiomyopathies. The most widely recognized classification is that promulgated jointly by the World Health Organization (WHO) and the International Society and Federation of Cardiology (ISFC) (Table 48-1) .[3] In the WHO/ISFC classification, the cardiomyopathies are classified based on their predominant pathophysiological features; other diseases that affect the myocardium that are associated with a specific cardiac disorder or are part of a generalized systemic disorder are termed *specific cardiomyopathies* (in the previous WHO/ISFC classification, they were termed *specific heart muscle diseases*).[3]

Three basic types of functional impairment have been described (Fig. 48-1; Table 48-2) : (1) *dilated* (DCM, formerly called congestive), the most common form, accounting for 60 percent of all cardiomyopathies[4] and characterized by ventricular dilatation, contractile dysfunction, and often symptoms of congestive heart failure (Fig. 48-2) ; (2) *hypertrophic* (HCM), recognized by inappropriate left ventricular hypertrophy, often with asymmetrical involvement of the interventricular septum, with

preserved or enhanced contractile function until late in the course; and (3) *restrictive* (RCM), the least common form in western countries, marked by impaired diastolic filling and in some cases with endocardial scarring of the ventricle. Two other forms of cardiomyopathy are recognized: *arrhythmogenic right ventricular cardiomyopathy* and *unclassified;* the latter includes fibroelastosis, systolic dysfunction with minimal dilatation, and mitochondrial involvement.[3] The distinction

TABLE 48-2 -- FUNCTIONAL CLASSIFICATION OF THE CARDIOMYOPATHIES

	DILATED	RESTRICTIVE	HYPERTROPHIC
Symptoms	Congestive heart failure, particularly left sided	Dyspnea, fatigue	Dyspnea, angina pectoris
	Fatigue and weakness	Right-sided congestive heart failure	Fatigue, syncope, palpitations
	Systemic or pulmonary emboli	Signs and symptoms of systemic disease: amyloidosis, iron storage disease, etc.	
Physical Examination	Moderate to severe cardiomegaly: S_3 and S_4	Mild to moderate cardiomegaly: S_3 or S_4	Mild cardiomegaly
			Apical systolic thrill and heave; brisk carotid upstroke
	Atrioventricular valve regurgitation, especially mitral	Atrioventricular valve regurgitation; inspiratory increase in venous pressure (Kussmaul sign)	S_4 common Systolic murmur that increases with Valsalva maneuver
Chest Roentgenogram	Moderate to marked cardiac enlargement, especially left ventricular	Mild cardiac enlargement	Mild to moderate cardiac enlargement
	Pulmonary venous hypertension	Pulmonary venous hypertension	Left atrial enlargement
Electrocardiogram	Sinus tachycardia	Low voltage	Left ventricular hypertrophy
	Atrial and ventricular arrhythmias	Intraventricular conduction defects	ST segment and T wave abnormalities
	ST segment and T wave abnormalities	Atrioventricular conduction defects	Abnormal Q waves
	Intraventricular conduction defects		Atrial and ventricular arrhythmias
Echocardiogram	Left ventricular dilatation and dysfunction	Increased left ventricular wall thickness and mass	Asymmetrical septal hypertrophy (ASH)
	Abnormal diastolic mitral valve motion secondary to abnormal compliance and filling pressures	Small or normal-sized left ventricular cavity	Narrow left ventricular outflow tract
		Normal systolic function	Systolic anterior motion (SAM) of the mitral valve
		Pericardial effusion	Small or normal-sized left ventricle
Radionuclide Studies	Left ventricular dilatation and dysfunction (RVG)	Infiltration of myocardium (^{201} Tl)	Small or normal-sized left ventricle (RVG)
		Small or normal-sized left ventricle (RVG)	Vigorous systolic function (RVG)
		Normal systolic function (RVG)	Asymmetrical septal hypertrophy (RVG or ^{201} Tl)
Cardiac Catheterization	Left ventricular enlargement and dysfunction	Diminished left ventricular compliance	Diminished left ventricular compliance
	Mitral and/or tricuspid regurgitation	"Square root sign" in ventricular pressure recordings	Mitral regurgitation
			Vigorous systolic function
	Elevated left- and often right-sided filling pressures	Preserved systolic function	Dynamic left ventricular outflow gradient
		Elevated left- and right-sided filling pressures	
	Diminished cardiac output		

RVG=Radionuclide ventriculogram; ^{201} Tl=thallium-201.

between the three major functional categories is not absolute, and often there is overlap; in particular, patients with HCM also have increased wall stiffness (as a consequence of the myocardial hypertrophy) and thus present some of the features of an RCM.[3] Late in their course, ventricular dilation and systolic heart failure, bearing some resemblance to DCM, may occur.

Examples of *specific cardiomyopathies* include ischemic cardiomyopathy, valvular cardiomyopathy, hypertensive cardiomyopathy, and inflammatory cardiomyopathy (myocarditis with cardiac dysfunction) (see Table 48-1). [3] Most forms of specific cardiomyopathy are characterized by the DCM pattern. The term *ischemic cardiomyopathy* (see Chap. 37) has been used to describe the condition in which coronary artery disease causes multiple infarctions, diffuse fibrosis, and/or severe ischemia that leads to left ventricular dilatation with congestive heart failure; it may or may not be associated with angina pectoris.[5]

Endomyocardial Biopsy

Evaluation of some patients suspected of suffering from a cardiomyopathy has been facilitated by the use of endomyocardial biopsy.[6] Using a flexible bioptome, the clinician may obtain tissue samples from the right ventricle (and left ventricle when required) through a transvenous (or transarterial) approach with ease and safety (see Chap. 11). The availability of disposable transfemoral bioptomes has further facilitated endomyocardial biopsy. Two-dimensional echocardiography may help guide the placement of the bioptome and reduce or eliminate radiation exposure.[7] Endomyocardial biopsy results in a small tissue sample (average size 1 to 2 mm),

and multiple samples (usually four or more) are required because pronounced topographical variations may be found within the myocardium. Which patients should be subjected to biopsy remains controversial, but there is general agreement that biopsy may be of benefit in certain specific situations (Table 48-3) .[6] There is little debate as to its clinical utility in detecting infiltrative disorders of the myocardium and in monitoring for anthracycline cardiotoxicity and cardiac transplant rejection.

Although on occasion endomyocardial biopsy may identify a specific etiological agent in an individual patient with cardiac disease of uncertain cause (Table 48-4) , the clinical utility of routine biopsy in cardiomyopathy is limited (particularly because no definitive pattern has been found in DCM) (Fig. 48-3) .[8] [9] It has been estimated that a specific etiological diagnosis is obtained by biopsy in fewer than 10 percent of patients with cardiomyopathy and a treatable disease is found in only about 2 percent.[6]

DALLAS CRITERIA.

Interpretation of biopsy specimens had been plagued by a high degree of interobserver variability; the adoption of a generally accepted set of histological definitions, the *Dallas criteria,* has improved agreement.[10] It is hoped that newer immunohistochemical and molecular biological techniques (such as the polymerase chain reaction or in situ hybridization techniques to detect viral infection of the heart) may expand further the diagnostic utility of endomyocardial biopsy.[10] [11] [12]

TABLE 48-4 -- SPECIFIC DIAGNOSES THAT CAN BE CONFIRMED BY MYOCARDIAL BIOPSY

Cardiac allograft rejection	Fabry disease of the heart	Henoch-Schonlein purpura
Myocarditis	Carcinoid disease	Rheumatic carditis
Giant cell myocarditis	Irradiation injury	Chagasic cardiomyopathy
Doxorubicin cardiotoxicity	Glycogen storage disease	Chloroquine cardiomyopathy
Cardiac amyloidosis	Cardiac tumors of cardiac origin	Lyme carditis
Cardiac sarcoidosis	Cardiac tumors of noncardiac origin	Carnitine deficiency cardiomyopathy
Cardiac hemochromatosis	Kearns-Sayre syndrome	Right ventricular lipomatosis
Endocardial fibrosis	Cytomegalovirus infection	Hypereosinophilic syndrome
Endocardial fibroelastosis	Toxoplasmosis

Dilated Cardiomyopathy

IDIOPATHIC DILATED CARDIOMYOPATHY

Dilated cardiomyopathy is a syndrome characterized by cardiac enlargement and impaired systolic function of one or both ventricles (see Fig. 48-2). Although it was formerly called congestive cardiomyopathy, the term *dilated cardiomyopathy* is now preferred because the earliest abnormality usually is ventricular enlargement and systolic contractile dysfunction, with the signs and symptoms of congestive heart failure often (but not invariably) developing later. In an occasional patient, the predominant finding is that of contractile dysfunction with only a mildly dilated left ventricle. In the WHO/ISFC classification scheme, this variant of DCM is placed in the unclassified cardiomyopathy group. Conversely, apparently normal elite athletes may demonstrate considerable ventricular enlargement with *normal* systolic performance. It is presumed that this is a physiological adaptation to intense athletic training and does not appear to represent a disease state, although the long-term consequences are not fully known.[13]

The incidence of DCM is reported to be 5 to 8 cases per 100,000 population per year and appears to be increasing, although the true figure likely is higher as a consequence of underreporting of mild or asymptomatic cases.[14] It occurs almost three times more frequently in blacks and males as in whites and females, and this difference does not appear to be related solely to differing degrees of hypertension, cigarette smoking, or alcohol use.[2] [15] [16] Survival in blacks and males appears to be worse than in whites and females.[17]

Although the cause is not definable in many cases, more than 75 specific diseases of heart muscle can produce the clinical manifestations of DCM. It is likely that this condition represents a final common pathway that is the end result of myocardial damage produced by a variety of cytotoxic, metabolic, immunological, familial, and infectious mechanisms. Alcohol, for example, may lead to severe cardiac dysfunction and may produce clinical, hemodynamic, and pathological findings identical to those present in idiopathic DCM (see p. 1758).

NATURAL HISTORY.

The natural history of DCM is not well established. Many patients have minimal or no symptoms, and the progression of the disease in these patients is unclear, although there is some evidence that the long-term prognosis is not good.[18] Nevertheless, in symptomatic patients the course usually is one of progressive deterioration, with one quarter of newly diagnosed patients referred to major medical centers dying within a year and half dying within 5 years, although a minority improve, with a reduction in cardiac size and longer survival.[14] Recent data suggest that in patients with mild dilatation not referred to a medical center the prognosis may be more favorable, no doubt reflecting at least in part earlier diagnosis and perhaps more effective treatment options now available in the community.[1] [19] [20] About a fourth of patients with recent-onset DCM improve spontaneously, even some sick enough initially to be considered for cardiac transplantation.[21] In some patients clinical and functional improvement may occur years after initial presentation.

PROGNOSIS.

A variety of clinical predictors of patients at enhanced risk of dying of DCM have been identified, including the presence of a protodiastolic (S_3) gallop, ventricular arrhythmias, advanced age, and specific endomyocardial biopsy features.[22] However, the predictive reliability of any single feature is not high,[23] and it may be difficult to predict with any accuracy the clinical course and outcome in an individual patient.[14] [20] Nevertheless, greater ventricular enlargement and worse dysfunction tend to correlate with poorer prognosis,[16] [22] [24] particularly if the right ventricle is dilated and dysfunctional as well.[25]

Cardiopulmonary exercise testing also can provide prognostic information (see Chap. 6). Marked limitation of exercise capacity manifested by reduced maximal systemic oxygen uptake (especially when below 10 to 12 ml/kg/min) is a reliable predictor of mortality and is used widely as an indicator for consideration of cardiac transplantation.[14] [16] It has been suggested that specific endomyocardial biopsy morphological findings (such as loss of intracellular myofilaments) may offer some predictive information regarding prognosis.[14] [26]

Pathology

MACROSCOPIC EXAMINATION.

This reveals enlargement and dilatation of all four cardiac chambers; the ventricles are more dilated than the atria (see Fig. 48-2). Although the thickness of the ventricular wall is increased in some cases, the degree of hypertrophy often is less than might be expected given the severe dilatation present.[14] The development of

left ventricular hypertrophy appears to have a protective or beneficial role in DCM, presumably because it reduces systolic wall stress and thus protects against further cavity dilatation. The cardiac valves are intrinsically normal, and intracavitary thrombi, particularly in the ventricular apex, are common.[14] The coronary arteries usually are normal. The right ventricle is preferentially involved in some cases of DCM, sometimes on a familial basis.

HISTOLOGICAL EXAMINATION.

Microscopic study reveals extensive areas of interstitial and perivascular fibrosis, particularly involving the left ventricular subendocardium (see Fig. 48-3). Small areas of necrosis and cellular infiltrate are seen on occasion, but these typically are not prominent features. There is marked variation in myocyte size; some myocardial cells are hypertrophied, and others are atrophied. No viruses or other etiological agents have been identified with any regularity in tissue from patients with DCM. Particularly disappointing has been the failure to identify any immunological, histochemical, morphological, ultrastructural, or microbiological marker that might be used to establish the diagnosis of idiopathic DCM or to clarify its cause.

Etiology

About a fourth of the cases of congestive heart failure in the United States are due to idiopathic DCM[27] ; most of the remainder are caused by the sequelae of coronary artery or hypertensive heart disease. It is likely that idiopathic DCM represents a common expression of myocardial damage that has been produced by a variety of as yet unestablished myocardial insults. Although the cause(s) remain unclear, interest has centered on three possible basic mechanisms of damage: (1) familial and genetic factors; (2) viral myocarditis and other cytotoxic insults; and (3) immunological abnormalities (Figs. 48-4 and 48-5) .[14] [28]

Familial linkage of DCM occurs more commonly than often is appreciated. In 20 percent or more of patients, a first-degree relative also shows evidence of DCM, suggesting that familial transmission is relatively frequent.[20] [29] [30] [31] [32] [33] [299A] Some asymptomatic relatives of patients with DCM have subclinical left ventricular enlargement and/or dysfunction that may progress to overt symptomatic DMC.[29] Most familial cases demonstrate autosomal dominant transmission; six chromosomal loci have been identified, and more are likely to be found.[34] However, the disease is genetically quite heterogeneous[32] and autosomal recessive [35] and X-linked inheritance[36] have been found. One form of familial X-linked DCM is due to a deletion in the promoter region and the first exon of the gene that codes for the protein dystrophin, a component of the cytoskeleton of myocytes.[37] [38] This has fueled speculation that a resulting deficiency of cardiac dystrophin is the cause of the associated DCM (see also Chap. 21). Mutations involving mitochondrial DNA have been reported as well. [39] [40] [41]

Whether any of the patients without apparent familial linkage has a genetic predisposition to DCM remains un

Figure 48-4 Diagram showing the cardiac myocyte and the molecules that have been implicated in dilated cardiomyopathy. The actin cytoskeleton is linked to the extracellular matrix by dystrophin and the dystrophin-associated glycoprotein complex. Linkage of the actin cytoskeleton to the contractile apparatus is hypothesized to occur through the muscle LIM (Lin-11, Isl-1, Mec-3) protein (MLP). A nuclear transcription factor, cyclic AMP response-element binding protein (CREB), is shown binding to a cyclic AMP response element in the myocyte DNA. Mutations in dystrophin and other members of the dystrophin-associated glycoprotein complex, as well as in MLP and CREB, have all been shown to result in dilated cardiomyopathy in mice or humans. (From Leiden JD: The genetics of dilated cardiomyopathy: Emerging clues to the puzzle. N Engl J Med 337:1080, 1997. Copyright 1997, Massachusetts Medical Society.)

Figure 48-5 Hypotheses to explain the pathogenesis of dilated cardiomyopathy. MHC=myosin heavy chain. *(From Mestroni L, Krajinovic M, Severini GM, et al: Familial dilated cardiomyopathy. Br Heart J 72:S35, 1994.)*

known. There is great interest in using molecular genetic techniques to identify markers of disease susceptibility in asymptomatic carriers at risk for the eventual development of overt clinical DCM.[36] [42] An example of such a marker may be the angiotensin-converting enzyme DD genotype that is found with increased frequency in DCM patients.[43] One intriguing familial metabolic deficiency is that of carnitine, with improvement occurring in the myopathy with carnitine repletion.[44]

SEQUELA OF VIRAL MYOCARDITIS.

Wide speculation exists that an episode of subclinical viral myocarditis initiates an autoimmune reaction that culminates in the development of full-blown DCM.[27] [45] Although this hypothesis is inviting, it remains largely unsupported[46] ; it has been estimated that only about 15 percent of patients with myocarditis progress to DCM. In some patients who exhibit the clinical features of DCM, endomyocardial biopsy reveals evidence of an inflammatory myocarditis (see Fig. 48-3 *B*). The reported frequency of evidence of an inflammatory infiltrate in DCM varies widely and undoubtedly depends largely on patient selection and the criteria used for diagnosis; using rigorous criteria, only about 10 percent (or less) of patients with DCM have biopsy evidence of myocarditis.[6] Other evidence favoring the concept that DCM is a postviral disorder includes the presence of high antibody viral titers, viral-specific RNA sequences, and apparent viral particles in patients with "idiopathic" DCM.[47] On the other hand, the more rigorous technique of polymerase chain reaction generally has not confirmed the presence of viral remnants in the myocardium of most cardiomyopathy patients,[48] although data are conflicting.[49] [50]

AUTOIMMUNITY.

Abnormalities of both humoral and cellular immunity have been found in patients with DCM,[28] [51] [52] although the findings have not been completely reproducible. There is speculation that antibodies might be the *result* of myocardial damage, rather than the cause.[53] There appears to be an association with specific HLA Class II antigens (particularly DR4), suggesting that abnormalities of immunoregulation may play a role in DCM.[31] [54] Circulating antimyocardial antibodies to a variety of antigens (including the myosin heavy chain, the beta adrenoreceptor, the muscarinic receptor, laminin, and mitochondrial proteins) have been identified.[28] [55] [56] [57] Additional evidence for the significance of circulating antimyocardial antibodies comes from the demonstration of short-term clinical improvement in the manifestations of heart failure in a small number of patients treated with immunoadsorption and elimination of anti-beta$_1$ -adrenergic receptor antibodies. [58] [58A] [58B] Abnormalities of various T cells, including cytotoxic T cells, suppressor T lymphocytes, and natural killer cells, have been found in some studies.[14] [59] These immunological abnormalities may be the consequence of prior viral myocarditis.[59] It has been postulated that viral components may be incorporated into the cardiac sarcolemma, only to serve as an antigenic source that directs the immune response to attack the myocardium. Nevertheless, the precise

role of either humoral or cellular immunomodulation in the pathogenesis of DCM remains unestablished.[14]

PROINFLAMMATORY CYTOKINES.

A variety of proinflammatory cytokines such as tumor necrosis factor-alpha (and the related tumor necrosis factor-alpha converting enzyme) are expressed in DCM and may play a role in producing contractile dysfunction; whether viral infection, autoimmune abnormalities, or other factors induce their expression is unknown.[60] [61] Similarly, the vasoconstrictor peptide endothelin is increased in decompensated DCM and has been implicated as a cause of the heightened vascular tone that accompanies congestive heart failure.[62]

OTHER POTENTIAL CAUSES.

A variety of other possible causes have been proposed, although none is accepted as *the* cause of DCM. Thus, endocrine abnormalities as well as the effects of chemicals or toxins have been suggested as possible etiological factors. It has been suggested that microvascular hyperreactivity (spasm) may lead to myocellular necrosis and scarring, with resultant heart failure, although this remains speculative.[5] Apoptosis, or programmed cell death, has been demonstrated in the hearts of patients with DCM and arrhythmogenic right ventricular cardiomyopathy, although there is some controversy regarding the veracity of these findings in DCM.[63] Even if true, the significance of this finding, and whether it is a primary or secondary event in the development of cardiomyopathy, remains unclear. From a clinical standpoint, the more important causes of nonidiopathic DCM include alcohol and cocaine abuse, human immunodeficiency virus (HIV) infection[64] (see Chap. 68), metabolic abnormalities, and the cardiotoxicity of anticancer drugs (especially doxorubicin).

ABNORMALITIES OF THE SYMPATHETIC NERVOUS SYSTEM.

Several abnormalities of the sympathetic nervous system have been demonstrated in DCM, but they appear to be the result rather than the cause of the disease.[14] [65] A reduction in density of membrane-associated beta adrenoreceptors[66] is believed to be a consequence of the development of anti-beta-adrenoreceptor

autoantibodies. An alteration in the signal transmission pathway by which the beta adrenoreceptors stimulate the contractile apparatus (the G-protein system) has been found as well. Inhibition of this system is enhanced in DCM patients, perhaps accounting for their depressed contractile function. An increase of the subunits of the inhibitory guanine nucleotide-binding protein (G_i) has been reported to occur in the membranes of myocytes from failing hearts.[67] This increase in G_i is associated with a striking reduction of basal adenylate cyclase activity and of the positive inotropic effects of isoproterenol and the phosphodiesterase inhibitor milrinone. These findings suggest that the increase of G_i might contribute to the reduced effects of endogenous catecholamines in DCM. The precise cause of contractile dysfunction at the cellular level in patients with DCM remains speculative. Although there are demonstrable abnormalities of cellular metabolism and calcium handling by cardiomyopathic tissue,[5] [68] [69] [70] the significance of these findings is not yet clear.[62]

Clinical Manifestations

HISTORY.

Symptoms usually develop gradually in patients with DCM. Some patients are asymptomatic and yet have left ventricular dilatation for months or even years. This dilatation may be recognized clinically only later when symptoms develop or when routine chest roentgenography demonstrates cardiomegaly. A relatively small number of patients develop symptoms of heart failure for the first time after recovery from what appears to be a systemic viral infection. In still others, severe heart failure develops acutely during an episode of myocarditis; although some recovery occurs, chronic manifestations of diminished cardiac reserve persist and heart failure reappears months or years later. It is important to question the patient and family carefully about alcohol consumption, because excessive alcohol consumption is a major cause of DCM, and its cessation may result in substantial clinical improvement.[14] Although patients of any age may be affected, the disease is most common in middle age and is more frequent in men than in women.

The most striking symptoms of DCM are those of left ventricular failure. Fatigue and weakness due to diminished cardiac output are common. Right-sided heart failure is a late and ominous sign and is associated with a particularly poor prognosis. Chest pain occurs in about one third of patients and may suggest concomitant ischemic heart disease.[1] [14] The demonstrated reduction in the vasodilator reserve of the coronary microvasculature in DCM suggests that subendocardial ischemia may play a role in the genesis of chest pain that occurs despite angiographically normal coronary arteries.[71] Chest pain secondary to pulmonary embolism and abdominal pain secondary to congestive hepatomegaly are frequent in the late stages of illness.

PHYSICAL EXAMINATION (See also Chaps. 4 and 17).

Examination usually reveals variable degrees of cardiac enlargement and findings of congestive heart failure. The systolic blood pressure is usually normal or low, and the pulse pressure is narrow, reflecting a diminished stroke volume. *Pulsus alternans* (see Fig. 17-5) is common when severe left ventricular failure is present. Cheyne-Stokes breathing may be present and is associated with a poor prognosis.[72] The jugular veins are distended when right-sided heart failure appears, but on initial presentation most patients do not have evidence of this.[14] Prominent *a* and *v* waves may be visible. Grossly pulsatile jugular veins with prominent regurgitant waves indicate the presence of tricuspid valvular regurgitation; this is usually a late and often ominous finding. The liver may be engorged and pulsatile. Peripheral edema and ascites are present when right-sided heart failure is advanced.

The precordium usually reveals left and, occasionally, right ventricular impulses, but the heaves are not sustained as they are in patients with ventricular hypertrophy. The apical impulse is usually displaced laterally, reflecting left ventricular dilatation. A presystolic *a* wave may be palpable on occasion and is generated in a similar manner as a presystolic (S_4) gallop heard on auscultation. The second heart sound (S_2) is usually normally split, although paradoxical splitting may be detected in the presence of left bundle branch block, an electrocardiographic (ECG) finding that is not unusual in DCM. If pulmonary hypertension is present, the pulmonary component of S_2 may be accentuated and the splitting may be narrow. Presystolic gallop sounds (S_4) are almost universally present and often precede the development of overt congestive heart failure.[14] Ventricular gallops (S_3) are the rule once cardiac decompensation occurs, and a summation gallop is heard when there is concomitant tachycardia.

Systolic murmurs are common and are usually due to mitral or, less commonly, tricuspid valvular regurgitation.[14] Mitral regurgitation results from enlargement and abnormal motion of the mitral annulus; ventricular dilatation with resultant distortion of the geometry of the subvalvular apparatus ("papillary muscle dysfunction") plays a lesser role. Gallop sounds and regurgitant murmurs can often be elicited or intensified by isometric handgrip exercise with its attendant enhancement of systemic vascular resistance and impedance to left ventricular outflow. Systemic emboli resulting from dislodgement of intracardiac thrombi from the left atrium and ventricle and pulmonary emboli that originate in the venous system of the legs are common late complications.

NONINVASIVE LABORATORY EXAMINATIONS.

To identify potentially reversible causes of DCM, several basic screening biochemical tests are indicated, including determination of levels of serum phosphorus (hypophosphatemia), serum calcium (hypocalcemia), and serum creatinine and urea nitrogen (uremia), thyroid function studies (hypothyroidism and hyperthyroidism), and iron studies (hemochromatosis). It is prudent to test for HIV as well, because this infection is an important and often unrecognized cause of congestive heart failure[64] (see Chap. 68). The chest roentgenogram usually reveals generalized cardiomegaly and pulmonary vascular redistribution; interstitial and alveolar edema are less common on initial presentation.[14] Pleural effusions may be present, and the azygos vein and superior vena cava may be dilated when right-sided heart failure supervenes.

Electrocardiography.

The ECG often shows sinus tachycardia when heart failure is present. The entire spectrum of atrial and ventricular tachyarrhythmias may be

seen. Poor R wave progression and intraventricular conduction abnormalities, especially left bundle branch block, are common.[14] Anterior Q waves may be present when there is extensive left ventricular fibrosis, even without a discrete myocardial scar or evidence of coronary artery disease.[14] ST segment and T wave abnormalities are common, as are P wave changes, especially left atrial abnormality. Ambulatory monitoring demonstrates the ubiquity of ventricular arrhythmias, with about half of monitored patients with DCM exhibiting nonsustained ventricular tachycardia.[14] There is no consensus that complex or frequent ventricular arrhythmias predict sudden (presumably arrhythmic) death, although they do appear to predict *total* mortality. [73] Perhaps ventricular arrhythmias as detected on ambulatory monitoring are a marker for the extent of myocardial damage in DCM and therefore are associated with sudden death without necessarily being its cause. In occasional cases, particularly in children, recurrent and/or incessant supraventricular or ventricular tachyarrhythmias may actually be the cause (rather than the result) of ventricular dysfunction.[74] [75] In those cases, restoration of sinus rhythm or slowing of the heart rate may reverse the cardiomyopathy.[76] [77]

Echocardiography.

Two-dimensional and Doppler forms of echocardiography are useful in assessing the degree of impairment of left ventricular function and for excluding concomitant valvular or pericardial disease (see Fig. 7-99).[20] In addition to examining all four cardiac valves for evidence of structural or functional abnormalities, echocardiography allows evaluation of the size of the ventricular cavity and thickness of the ventricular walls. A pericardial effusion may be demonstrated on occasion. Doppler studies are useful in delineating the severity of mitral (and tricuspid) regurgitation. Patients with a pattern of left ventricular filling on Doppler studies that simulates that seen with RCM appear to have more advanced disease.[78] Combining echocardiography with dobutamine infusion may identify patients with left ventricular dysfunction due to coronary artery disease by demonstrating provocable differences in regional wall motion and thus distinguish them from patients with idiopathic DCM.[79] It has been suggested that thallium-201 imaging may be helpful in distinguishing left ventricular enlargement caused by DCM from that caused by coronary artery disease,[80] although there is not complete agreement on this point.[14] [81] Scanning with gallium or antimyosin antibody (see Chap. 9) may help to identify patients more likely to have evidence of myocarditis on biopsy, although whether this finding is useful clinically is not yet established.[14] [82]

Radionuclide Ventriculography.

Like echocardiography, radionuclide ventriculography reveals increased end-diastolic and end-systolic left ventricular volumes, reduced ejection fraction in one or both ventricles, and wall motion abnormalities (see Chap. 9); it is used most commonly when echocardiography is technically suboptimal.[14] Like echocardiography, it may demonstrate segmental wall motion abnormalities in DCM even in the absence of coronary artery disease, the disease process that most commonly produces regional dysfunction. In most patients it is not necessary to carry out serial studies or batteries of noninvasive tests to follow patients with DCM and evaluate their response to treatment; adjustments in pharmacological therapies usually are made based on routine bedside clinical features and symptomatic response.

CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY.

Only certain patients with DCM require cardiac catheterization (particularly those with chest pain and a suspicion of ischemic disease or patients thought to have a treatable systemic disease such as sarcoidosis or hemochromatosis, where myocardial biopsy is an important part of the catheterization procedure).[14] When cardiac catheterization is carried out, the left ventricular end-diastolic, left atrial, and pulmonary artery wedge pressures usually are elevated. Modest degrees of pulmonary arterial hypertension are common. Advanced cases may demonstrate right ventricular dilatation and failure as well, with resultant elevation of the right ventricular end-diastolic, right atrial, and central venous pressures.

Left ventriculography demonstrates enlargement of this chamber, typically with diffuse reduction in wall motion. Segmental wall motion abnormalities are not uncommon and may simulate the angiographic findings in ischemic heart disease. However, prominent localized wall motion disturbances are more characteristic of ischemic heart disease, whereas diffuse global dysfunction is more typical of DCM. The ejection fraction is reduced and the end-systolic volume is increased as a result of the impairment of left ventricular contractility. Sometimes left ventricular thrombi may be visualized within the left ventricle as intracavitary filling defects. Mild mitral regurgitation is often present. On occasion, it may be difficult to distinguish left ventricular dilatation secondary to severe mitral regurgitation due to intrinsic mitral valve disease from DCM with secondary mitral regurgitation.

Coronary arteriography usually reveals normal vessels, although coronary vasodilatory capacity may be impaired[83] [84] ; in some cases this may relate to marked elevation of the left ventricular filling pressures.[85] This examination may be of particular value in excluding coronary artery disease in patients with abnormal Q waves on the ECG or regional left ventricular wall motion abnormalities on noninvasive evaluation (although noninvasive testing, including electron-beam computed tomography [CT], may be sufficiently reliable to exclude important coronary artery disease without resorting to arteriography).[86] Coronary arteriography, when necessary, thus helps to distinguish between myocardial infarction as a result of obstructive coronary artery disease and extensive localized myocardial fibrosis secondary to severe DCM in the absence of coronary artery obstruction.

Management

Because the cause of idiopathic DCM, by definition, is unknown, specific therapy is not possible.[27] Treatment, therefore, is for heart failure, as discussed in Chapters 18 and 21 .

Many of the therapeutic approaches are directed at modifying the results of the long-term activation of two interrelated neurohormonal/autocrine-paracrine systems, the adrenergic and renin-angiotensin systems.[87] Physical, dietary, and pharmacological interventions may help to control symptoms; regular physical exercise (as tolerated) increases exercise capacity by improving endothelial dysfunction and augmenting blood flow in skeletal muscles.[88] Only cardiac transplantation (see Chap. 20) and specific pharmacological therapy (the vasodilators enalapril or hydralazine plus nitrates, the beta-adrenoceptor blocker carvedilol, and the aldosterone receptor blocker spironolactone) have been shown to prolong life.[14] [27] [89] [90] [91]

BETA-ADRENERGIC RECEPTOR BLOCKADE.

Because of evidence that activation of the adrenergic system may have deleterious cardiac effects (rather than being an important compensatory mechanism as traditionally thought), beta-adrenoceptor blockade has been suggested as treatment for DCM (see Chaps. 18 and 21).[78] [92] Results to date generally have been favorable, with evidence of improved symptoms, exercise capacity, and left ventricular function and a suggestion that survival has been improved.[14] [93] [94] [95] [96] [97] [97A] Beta-adrenoceptor blockade has been surprisingly well tolerated, with infrequent aggravation of heart failure (which, on occasion, may be profound). The mechanism of beneficial action of beta-adrenoceptor blockers is unknown but may relate to (1) negative chronotropic effect with reduced myocardial oxygen demand, (2) reduced myocardial damage due to catecholamines, (3) improved diastolic relaxation (both early active and late passive properties), (4) inhibition of sympathetically mediated vasoconstriction, (5) increase ("upregulation") in myocardial beta-adrenoceptor density, (6) improved calcium handling at slower heart rates, (7) modulation of postreceptor inhibitory G proteins, and/or (7) a direct effect on myocyte and interstitial growth, with attendant inhibition of the remodeling process (remodeling refers to the change in ventricular shape, size, and geometry that occurs after myocyte dysfunction).[90] [92] [98] [99] [100] Modulation of the remodeling process has also

been implicated in the successful use of growth hormone in a small number of patients with DCM.[101]

Beta-adrenergic blocker therapy is now accepted as part of the four-drug approach (along with digoxin, vasodilators and diuretics) advocated for all suitable patients with symptomatic congestive heart failure (see Chap. 21). Patients with advanced heart failure or in a decompensated state should not ordinarily be given a beta-adrenergic blocker for fear of worsening the failure.[102] Recent data indicate that carvedilol (a beta-adrenoceptor blocker with alpha-adrenoceptor blocking and antioxidant effects) substantially reduces mortality in DCM.[90] It remains unestablished whether carvedilol has additional clinical benefits beyond those found with the other beta-adrenergic blockers, although some patients appear to respond more favorably.[103] [104]

CALCIUM ANTAGONISTS.

Because of the possible link between DCM, microvascular circulatory abnormalities, and abnormal myocardial calcium handling, there has been interest in the use of calcium antagonists. These agents have generally been well tolerated when used in DCM patients, although myocardial depression is an important potential side effect of the calcium antagonists as a group. Unfortunately, combining a calcium antagonist with traditional standard therapy (digoxin, diuretics, and vasodilator) does not appear to have substantial clinical benefit, nor does it reduce further the mortality in DCM.[105] At present, the routine use of calcium antagonists in DCM is considered nonstandard and not first-line therapy.[106]

ANTIARRHYTHMICS.

Although there is no definitive evidence that antiarrhythmic agents prolong life or prevent sudden death in DCM,[14] [73] [107] it may be appropriate to use them in the treatment of symptomatic arrhythmias. Because of the adverse effects of most available agents, many of which depress myocardial contractility and have a proarrhythmic effect (see Chap. 23), treatment should be individualized, with both efficacy and toxicity carefully monitored. Unfortunately, electrophysiological testing is of limited utility in DCM because it is positive in a minority of patients at risk,[14] [108] the lack of inducibility of ventricular tachyarrhythmias does not identify a low-risk group, and pharmacological suppression of provoked arrhythmias does not necessarily predict freedom from recurrences.[109] The recording of late potentials by the signal-averaged ECG has appeared to be of benefit in assessing the risk of death in some studies, although this has not been a universal finding and awaits further confirmation.[110] [111] The implantable cardioverter-defibrillator (ICD) (see Chap. 24) should be considered in appropriate candidates with symptomatic ventricular tachyarrhythmias.[112] [113] Even patients with unexplained syncope and no demonstrated tachyarrhythmia (even during electrophysiological testing) may profit from the insertion of an ICD.

ANTICOAGULANTS.

There is a lack of agreement as to the appropriateness and usefulness of chronic anticoagulant therapy in DCM to protect against pulmonary and especially systemic emboli.[114] [115] Even in the absence of controlled clinical trials demonstrating their efficacy,[116] we believe that the available observational data support the use of anticoagulants in good-risk patients with DCM and heart failure.[114] [117] There is general agreement that anticoagulants should be used in the presence of atrial fibrillation, if the patient has previously had a stroke, and when there is visible thrombus on echocardiography. Oral warfarin is used to achieve a prolongation of the prothrombin time of 2.0 to 3.0 international normalized ratio.

IMMUNOSUPPRESSIVES.

In those patients with chronic heart failure secondary to DCM and lymphocytic infiltrate on myocardial biopsy, treatment with corticosteroids and immunosuppressive agents had been advocated in the past. Unfortunately, such therapy does not appear to have a clinically important effect on symptoms, exercise performance, or ejection fraction (in more than just the short term) and may be associated with significant complications.[118] Routine clinical use of immunosuppressive therapy thus cannot be recommended at present.

DUAL CHAMBER PACING.

This has been used in some patients with DCM and intact atrioventricular conduction in an attempt to change the sequence of ventricular depolarization, reduce functional mitral regurgitation, and thus improve clinical status; some symptomatic and hemodynamic improvement has been reported, especially in patients with intraventricular conduction delay or those with disturbed timing of atrioventricular mechanical activation.[119] [120] In a small number of patients followed short term, biventricular or left ventricular pacing appeared to be preferable to traditional right ventricular pacing.[120A] However, the data to date are largely anecdotal and equivocal, and demonstration of long-term benefit is lacking.[109] [121]

SURGICAL TREATMENT.

Mitral annuloplasty or replacement of regurgitant valves has been attempted in some patients with DCM and prominent atrioventricular valvular regurgitation. The results of operation are usually less than satisfactory because of the degree of preexisting cardiac dysfunction and damage, although some patients have shown some degree of symptomatic improvement, at least over the intermediate term.[122] In appropriately selected patients, cardiac transplantation (see Chap. 20) may be an attractive alternative to medical therapy, with a 5-year survival rate of about 75 percent. Surgical translocation of the latissimus dorsi muscle to wrap around the heart and augment cardiac performance (dynamic cardiomyoplasty) appears to have benefited some patients who are not otherwise suitable candidates for cardiac transplantation.[53] [123] Excision of part of the left ventricle (partial ventriculotomy) has been proposed as an additional surgical alternative to cardiac transplantation[124] ; the lack of a randomized control trial demonstrating efficacy has limited the widespread adoption of the procedure.

ALCOHOLIC CARDIOMYOPATHY

Chronic excessive consumption of alcohol may be associated with congestive heart failure, hypertension, cerebrovascular accidents, arrhythmias, and sudden death; it is the major cause of secondary, nonischemic DCM in the western world and accounts for upward of one third of all cases of DCM.[125] It is estimated that two thirds of the adult population use alcohol to some extent, and more than 10 percent are heavy users.[126] Therefore, it is not surprising that alcoholic cardiomyopathy is a major problem. Ceasing alcohol consumption early in the course of alcoholic cardiomyopathy may halt the progression of or even reverse left ventricular contractile dysfunction, unlike nonalcoholic cardiomyopathy, which often is marked by progressive clinical deterioration.[9] [127]

The consumption of alcohol may result in myocardial damage by three basic mechanisms: (1) a presumed direct toxic effect of alcohol or its metabolites; (2) nutritional effects, most commonly in association with thiamine deficiency that leads to beriberi heart disease (see Chap. 17); and (3) rarely, toxic effects due to additives in the alcoholic beverage (cobalt) (see p. 1759).[9] [128] There had been speculation that alcohol caused myocardial damage only through dietary deficiencies, but it is now clear that alcoholic cardiomyopathy occurs in the absence of nutritional deficiencies.[125] [126] [129]

Typical Oriental beriberi (see Chap. 17) may coexist with alcoholic cardiomyopathy, although it is no longer noted with any frequency.[130] The distinguishing features of each include peripheral vasodilatation and high-output heart failure, often right sided, in the former and reduced contractility with typically left-sided low-output failure in the latter.[125] [130]

Alcohol results in acute as well as chronic depression of myocardial contractility and may produce reversible cardiac dysfunction even when ingested by normal nonalcoholic individuals. What is responsible for the transition from the reversible acute effects to permanent myocardial damage remains unclear.[126]

The precise mechanisms of cardiac depression produced by alcohol are undetermined, but a direct toxic effect on striated muscle is likely (particularly because alcoholics often demonstrate concomitant skeletal myopathy and cardiomyopathy).[125] [126] In acute studies, alcohol and its metabolite acetaldehyde have been shown to interfere with a number of membrane and cellular functions that involve the transport and binding of calcium, mitochondrial respiration, myocardial lipid metabolism, myocardial protein synthesis, and signal transduction.[126] Studies in isolated ferret papillary muscles have shown that ethanol in concentrations similar to those occurring in intoxicated humans depresses myocardial contractility by interfering with excitation-contraction coupling through inhibition of the interaction between calcium and the myofilaments.[126] There are data supporting the role of free radical damage and defects in protein synthesis in the genesis of alcohol-induced myocardial damage.[126] The role that other associated electrolyte imbalances (hypokalemia, hypophosphatemia, hypomagnesemia) may play in alcohol-mediated damage has not been settled.

PATHOLOGY.

The gross and microscopic pathological findings are nonspecific and similar to those observed in idiopathic DCM, with interstitial fibrosis, myocytolysis, evidence of small vessel coronary artery disease, and myocyte hypertrophy.[125] [131] Electron microscopy shows enlarged and disorganized mitochondria, with large glycogen-containing vacuoles.[126]

Clinical Manifestations

Alcoholic cardiomyopathy most commonly occurs in men 30 to 55 years of age who have been heavy consumers of whisky, wine, or beer, usually for more than 10 years. Female alcoholics who develop cardiomyopathy appear to have a lower cumulative lifetime dose of alcohol than men.[127] Although alcoholic cardiomyopathy may be observed

in the homeless, malnourished, "skid row" alcoholic man, many patients are well-nourished individuals of middle and even upper socioeconomic status without liver disease or peripheral neuropathy. Accordingly, unless a high index of suspicion is maintained, it may be easy to miss a history of alcohol abuse.[132] Persistent questioning of the patient and particularly the relatives of patients with unexplained cardiomegaly or cardiomyopathy is often required to elicit a history of alcoholism.

It is frequently possible to demonstrate mild depression of cardiac function in chronic alcoholics even before cardiac dysfunction becomes clinically manifest. Abnormalities of both systolic function (reduced ejection fraction) and diastolic function (increased myocardial wall stiffness) have been demonstrated in alcoholic patients without cardiac symptoms by a variety of invasive and noninvasive techniques.[132A] Although overt alcoholic liver disease and cardiac involvement usually do not occur together, even cirrhotic patients without signs or symptoms of heart disease have demonstrable evidence of asymptomatic myocardial disease.

The development of symptoms may be insidious, although some patients have acute and florid left-sided congestive heart failure. A paroxysm of atrial fibrillation is a relatively frequent initial presenting finding. More advanced cases demonstrate findings of biventricular failure, with left ventricular dysfunction usually dominating. Dyspnea, orthopnea, and paroxysmal nocturnal dyspnea frequently are observed. Palpitations may be present and usually are due to supraventricular tachyarrhythmias. Syncope may be seen as well and may be the result of supraventricular, or more likely ventricular, tachyarrhythmias. Angina pectoris does not occur unless there is concomitant coronary artery disease or aortic stenosis, although atypical chest pain may be seen.

PHYSICAL EXAMINATION.

The cardiac findings resemble those seen in idiopathic DCM (see p. 1756). Examination usually reveals a narrow pulse pressure, often with an elevated diastolic pressure secondary to excessive peripheral vasoconstriction. There is cardiomegaly, and protodiastolic (S_3) and presystolic (S_4) gallop sounds are common. An apical systolic murmur of mitral regurgitation often is found. The severity of right-sided heart failure varies, but jugular venous distention and peripheral edema are common. A concomitant skeletal muscle myopathy involving the shoulder and pelvic girdle is a frequent finding, and the degree of muscle weakness and histological abnormality in the skeletal muscles parallels that in the heart.[125]

LABORATORY EXAMINATION.

The chest roentgenogram in advanced cases demonstrates considerable cardiac enlargement, pulmonary congestion, and pulmonary venous hypertension (see Chap. 8). Pleural effusions often are seen. ECG abnormalities are common and frequently are the only indication of alcoholic heart disease during the preclinical phase. Alcoholic patients without other evidence of heart disease often are seen after developing palpitations, chest discomfort, or syncope, typically after a binge of alcohol consumption on a weekend, particularly during the year-end holiday season. This is dubbed the "holiday heart syndrome." The most common arrhythmia observed is atrial fibrillation, followed by atrial flutter and frequent ventricular premature contractions. Alcohol consumption may predispose to atrial flutter or fibrillation, even in nonalcoholics. Hypokalemia may play a role in the genesis of some of these arrhythmias. Supraventricular arrhythmias are also frequently observed in patients with overt alcoholic cardiomyopathy. Sudden unexpected death is not uncommon in young adult alcoholics, and it is likely that ventricular fibrillation is responsible.

Atrioventricular conduction disturbances (most commonly first-degree heart block), bundle branch block, left ventricular hypertrophy, poor R wave progression across the precordium, and repolarization abnormalities are common ECG findings. Prolongation of the QT interval is noted frequently. ST segment and T wave changes are often restored to normal within several days after cessation of alcohol consumption.

The hemodynamic findings observed at cardiac catheterization and the assessment of left ventricular function by noninvasive methods (echocardiography and isotope angiography) resemble those found in idiopathic DCM.

MANAGEMENT.

The natural history of alcoholic cardiomyopathy depends on the drinking habits of the patient. Total abstinence in the early stages of the disease may lead to resolution of the manifestations of congestive heart failure and a return of heart size toward normal, although patients with severe heart failure may show no improvement in function or prognosis.[9] [133] Continued alcohol consumption leads to further myocardial damage and fibrosis, with the development of refractory congestive heart failure. Death may be due to arrhythmia, heart block, or systemic or pulmonary embolism, in addition to myocardial failure.

The key to the long-term treatment of alcoholic cardiomyopathy is immediate and total abstinence as early in the course of the disease as possible. This may be quite effective in improving the signs and symptoms of congestive heart failure.[133] The reversibility of alcoholic myocardial depression is supported by the demonstration of a reduction of myocardial uptake of labeled monoclonal antimyosin antibodies (a marker of myocyte damage) in alcoholics who stop drinking.[82] The prognosis in patients who continue to drink is poor, particularly if they have been symptomatic for a long time. Prolonged bed rest is thought to result in functional improvement, although its major benefit may simply be the decreased alcohol consumption.

The management of acute episodes of congestive heart failure is similar to that of idiopathic DCM (see p. 1757). For patients with severe congestive heart failure, it is prudent to administer thiamine on the chance that beriberi may be contributing to the heart failure.[130] Whether to use chronic anticoagulation (as is often considered in idiopathic DCM) is a difficult question; we usually do not prescribe warfarin unless there are unequivocal and pressing indications because of the risk of bleeding due to noncompliance, trauma, and over-anticoagulation due to hepatic dysfunction.

COBALT CARDIOMYOPATHY

A previously unrecognized syndrome of severe congestive heart failure appeared in the mid 1960s, first in Canada and subsequently in the United States and Europe.[129] The disease was found in people who drank a particular brand of beer to which cobalt sulfate had been added as a foam stabilizer. Since cobalt was removed from the process, no more cases of the disease have been reported. On very rare occasions occupational exposure to cobalt may result in myocardial damage and attendant congestive heart failure.[129] [134]

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY (See also Chap. 25)

This unique cardiomyopathy (which is also called arrhythmogenic right ventricular dysplasia [ARVD]) is marked by myocardial cell loss with partial or total replacement of right ventricular muscle by adipose and fibrous tissue; apoptosis appears to be a principal cause of the cell death (Fig. 48-6) .[135] [136] ARVD is associated with reentrant ventricular tachyarrhythmias of right ventricular origin (producing a left bundle branch block configuration of the QRS complex) and the risk of sudden death.[137] [138] In about one third of the cases there is autosomal dominant inheritance of the disease, and several distinct genetic mutations have been reported.[137] [139] One variant, found on the Greek island

Figure 48-6 Top left, Postmortem pathological section of heart (four-chamber) in a patient with right ventricular cardiomyopathy (arrhythmogenic right ventricular dysplasia) and biventricular involvement. Severe widespread fatty infiltration of right ventricular (RV) wall is present; an apical aneurysm is present at the left ventricular level (arrow). \i\Top right,\r\ Histological section at level of RV inflow (hematoxylin-eosin, ;ts 2.5). Severe transmural fibrofatty infiltration of RV wall is present, compatible with RV dysplasia. \i\Bottom,\r\ Histological section at the level of the left ventricle (outflow) (hematoxylin-eosin, ;ts2.5) shows focal severe [chfibrofatty infiltration with myo[chcellular atrophy, compatible with left ventricular involvement. (From Pinamonti B, Pagnan L, Bussani R, et al: Right ventricular dysplasia with biventricular involvement. Circulation 98:1943\en\1945, 1998. Copyright 1998, American Heart Association.)

of Naxos, is inherited as a recessive trait but with a high degree of penetrance.[138]

ARVD appears to be distinct from *Uhl disease,* which is marked by extreme thinning of the ventricular wall.[138] [140] The diagnosis is based on a constellation of clinical, ECG, histological, and echocardiographic findings.[137] Typical clinical features include male predominance, normal physical examination, inverted T waves in the right precordial ECG leads, symptoms of palpitations and syncope, and a risk of sudden death.[137] [141] [142] In some patients with ventricular arrhythmias of no evident cause, clinically subtle right ventricular dysplasia may be etiological.[143]

Noninvasive and invasive evaluation demonstrate a dilated, poorly contractile right ventricle, usually with a normal left ventricle, although some degree of left ventricular dysfunction has been seen.[138] [141] [144] Magnetic resonance imaging (MRI) shows promise for identifying patients with this condition.[145] Antiarrhythmic therapy, especially with beta-adrenoceptor blockers, sotalol, or amiodarone, often is effective in controlling the arrhythmias.[140] The arrhythmias may be related to abnormalities of regional right ventricular sympathetic innervation, or impaired presynaptic catecholamine reuptake, as has been demonstrated by noninvasive scintigraphy.[146] Cryo- or catheter-based radiofrequency ablation of the presumed arrhythmogenic focus has been successful in resolving the ventricular arrhythmia in some patients unresponsive to or intolerant of antiarrhythmic drug therapy.[147] [148] Insertion of an ICD or cardiac transplantation is reserved for recalcitrant cases.[140]

Hypertrophic Cardiomyopathy

Although first described over a century ago, the unique features of HCM were not studied systematically until the late 1950s.[148] [149] [150] [151] [152] [153] [154] The characteristic finding was inappropriate myocardial hypertrophy that occurred in the absence of an obvious cause for the hypertrophy (e.g., aortic stenosis or systemic hypertension), often predominantly involving the interventricular septum of a nondilated left ventricle that showed hyperdynamic systolic function (Fig. 48-7; see also Fig. 48-13 (Figure Not Available)).[152] [153] A distinctive clinical feature was soon recognized in some patients with HCM--a dynamic pressure gradient in the subaortic area that divided the left ventricle into a high-pressure apical region and a lower-pressure subaortic region (Fig. 48-8) . Although subsequent studies have shown that only a minority of patients (perhaps a fourth)[155] demonstrate this outflow gradient, its unique features attracted much attention and led to a myriad of terms (more than 75) used to describe the disease (among the more popular terms were *idiopathic hypertrophic subaortic stenosis* [*IHSS*] and *muscular subaortic stenosis*).[156] The term *hypertrophic cardiomyopathy* (HCM) is now preferred because most patients do not have an outflow gradient or "stenosis" of the left ventricular outflow tract.[153] Because hypertrophy typically occurs in the absence of a pressure gradient, the characteristic distinguishing feature of HCM is myocardial hypertrophy that is out of proportion to the hemodynamic load.

Figure 48-7 *A,* Pathological findings in a patient with hypertrophic cardiomyopathy who had a left ventricular outflow tract gradient during life. The heart is opened in the longitudinal plane. This patient had mitral regurgitation that was due partially to abnormal insertion of an anomalous papillary muscle (arrow) onto the ventricular surface of the anterior mitral leaflet. *(Modified from Wigle ED, Sasson Z, Henderson MA, et al: Hypertrophic cardiomyopathy: The importance of the site and the extent of hypertrophy. A review. Prog Cardiovasc Dis 28:1, 1985.) B,* Histological specimen of a patient with hypertrophic cardiomyopathy showing myofibrillar disarray. In the central area the myofibrils cross each other in a disorganized manner, but in adjacent areas on each side the appearance is more normal, with parallel arrays of myofibrils. (PTHA stain, 240×.) *(From Davies MJ, McKenna WJ: Hypertrophic cardiomyopathy: An introduction to pathology and pathogenesis. Br Heart J 72:S2, 1994.) C,* Diagrammatic representation showing usual location of myocyte disarray in interventricular septum in hypertrophic cardiomyopathy. This explains why disarray is usually deep or absent in septectomy specimen, and why endomyocardial biopsy (3-mm maximum dimension) is also unlikely to sample a zone of disarray. RV=right ventricle, LV=left ventricle. *(From Tazelaar HD, Billingham ME: The surgical pathology of hypertrophic cardiomyopathy. Arch Pathol Lab Med 111:257, 1987.)*

Figure 48-8 Left-sided heart pressures in various conditions. In each horizontal panel there is an idealized depiction of the pressure tracing that would be obtained as a catheter is withdrawn from the left ventricular body through the left ventricular outflow tract into the proximal aortic root. On the far right is a superimposition of the pressures in the left ventricular body and in the aorta. The vertical lines bound the regional catheter position within the heart during withdrawal. All forms of discrete stenosis (supravalvular, valvular, and subvalvular) have delayed aortic upstroke rates downstream from the stenosis. Only in hypertrophic cardiomyopathy is the aortic upstroke rate rapid and parallel to the left ventricular pressure. L.V. = left ventricular; Out = outflow tract. *(From Criley JM, Siegel RJ: Subaortic stenosis revisited: The importance of the dynamic pressure gradient. Medicine 72:412, 1993.)*

The physiological characteristics of HCM differ substantially from those of DCM (Table 48-5) . The most characteristic pathophysiological abnormality in HCM is *diastolic* rather than systolic dysfunction (see Chap. 15) . Thus, HCM is characterized by abnormal stiffness of the left ventricle with resultant impaired ventricular filling. This abnormality in diastolic relaxation produces increased left ventricular end-diastolic pressure with resulting pulmonary congestion and dyspnea, the most common symptoms in HCM, despite typically hyperdynamic left ventricular systolic function. The overall prevalence of HCM is low, although probably higher than thought previously; it is found in about 0.2 percent (1 in 500) of the general population and in 0.5 percent of unselected patients referred for an echocardiographic examination.[152] It may be the most common genetically transmitted cardiac disorder.[153]

Pathology

MACROSCOPIC EXAMINATION.

This typically discloses a marked increase in myocardial mass, and the ventricular cavities are small (see Fig. 48-7 *A*).[157] [158] The left ventricle is usually more involved in the hypertrophic process than is the right. The atria are dilated and often hypertrophied, reflecting the high resistance to filling of the ventricles caused by diastolic dysfunction and the effects of atrioventricular valve regurgitation. The pattern and extent of left ventricular hypertrophy in HCM vary greatly from patient to patient, and a characteristic feature is heterogeneity in the amount of hypertrophy evident in different regions of the left ventricle.[153] [157] [158] A feature found in most patients with HCM is disproportionate involvement of the interventricular septum and anterolateral wall compared with the posterior segment of the free wall of the left ventricle.[153] [157] When hypertrophy is largely localized to the anterior septum, the process has been called asymmetrical septal hypertrophy (ASH). A wide variety of other patterns of hypertrophy may be seen, and about 30 percent of patients show only localized and relatively mild hypertrophy in a single region of the ventricle.[153] The differentiation of the "physiological" hypertrophy that occurs in some highly trained male athletes from that seen in HCM may be difficult; athletes may demonstrate left ventricular wall thicknesses up to 16 mm in the absence of HCM (normal <12 mm).[159] Additional features that may permit differentiation of the two are the abnormal response of Doppler ultrasound-derived indices of diastolic function in response to isometric handgrip and the identification of HCM in a relative.[153] [160] Some patients with HCM have substantial hypertrophy in unusual locations, such as the posterior portion of the septum, the posterobasal free wall, and the midventricular level.[157]

The degree of hypertrophy is dynamic in most patients; although prominent hypertrophy may be found in infants, the typical patient develops hypertrophy during adolescence.[153] Development of the morphological features of HCM is unusual after the age of about 18 years,[153] although when it occurs it is seen especially with a mutation of cardiac myosin-binding protein C (where hypertrophy may occur at any time during adult life).[161] [162] There usually is an inverse relationship between the extent of hypertrophy

in HCM and age. Whether this is due to premature death of younger patients with greater hypertrophy or progressive reduction in the extent of hypertrophy is unknown.[153] [157]

Other morphological abnormalities include enlargement and elongation of the mitral valve leaflets and anomalous papillary muscle insertion directly into the anterior mitral valve leaflet.[153]

APICAL HCM.

A variant with predominant involvement of the apex is common in Japan and is estimated to represent a fourth of Japanese HCM patients.[163] In other parts of the world, apical HCM is much less common. Typical features include a characteristic spadelike configuration of the left ventricle during angiographic study (although some patients with this variant do not demonstrate this abnormality),[164] giant negative T waves in the precordial ECG leads, the absence of an intraventricular pressure gradient, mild symptoms, and a generally benign course (Fig. 48-9) .[157] [165]

HCM may on occasion present in the elderly and often demonstrates unique features, including an especially small left ventricular cavity but with relatively mild hypertrophy.[166] Other findings include marked anterior displacement of the mitral valve, extensive submitral (annular) calcification in some patients, a left ventricular outflow gradient, and the late appearance of severe and progressive symptoms.[167]

Gross cardiac morphological features similar to those in HCM may be seen in infants of diabetic mothers and in patients with hyperparathyroidism, neurofibromatosis, generalized lipodystrophy, lentiginosis, pheochromocytoma, Friedreich ataxia, and Noonan syndrome.[168] Rarely, the findings may be simulated by amyloid, glycogen storage disease, or tumor involvement of the septum.[169]

HISTOLOGY.

Microscopic findings in HCM are distinctive,

Figure 48-10 Cartoon showing components of the sarcomere and mutations in hypertrophic cardiomyopathy. Cardiac contraction occurs when calcium binds the troponin complex (subunits C, I, and T) and alpha-tropomyosin. Actin stimulates ATPase activity in the globular myosin head and results in the production of force along actin filaments. Cardiac myosin-binding protein C binds myosin and modulates contraction. In hypertrophic cardiomyopathy, mutations may impair these and other protein interactions, result in ineffectual contraction, and produce hypertrophy. Percentages represent the estimated frequency with which a mutation causes hypertrophic cardiomyopathy. (From Spirito P, Seidman C, McKenna WJ, et al: The management of hypertrophic cardiomyopathy. N Engl J Med 336:775, 1997. Copyright 1997, Massachusetts Medical Society.)

with myocardial hypertrophy and gross disorganization of the muscle bundles resulting in a characteristic whorled pattern; abnormalities are found in the cell-to-cell arrangement (disarray) (see Fig. 48-7 *B*) and disorganization of the myofibrillar architecture within a given cell.[157] Fibrosis is usually prominent and may be extensive enough to produce grossly visible scars. Foci of disorganized cells are often interspersed between areas of hypertrophied but otherwise normal-appearing muscle cells. Interstitial (matrix) connective tissue elements are increased.[157] Disarray in HCM patients is found in grossly hypertrophied myocardial segments as well as relatively normal segments.[170] Although abnormally arranged cardiac muscle cells initially were considered specific for HCM, it is now recognized that they may be found in a variety of acquired and congenital heart conditions. [157] What is unique about the disarray in HCM is its ubiquity and frequency. Almost all HCM patients have some degree of disarray, and most have involvement of 5 percent or more of the myocardium; in general, a fourth or more of the myocardium demonstrates disarray.[153] In contrast, disarray in non-HCM patients (when it occurs) usually involves only about 1 percent of the myocardium.[157]

Abnormal intramural coronary arteries, with a reduction in the size of the lumen and thickening of the vessel wall, are common in HCM, occurring in more than 80 percent of patients.[155] [157] The prominence of abnormal intramural coronary arteries in areas of extensive myocardial fibrosis is consistent with the hypothesis that these abnormalities may

be responsible for the development of myocardial ischemia.[153]

Etiology

GENETICS OF HYPERTROPHIC CARDIOMYOPATHY (see also Chap. 56).

Familial HCM occurs as an autosomal dominant mendelian-inherited disease at least 50 percent of the time.[166] [171] [172] It is thought that some if not all of the sporadic forms of the disease are due to spontaneous mutations.[171] [173] At least eight different genes, all encoding sarcomeric polypeptides, are associated with HCM (Fig. 48-10) . Over 125 different mutations have been discovered thus far. It is clear that not all of the genetic defects have been identified yet.[172] Most of the mutations are of the missense type. Familial HCM thus is a genetically heterogeneous disease (i.e., it can be caused by genetic defects at more than one locus).[174] However, the genetic heterogeneity does *not* appear to explain the clinical variability.

The genetic basis of HCM was first reported in 1989 by Seidman and her collaborators, who reported the existence of a disease gene located on chromosome 14q11-12.[175] Subsequently they found this to be the gene encoding for beta cardiac myosin heavy chain (MHC). Sequencing of this gene in one family with HCM revealed that the abnormality was caused by a gene duplication in which the alpha and beta MHC genes were fused and present in an extra copy. In the second family, there was a point mutation in the beta MHC sequence that altered the myosin's arginine to glutamine. Both of these mutations affect the polypeptides crucial to the structure of myofibrils and might be responsible for the myocyte and myofibrillar disarray characteristic of familial HCM. Other disease loci that have been identified include chromosome 1g3 (encoding troponin T); chromosome 19p13 (encoding troponin I); chromosome 15q2 (encoding alpha-tropomyosin); chromosome 11p11 (encoding myosin-binding protein C); chromosomes 3p21 and 12q23 (encoding essential and regulatory myosin light chains); and chromosome 15q11-14 (encoding actin).[166] [172] [176] [176A] There is an (as yet) unidentified mutation on chromosome 7q3 that has been found in a large Irish family with HCM and the Wolff-Parkinson-White syndrome.[177]

It is estimated that about 30 percent of familial HCM is due to mutations of the cardiac MHC gene, 15 percent is caused by mutations of the cardiac troponin T gene, less than 3 percent is due to mutations of the tropomyosin gene, and the remainder is due to mutations of other genes.[178] It now appears that HCM is genetically transmitted in most patients as an autosomal dominant trait with disease loci on one of at least eight different chromosomes (chromosomes 1, 3, 7, 11, 12, 14, 15, and 19).[166] The cause of HCM in the remainder of patients is unknown. Morphological evidence of the disease is found in about one fourth of the first-degree relatives of a patient with HCM; in many of the relatives the disease is milder than in the propositus, the degree of hypertrophy is less and is more localized, and outflow gradients usually are lacking. Symptoms often are absent or minimal, and the disease is detected only by echocardiography.

Thus, there is wide variation in the phenotypical expression of a specific mutation of a given gene, with variability in clinical symptoms and the degree as well as time course of appearance of hypertrophy.[179] [180] [181] Of particular interest are mutations of the troponin T gene that typically result in only modest (or no) hypertrophy but indicate a poor prognosis and a high risk of sudden death (although at least one mutation has a favorable prognosis).[166] [178] [182] Conversely, certain genes and

mutations are associated with more favorable prognoses (Fig. 48-11) (Figure Not Available) .[183] [184] In some patients with an abnormal gene and no echocardiographic evidence of HCM, the ECG is abnormal. Therefore, otherwise unexplained abnormalities

Figure 48-11 (Figure Not Available) Kaplan-Meier product-limit curves for survival of individuals with hypertrophic cardiomyopathy and three gene mutations. Survival was good in patients with Phe110Ile mutation in the troponin T gene and similar to that for benign Phe513Cys beta-cardiac myosin heavy chain gene mutation. A significant difference (p = 0.0002) in the life expectancy was observed in individuals with Phe110Ile versus malignant Arg719Trp mutation in the beta-cardiac myosin heavy chain gene. *(From Anan R, Shono H, Kisanuki A: Patients with familial hypertrophic cardiomyopathy caused by a Phe110Ile missense mutation in the cardiac troponin T gene have variable cardiac morphologies and a favorable prognosis. Circulation 98:391, 1998. Copyright 1998, American Heart Association.)*

of the ECG in first-degree relatives of patients with HCM may be indicative of a carrier or preclinical state. Unfortunately, genetic testing is not yet easily available for routine clinical use and remains largely a research tool.

Pathophysiology

SYSTOLE.

Since the initial descriptions of HCM, the feature that has attracted the greatest attention is the dynamic pressure gradient across the left ventricular outflow tract (Figs. 48-8 and 48-12 (Figure Not Available)). Although this pressure gradient was initially attributed to a muscular sphincter action in the subaortic region or was believed by some to be an artifact,[156] it is now considered to be related to further narrowing of an already small outflow tract (narrowed by the prominent septal hypertrophy and possibly abnormal location of the mitral valve) by systolic anterior motion of often elongated mitral valve leaflets against the hypertrophied septum.[154] [157]

There continues to be considerable controversy about the cause and significance of the outflow gradient.[156] [185] Central to the disagreement is whether there is true obstruction to left ventricular ejection or whether the pressure gradient is simply the consequence of vigorous ventricular

Figure 48-12 (Figure Not Available) Hypertrophic cardiomyopathy with intracardiac pressure and phonocardiographic (phono) recordings from aorta (AO), left ventricle (LV), left ventricular outflow tract (LVOT), and left atrium (LA). Note the marked accentuation of the murmur and gradient (shaded) (in the third cycle) after a premature ventricular contraction with failure of the aortic pulse pressure to rise in the post premature ventricular contraction beat (Brockenbrough-Braunwald sign). ECG = electrocardiogram; SSC = systolic anterior motion of the mitral valve septal contact. *(From Murgo JP: Systolic ejection murmurs in the era of modern cardiology: What do we really know? J Am Coll Cardiol 32:1596, 1998.)*

emptying. Most now favor the view that a true mechanical impediment to left ventricular ejection occurs when outflow gradients are present and is the result of distal portions of the mitral valve apparatus moving anteriorly across the outflow tract and contacting the ventricular septum in mid systole.[153] It is likely that the mitral valve is displaced anteriorly because of Venturi effects and as a result of the increased ejection velocities produced by the abnormal left ventricular outflow tract orientation and geometry.[185]

DIASTOLE.

Most patients with HCM demonstrate abnormalities of diastolic function (see Chap. 15) at rest or with stress, whether or not a pressure gradient is present and whether or not they are symptomatic.[160] [186] These abnormalities of global diastolic filling are largely independent of the extent and distribution of myocardial hypertrophy; patients with mild and apparently localized hypertrophy may demonstrate prominent diastolic dysfunction, suggesting that the myopathic process occurs in ventricular regions that are not macroscopically hypertrophied.[163] Others have found that diastolic filling varies in different regions of the left ventricle and is influenced by the thickness of the septum.[187] Diastolic dysfunction in turn leads to increased filling pressure despite a normal or small left ventricular cavity and appears to result from abnormalities of left ventricular relaxation and distensibility. Early diastolic filling is impaired when relaxation is prolonged, perhaps related to abnormal calcium kinetics, subendocardial ischemia, or the abnormal loading conditions found in HCM.[188] Late diastolic filling is altered when left ventricular distensibility is impaired; as a consequence, filling pressures rise. HCM may cause abnormal distensibility of the ventricle because of fibrosis or cellular disorganization.[189]

MYOCARDIAL ISCHEMIA.

Myocardial ischemia is common and multifactorial in HCM (Table 48-6) .[190] Major

TABLE 48-6 -- PROPOSED CAUSES OF ISCHEMIA IN HYPERTROPHIC CARDIOMYOPATHY DESPITE NORMAL EPICARDIAL CORONARY ARTERIES

Increased muscle mass
Inadequate capillary density
Elevated diastolic filling pressures
Abnormal intramural coronary arteries
Impaired vasodilatory reserve
Systolic compression of arteries
Enhanced myocardial oxygen demand (increased wall stress)

causes include impaired vasodilator reserve (perhaps related to the thickened and narrowed small intramural coronary arteries found in HCM)[191] ; increased oxygen demand, especially in patients with outflow gradients; and elevated filling pressures with resultant subendocardial ischemia.[157] [190] [192] [193] [194] In children, compression of intramyocardial segments of the left anterior descending coronary artery (so-called myocardial bridge) may predispose to myocardial ischemia and sudden death.[195]

Clinical Manifestations

SYMPTOMS.

The majority of patients with HCM are asymptomatic or only mildly symptomatic[152] and often are identified during screening of relatives of a patient with HCM. Unfortunately, the first clinical manifestation of the disease in such individuals may be sudden death. The disease is identified most often in adults in their 30s and 40s; it occurs more often than is commonly suspected in elderly patients. The condition has been observed at necropsy in stillborns and both clinically and pathologically in octogenarians. The importance of recognizing this disorder in children at the earliest possible time is highlighted by the higher mortality rate in younger patients; death is often sudden and unexpected. When HCM is first diagnosed in older patients, several features are distinctive and are in contrast to findings in younger patients: generally mild degrees of left ventricular hypertrophy; frequent demonstration of outflow gradients; and appearance of marked symptoms late in life (typically after age 55).[167] A particularly high index of suspicion of this condition must be maintained to make the clinical diagnosis in the elderly because their symptoms may easily be confused with those due to coronary artery or aortic valve disease. Because syncope and sudden death have been associated with competitive sports and severe exertion in patients with HCM, it is important to diagnose this condition so that these activities may be proscribed. The disease is slightly more common in men, although women may be more likely to be severely disabled and may initially present at a younger age than men.[196]

The clinical picture varies considerably, ranging from the asymptomatic relative of a patient with recognized HCM who has a slightly abnormal echocardiogram but no other overt manifestation of the disease to the patient with incapacitating symptoms. A general relationship exists between

the extent of hypertrophy and the severity of symptoms, but the relationship is not absolute, and some patients have severe symptoms with only mild and apparently localized hypertrophy, and vice versa.[157] A complex interaction occurs between left ventricular hypertrophy, the left ventricular pressure gradient, diastolic dysfunction, and myocardial ischemia, which accounts for the great variability in symptoms from patient to patient.

The most common symptom is *dyspnea,* occurring in up to 90 percent of symptomatic patients, which is largely a consequence of the elevated left ventricular diastolic (and therefore left atrial and pulmonary venous) pressure, which results principally from impaired ventricular filling owing to diastolic dysfunction.[157] Angina pectoris

(found in about three fourths of symptomatic patients), fatigue, presyncope, and syncope are also common. Palpitations, paroxysmal nocturnal dyspnea, overt congestive heart failure, and dizziness are found less frequently, although severe congestive heart failure culminating in death may be seen. Exertion tends to exacerbate many of the symptoms.[197] A variety of mechanisms may contribute to the production of angina pectoris (see Table 48-6). It is at least in part the result of an imbalance between oxygen supply and demand as a consequence of the greatly increased myocardial mass. Abnormalities of the small coronary arteries may contribute to myocardial ischemia, particularly during exertion, and perhaps 20 percent of older patients with HCM may have concurrent atheromatous obstructive coronary artery disease. Transmural infarction may occur in the absence of narrowing of the extramural coronary arteries.[157] Impaired diastolic relaxation may produce subendocardial ischemia as a result of prolonged maintenance of wall tension with a concomitant slower-than-normal decrease in the impedance to coronary blood flow. Syncope may result from inadequate cardiac output with exertion or from cardiac arrhythmias. It occurs most commonly in young patients with small left ventricular chamber size and evidence of ventricular tachycardia on ambulatory monitoring.[198] Near-syncopal ("graying out") spells that occur in the erect posture and that can be relieved by immediately lying down are common. However, in contrast to valvular aortic stenosis, syncope or near-syncope may not be an ominous finding in adult patients with HCM; some patients have a history of such episodes dating back many years without clinical deterioration.[152] In children and adolescents, however, presyncope and syncope identify patients at increased risk of sudden death (see Natural History).

PHYSICAL EXAMINATION.

This may be normal in asymptomatic patients without gradients, particularly those with the apical variant of HCM, save for a left ventricular lift and a loud S_4 , but findings are usually prominent in patients with a left ventricular outflow tract pressure gradient. The apical precordial impulse is often displaced laterally and is usually abnormally forceful and diffuse.[196] Because of decreased left ventricular compliance, a prominent presystolic epical impulse that results from forceful atrial systole often is present. This may result in a double apical impulse as a result of the prominent *a* wave.[154] A more characteristic but less frequently recognized abnormality is a triple apical beat, the third impulse consisting of a late systolic bulge that occurs when the heart is almost empty and is performing near-isometric contraction.[196] The jugular venous pulse may demonstrate a prominent *a* wave, reflecting diminished right ventricular compliance secondary to massive hypertrophy of the ventricular septum.[159] The carotid pulse typically rises briskly and then declines in midsystole as the gradient develops, followed by a secondary rise.[196] This may be appreciated on physical examination but can be demonstrated more clearly by means of indirect carotid pulse tracings.

Auscultation.

The S_1 is normal and is often preceded by an S_4 that corresponds to the apical presystolic impulse.[196] The S_2 usually is normally split. In some patients, however, it is narrowly split and in others, particularly those with severe outflow gradients, paradoxical splitting may be noted.[154] An S_3 may be present but does not have the same ominous significance as in patients with valvular aortic stenosis. Systolic ejection sounds relating to rapid acceleration of blood flow may be found on occasion. The auscultatory hallmark of HCM associated with an outflow gradient is a systolic murmur that typically is harsh and crescendo-decrescendo in configuration (Fig. 4-46) ; it usually commences well after S_1 and is best heard between the apex and the left sternal border.[196] It often radiates well to the lower sternal border, the axillae, and base of the heart but not into the neck vessels. In patients with large gradients, the murmur usually reflects both left ventricular outflow tract turbulence and concomitant mitral regurgitation.[154] Accordingly, the murmur is often more holosystolic and blowing at the apex and in the axillae (due to mitral regurgitation) and midsystolic and harsher along the lower sternal border (due to turbulent flow across the narrowed outflow tract).[196]

The systolic murmur is labile in intensity and duration, and a variety of maneuvers may be used to augment or suppress it (Table 48-7) . [154] A diastolic rumbling murmur, reflecting increased transmitral flow, may occur in patients with marked mitral regurgitation. The murmur of aortic regurgitation is observed in about 10 percent of patients, although mild aortic regurgitation can be demonstrated by Doppler echocardiography in one third.[199] It may develop after operation to correct the outflow gradient or following infective endocarditis.

Differentiation from Valvular Aortic Stenosis.

It is important to emphasize the features of physical examination that permit differentiation of HCM from fixed orifice obstruction, most commonly due to valvular aortic stenosis (see Chap. 46). The character of the carotid pulse and features of the murmur are most useful in this regard. Because there is obstruction to left ventricular emptying from the

beginning of systole with fixed valvular stenosis, the carotid upstroke is slowed and of low amplitude (pulsus parvus et tardus).[200] With HCM, initial ejection of blood from the left ventricle is actually enhanced, and therefore the arterial upstroke is brisk. The murmur of HCM, as opposed to that of aortic stenosis, can be reliably identified by its increase with the Valsalva maneuver and during standing from a squatting position, and its decrease during squatting from a standing position, passive leg elevation, and hand grip (see Table 48-7).[196] Other features that may be helpful but are of considerably less significance are the location of the murmur (it radiates along the carotid arteries in valvular aortic stenosis but not in HCM) and the location of the systolic thrill when present (most prominent in the second right intercostal space in valvular aortic stenosis and in the fourth interspace along the left sternal border in HCM).

ELECTROCARDIOGRAM.

This is usually abnormal in HCM[201] and invariably so in symptomatic patients with left ventricular outflow tract gradients.[157] Entirely normal ECGs are seen in only 15 to 25 percent of patients and usually are found in the presence of only localized left ventricular hypertrophy.[202] The most common abnormalities are ST segment and T wave abnormalities, followed by evidence of left ventricular hypertrophy, with QRS complexes that are tallest in the midprecordial leads.[157] Progressive ECG evidence of hypertrophy may develop over time. Giant negative T waves in the midprecordial leads of Japanese patients are characteristic of HCM involving the apex[203] (see p. 1762), but such a pattern in whites may be found with HCM involving segments other than the apex. Prominent Q waves are relatively common, occurring in 20 to 50 percent of patients. The Q wave abnormalities often involve the inferior (II, III, aV_F) and/or precordial (V_2 -V_6) leads. The cause of the Q waves remains unestablished; although they do not correlate simply with the degree of septal hypertrophy,[157] they may relate to the balance of electrical forces emanating from the left versus the right ventricle.[154] A variety of other ECG abnormalities may occur, including abnormal electrical axis (usually left-axis deviation) and P wave abnormalities (usually left atrial abnormality). Accessory atrioventricular pathways have been found in HCM, although they are uncommon.[204] Clinically significant abnormalities of atrioventricular conduction are uncommon but may cause syncope.[205]

ARRHYTHMIAS.

Although hemodynamic or ischemic mechanisms may play roles in the death of patients with HCM (particularly the young),[206] many deaths, particularly those that are known to have been sudden, likely are due to an arrhythmia.[207] [208] Because of the systolic and diastolic abnormalities in this disorder, rhythm disturbances are less well tolerated.

Ventricular arrhythmias are common in patients with HCM, occurring in more than three fourths of patients undergoing continuous ambulatory ECG monitoring. Runs of nonsustained ventricular tachycardia are found in about one fourth of patients with HCM, although sustained monomorphic tachycardia is uncommon.[207] In some it is a harbinger of subsequent sudden death; however, its overall predictive value in identifying patients at high risk for sudden death is limited. Treadmill testing may expose arrhythmias that are not present at rest, although continuous ambulatory monitoring is superior in detecting repetitive ventricular tachyarrhythmias.

Supraventricular tachycardia may be found in one fourth to one half of patients.[207] Atrial fibrillation occurs in about 10 percent of patients (often those with no gradient and mild hypertrophy), and the resultant loss of the atrial contribution to the filling of a hypertrophied, stiff ventricle may result in clinical deterioration.[157] [209] Treatment is often effective in controlling symptoms and restoring sinus rhythm; if this is done, long-term survival usually is not jeopardized.[210] The signal-averaged ECG has not proved to be helpful in identifying patients at increased risk of sustained or lethal ventricular arrhythmia, although additional studies are necessary.[211] Reduced heart rate variability on ambulatory monitor recordings, a predictor of increased sudden death risk after myocardial infarction, appears to be less useful in risk stratification in HCM patients.[212]

ELECTROPHYSIOLOGICAL TESTING.

The role of electrophysiological studies in identifying HCM patients at increased risk of sudden death is controversial; despite earlier enthusiasm, it is now generally believed that it is of limited predictive value.[152] [157] These studies may identify a variety of abnormalities in HCM patients; they induce polymorphic ventricular tachycardia in many patients with HCM, but such a response is generally believed to be nonspecific and does not identify high-risk patients.[152] Unfortunately, unlike its utility in ischemic heart disease, the predictive value of the more typical inducible sustained ventricular arrhythmias during electrophysiological testing is low in HCM. Aggressive stimulation protocols are required to induce a sustained arrhythmia in high-risk HCM patients, often resulting in arrhythmias in low-risk patients as well.[208] Tilt-table testing has not been particularly useful in identifying the cause of syncope in HCM; neurally mediated syncope is uncommon in this setting and true positive tests are uncommon, but false-positive tests are frequent and significantly limit the usefulness of the test.[213]

CHEST ROENTGENOGRAM.

The findings on radiographic examination are variable; the cardiac silhouette may range from normal to markedly increased, and in most cases of apparent "cardiomegaly" the enlarged cardiac silhouette is the result of left ventricular hypertrophy and/or left atrial enlargement.[157] Left atrial enlargement is observed frequently, especially when significant mitral regurgitation is present.[154] Aortic root enlargement and valvular calcification are not seen unless associated diseases are present, although calcification of the mitral annulus is common in HCM.

ECHOCARDIOGRAPHY.

Because echocardiography combines the attributes of high resolution and no known risk, it has been widely used in the evaluation of HCM. It is useful in the study of patients with suspected HCM and also in the screening of relatives of HCM patients. The echocardiogram is of value in identifying and quantifying morphological features (i.e., distribution of septal hypertrophy), functional aspects (e.g., hypercontractile left ventricle), and (when combined with Doppler recordings) hemodynamic findings (e.g., magnitude of outflow gradient). (See Figs. 7-99 , 7-100 , and 7-101 .)

Left Ventricular Hypertrophy.

The cardinal echocardiographic feature of HCM is left ventricular hypertrophy. Although the characteristic feature is hypertrophy of the septum and anterolateral free wall, the echocardiogram is useful in identifying involvement of other left ventricular locations, including portions of the free wall and the apex.[157] [170] [214] Considerable variability exists in the degree and pattern of hypertrophy; in most patients, there is variation in the extent of hypertrophy from one left ventricular region to another.[157] Maximal hypertrophy of the septum often occurs midway between the base and apex of the left ventricle. The finding of a thickened septum that is at least 1.3 to 1.5 times the thickness of the posterior wall when measured in diastole just before atrial systole has been the time-honored criterion for the diagnosis of ASH. The septum not only is relatively thicker than the posterior wall but is typically at least 15 mm in thickness (normal 11 mm). Although the average wall thickness detected on echocardiography is about 20 mm (i.e., almost twice normal), there is great variation, ranging from very mild hypertrophy (13 to 15 mm) to massive hypertrophy (50 mm).[159]

An unusual echocardiographic pattern consisting of a ground-glass appearance has been noted in portions of the hypertrophied myocardium in some patients with HCM. Even when abnormalities are not apparent on visual inspection, quantitative texture analysis often identifies them in both nonhypertrophied (but presumably abnormal) and hypertrophied regions of the ventricle and can be used to distinguish HCM patients from those with secondary hypertrophy.[215] It has been speculated that this pattern may be related to the abnormal cellular architecture and myocardial fibrosis that has been noted in pathological studies.[216]

Outflow Tract Obstruction.

A second echocardiographic feature often found in HCM in addition to left ventricular hypertrophy is narrowing of the left ventricular outflow tract, which is formed by the interventricular septum anteriorly and the anterior leaflet of the mitral valve posteriorly. The mitral valve leaflets are abnormally large and elongated and are associated with abnormal left ventricular outflow tract geometry that culminates in the production of a pressure gradient.[214] [217] [218] This abnormal geometry is causally

related to the mitral regurgitation that accompanies an outflow gradient; the degree of mitral regurgitation correlates with the extent of anterior and posterior leaflet malcoaptation.[219] When HCM is associated with a pressure gradient, there is abnormal systolic anterior motion of the anterior leaflet, and occasionally the posterior leaflet of the mitral valve.[214] A close relationship exists between the degree of systolic anterior motion and the magnitude of the outflow gradient. Prolonged interventricular septal contact of the mitral apparatus is limited to HCM with resting pressure gradients, and a close temporal relationship exists between the onset of the pressure gradient and the onset of septal apposition of the mitral apparatus.

MECHANISMS OF SYSTOLIC ANTERIOR MOTION.

Three explanations have been offered for systolic anterior motion: (1) the mitral valve is *pulled* against the septum by contraction of abnormally oriented papillary muscles and elongated leaflets[220] ; (2) the mitral valve is *pushed* against the septum (perhaps by the left ventricular posterior wall) because of its abnormal position in the outflow tract; and (3) the mitral valve is drawn toward the septum because of the lower pressure that occurs as blood is ejected at a high velocity through a narrowed outflow tract (Venturi effect).[221] In a minority of cases (less than 15 percent), one or both papillary muscles insert anomalously directly into the anterior mitral leaflet, causing a long area of midventricular narrowing that results in an intraventricular pressure gradient.

Systolic anterior motion of the mitral valve and dynamic left ventricular gradients are not pathognomonic of HCM but may be found in a variety of other conditions, including hypercontractile states, left ventricular hypertrophy, transposition of the great arteries, and infiltration of the septum. Even mild degrees of left ventricular hypertrophy may be associated with systolic anterior motion and outflow gradients, particularly under conditions of enhanced sympathetic tone. In many cases in conditions other than HCM, systolic anterior motion is due to buckling of the chordae tendineae rather than to movement of the anterior mitral valve leaflet as occurs in HCM (although the chordae tendineae and papillary muscles may contribute to systolic anterior motion in HCM).

Other Echocardiographic Findings.

The following may be present: (1) a small left ventricular cavity; (2) reduced septal motion and thickening during systole, particularly of the upper septum (presumably because of the disarray of the myofibrillar architecture and abnormal contractile function)[222] ; (3) normal or increased motion of the posterior wall; (4) a reduced rate of closure of the mitral valve in mid diastole secondary to a decrease in left ventricular compliance or abnormal transmittal diastolic flow; (5) mitral valve prolapse; and (6) partial systolic closure or, more commonly, coarse systolic fluttering of the aortic valve related to turbulent blood flow in the outflow tract. MRI studies have shown that regional left ventricular function and the degree of local hypertrophy are inversely related and the hypertrophied septum typically is hypokinetic.[222] [223] The echocardiographic findings that accompany a left ventricular outflow tract gradient (systolic anterior motion and aortic valve partial closure) may be quite labile, and provocative measures such as the Valsalva maneuver, pharmacologically induced vasodilatation with amyl nitrite, stimulation of contractility with isoproterenol, or an induced premature ventricular contraction may be required to precipitate the findings.[150] [224]

Abnormalities of diastolic function (see Chap. 15) may be demonstrated by echocardiography and Doppler recordings in about 80 percent of patients with HCM, independent of the presence or absence of a systolic pressure gradient.[157] Because the septum typically is hypokinetic, the rate of left ventricular filling is determined primarily by the rate of free wall thinning. Little relationship exists between the extent of hypertrophy and the severity of abnormalities of diastolic function. Doppler ultrasonography has confirmed the virtual ubiquity of mitral regurgitation when an outflow pressure gradient is present[157] and has accurately measured the magnitude of the outflow tract gradient.[155] Doppler color flow imaging reveals mitral regurgitation, most prominent in late systole, accompanying the appearance of turbulent flow in the left ventricular outflow tract. Recordings from the left ventricular outflow tract support the concept that true obstruction to flow occurs and accounts for the pressure gradient.[155]

RADIONUCLIDE SCANNING.

Thallium-201 myocardial imaging, particularly when tomographic imaging (single-photon emission computed tomography [SPECT]) is performed (see Chap. 9), permits direct determination of the relative thicknesses of the septum and free wall and may be of particular value when technical constraints limit the reliability of echocardiographic evaluation in a given patient with presumed HCM. Reversible thallium defects, presumably indicative of ischemia, are common findings in HCM in the absence of obstructive coronary artery disease.[225] They are common in adult patients with HCM and in those young patients with a history of sudden death or syncope, suggesting that myocardial ischemia is an important factor and probably a mechanism of demise in younger patients.[226] Fixed defects, probably indicative of myocardial scarring, occur primarily in patients with impaired systolic function. Gated radionuclide ventriculography with blood pool labeling permits the evaluation of not only the size but also the motion of the septum and left ventricle. As with the echocardiogram, abnormal diastolic filling of the ventricle has been observed in patients with HCM (both with and without gradients) by computer analysis of the blood pool scan.[227] Because of the ease and availability of transthoracic and transesophageal echocardiography, this technique is not widely used in the evaluation of HCM.

Hemodynamics and Angiography

CARDIAC CATHETERIZATION.

Heart catheterization is not required for the diagnosis of HCM, because noninvasive evaluation almost always suffices; it is reserved for situations where concomitant coronary artery disease is a consideration, or when invasive modalities of therapy (e.g., pacemaker, surgery) are being considered.[154] It discloses diminished diastolic left ventricular compliance and in some patients a systolic pressure gradient within the body of the left ventricle (see Fig. 48-8) , which is separated from a subaortic chamber by the thickened septum and the anterior leaflet of the mitral valve that abuts the septum (see Fig. 48-12 (Figure Not Available)).[155] The pressure gradient may be quite labile and may vary between 0 and 175 mm Hg in the same patient under different conditions (see later). The arterial pressure tracing may demonstrate a "spike and dome" configuration similar to the carotid pulse recording.[155] As a consequence of diminished left ventricular compliance, the mean and particularly the *a* wave in the left atrial pressure pulse and the left ventricular end-diastolic pressures are usually elevated. Artifactual outflow gradients may occur if the left ventricular catheter becomes entrapped in the trabeculae of a markedly hypertrophied left ventricle.[156] Proper technique and choice of catheters with side holes should clarify the mechanism of such gradients. Cardiac output may be depressed in patients with long-standing severe gradients, but in the majority of patients it is normal; occasionally it is elevated.

Hemodynamic abnormalities in HCM are not limited to the left side of the heart. Approximately one fourth of patients demonstrate pulmonary hypertension, which is usually mild but in some cases may be moderate to severe. This is due (at least in part) to elevated mean left atrial pressures as a consequence of diminished left ventricular compliance. A pressure gradient in the right ventricular outflow tract occurs in approximately 15 percent of patients who have obstruction to left ventricular outflow[196] [228] and

appears to result from markedly hypertrophied right ventricular tissue.[229] Right atrial and right ventricular end-diastolic pressures may be slightly elevated.

LABILITY OF GRADIENT.

A feature characteristic of HCM is the variability and lability of the left ventricular outflow gradient (see Table 48-7).[149] [150] [230] A given patient may demonstrate a large outflow gradient on one occasion but have none at another time. In some patients without a resting gradient, it may be temporarily provoked. Three basic mechanisms are involved in the production of dynamic gradients, all of which act by reducing ventricular volume and presumably accentuate the apposition of the anterior mitral leaflet against the septum[150] : (1) increased contractility, (2) decreased preload, and (3) decreased afterload. In a minority of patients with HCM, the gradient is midventricular and may be intensified by increased contractility, which exerts a direct muscular sphincter action.[154] [155] The stimuli that provoke or intensify left ventricular outflow tract gradients in HCM generally improve myocardial performance in normal subjects and in patients with most other forms of heart disease. Conversely, reductions in contractility or increases in preload or afterload, which increase left ventricular dimensions, reduce or abolish the left ventricular outflow gradient.

Alterations in the magnitude of the gradient are reflected by changes in the findings on physical examination, noninvasive tests, and left-sided heart catheterization. *This dynamic characteristic of HCM distinguishes it from the discrete forms of obstruction to ventricular outflow.* An increase in the gradient usually results in a louder murmur, a longer ejection period with a more characteristic spike and dome configuration in the carotid pulse, and more flagrant echocardiographic evidence of systolic anterior motion of the anterior mitral leaflet. In some patients, the intensity of the murmur may *not* track with the gradient, perhaps because in many cases the murmur reflects mitral regurgitation (at least in part).[154]

A number of bedside procedures may be useful in the evaluation of suspected HCM.[154] Perhaps the most helpful is sudden standing from a squatting position. Squatting results in an increase in venous return and an increase in aortic pressure, which increases ventricular volume, diminishing the gradient and decreasing the

intensity of the murmur. Sudden standing has the opposite effects and results in accentuation of the gradient and the murmur.

VALSALVA MANEUVER.

This is another useful bedside technique for eliciting or exacerbating the gradient. After a transient increase in arterial pressure that usually lasts for four or five cardiac cycles after the onset of the strain and coincident with an increase in heart rate, the arterial systolic and pulse pressures and ventricular volume decline and the gradient (and murmur) increases. After release of the strain, a compensatory overshoot of arterial pressure and venous return with cardiac slowing occur, all of which increase ventricular volume and reduce the magnitude of the gradient and the murmur. Occasional patients may show paradoxical attenuation of the systolic murmur despite an increase in the pressure gradient, presumably related to a critical reduction in stroke volume. Inhalation of amyl nitrite also intensifies the murmur and the abnormality of the arterial pulse. The murmur of HCM is attenuated by passive leg elevation, hand grip, and sudden squatting from a standing position.

Postextrasystolic Changes.

One of the most potent stimuli for enhancing the gradient is *postextrasystolic potentiation* (see Chap. 14), which may occur after a spontaneous premature contraction or be induced by mechanical stimulation with a catheter.[231] The resultant increase in contractility in the beat after the extrasystole is so marked that it outweighs the otherwise salutary effect of increased ventricular filling caused by the compensatory pause and produces an increase in the gradient and often of the murmur as well. A characteristic change often occurs in the directly recorded arterial pressure tracing, which, in addition to displaying a more marked spike and dome configuration, exhibits a pulse pressure that fails to increase as expected or actually decreases (the so-called Brockenbrough-Braunwald phenomenon) (see Fig. 48-12 (Figure Not Available)). This is one of the more reliable signs of dynamic obstruction of the left ventricular outflow tract. In some patients, the postextrasystolic murmur is attenuated despite an increase in the outflow gradient, apparently because in this setting the murmur (a hybrid of outflow tract turbulence and mitral regurgitation) is mirroring to a greater degree changes in the severity of mitral regurgitation rather than changes in the outflow tract gradient.

POSITIVE INOTROPIC AGENTS.

Digitalis glycosides and the beta-adrenoceptor agonist isoproterenol augment the gradient because they increase myocardial contractility, whereas nitroglycerin and amyl nitrite exaggerate the gradient by decreasing arterial pressure and ventricular volume. The ingestion of alcoholic beverages may exacerbate the outflow pressure gradient by producing systemic vasodilatation.[232] Hypovolemia (as a result of hemorrhage or overly aggressive diuresis) may also provoke overt obstruction to left ventricular outflow. The intensity of the murmur and the left ventricular outflow gradient may be decreased by beta-adrenoceptor blockade, although the effect of the latter is often not dramatic and is of greatest hemodynamic benefit in protecting against the *increase* in the gradient that may be provoked by exercise. In most patients the severity of mitral regurgitation and the intensity of the apical blowing regurgitant murmur vary with the degree of obstruction of left ventricular outflow.

ANGIOGRAPHY.

Left ventriculography shows a hypertrophied ventricle; when an outflow gradient is present, the anterior leaflet of the mitral valve moves anteriorly during systole and encroaches on the outflow tract. Associated with this motion of the leaflet is mitral regurgitation, which is a constant finding in patients with gradients. The left ventricular cavity is often small, and systolic ejection is typically vigorous, resulting in virtual obliteration of the cavity at end systole (Fig. 48-13) (Figure Not Available) , although the apparent hypercontractile state may relate more to reduced afterload (low end-systolic wall stress) than to enhanced inotropy. The papillary muscles are often prominent and may fill the left ventricular cavity in late systole. In patients with apical involvement, the extensive hypertrophy may convey a spadelike configuration to the left ventricular angiogram.[165]

It may be helpful to supplement angiographic evaluation of the left ventricle with simultaneous right ventriculography in a cranially angulated left anterior oblique projection to obtain optimal visualization of the size, shape, and configuration of the interventricular septum. The left septal surface either is flat or bulges into the left ventricular cavity at its mid or lower portion, in contrast to the normal findings of the septum curving toward the right ventricle.

In patients older than 45 years of age, obstructive coronary artery disease may be present, although the symptoms of ischemic pain are indistinguishable from those of patients with normal coronary angiograms and HCM. The left anterior descending and septal perforator coronary arteries may demonstrate phasic narrowing and associated abnormalities of flow during systole.[233]

Natural History

The clinical course in HCM is varied; in many patients symptoms are absent or mild, remain stable, and in some instances improve over a period of 5 to 10 years. The annual mortality is about 3 percent in adults seen in large referral centers[234] but probably is closer to 1 percent when all patients with HCM are included.[235] [236] [237] The risk of sudden death is higher in children, perhaps as high as 6 percent per year.[171] Clinical deterioration (aside from sudden death) usually is slow. Although symptoms are unrelated to the severity or even the presence of a gradient,[157] the percentage of severely symptomatic patients does increase with age. The onset of atrial fibrillation may lead to an increase in symptoms, although counterintuitively often it appears to be well tolerated.[210] Conversion to sinus rhythm by pharmacological or electrical cardioversion should be

There is marked left ventricular hypertrophy particularly affecting the interventricular septum (approximately 4.5 cm) with associated fibrosis and virtual obliteration of the left and right ventricular cavities. *(From Davies MK: Images in cardiology. Hypertrophic cardiomyopathy. Br Heart J 74:527, 1995.)*

attempted, although maintenance of sinus rhythm may be difficult.[157] Patients who develop atrial fibrillation ordinarily are started on long-term therapy with oral anticoagulants.

Progression of HCM to left ventricular dilatation and dysfunction without a gradient (i.e., DCM) occurs in 10 to 15 percent of patients.[157] [238] It appears to result, at least in part, from wall thinning and scar formation as a consequence of myocardial ischemia caused by small vessel coronary artery disease and abnormal coronary vasodilator reserve (Fig. 48-14) (Figure Not Available) .[157] It is more likely to occur in patients with marked septal hypertrophy and generally is associated with a poor prognosis. The extent of left ventricular hypertrophy in adults usually remains stable over time, although a majority of children demonstrate increasing degrees of hypertrophy (often considerable) and many adults demonstrate a very gradual degree of regression of hypertrophy over time (Fig. 48-15) (Figure Not Available) .[239] In some children, the findings of HCM may develop despite a previous normal echocardiogram; this is not common in adults, but it may be seen in particular with the cardiac myosin-binding protein C mutation.[161] [166] Its occurrence emphasizes that a single normal echocardiogram does *not* exclude HCM in a child or adolescent; cellular disarray and the attendant risk of sudden death may be present even in the absence of left ventricular hypertrophy. A marker for the later appearance of clinical HCM may be an initially abnormal ECG demonstrating increased QRS voltage.

SUDDEN DEATH.

Death is most often sudden in HCM and may occur in previously asymptomatic patients, in individuals who were unaware they had the disease, and in patients with an otherwise stable course (Fig. 48-16) (Figure Not Available) . There is great difficulty in identifying those patients at particular risk of sudden death[240] [240A] ; nevertheless, the features that most reliably identify high-risk patients include young age (< 30 years) at diagnosis, a family history of HCM with sudden death (so-called malignant family history), an abnormal blood pressure response to exercise (presumably related to subendocardial ischemia[241]), and genetic abnormalities associated with increased prevalence of sudden death.[152] [234] [242] [242A] The presence or severity of an outflow tract gradient, the degree of functional limitation, and symptoms in general do not correlate with the risk of death.[208] [234] A history of syncope is ominous in children but less so in adults. In the latter, nonsustained ventricular tachycardia (NSVT) on 48-hour electrocardiographic monitoring has some predictive value for subsequent sudden

Figure 48-14 (Figure Not Available) Hypothetical model for the pathogenesis of the end-stage phase of hypertrophic cardiomyopathy. Asterisk designates the following possibilities: (1) enhanced myocardial oxygen requirements and reduced myocardial capillary density relative to marked left ventricular (LV) hypertrophy (LVH) and (2) increased diastolic wall tension and coronary vascular resistance resulting from abnormal LV relaxation and impaired filling. death, although most patients (more than 75 percent) with NSVT do *not* die suddenly.[243] The absence of NSVT is a stronger predictor of a good prognosis than is the presence of NSVT of a bad one.[207] It is presumed, but not established, that sudden death is due to a ventricular arrhythmia, although atrial arrhythmias may play a role in sensitizing the heart so that ventricular arrhythmias appear subsequently.[242]

Despite the difficulty in identifying patients at high risk of sudden death, the *absence* of a variety of characteristics (including the absence of severe symptoms, malignant family history, NSVT, marked hypertrophy, marked left atrial dilatation, and abnormal blood pressure response to exercise) identifies a low-risk group who require little in the way of routine therapy.[152] [244] Although avoidance of intense physical exertion is probably appropriate, participation in recreational sports activities is not believed to be contraindicated.[152]

Children.

The mechanism of death may be different in children with HCM, because spontaneous ventricular arrhythmias and inducibility on electrophysiological testing are much less common. It is thought that ischemia may play a prominent role in these patients.[226] [245] [246] Hemodynamic mechanisms may also be involved, because younger patients are more likely to demonstrate abnormal changes in peripheral vascular resistance in response to exercise.[247] Sudden death often occurs during exercise but also demonstrates a circadian distribution, with clustering of deaths in the morning and early evening.[248]

Competitive Sports.

Guidelines for participation in competitive sports have been developed; strenuous exertion should probably be proscribed in all patients with HCM whether or not symptoms are prominent, especially if high-risk clinical characteristics are present. Unsuspected HCM is the most common abnormality found at autopsy in young competitive athletes who die suddenly. Cardiovascular screening before participation in competitive sports appears to reduce the frequency of unexpected sudden death from HCM,[142] although whether large-scale screening of athletes is administratively feasible or cost effective is another matter.[249]

Why some athletes with HCM die suddenly and others are able to continue to compete without limitation or death is not known.[250] It has been speculated that the extent and severity of myocardial disarray may play an important role in determining prognosis, although this is not a finding that is ordinarily or easily obtainable in a living patient! Patients with marked hypertrophy are at increased risk.[251] Sudden death is unlikely, however, in asymptomatic or mildly symptomatic patients with mild hypertrophy.[252] Bradyarrhythmias and disease of the atrioventricular conduction system may also play a role in sudden death.

Management

Management of patients with HCM is directed toward alleviation of symptoms, prevention of complications, and reduction in the risk of death (Fig. 48-17) . Whether asymptomatic patients should receive drug therapy is not established because no adequate controlled studies are available.[152] [157] Digitalis glycosides should generally be avoided unless atrial fibrillation or systolic dysfunction develops. Diuretics were previously thought to be contraindicated

Figure 48-16 (Figure Not Available) Assessment of risk of sudden cardiac death (SD) in overall hypertrophic cardiomyopathy (HCM) population. Treatment for prevention of sudden death is limited to the small subset perceived to be at the highest risk. Asterisk indicates asymptomatic individuals with mild left ventricular hypertrophy (LVH) and without ventricular tachycardia (VT) on Holter monitoring, hypotensive blood pressure response to exercise, and family history of premature HCM-related death. to avoid precipitating or worsening the outflow gradient. More recent experience indicates that cautious use of diuretics often helps reduce symptoms of pulmonary congestion, particularly when they are combined with beta-adrenergic blockers or calcium antagonists.[154] [253] Beta-adrenergic agonists may improve diastolic filling but should not be used because they may produce ischemia and usually worsen the outflow gradient. The vast majority of patients with HCM require only medical management; invasive interventions are needed in only 5 to 10 percent of patients, and then only in those patients with outflow gradients who remain severely symptomatic despite optimal medical therapy.[152]

BETA-ADRENOCEPTOR BLOCKERS.

These drugs are the mainstay of medical therapy of HCM. With their use, angina, dyspnea, and presyncope may all be improved. In patients with resting or provocable gradients beta-adrenoceptor blockade may prevent the increase in outflow obstruction that accompanies exertion, although resting gradients are largely unchanged.[152] The drugs reduce the determinants of myocardial oxygen consumption and thus angina pectoris and perhaps exert an antiarrhythmic action as well. Angina pectoris generally responds more favorably to treatment with a beta-adrenoceptor blocker than does dyspnea. It has been suggested that beta-adrenoceptor blockade may prevent sudden death, and accordingly some use prophylactic beta-adrenoceptor blockade therapy in asymptomatic patients. However, its efficacy for this purpose has not been established.[155] [171] Beta-adrenoceptor blockade also blunts the heart's chronotropic response, thus limiting the demand for increased myocardial oxygen delivery. Beta-adrenoceptor blockade previously was thought to have a beneficial effect on diastolic ventricular filling, but it now appears that any benefit is simply the consequence of a slower heart rate.[155] The overall clinical response to beta-adrenoceptor blockade is variable, and only about one third to two thirds of patients experience symptomatic improvement.[155] One small blinded trial of beta-adrenoceptor blocker therapy found that nadolol improved symptoms more than placebo or a calcium antagonist but did not improve exercise capacity.[254] If beta-adrenoceptor blockers are discontinued, they probably should be withdrawn slowly to avoid rebound adrenergic hypersensitivity.

CALCIUM ANTAGONISTS.

These are an alternative to beta-adrenoceptor blockade in the management of HCM; most of the experience has been with verapamil, with more limited use of nifedipine, diltiazem, and amlodipine.[155] [157] No clear consensus exists as to whether therapy should be initiated first with a beta-adrenoceptor blocker or a calcium antagonist, although verapamil often is effective in improving symptoms in patients who have failed beta-adrenoceptor blockade.[157] Exercise performance in particular may be improved when patients are changed from a beta-adrenoceptor blocker to verapamil. Both the hypercontractile systolic function and the abnormalities of diastolic filling may be related to abnormal calcium kinetics, and drugs that block the inward transport of calcium across the myocardial cell membrane may be able to rectify both abnormalities.

Verapamil has been the most widely used calcium antagonist in this condition.[157] Its use was suggested, at least in part, by the observation that it produces a protective and beneficial effect in the hereditary cardiomyopathy of the Syrian hamster, a condition marked by intracellular calcium overload in which propranolol is ineffective.[255] Although the vasodilator effects of verapamil should not be helpful in HCM, it appears that by depressing myocardial contractility, verapamil can decrease the left ventricular outflow gradient when given intravenously or orally. Perhaps more important from a symptomatic point of view, verapamil improves diastolic filling in HCM, at least in part by reducing asynchronous regional diastolic performance.[155] [157] It also improves regional myocardial blood flow

in some patients, which may contribute to the improvement in diastolic behavior.[256] Verapamil appears to improve diastolic filling by improving relaxation rather than by changing left ventricular diastolic stiffness; at any given diastolic volume, filling pressure is reduced. Although variable clinical responses have been reported with

verapamil, about two thirds or more of patients show increased exercise capacity and an improved symptomatic status. Sustained symptomatic improvement has been noted with the long-term administration of verapamil in ambulatory patients, although important adverse effects, including sudden death, have been observed in a small fraction of patients so treated.[152] Complications with verapamil include suppression of sinus node automaticity and inhibition of atrioventricular conduction, vasodilatation, and negative inotropic effects. These side effects may culminate in hypotension, pulmonary edema, and death; antiarrhythmic agents, especially quinidine, may exacerbate the deleterious hemodynamic effects of verapamil. Because of these adverse effects, it has been suggested that verapamil should not be used, or should be used only with extreme caution, in patients with high left ventricular filling pressure or symptoms of paroxysmal nocturnal dyspnea or orthopnea.[152] Unfortunately, these are usually the patients in greatest need of therapy.

Nifedipine has also been used in HCM, and it may have theoretical advantages over verapamil because it causes less depression of atrioventricular conduction. This may be counteracted by its more potent vasodilator action. Its effect on diastolic function have been inconsistent.[155] Nifedipine may alleviate the chest pain in HCM patients. Combined administration of nifedipine and propranolol may be of benefit in some patients, particularly those with outflow gradients. However, it should be recognized that the potent vasodilator effects of nifedipine may lead to systemic hypotension and an increase in the outflow gradient,[152] and in high doses it may depress left ventricular function. *Diltiazem* has also shown beneficial effects in HCM, producing improved diastolic function, although like verapamil and nifedipine it has caused an increase in the outflow gradient and a worrisome elevation of pulmonary capillary pressure.[155] [257]

The combination of a beta-adrenoceptor blocker and a calcium antagonist may be effective in patients responding inadequately to monotherapy, although there are only anecdotal reports of the superiority of combination therapy.[152] [258]

OTHER DRUGS.

Disopyramide, an antiarrhythmic drug that alters calcium kinetics, has produced symptomatic improvement and abolition of the pressure gradient in patients with HCM, presumably as a consequence of depression of left ventricular systolic performance as well as a peripheral vasoconstrictor effect.[259] It does not appear to have significant effects on diastolic function,[259] although this issue has not been entirely resolved.[260] Long-term experience with disopyramide is limited, particularly in asymptomatic patients and those without outflow gradients, although the initial benefits appear to decrease with time.[152]

Beta-adrenoceptor blockers, calcium antagonists, and the conventional antiarrhythmic agents do not appear to suppress serious ventricular arrhythmias or reduce the frequency of supraventricular arrhythmias. However, amiodarone is effective in the treatment of both supraventricular and ventricular tachyarrhythmias in HCM.[243] Although there is some belief that amiodarone improves prognosis in HCM, only limited and inconclusive data are available.[152] [153] [261] Amiodarone may also improve symptoms and exercise capacity, although its putative beneficial effects on diastolic ventricular function are controversial. [155] Experience with sotalol, although limited, has been generally favorable; in addition to its antiarrhythmic effects on supraventricular and ventricular arrhythmias, its beta-adrenoceptor blocking effects are beneficial.[262] We do not favor empirical use of amiodarone (or other antiarrhythmic agents for that matter) in unselected HCM patients, and we worry about possible proarrhythmic effects and potential toxicity, including sudden death.[213] [214] [236]

Strenuous exercise should be avoided because of the risk of sudden death; almost half of deaths in HCM occur during or just after strenuous physical activity.[263] Even though many individuals with subclinical HCM exercise vigorously, the threat of sudden death is sufficiently real that competitive sports are proscribed in patients with marked hypertrophy or other factors believed to be associated with increased risk (see Figs. 48-16 (Figure Not Available) and 48-17). Atrial fibrillation should usually be pharmacologically or electrically converted because of the hemodynamic consequences of the loss of the atrial contribution to ventricular filling in this disorder. Anticoagulants should be given to patients with chronic atrial fibrillation when no contraindication exists. Infective endocarditis may occur in about 5 percent of patients but appears to be limited to those with an outflow gradient; accordingly, appropriate antibiotic prophylaxis is indicated in this group.[157] [264] The infection usually occurs on the aortic valve or mitral apparatus, on the endocardium, or at the site of the contact lesion on the septum; thus, chronic endocardial trauma may provide a nidus for subsequent infection.

DEVICES AND SEPTAL ABLATION.

Insertion of a dual-chamber DDD pacemaker may be useful in some patients with an outflow gradient and severe symptoms, especially the elderly,[265] [266] [267] [268] but it is likely that no more than 10 percent of HCM patients are candidates. Symptoms generally are improved, and the gradient is reduced by an average of about 25 percent, although better symptomatic and hemodynamic results appear to follow surgery (Fig. 48-18) .[157] Benefits have been described even after termination of pacing, suggesting a modification of myocardial properties. [265] The long-term utility of pacing, however, is not known at present, and a substantial placebo effect has been demonstrated.[267] [269] [270] [271] [271A] The benefit of its use in patients without a resting outflow gradient is even more equivocal; it usually improves symptoms and exercise capacity, but there is no improvement or even worsening of various hemodynamic variables and pharmacological therapy usually needs to be reinstituted.[272] Therefore, its use in this setting generally is not recommended at present.

In high-risk patients (especially the minority of HCM patients with sustained monomorphic ventricular tachycardia) or those with aborted sudden death, an ICD should be inserted,[242] [273] although an ICD may be less beneficial in HCM than in other conditions with aborted sudden death.[274]

A number of patients with severe obstruction have derived benefit at least over the short-term from intentional infarction of a portion of the interventricular septum by the infusion of alcohol into a selectively catheterized septal artery, with reduction of the outflow gradient and improvement in symptoms (Fig. 48-19) .[275] [276]

SURGICAL TREATMENT.

A number of surgical procedures aimed at reducing the outflow gradient have been developed. They are most commonly used in the markedly symptomatic patient with a gradient at rest above 50 mm Hg who has not responded well to medical management.[157] [277] [278]

Myectomy.

The most widely used operation for HCM consists of excising a portion of the hypertrophied septum using a transaortic approach (the operation has been called the Morrow procedure, named after the cardiac surgeon who developed the technique).[279] Left transventricular as well as combined transaortic and left ventricular approaches have also been used successfully. Operative management is facilitated by intraoperative echocardiography, and operative mortality is now less than 5 percent[280] ; large centers have reported mortalities of 3 percent or less.[157] [228]

Figure 48-18 Change in Doppler ultrasound-derived resting left ventricular outflow tract (LVOT) gradient from baseline (pre) to follow-up assessment (post) in patients with hypertrophic cardiomyopathy undergoing surgery or pacemaker insertion. Both groups (surgical myectomy, *left;* dual-chamber pacing, *right*) show significant reductions in resting gradient ($p < 0.05$). *(From Ommen SR, Nishimura RA, Squires RW, et al: Comparison of dual-chamber pacing versus septal myectomy for the treatment of patients with hypertrophic obstructive cardiomyopathy. J Am Coll Cardiol 34:191, 1999.)*

[281] [282] Operation often relieves the obstruction (Figs. 48-18 and 48-20) as well as the mitral regurgitation. [281] The reduction in the left ventricular systolic pressure produced by the operation leads to reduced evidence of postoperative myocardial ischemia on thallium stress testing.[283] Patients older than the age of 65 as well as younger than the age of 10 years have undergone successful operations; the operative risk is higher in older patients.[282] [284]

Surgery results in long-term improvement in symptoms and exercise capacity in most patients.[281] [282] [285] [286] Occasional patients experience myocardial damage and fibrosis as a consequence of the procedure.[283] Significant aortic regurgitation

J Am Coll Cardiol 31:1641, 1998.)*

is an uncommon complication of the transaortic valve approach, occurring in less than 4 percent of patients.[287] Myotomy-myectomy may be combined with other necessary operative procedures (particularly coronary artery bypass grafting), although the surgical risk is increased.[280] There has been recent enthusiasm for combining septal myotomy-myectomy with plication of the anterior leaflet of the mitral valve and reconstruction of the submitral valvular apparatus.[288]

Mitral Valve Replacement.

Although this procedure or mitral valve repair is performed in fewer centers than myotomy-myectomy, the long-term results also have been favorable, with symptomatic benefit and an improvement in hemodynamics.[289] The rationale for this operation is that it abolishes obstruction by preventing systolic anterior motion of the mitral valve. It appears to be of particular value in patients with less than severe (<18 mm) hypertrophy of the upper septum or other atypical septal morphology, in those with previous myotomy-myectomy with persistent severe symptoms and obstruction, and in patients with intrinsic mitral valve disease. In appropriate candidates not responding to maximal standard medical and surgical therapy, cardiac transplantation may be considered; this usually is required only for patients who have entered the dilated phase of HCM and have intractable symptoms of congestive heart failure.[290]

Restrictive and Infiltrative Cardiomyopathies

Of the three major functional categories of the cardiomyopathies (dilated, hypertrophic, and restrictive), restrictive cardiomyopathy (RCM) is the least common form in Western countries, although nonidiopathic forms of RCM such as endomyocardial disease (Table 48-8) are common in specific geographical regions of the world.[291] [292] The hallmark of the RCMs is abnormal diastolic function; the ventricular walls are excessively rigid and impede ventricular filling. Systolic function, on the other hand, often is unimpaired, even in many cases with extensive infiltration of the myocardium.[291] [293] [294] Thus, RCM bears some functional resemblance to constrictive pericarditis, which is also characterized by normal or nearly normal systolic function but abnormal ventricular filling (see Chap. 50). [291] Differentiation of the two conditions is mandatory because of the potential for successful surgical treatment of constriction.[292] [295]

A variety of specific pathological processes may result in restrictive cardiomyopathy, although the cause often remains unknown. Myocardial fibrosis (Fig. 48-21) , infiltration, or endomyocardial scarring is usually responsible for the abnormal diastolic behavior; in the idiopathic variety there often is histological evidence of myocyte hypertrophy.[291] [296] Myocardial involvement with amyloid is a common cause of RCM, although it can be caused by a variety of other conditions (see Table 48-8).[291] [292]

Some patients may manifest the clinical features of an RCM and yet exhibit the pathological findings of left ventricular hypertrophy and fibrosis[294] ; certainly ventricular hypertrophy, especially HCM, can cause diminished ventricular compliance, but not RCM per se. RCM on occasion is inherited; in such cases there may be an associated skeletal muscle disease.[291]

HEMODYNAMICS.

The clinical and hemodynamic features of restrictive heart disease simulate those of chronic constrictive pericarditis; endomyocardial biopsy, CT and radionuclide angiography may be particularly useful in differentiating the two diseases by demonstrating myocardial scarring or infiltration (biopsy) or thickening of the pericardium (CT and MRI).[292] [297] With the use of these modalities, exploratory thoracotomy should rarely be required; nevertheless, if the differentiation between constriction and restrictive cardiomyopathy cannot be established with certainty, surgical exploration is in order.[291] The characteristic hemodynamic feature in both conditions is a deep and rapid early decline in ventricular pressure at the onset of diastole, with a rapid rise to a plateau in early diastole

Figure 48-21 Endomyocardial biopsy specimens from patients with idiopathic restrictive cardiomyopathy. \i\A,\r\ This histologic specimen (hematoxylin-eosin, ;ts250) shows myocytes with slight hypertrophy but is otherwise normal. \i\B,\r\ Another specimen (hematoxylin-eosin, ;ts40), from another patient, shows marked interstitial fibrosis, which may also occur in idiopathic restrictive cardiomyopathy. *This condition is more likely than the others to be encountered in clinical practice.

(although this finding is absent in some patients with RCM).[291] This dip and plateau has been termed the *square root sign* (see Chap. 50) and is manifested in the atrial pressure tracing as a prominent *y* descent followed by a rapid rise and plateau. The *x* descent may also be rapid, and the combination results in the characteristic M or W waveform in the atrial pressure tracing.[291] The *a* wave is prominent and often is of the same amplitude as the *v* wave. Both systemic and pulmonary venous pressures are elevated, although patients with restrictive heart disease typically have left ventricular filling pressures that exceed right ventricular filling pressure by more than 5 mm Hg; this difference is accentuated by exercise, fluid challenge, and Valsalva maneuver (although not all patients demonstrate this finding).[291] [298]

In this respect they differ from patients with constrictive pericarditis, in whom diastolic pressures are similar in both ventricles, usually differing by no more than 5 mm Hg. The pulmonary artery systolic pressure is often greater than 50 mm Hg in patients with RCM but is lower in constrictive pericarditis.[291] Furthermore, the plateau of the right ventricular diastolic pressure is usually at least one third of the peak right ventricular systolic pressure in patients with constrictive pericarditis, whereas it is frequently lower in RCM.[291]

CLINICAL MANIFESTATIONS.

Exercise intolerance is frequent because of the inability of patients with RCM to increase their cardiac output by tachycardia without further compromising ventricular filling. Weakness and dyspnea are often prominent. Exertional chest pain may be prominent in some patients but is usually absent. Particularly in advanced cases, the central venous pressure is elevated, with attendant peripheral edema, enlarged liver, ascites, and anasarca. *Physical examination* may reveal jugular venous distention and an S_3 , S_4 , or both. An inspiratory increase in venous pressure may be seen. However, in contrast to constrictive pericarditis, the apex impulse is usually palpable in RCM.[291]

LABORATORY STUDIES.

Various ancillary laboratory findings in addition to endomyocardial biopsy, CT and MRI[297] (see Chap. 10) may be useful in distinguishing between constrictive and restrictive disease. Although pericardial calcification is neither absolutely sensitive nor specific for constrictive pericarditis (see Chap. 50), its presence in a patient in whom the differential diagnosis rests between RCM and constrictive pericarditis lends strong support to the latter diagnosis. The echocardiogram may demonstrate thickening of the left ventricular wall and an increase of left ventricular mass in patients with infiltrative disease causing RCM. The pattern of filling of the left ventricle differs in the two conditions, as can be demonstrated by transthoracic and transesophageal Doppler ultrasonography.[291] [295] [299] In patients with RCM, there is increased early left ventricular filling velocity, decreased atrial filling velocity, and decreased isovolumetric relaxation time.[291]

The prognosis in RCM is variable; usually it is one of relentless symptomatic progression and high mortality.[295] [299A] No specific therapy (other than symptomatic) is available (excepting the cardiomyopathy due to iron overload which is improved by removal of the iron and amyloidosis, in which some patients appear to benefit from alkylating-based chemotherapy).[295]

AMYLOIDOSIS

ETIOLOGY AND TYPES.

Amyloidosis is a disease complex that results from deposition of unique twisted beta-pleated sheet fibrils formed from various proteins by several different pathogenic mechanisms.[300] Amyloid may be found in almost any organ, but clinically evident disease does not appear unless infiltration is extensive. Several classification systems have been used to characterize the different clinical presentations of amyloidosis. The condition with the traditional designation of primary amyloidosis is now known to be caused by the production of an amyloid protein composed of portions of immunoglobulin light chain (designated *AL*) by a monoclonal population of plasma cells, often as a consequence of multiple myeloma. Secondary amyloidosis is due to the production of a nonimmunoglobulin protein termed *AA*.[300]

Familial Amyloidosis.

This condition, inherited as an autosomal dominant trait, results from the production of a variant prealbumin protein termed *transthyretin;* more than 50 different point mutations have been described so far.[301] [302] It generally occurs in one of three clinical presentations: progressive neuropathy, cardiomyopathy, or nephropathy. Senile systemic amyloidosis is due to the production of either an atrial natriuretic-like protein or transthyretin[300] and is becoming increasingly common as the average age of the population increases. It is four times as common in blacks as in whites.[303] Scattered deposits of amyloid localized to the aorta or atria are virtually ubiquitous in individuals older than the age of 80.[292] [300] Small deposits of amyloid may often be found in the pulmonary vessels or the vessels of other organs as well.

Cardiac Amyloidosis

Involvement of the heart is a common finding and is the most frequent cause of death in amyloidosis associated with an immunocyte dyscrasia.[304] Clinically apparent heart disease is present in one third of patients, although the heart is virtually always involved when studied pathologically. In secondary amyloidosis, on the other hand, clinically significant cardiac involvement is uncommon; the myocardial deposits are typically small and perivascular and usually do not result in significant myocardial dysfunction.[300] Familial amyloidosis is associated with overt cardiac involvement in about one fourth of the afflicted patients, usually late in the course of the disease.[305] The clinical course is usually dominated by neurological or renal dysfunction, although death is due to heart failure or

arrhythmia about half the time.[305] Cardiac involvement in senile amyloidosis varies from small atrial deposits that do not result in functional impairment to extensive ventricular involvement with resultant cardiac failure.[302]

Cardiac amyloidosis occurs more commonly in men than in women, and it is rare before the age of 30 years. Even in the familial form, the onset of clinical cardiac disease usually does not occur before the age of 35 years and generally occurs much later in life.[305]

PATHOLOGY.

The pathological findings often include mild atrial enlargement, usually without significant ventricular dilatation. The walls of both ventricles are typically firm, rubbery, noncompliant, and thickened. Amyloid is present between the myocardial fibers, often with extensive deposition in the papillary muscles. Endocardial involvement of the atria and ventricles is frequent. Amyloidosis often results in focal thickening of or deposits on the cardiac valves, but these abnormalities do not appear to interfere with valvular function other than to produce murmurs. The intramural coronary arteries and veins frequently contain amyloid deposits in the media and adventitia, occasionally compromising the lumina of the vessels.[293] [301]

CLINICAL MANIFESTATIONS.

Involvement of the cardiovascular system by amyloidosis occurs in four general forms:

1. The most common presentation of cardiac amyloidosis is that of RCM.[291] Right-sided findings dominate the clinical presentation; peripheral edema is a prominent finding, whereas paroxysmal nocturnal dyspnea and orthopnea are absent.[292] Amyloid infiltration of the myocardium results in increased stiffness of the myocardium, producing the characteristic diastolic dip and plateau (square root sign) in the ventricular pressure pulse that may simulate constrictive pericarditis. In contrast to the accelerated early left ventricular diastolic filling found in constrictive pericarditis, cardiac amyloidosis is marked by an impaired rate of early diastolic filling.
2. A second common presentation is congestive heart failure due to systolic dysfunction.[302] Hemodynamic evidence of restriction of ventricular filling may not be prominent in these patients. In some patients amyloid deposition in the atria may be responsible for loss of atrial transport function despite the maintenance of electrical "sinus" rhythm, with the production of congestive heart failure.[306] The course of this form of the disease is often one of relentless progression, usually poorly responsive to treatment. Angina pectoris occurs on occasion despite angiographically normal coronary arteries.[293]
3. Orthostatic hypotension occurs in about 10 percent of cases. Although most likely due to amyloid infiltration of the autonomic nervous system or of blood vessels, amyloid deposition in the heart and adrenals may contribute to the pathogenesis of this variant. Hypovolemia as a result of the nephrotic syndrome secondary to renal amyloidosis may aggravate the postural hypotension.[305]
4. An abnormality of cardiac impulse formation and conduction is the fourth and least common mode of presentation and may result in arrhythmias and conduction

disturbances. Sudden death, presumably arrhythmic in origin, is relatively common and may be preceded by episodes of syncope.[305] [307]

PHYSICAL EXAMINATION.

This often reveals congestive heart failure, especially right sided[292] ; a systolic murmur due to atrioventricular valvular regurgitation may be present. Jugular venous distention, a protodiastolic gallop, hepatomegaly, peripheral edema, and a narrow pulse pressure are found in patients presenting with RCM. An S_4 is uncommon, presumably due to amyloid infiltration of the atrium with attendant reduced systolic function of the atrial myocardium.[306] Patients typically are normotensive or hypotensive; even previously hypertensive individuals usually have a fall in blood pressure as the disease progresses.

NONINVASIVE TESTING.

The chest roentgenogram usually shows cardiomegaly in patients with systolic dysfunction, although heart size may be normal in patients with the restrictive form.[92] Pulmonary congestion may be prominent in patients with congestive heart failure. The ECG is often abnormal; the most characteristic feature (but often absent) is diffusely diminished voltage.[292] Myocardial infarction is often simulated because of small or absent R waves in right precordial leads or, less frequently, by Q waves in the inferior leads.[300] Arrhythmias, particularly atrial fibrillation, are common, although they rarely are the presenting feature of cardiac amyloidosis. Complex ventricular arrhythmias are found frequently in patients with cardiac amyloidosis and may be a harbinger of sudden death.[301] Various forms of atrioventricular conduction defects are often seen and may be associated with increased mortality, although significant infra-Hisian block may only be apparent on electrophysiological testing.[305] [308] Abnormalities of atrioventricular conduction appear to be particularly common in familial amyloidosis with polyneuropathy.[305] Sinus node involvement is common, and the clinical and ECG features of the sick sinus syndrome may be present (see Chap. 25).

Echocardiography (see Fig. 7-103).

In advanced cases this most commonly reveals increased thickness of the walls of the ventricles, small ventricular chambers, dilated atria, and thickening of the interatrial septum (Fig. 48-22) ,[309] although the findings are more prominent in the familial than in the primary (AL) form.[293] Left ventricular dysfunction may be seen, especially in advanced cases, but systolic function often is surprisingly normal.[293] Early preclinical unsuspected cardiac involvement may be detectable only by echocardiography or Doppler ultrasonography.[291] Although the cardiac valves may be thickened, they usually move normally.[302] A pericardial effusion is common but rarely results in tamponade. The appearance of the thickened cardiac walls is often distinctive on two-dimensional echocardiography, demonstrating a granular sparkling texture, presumably due to the amyloid deposit.[309] In some cases the pattern of increased wall thickness is nonuniform and may resemble HCM. Echocardiographic demonstration of thick left ventricular walls with concomitant low voltage on the ECG appears to distinguish cardiac amyloidosis from pericardial disease or left ventricular hypertrophy, and this distinctive voltage/mass ratio is characteristic of myocardial infiltration by amyloid.[309] Doppler ultrasonography and radionuclide ventriculography routinely demonstrate abnormalities of diastolic function, and, by estimating the degree of cardiac involvement by amyloid, provide prognostic information.[310] MRI may be of some help by using tissue characterization signatures to identify myocardial infiltration.[311]

Nuclear Imaging.

Scintigraphy with technetium-99m pyrophosphate is often strongly positive with prominent amyloid involvement, although in some patients it is falsely negative.[309] [312] Positive scans tend to correlate with extensive cardiac involvement. Scanning with indium-labeled antimyosin antibody may also detect cardiac amyloid involvement.[313] Scanning with specialized agents has shown sympathetic denervation in patients with cardiac amyloidosis.[312]

DIAGNOSIS.

Whereas two or three decades ago the clinical diagnosis of systemic amyloidosis was made correctly ante mortem in about one fourth of cases, with more recent clinical awareness of the disease and the utilization of *biopsy techniques* the diagnosis is now made before death in the majority of patients. An abdominal fat aspirate has been the single most useful diagnostic procedure, combining the attributes of ease of performance, sensitivity, and safety.[292] Biopsy of rectum, gingiva, bone marrow, liver, kidney, and various other tissues has also been used. Endomyocardial biopsy of the right or left ventricles may be

Figure 48-22 Serial echocardiographic findings in a patient developing cardiac amyloidosis. *Top,* Serial two-dimensional echocardiographic findings. helpful in establishing the diagnosis of cardiac amyloidosis (Fig. 48-23) if the abdominal fat aspirate is negative.[292] Immunohistochemical staining of tissue samples is important to distinguish systemic senile, familial, and primary forms of amyloidosis in otherwise equivocal presentations, because prognosis and management differ in the various forms.[302] [314]

MANAGEMENT.

The treatment of cardiac amyloidosis is generally unsatisfactory, although there has been some improvement in survival and functional state with the use of alkylating agents in primary (AL) amyloidosis.[302] [315] [316] Digitalis glycosides should be used with caution because patients with cardiac amyloidosis appear to be particularly sensitive to digitalis preparations, and the use of ordinary doses may lead to serious arrhythmias; this may relate to selective binding of digoxin to amyloid fibrils in the myocardium.[292] Similarly, nifedipine binds to amyloid fibrils; its use and that of the other calcium antagonists may lead to exacerbation of congestive heart failure symptoms due to an enhanced negative inotropic effect.[292] [317] Insertion of a permanent pacemaker may be beneficial in the short term in patients with symptomatic conducting system disease.[318] Careful use of low doses of diuretics and vasodilators may afford some symptomatic benefit, but there is a risk of hypotension and hypoperfusion with use of these agents.[291] In patients with atrial standstill due to amyloid infiltration, anticoagulation may be appropriate even in the absence of atrial arrhythmias, because there is some risk of thrombus formation, presumably as a consequence of stasis in the atrium.[306]

Autologous stem cell transplantation is being used with increasing frequency in primary (AL) amyloidosis, but the long-term benefit, especially in patients with cardiac involvement, is not known.[319] A small number of patients have undergone cardiac transplantation, with poor long-term results (39 percent survival at 4 years in one study) due to progressive amyloidosis in other organs or recurrence in the transplanted heart, although a few carefully selected patients have shown long-term survival and functional improvement.[291] [320] An heroic alternative approach for the familial form of cardiac amyloidosis is simultaneous heart and liver transplantation because the circulating transthyretin in these patients is produced in the liver and can be corrected with liver transplantation.[301] [302] No therapy is effective for the senile form, but survival is about 10 times longer than in the primary form (60 vs. 6 months).[314]

INHERITED INFILTRATIVE DISORDERS CAUSING RESTRICTIVE CARDIOMYOPATHY

The intramyocardial accumulation or infiltration of an abnormal metabolic product typically produces a restrictive picture with impaired diastolic ventricular filling. Systolic impairment may be seen as well but is not invariably found. A variety of infiltrative diseases, often inherited, may result in this hemodynamic picture, including the glycogenoses, the mucopolysaccharidoses, Fabry disease, and Gaucher disease.

FABRY DISEASE

Fabry disease (angiokeratoma corporis diffusum universale) is an X-linked recessive disorder of glycosphingolipid metabolism due to a deficiency of the lysosomal enzyme alpha-galactosidase A that is caused by one of more than four dozen mutations.[321] Some mutations result in no detectable alpha-galactosidase A activity and

widespread manifestations throughout the body, whereas others produce

some degree of enzyme activity with attendant atypical variants of Fabry disease with involvement limited solely to the myocardium.[322] The disease is characterized by an intracellular accumulation of a neutral glycolipid, with prominent involvement of the skin and kidneys as well as the myocardium in the classic form. *Histological examination* often reveals widespread involvement of the myocardium, vascular endothelium, conducting tissues, and valves, particularly the mitral valve. The major clinical manifestations of the disease result from the accumulation of the glycolipid substrate in endothelial cells, with eventual occlusion of small arterioles. The accumulation of the glycolipid occurs in the lysosomes of the cardiac tissues and is responsible for the multiple cardiovascular manifestations of Fabry disease (Fig. 48-24) .

CARDIAC FINDINGS.

These typically include angina and myocardial infarction caused by accumulation of lipid moieties in coronary endothelial cells, but coronary arteries are usually angiographically normal. There is increased left ventricular wall thickness simulating HCM, left ventricular dysfunction and failure due to lipid accumulation in myocytes, and mitral regurgitation (due to deposition in valvular fibroblasts).[323] Symptomatic cardiovascular involvement occurs eventually in most affected males, whereas female carriers usually are asymptomatic or only minimally symptomatic. Systemic hypertension, mitral valve prolapse, and congestive heart failure are common clinical manifestations. ECG abnormalities may include a short PR interval, atrioventricular block, and ST segment and T wave abnormalities.[323] The echocardiogram usually reveals increased left ventricular wall thickness as a result of glycolipid deposition, which may simulate HCM.[323] Differentiation from other hypertrophic or restrictive processes (such as cardiac amyloidosis) may not be possible on echocardiographic grounds but may be possible with MRI (Fig. 48-25) . Endomyocardial biopsy may be of considerable value in making a definitive diagnosis, as is low plasma alpha-galactosidase A activity.

GAUCHER DISEASE

Gaucher disease is an uncommon inherited disorder of glycosyl ceramide metabolism. It is secondary to a deficiency of the enzyme beta-glucosidase and results in accumulation of cerebrosides in the spleen, liver, bone marrow, lymph nodes, brain, and myocardium. Diffuse interstitial infiltration of the left ventricle by cells laden with cerebroside produces reduced left ventricular compliance and cardiac output. Clinical evidence of cardiac involvement is uncommon, but when present it is characterized by left ventricular dysfunction, hemorrhagic pericardial effusion, increased left ventricular wall mass, and thickening of the left-sided valves.[324] Liver transplantation may produce a reduction in tissue infiltration by cerebrosides.[325]

HEMOCHROMATOSIS (See also Chap. 69)

Hemochromatosis is characterized by excessive deposition of iron in a variety of parenchymal tissues (heart, liver, gonads, and pancreas). It may occur (1) as a familial (autosomal recessive) or idiopathic disorder; (2) in association with a defect in hemoglobin synthesis resulting in ineffective erythropoiesis; (3) in chronic liver disease; and (4) with excessive oral or parenteral intake of iron (or blood transfusions) over many years.[326] [327] Although patients who have iron deposits in the myocardium almost always have deposits in other organs (e.g., liver, spleen, pancreas, bone marrow), the severity of myocardial involvement varies widely and only roughly parallels that in other organs.

Coronal view. *(From Cantor WJ, Butany J, Iwanochko M, Liu P: Restrictive cardiomyopathy secondary to Fabry's disease. Circulation 98:1457, 1998. Copyright 1998, American Heart Association.)*

Cardiac involvement leads to a mixed DCM/RCM with both systolic and diastolic dysfunction, often with associated arrhythmias.[326] [328] [329] [330] Myocardial damage is thought to be due to direct tissue toxicity of the free iron moiety rather than simply to tissue infiltration.[326] Although cirrhosis and hepatocellular carcinoma are the most common causes of death, cardiac mortality is an important additional concern (especially in the group of patients--usually men--who present at a young age).[327]

PATHOLOGICAL FINDINGS.

These consist of a dilated heart with thickened ventricular walls. Myocardial iron deposits are found within the sarcoplasmic reticulum and are most common in the subepicardial region, followed by the subendocardial region, and are least common in the midmyocardial wall.[326] They are more extensive in ventricular than in atrial myocardium. Involvement of the cardiac conducting system is common. Myocardial degeneration and fibrosis may also occur.

The severity of myocardial dysfunction is proportional to the quantity of iron present in the myocardium.[331] Extensive deposits of cardiac iron (particularly those grossly visible at postmortem examination) are invariably associated with cardiac dysfunction.

CLINICAL MANIFESTATIONS.

These vary widely, depending on the extent of myocardial involvement. Some patients remain asymptomatic despite echocardiographic evidence of myocardial involvement, which is expressed initially as increased left ventricular wall thickness and later as chamber enlargement and contractile dysfunction.[331] In such cases, a variety of noninvasive techniques (CT and especially MRI) may demonstrate early subclinical myocardial involvement in which treatment is most effective (Fig. 48-26) .[226] [332] Symptomatic cardiac involvement is usually associated with ECG abnormalities, including ST segment and T wave abnormalities, as well as supraventricular arrhythmias[331] ; these ECG changes correlate with the degree of iron deposit in the heart.

Cardiac involvement usually is evident from the clinical and echocardiographic features; endomyocardial biopsy may be useful to confirm (but not exclude) the diagnosis.[327] The diagnosis is aided by finding an elevated plasma iron level, a normal or low total iron-binding capacity, and markedly elevated values for serum ferritin, urinary iron, liver iron, and especially saturation of transferrin.[327] Repeated phlebotomies or the use of the chelating agent desferrioxamine may be clinically beneficial.[326] [333]

GLYCOGEN STORAGE DISEASES

Adult patients may demonstrate cardiac involvement in these diseases; in type III (glycogen debranching enzyme deficiency), cardiac involvement is found only in patients with deficient enzyme in muscle tissue.[334] Cardiac involvement is marked most commonly by apparent left ventricular hypertrophy on the ECG and echocardiogram. [169] [334] [335]

Figure 48-26 Standard-plane CT of chest without contrast medium enhancement at level of seventh thoracic vertebra in a patient with cardiac hemochromatosis. Gated scanning was not used, and scanning speed was one scan per 4 seconds. Right ventricle (*top*), left ventricle (*bottom*), and left atrium were scanned at this level. Left ventricular wall and part of right ventricular wall could be identified as a high-density area as a result of iron deposition in the myocardium. *(From Niwano S, Yokoyama J, Niwano H, et al: Images in cardiovascular medicine: Iron deposition in myocardium documented on standard computed tomography in cardiac hemochromatosis. Circulation 97:2371, 1998. Copyright 1998, American Heart Association.)*

Sarcoidosis

Sarcoidosis is a granulomatous disorder of unknown cause, characterized by multisystem involvement. Infiltration of the lungs, reticuloendothelial system, and skin

usually dominates the clinical picture, but virtually any tissue may be affected. The most important manifestation results from pulmonary involvement. This often leads to diffuse fibrosis that may result in fatal right-sided heart failure. Primary cardiac involvement is not often recognized clinically, although it may be demonstrated at autopsy in 20 to 30 percent of cases, most of which demonstrate generalized sarcoidosis.[336]

Clinical manifestations of sarcoid heart disease are present in less than 5 percent of patients, although myocardial involvement may result in heart block, congestive heart failure, ventricular arrhythmias, and sudden death.[337] [338] Myocardial sarcoidosis may have restrictive as well as congestive features because cardiac infiltration by sarcoid granulomas results not only in increased stiffness of the ventricular wall but in diminished systolic contractile function as well. Myocardial sarcoidosis typically affects young or middle-aged adults of either gender; there usually is evidence of generalized sarcoidosis.[336]

PATHOLOGY.

The typical pathological feature of sarcoidosis is the presence of noncaseating granulomas, which occur in many organs. They infiltrate the myocardium and may eventually form fibrotic scars.[336] The granulomas may involve any region of the heart, although the left ventricular free wall and the interventricular septum are the most common sites, and extensive granulomas and scar tissue in the cephalad portion of the interventricular septum are constant findings in patients with abnormalities of the conduction system.[339] Cardiac infiltration may range from a few scattered lesions to extensive involvement. Because of the variable cardiac involvement, myocardial biopsy may be positive in only about half of the patients, and therefore a negative biopsy by no means excludes the diagnosis.[336] Transmural involvement is common, and large portions of the ventricular wall may be replaced by scar tissue, which may lead to aneurysm formation. Although involvement of small coronary artery branches may be found in sarcoidosis, the larger conductance vessels are uninvolved.[336]

CLINICAL MANIFESTATIONS.

Sudden death is the most feared and unfortunately one of the more common manifestations of cardiac sarcoidosis.[336] [340] Conduction disturbances and congestive heart failure are common manifestations of symptomatic involvement in nonfatal cases, but many patients are asymptomatic despite extensive cardiac involvement.[337] Syncope is common and may reflect paroxysmal arrhythmias or conduction disturbances.[336] Atrial and ventricular arrhythmias, especially ventricular tachycardia, are observed frequently.[336] Although cor pulmonale as a consequence of pulmonary sarcoidosis accounts for some of the symptoms of heart failure, many symptoms are caused by direct myocardial involvement by granulomas and scar tissue, and patients show the clinical features of RCM and/or DCM[336] Symptoms of myocardial sarcoid may be present for variable lengths of time; however, the disease may progress rapidly to death, and in some patients the interval from the onset of cardiac symptoms to death is measured in months. In others, survival may be considerably longer.[336]

Cardiac dysfunction is often severe and progressive. Occasionally, patients with extensive involvement develop overt left ventricular aneurysms. Pericardial effusions are not uncommon.[341]

The physical examination may reveal findings of extracardiac sarcoid or may be totally normal. A systolic murmur reflecting mitral regurgitation is common. This appears to be more the result of left ventricular dilatation than of direct sarcoid involvement of the papillary muscles.

The ECG frequently is abnormal and most commonly demonstrates T wave abnormalities. Sarcoidosis appears to have an affinity for involvement of the atrioventricular junction and bundle of His, and thus varying degrees of intraventricular or atrioventricular block are common.[336] [340] With extensive myocardial involvement, pathological Q waves may appear and simulate myocardial infarction (Fig. 48-27) . Characteristic echocardiographic features include left ventricular dilatation and dysfunction, often with regional wall motion abnormalities suggestive of ischemic heart disease[336] ; wall thinning and increased echogenicity

Figure 48-27 Electrocardiogram in patient with cardiac sarcoidosis shows abnormal Q wave in leads II, III, and aVF and ST segment elevation in V_5 and V_6 . *(From Shindo T, Kurihara H, Ohishi N, et al: Images in cardiovascular medicine: Cardiac sarcoidosis. Circulation 97: 1306, 1998. Copyright 1998, American Heart Association.)*

are sometimes observed (Fig. 48-28) . A small to moderate-sized pericardial effusion is seen in about 20 percent.[341]

DIAGNOSIS.

In many cases the diagnosis may be suspected in patients with bilateral hilar lymphadenopathy on chest roentgenogram in whom there is clinical or ECG evidence of myocardial disease. Endomyocardial biopsy may be useful in establishing the diagnosis, although the nonuniform involvement of the heart by sarcoidosis means that a negative biopsy does not exclude the diagnosis. The echocardiogram demonstrates diffuse and often regional left ventricular wall motion abnormalities in patients with clinical cardiac involvement (see Fig. 48-28). Myocardial imaging with thallium-201 or technetium-99m sestimibi may be helpful in demonstrating segmental perfusion defects that result from sarcoid infiltration of the myocardium.[337] [342] [343] Imaging may also indicate the presence of right ventricular hypertrophy in patients with right ventricular overload due to pulmonary fibrosis and pulmonary hypertension. Uptake of technetium pyrophosphate, gallium, and labeled antimyosin antibody may aid in the diagnosis, as may MRI.[336] [343] [344] [345] [346] [347]

MANAGEMENT.

The treatment of myocardial sarcoidosis is difficult.[340] Arrhythmias are often refractory to antiarrhythmic drugs. Permanent pacing may be helpful in patients with involvement of the atrioventricular conduction system. Although the matter is not settled, corticosteroids may be of some benefit in treating the conduction disturbances, arrhythmias, and myocardial dysfunction of sarcoidosis.[336] [348]

Figure 48-28 Echocardiographic findings in cardiac sarcoidosis. *Top,* Parasternal long-axial echocardiographic view. Arrows show wall thinning and increased echogenicity of inferior wall. *Bottom,* Parasternal short-axial view showing end-diastolic (*lower left*) and end-systolic (*lower right*) phases. These is impaired systolic shortening. Arrows show increased echogenicity. *(From Shindo T, Kurihara H, Ohishi N, et al: Images in cardiovascular medicine. Cardiac sarcoidosis. Circulation 97:1306, 1998. Copyright 1998, American Heart Association.)*

It has been suggested that further benefit may be derived from the addition of hydroxychloroquine, methotrexate, or cyclophosphamide.[340] Because the risk of sudden death appears to be greatest in patients with extensive myocardial involvement, it may be reasonable to attempt to halt the progression of the disease with corticosteroids before irreversible fibrosis occurs. Insertion of an ICD may be considered in appropriate patients at high risk of sudden death.[349] Heart or heart-lung transplantation has been used in selected patients with intractable heart failure, although recurrent sarcoid involvement of the transplanted heart can occur.[291]

ENDOMYOCARDIAL DISEASE

DEFINITION AND PATHOGENESIS.

Endomyocardial disease (EMD) is a common form of restrictive cardiomyopathy that typically is found in a geographical distribution near the equator.[350] It is most frequent in equatorial Africa and is encountered with less frequency in South America, Asia, and nontropical countries, including the United States.[351] It is marked by intense endocardial fibrotic thickening of the apex and subvalvular regions of one or both ventricles that results in obstruction to inflow of blood into the respective ventricle, thus producing restrictive physiology. For many years it had been thought that there are two variants of the disease, one occurring principally in tropical countries (termed *endomyocardial fibrosis* [EMF] or Davies disease) and the other in temperate countries (Loffler's endocarditis parietalis fibroplastica or hypereosinophilic syndrome).[292] However, despite the pathological similarities,[352] there are important contrasts in clinical presentation that challenge the concept of a single disease process.[353] In addition to the geographical differences, the temperate form of the disease is a more aggressive and rapidly progressive disorder, affecting principally males, and is associated with hypereosinophilia, thromboembolic phenomena, and generalized arteritis. EMF, conversely, shows no gender predilection, occurs in younger patients, and is not associated with an intense eosinophilia.[292]

DIFFERENCES BETWEEN LOFFLER ENDOCARDITIS AND EMF.

Part of the thesis that Loffler endocarditis and EMF are different phases of a single disease is based on a theory of pathogenesis involving the toxic effect of

eosinophils on the heart.[354] Under this formulation, an initial hypereosinophilia of whatever cause results in damage to the myocardium that produces the first phase of EMD: a necrotic phase, marked by an intense myocarditis, rich in eosinophils, and with an associated arteritis (i.e., Loffler endocarditis).[354] This initial phase occurs within the first few months of illness. It may be followed by a thrombotic stage, occurring about a year after initial presentation, during which the myocarditis has receded, nonspecific thickening of the myocardium is beginning, and there is a variable degree of superimposed thrombus formation.[354] The putative last stage is one of fibrosis, presenting all of the features of EMF. The three stages--necrotic, thrombotic, and fibrotic--have been defined on the basis of postmortem material, and it is not suggested by proponents of the unified pathogenesis hypothesis that each patient with advanced disease (manifested by EMF) has necessarily passed through the earlier phases.

ROLE OF EOSINOPHILS.

The possible role of eosinophils in the production of the cardiac abnormalities has intrigued investigators for years.[354] [355] Eosinophils may damage tissues by direct invasion or by the release of toxic substances. The presence of degranulated eosinophils in the peripheral blood of patients with Loffler endocarditis suggests that the protein constituents of the eosinophil's granule may be cardiotoxic, first producing the necrotic phase of EMD, followed by the thrombotic and fibrotic phases after the disappearance of the initial eosinophilia.[353]

There is now, however, increasing speculation that this continuum occurs only in the temperate countries, and the endemic EMF found in tropical countries is a distinct and separate disease, because a link with eosinophilia has been difficult to document, despite the frequency of parasitic diseases.[292] [356] [357] [358] Other etiological factors have been implicated (Fig 48-29) ; the fibrosis of tropical EMF has been linked to the higher levels of cerium and lower concentrations of magnesium that apparently are found in endemic areas.[356] [359] [360]

Because the clinical manifestations of EMD demonstrate geographical and clinical differences, Loffler endocarditis and EMF are discussed separately, even though they could be part of the same disease continuum.

Loffler Endocarditis: The Hypereosinophilic Syndrome

Marked eosinophilia of any cause may be associated with endomyocardial disease. The typical patient who presents

Figure 48-29 The pathogenesis of Loffler syndrome. Tissue damage is caused by major basic and cationic proteins derived from cytotoxic eosinophils. These cytotoxic proteins may stay in the myocardium for a prolonged period and produce continuous tissue damage. In the fibrotic phase, various types of heart diseases, such as endomyocardial fibrosis, dilated cardiomyopathy, atrioventricular block, or valvular regurgitation can be seen according to the site of the most dominant involvement. *(From Hirota Y: Restrictive cardiomyopathy, cardiac amyloidosis, and hypereosinophilic heart disease. In Abelmann WH, Braunwald E [eds]: Atlas of Heart Diseases. Vol 2. Cardiomyopathies, Myocarditis, and Pericardial Disease. Philadelphia, Current Medicine, 1995.)*

with Loffler endocarditis is a man in his fourth decade who lives in a temperate climate and has the hypereosinophilic syndrome (i.e., persistent eosinophilia with 1500 eosinophils/mm^3 for at least 6 months or until death, with evidence of organ involvement).[292] [354] [361] Cardiac involvement in the hypereosinophilic syndrome is the rule, occurring in more than three fourths of patients.[362] Hypereosinophilia and cardiac involvement are also seen in the Churg-Strauss syndrome, which is differentiated by asthma or allergic rhinitis and a necrotizing vasculitis.[292] The cause of the eosinophilia in most patients with Loffler endocarditis is unknown, although in some it may be the result of leukemia, or it may be reactive (i.e., secondary to various parasitic, allergic, granulomatous, hypersensitivity, or neoplastic disorders).[355]

PATHOLOGY.

In the hypereosinophilic syndrome, a variety of organs are usually involved besides the heart, including the lungs, bone marrow, and brain.[354] Cardiac involvement is often biventricular, with mural endocardial thickening of the inflow portions and apex of the ventricles.[292] Histological findings include variable degrees of (1) an acute inflammatory eosinophilic myocarditis involving the myocardium and endocardium; (2) thrombosis, fibrinoid change, and inflammatory reaction involving small intramural coronary vessels; (3) mural thrombosis, often containing eosinophils; and (4) fibrotic thickening of up to several millimeters.[292] [354]

CLINICAL MANIFESTATIONS.

The principal clinical features include weight loss, fever, cough, rash, and congestive heart failure. Although early cardiac involvement may be asymptomatic, overt cardiac dysfunction occurs in more than half of the patients and may be right and/or left sided.[362] Cardiomegaly, often without overt symptoms of congestive heart failure, may be present, and the murmur of mitral regurgitation is common.[354] Systemic embolism is frequent and may lead to neurological and renal dysfunction. Death is usually due to congestive heart failure, often with associated renal, hepatic, or respiratory dysfunction. [292]

LABORATORY EXAMINATION.

The chest roentgenogram may reveal cardiomegaly and pulmonary congestion or, less commonly, pulmonary infiltrates. The ECG most commonly shows nonspecific ST segment and T wave abnormalities.[292] Arrhythmias, especially atrial fibrillation, and conduction defects, particularly right bundle branch block, may also be present.

The echocardiogram commonly demonstrates localized thickening of the posterobasal left ventricular wall, with absent or markedly limited motion of the posterior leaflet of the mitral valve.[292] There may be obliteration of the apex by thrombus. Enlargement of the atria may be seen, along with Doppler ultrasound evidence of atrioventricular regurgitation. Systolic function often is well preserved, in keeping with the restrictive picture seen in this condition.

The hemodynamic consequences of the dense endocardial scarring seen in Loffler endocarditis are those of an RCM, with abnormal diastolic filling due to increased stiffness of the ventricles and a reduction in the size of the ventricular cavity by organized thrombus.[354] Atrioventricular valvular regurgitation may occur because of involvement of the supporting apparatus of the mitral or tricuspid valves.[362] *Cardiac catheterization* reveals markedly elevated ventricular filling pressures, and there may be evidence of tricuspid or mitral regurgitation. A characteristic feature on angiocardiography is largely preserved systolic function with obliteration of the apex of the ventricles.[354] The diagnosis is often confirmed by percutaneous endomyocardial biopsy, but the biopsy is not invariably positive.

MANAGEMENT.

Medical therapy during the course of early Loffler endocarditis and surgical therapy during the later phases of fibrosis may have a positive effect on symptoms and survival. Corticosteroids appear to have a beneficial effect on acute myocarditis[363] and together with cytotoxic drugs (hydroxyurea in particular) may improve survival substantially.[291] [354] A limited number of patients not responding to standard therapy have responded to treatment with interferon.[355] [361] Routine cardiac therapy with digitalis, diuretics, afterload reduction, and anticoagulation as indicated are adjuncts in the management of these patients.[354] Surgical therapy (see p. 1782) appears to offer significant palliation of symptoms once the fibrotic stage has been reached.[292] [354]

Endomyocardial Fibrosis

Endomyocardial fibrosis occurs most commonly in tropical and subtropical Africa, particularly Uganda and Nigeria. It is characterized by fibrous endocardial lesions of the inflow of the right or left ventricle or both and often involves the atrioventricular valves, resulting in regurgitation.[356] It is a relatively frequent cause of heart failure and death in equatorial Africa, accounting for 10 to 20 percent of deaths due to heart disease.[353]

Although most prominent in Africa, it is also found in tropical and subtropical regions in the rest of the world, typically within 15 degrees of the equator,[350] including India,[360] Brazil, Colombia, and Sri Lanka.[353] EMF is most common in specific ethnic groups, notably the Rwanda tribe in Uganda, and in people of low socioeconomic status.[364] The disease is equally frequent in both genders, and, although most common in children and young adults, its reported age

range is 4 to 70 years.[351] It is most common in blacks, but cases have been reported occasionally in whites in temperate climates, rarely in the absence of prior

residence in tropical areas.

PATHOLOGY.

A pericardial effusion, which may be quite large, may be present. The heart is normal in size or slightly enlarged, but massive cardiomegaly does not occur. The right atrium is often dilated, and in patients with severe right ventricular involvement there may be massive enlargement of this chamber. Indentation of the right border of the heart above the apex as a result of apical scarring may occur.

Combined right and left ventricular disease occurs in about half the cases, with pure left ventricular involvement occurring in 40 percent and pure right ventricular involvement in the remaining 10 percent of patients who are examined post mortem.[352] When affected, the right ventricle exhibits extensive dense fibrous thickening of the inflow tract and apex, with involvement of the papillary muscles and chordae tendineae. Involvement of the right ventricle may lead to obliteration of the apex, with a mass of thrombus and fibrous tissue filling the cavity.[352] The tricuspid valve is often distorted by the fibrous process involving the supporting structures. Right atrial thrombi occur commonly. Left ventricular involvement is similar, with fibrosis extending from the apex up the inflow portion of the left ventricle to the posterior mitral valve leaflet. The anterior leaflet of the mitral valve and the outflow portion of the left ventricle are usually spared. Thrombi often overlie the endocardial lesions, and widely distributed endocardial calcific deposits may occur.[353] The epicardial coronary arteries are free of obstructive lesions.

HISTOLOGIC FINDINGS.

Microscopically, the involved endocardium demonstrates a thick layer of collagen tissue on top of a layer of loosely arranged connective tissue.[351] Septa composed of fibrous and granulation tissue extend for variable distances into the myocardium.[353] Interstitial edema is often present, but there is no prominent cellular infiltration. Small patches of fibroelastosis may occur in both ventricular outflow tracts beneath the semilunar valves but are thought to be a secondary phenomenon due to local trauma rather than a result of the basic pathological process. The intramural coronary arteries may show medial degeneration and fibrosis and fibrin deposits.[353]

CLINICAL MANIFESTATIONS.

Because EMF may involve both ventricles or either ventricle selectively, symptoms vary. Left-sided involvement results in symptoms of pulmonary congestion, whereas predominant right-sided disease may present features of an RCM and therefore simulate constrictive pericarditis. There is often regurgitation of one or both atrioventricular valves. The onset of the disease is usually insidious, but it is sometimes ushered in by an acute febrile illness. Rarely, the disease appears to stabilize; although survival for up to 12 years has been observed, EMF is usually relentlessly progressive.[292] Death is due to progressive myocardial failure, often associated with pulmonary congestion, infection, or infarction, or sudden, unexpected cardiovascular collapse, presumably arrhythmic in origin. Survival appears to be unrelated to the site of predominant involvement (right or left ventricle), although patients presenting in advanced right-sided failure have a worse prognosis than other patients.[292]

RIGHT VENTRICULAR EMF.

Pure or predominant right ventricular involvement is characterized by fibrous obliteration of the right ventricular apex that diminishes the capacity of this chamber.[352] The fibrosis often extends to the supporting apparatus of the tricuspid valve,[365] resulting in tricuspid regurgitation. Clinical manifestations in patients with right-sided involvement include an elevated jugular venous pressure, a prominent *v* wave, and a rapid *y* descent. A protodiastolic gallop sound may be heard along the lower sternal border, reflecting right ventricular dysfunction.[352] The liver is usually large and pulsatile, and ascites, splenomegaly, and peripheral edema are common. Pulmonary congestion is not present in the absence of left-sided involvement, and the pulmonary artery and pulmonary capillary wedge pressures are normal. A pericardial effusion, which is sometimes quite large, may be present. The right atrium is often enlarged, sometimes massively so.

Laboratory Findings.

The ECG is usually abnormal, with diminished QRS voltage (probably resulting from the presence of a pericardial effusion), ST segment and T wave abnormalities, and findings suggestive of right-sided enlargement, especially a qR pattern in lead V_1 .[351] The chest roentgenogram demonstrates cardiac enlargement, usually with gross prominence of the right atrium and a pericardial effusion. Calcification in the walls of the right or, less commonly, the left ventricle may be seen.[353] Echocardiography may demonstrate right ventricular thickening, obliteration of the apex, dilated atrium, strong echoes emanating from the endocardial surface, and abnormal septal motion in patients with tricuspid regurgitation.[352] [357] [366] At angiography the right ventricular apex is characteristically not visualized because of obliteration by the fibrous endocardium, but tricuspid regurgitation, right atrial enlargement, and filling defects in the right atrium due to intraatrial thrombi are sometimes seen.[351] Early angiographic changes that may be present before advanced disease develops include a change in the endocardial appearance, small apical filling defects, and mild tricuspid regurgitation.

LEFT VENTRICULAR EMF.

With predominant *left-sided* involvement, the endomyocardial fibrosis invades the apex of the ventricle and usually the chordae tendineae or the posterior mitral valve leaflet as well, leading to mitral regurgitation.[367] The murmur may be confined to late systole, as is characteristic of the papillary muscle dysfunction type of murmur, or it may be pansystolic. Findings of pulmonary hypertension may be prominent. A protodiastolic gallop is commonly heard.

Laboratory Findings.

The ECG usually shows T wave abnormalities. QRS voltage may be diminished in the presence of a pericardial effusion, although left ventricular hypertrophy may be present.[292] There may be findings of left atrial abnormality. As with right-sided involvement, atrial fibrillation often is present. Echocardiographic features include thickening and reduced motion of the posterobasal wall and posterior mitral leaflet, increased echoreflectivity of the endocardium, preserved systolic wall motion in the presence of apical obliteration, dilated atrium, and Doppler ultrasound evidence of mitral regurgitation.[292] Cardiac catheterization often reveals pulmonary hypertension, with elevated left ventricular filling pressures and a reduced cardiac index.[367] The left ventriculogram usually shows mitral regurgitation, and a filling defect due to an intracavitary thrombus within the ventricle may be seen on occasion. Coronary arteriography does not reveal obstructive disease.

BIVENTRICULAR EMF.

This form of EMF occurs more frequently than either isolated right- or left-sided disease.[351] If there is more than minimal right ventricular involvement, severe pulmonary hypertension does not occur and the right-sided findings dominate the clinical presentation. Typical patients with biventricular involvement may have the features of right ventricular EMF, with only a mitral regurgitant murmur to suggest left ventricular involvement. Systemic embolization may occur in up to 15 percent of patients; infective endocarditis is even less frequent and is found in less than 2 percent.

DIAGNOSIS.

This is based on the presence in an individual of the typical clinical and laboratory features, particularly angiography, from the appropriate geographical area. Eosinophilia is usually not a prominent feature and when present may reflect associated parasitic infestation. Endomyocardial biopsy may occasionally be helpful in establishing the diagnosis. However, this risks dislodging a mural thrombus, with resultant embolization. Left-sided biopsy is *not* recommended. In addition, because the disease is often focal, the biopsy may miss the pathological process, particularly if a right ventricular biopsy is performed in a patient with isolated left-sided disease.

MANAGEMENT.

The medical treatment of EMF is often difficult and not particularly effective. In patients with advanced disease, the outlook is poor, with a 35 to 50 percent 2-year mortality. Substantially better survival may be seen in less symptomatic patients who have milder forms of the disease. Digitalis glycosides may be helpful in controlling the ventricular rate in patients with atrial fibrillation,[292] but the response of congestive symptoms is disappointing, and the development of atrial fibrillation is a poor prognostic sign.[368] Diuretics are not particularly helpful in the treatment of ascites.[292] Once endomyocardial disease has reached the fibrotic stage, surgery offers the possibility of symptomatic improvement and is the treatment of choice.[369] Operative excision of the fibrotic endocardium and replacement of the mitral and/or tricuspid valves have led to substantial symptomatic improvement, especially with predominant left-sided involvement.[291] [370] Mitral valve repair, rather than replacement, can be accomplished in some patients.[371] Postoperative catheterization has provided objective evidence of hemodynamic improvement with a reduction in ventricular filling pressures, an increase in cardiac output, and normalization of the angiographic appearance. Operative mortality has been high, running between 15 and 25 percent in the larger series,[291] [292] [369] although it appears to be lower if valve replacement can be avoided.[371] Long-term results suggest that surgery is at best palliative, with

recurrent fibrosis, continued functional limitation, and cumulative mortality limiting the overall success of an operative approach.[369]

Endocardial Fibroelastosis (See Chap. 45)

Carcinoid Heart Disease (See also Chap. 46)

ETIOLOGY.

The carcinoid syndrome is caused by a metastasizing carcinoid tumor and is characterized by cutaneous flushing, diarrhea, bronchoconstriction, and endocardial plaques composed of a unique type of fibrous tissue. The vasomotor, bronchoconstrictor, and cardiac manifestations are undoubtedly related to circulating humoral substances secreted by the tumor,[372] although the precise substance(s) responsible remains to be elucidated.[373] Virtually all patients develop diarrhea and flushing, and cardiac abnormalities are found on echocardiography in more than half; clinically apparent and severe right-sided disease is seen in a fourth of patients.[372] [374]

Sixty to 90 percent of tumors arise in the small bowel and appendix, and the rest originate in other areas of the

gastrointestinal tract and bronchus.[372] Carcinoid tumors of the ileum are the most likely to metastasize, with involvement of the regional lymph nodes and liver. Usually only carcinoid tumors that invade the liver result in carcinoid heart disease.[372] The cardiac lesions may be related to large circulating quantities of serotonin, bradykinin, or other substances secreted by the tumor, which usually are inactivated by the liver, lungs, and brain.[375] Hepatic metastases apparently allow large quantities of tumor products to reach the heart.[374] The preferential right-sided involvement presumably is related to inactivation of the offending humoral substance(s) by the lungs. In 5 to 10 percent of cases, significant left-sided valvular disease develops,[376] related in most to passage of blood directly from the right to the left side of the heart through a patent foramen ovale, or less commonly by tumor involvement of the lungs.[372]

PATHOLOGY.

The characteristic pathological findings are fibrous plaques that involve the "downstream" aspect of the tricuspid and pulmonic valves, the endocardium of the cardiac chambers, and the intima of the venae cavae, pulmonary artery, and coronary sinus (see Figs. 46-45 and 46-47). The fibrous tissue in the plaques results in structural and functional distortion of the valves, leading to both stenosis and regurgitation. [372] Histologically, the plaques consist of deposits of fibrous tissue located superficially on the endocardium, often with extension into the underlying layers. Identical morphological features have been found in some patients treated with the anorectic drugs fenfluramine and dexfenfluramine.[374] Ultrastructural and immunohistochemical studies have demonstrated that the plaques are composed of smooth muscle cells embedded in a stroma rich in acid mucopolysaccharides and collagen. Metastatic involvement of the myocardium itself is rare.[372]

CLINICAL MANIFESTATIONS.

Physical examination usually reveals a systolic murmur along the left sternal border, produced by tricuspid regurgitation; in some cases, there may be a concomitant murmur of pulmonic stenosis and/or regurgitation.[372]

The chest roentgenogram is normal in half of the patients, but it may reveal enlargement of the heart and pleural effusions or nodules; the pulmonary artery trunk is typically of normal size, without evidence of poststenotic dilatation as occurs in congenital pulmonic stenosis. No specific ECG pattern is diagnostic of carcinoid heart disease.[372] Right atrial enlargement may be seen on occasion, but ECG evidence of right ventricular hypertrophy usually is lacking. Nonspecific ST segment and T wave abnormalities and sinus tachycardia are the most common findings, although severely symptomatic patients usually have low QRS voltage.[377] Echocardiography may reveal tricuspid and/or pulmonary valve thickening, along with right atrial and right ventricular dilatation; small pericardial effusions are present in a minority.[372]

The hemodynamic findings most commonly encountered are those of tricuspid regurgitation and occasionally pulmonic stenosis. A rare patient with the carcinoid syndrome demonstrates a hyperkinetic state (which may lead to high-output heart failure) but without the typical cardiac lesions; in one patient this was caused by profound vasodilatation by substance P.[378]

MANAGEMENT.

In patients with mild congestive heart failure therapy includes digitalis and diuretics. Symptomatic improvement and improved survival have been noted with the use of somatostatin analogs.[374] [375] Balloon valvuloplasty of the right-sided valves has produced symptomatic improvement in some patients with stenotic tricuspid or pulmonary valves,[379] although others have developed recurrent symptoms despite "successful" valvuloplasty.[380] Surgical replacement of the tricuspid valve and pulmonic valvotomy or valvectomy may result in symptomatic improvement in severely symptomatic patients with serious valvular dysfunction, although the operative mortality is high (35 percent in one series).[377] Surgery may improve the functional status and survival of patients with carcinoid heart disease, but patients older than the age of 60 years have a very high surgical mortality (reportedly over 50 percent).[376] The long-term mortality remains high regardless of treatment modality, with half the patients dead within 1 to 2 years.[372] [377]

Myocarditis

Myocarditis is considered to be present when the heart is involved in an inflammatory process, often caused by an infectious agent. The inflammation may involve the myocytes, interstitium, vascular elements, and/or pericardium; involvement of the latter structure is discussed in Chapter 50 .

Etiology

Myocarditis has been described during and after a wide variety of viral, rickettsial, bacterial, protozoal, and metazoal diseases; indeed, virtually any infectious agent may produce cardiac inflammation (Table 48-9) (Table Not Available) . Infectious agents cause myocardial damage by three basic mechanisms: (1) invasion of the myocardium, (2) production of a myocardial toxin (e.g., diphtheria), and (3) immunologically mediated myocardial damage.[381] The principal mechanism of cardiac involvement in viral myocarditis is believed to be a cell-mediated immunological reaction to new cell surface changes or a new antigen related to the virus, and not merely the result of cell damage caused by viral replication. [382] [383] Additional evidence for an immune-mediated mechanism is the demonstration of a marked increase in major histocompatibility complex antigen expression in the biopsy specimens from patients with myocarditis.[384] Antibodies against intracellular components may also play a role.[385] Such cross-reactivity of antibodies to both virus and myocardial proteins (termed *molecular mimicry*) may play a role in producing immune-mediated myocardial damage.[386] Patients with ongoing myocarditis (unlike those with resolved myocarditis) have myocytes that express intercellular adhesion molecule-1 (ICAM-1), and it is speculated that the persistent expression of ICAM-1 may play a role in continued myocardial inflammation. Thus, the ultimate impact of the immune response associated with viral infection is a result of the balance between its protective and deleterious effects.[386] Although the term is often mistakenly used to indicate myocardial inflammation solely due to an infective agent, myocarditis may also be caused by allergic reactions and pharmacological agents, as well as occurring during the course of some systemic diseases such as vasculitis.

Myocarditis may be an acute or a chronic process and may occur during the peripartum period (see Chap. 65).[387] In North America, viruses (especially enteroviruses) are believed to be the most common agents producing myocarditis,[388] whereas in South America, Chagas disease (produced by *Trypanosoma cruzi*) is far more common. The identification

TABLE 48-9 -- INFECTIOUS CAUSES OF MYOCARDITIS

(Not Available)

of the specific etiological agent responsible for infective myocarditis usually rests on the associated extracardiac findings because the cardiovascular signs and symptoms are often nonspecific. The histological findings vary, depending on the stage of the disease, the mechanism of myocardial damage, and the specific etiological agent. Myocardial involvement may be focal or diffuse; it appears that myocarditis may begin as a focal process but then spread to involve the myocardium diffusely over a period of several weeks.[389] The clinical consequences depend to a large extent on the size and distribution of the myocarditic lesions. However, a single small lesion may have profound consequences if it is located within the cardiac conducting system. The histological findings are usually nonspecific (except for some parasitic and granulomatous forms of myocarditis), and with certain exceptions (see p. 1753) myocardial biopsy seldom elucidates the specific etiological agent.

Clinical Manifestations

The clinical expression of myocarditis ranges from the asymptomatic state associated with limited and focal inflammation to fulminant fatal congestive heart failure due to diffuse myocarditis.[27] In some patients, otherwise unexplained ventricular arrhythmias may be due to silent myocarditis.[390] An initial episode of viral myocarditis, perhaps unrecognized and forgotten, may be the initial event that eventually culminates in an "idiopathic" DCM.[10] In experimental animals, the structural and functional myocardial alterations that follow viral myocarditis may persist well beyond the stage of viral replication and myocardial inflammatory response, and the late changes resemble those of DCM.

The outcome after viral myocarditis is quite variable,[27] [390A] perhaps related to differing genetic susceptibility of individual patients. In most patients, the event is entirely self-limited and often unrecognized.[388] [391] More overt myocarditis may result in acute congestive heart failure.[338] In others, unrecognized myocarditis may be the cause of arrhythmias in what appears to be a structurally normal heart.[392] Some patients with chest pain and angiographically normal coronary arteries may have had subclinical myocarditis at some point in the past. Most intriguing is the possibility that viral myocarditis may culminate in DCM, presumably as a consequence of viral-mediated immunological cardiac damage.[391]

Although transient ECG abnormalities suggesting myocardial involvement are noted in many patients with infectious disease, most patients do not have other clinical manifestations of myocarditis. It is postulated that these ECG changes reflect subclinical myocardial involvement. That unrecognized myocardial involvement occurs with systemic infections is supported by histological evidence of unsuspected myocarditis found during routine postmortem examinations; this occurs about 1 percent of the time.[338] Some degree of myocardial involvement, often subepicardial in location, also frequently occurs in patients with acute pericarditis.

Because myocardial involvement is subclinical in most acute infectious diseases, the majority of patients have no

specific complaints referable to the cardiovascular system; the presence of myocarditis is often inferred from ST segment and T wave abnormalities on the ECG. From a clinical viewpoint, myocardial involvement is associated with nonspecific symptoms including fatigue, dyspnea, palpitations, and precordial discomfort.[338] Chest pain usually reflects associated pericarditis, but precordial discomfort suggestive of myocardial ischemia is occasionally observed. In some cases, the clinical presentation (with chest pain, ECG abnormalities, increased muscle enzyme levels in the blood, and regional wall motion abnormalities) may simulate an acute myocardial infarction.[393] [394]

PHYSICAL EXAMINATION.

Tachycardia is usual and may be out of proportion to the temperature elevation. The S_1 is often muffled, and a protodiastolic gallop may be present. A transient apical systolic murmur may appear,[338] but diastolic murmurs are rare. Clinical evidence of congestive heart failure occurs only in the more severe cases. The heart is usually normal in size in the clinically silent cases, but it may be dilated in patients with congestive heart failure. Pulmonary and systemic emboli may occur.

LABORATORY FINDINGS.

ECG abnormalities are usually transient and occur far more frequently than does clinical myocardial involvement. The most common changes are abnormalities of the ST segment and T wave, but atrial and, in particular, ventricular arrhythmias, artrioventricular and intraventricular conduction defects, and, rarely, Q waves may be seen.[395] Complete artrioventricular block is usually transient and resolves without sequelae, but it is occasionally a cause of sudden death in patients with myocarditis. Intraventricular conduction abnormalities are associated with more severe myocardial damage and a worse prognosis.[396] On radiological examination, heart size may range from normal to markedly enlarged, and pulmonary congestion may be present in patients with fulminant disease. Blood levels of myocardial enzymes (serum transaminases, creatine kinase) may be normal or elevated, reflecting the absence or presence of variable degrees of clinically detectable myocardial necrosis; cardiac troponin levels are more sensitive to myocardial damage and may be detected when other enzymes are not elevated.[397] Echocardiography demonstrates some degree of left ventricular dysfunction (surprisingly often regional in nature) in many patients with clinical myocarditis, although wall motion may be normal. Other findings may include increased wall thickness, left ventricular thrombi, and abnormal diastolic filling despite normal systolic function.[398] Radionuclide scanning after the administration of gallium-67, indium-111 antimyosin antibody, or technetium-99m pyrophosphate may identify inflammatory and necrotic changes characteristic of myocarditis, as may MRI (Fig. 48-30) . [338] [399]

DIAGNOSIS.

This is often predicated on the identification of the associated systemic illness and its characteristic features.[10] The diagnosis of viral myocarditis is supported by the identification of the virus in stool, throat washings, blood, myocardium, or pericardial fluid or by a distinct (usually fourfold) increase in virus-neutralizing antibody, complement-fixation, or hemagglutination inhibition titers, but cultures usually are negative and serological tests nondiagnostic.[338] [400] Even in fatal cases, isolation of virus from the myocardium at necropsy is unusual.[401] Endomyocardial biopsy frequently is used to confirm the diagnosis of myocarditis.[10] A borderline or negative biopsy does not exclude the diagnosis, and, if clinically indicated, a repeat biopsy may be appropriate and diagnostic.[338] Molecular biological techniques such as the polymerase chain reaction (using tissue obtained by endomyocardial biopsy or samples obtained from other sites) offer promise as a way of rapidly and confidently diagnosing acute myocarditis.[11] [402] Coronary arteriography is not usually required nor is its use routinely recommended. It may, in fact, provide confusing information; some patients with myocarditis are discovered

Figure 48-30 *A,* Precontrast T1-weighted transaxial (*upper*) and coronal (*lower*) magnetic resonance (MR) images through the left ventricle in case with myocarditis. *B,* Postcontrast MR images at the same levels after contrast injection. Note enhancement of the myocardial signal in the septum and apical region (arrows). *(From Matsouka H, Hamada M, Honda T, et al: Evaluation of acute myocarditis and pericarditis by Gd-DTPA enhanced magnetic resonance imaging. E Heart J 15:283, 1994.)*

to have coincidental coronary artery disease that is not playing a significant role in their illness.[403]

PATHOLOGY.

Patients with myocarditis demonstrate a wide spectrum of gross and histological changes, reflecting the range of disease seen clinically. Grossly, the hearts in acute cases are flabby, with focal hemorrhages; in chronic cases, the hearts are enlarged and hypertrophied. The histological hallmark of myocarditis is an inflammatory myocardial infiltrate, with associated evidence of myocyte damage.[338] The inflammatory infiltrate may be composed of a variety of cell types, including polymorphonuclear cells, lymphocytes, macrophages, plasma cells, eosinophils, and/or giant cells. In bacterial myocarditis, polymorphonuclear cells predominate; in viral infections, lymphocytes predominate; and in hypersensitivity myocarditis, eosinophils are seen in abundance. In some cases, morphological changes are absent and evidence of inflammation is provided by immunohistologic techniques.[12] Routine histological examination of the heart rarely provides a specific diagnosis, although in some instances electron microscopic and immunofluorescent techniques may allow elucidation of a specific cause.

Management

Therapy is often supportive and is usually directed at the more prominent systemic manifestations of the disease.[27] The demonstration of a particular predilection for involvement of the artrioventricular conducting system in some forms of myocarditis suggests that patients with suspected myocarditis should be observed closely for any evidence of conduction abnormality. Bed rest (or at least restricted activity) is advisable because exercise in experimental animals with myocarditis is deleterious.[338] Because myocarditis often occurs in young adults, it is important to limit their athletic activities; it is recommended that athletes abstain from sports for a 6-month convalescent period, and until heart size and function have returned to normal. Congestive heart failure responds to routine management, including digitalization and diuresis,[338] although patients

with myocarditis appear to be particularly sensitive to digitalis and toxicity should be watched for. Significant symptomatic arrhythmias should be treated with antiarrhythmic agents, although beta-adrenoceptor blockers are probably best avoided in view of their negative inotropic action (it should be noted that there have been too few reports of their use in humans to make a firm recommendation).[338] [404] Participation in athletic and sporting activities should be proscribed until arrhythmias have resolved.

The use of corticosteroids is controversial.[27] [381] [405] Although these agents were previously thought to be proscribed in acute viral myocarditis (because increased tissue necrosis and viral replication have been demonstrated after their use in experimental myocarditis), their use in a small number of patients has not been associated with similar dire short-term consequences.[391] A randomized trial of immunosuppression in myocarditis found no improvement in left ventricular ejection fraction or survival, however, and they are generally believed to be of limited value.[118] [406] Nonsteroidal antiinflammatory agents--indomethacin, salicylates, and ibuprofen, along with cyclosporine--are contraindicated during the acute phase of viral myocarditis (the first 2 weeks) because they increase myocardial damage in animal models.[381] [400] On the other hand, nonsteroidal antiinflammatory agents appear to be safe in the late phase of myocarditis. High-dose intravenous gamma globulin appears to be associated with more rapid resolution of left ventricular dysfunction and perhaps improved survival, at least in children (and in a small number of adults who have been so treated).[407] [408] In experimental models of myocarditis, the converting enzyme inhibitor captopril has beneficial effects in the acute phase of myocarditis; human data are not yet available.[338] [409]

It is hoped that effective antiviral agents, immunosuppressive agents, or immunomodulating agents for treating viral myocarditis will become available for clinical use.[118] [410] [411] Antibiotics may be employed with benefit in infections caused by atypical pneumonia and psittacosis.

VIRAL MYOCARDITIS

Approximately two dozen viruses may be associated with clinical evidence of myocarditis (see Table 48-9 (Table Not Available)). [338] The myocarditis characteristically develops after a latent period of several weeks after the initial systemic infection, suggesting involvement of an immunological mechanism.[412] In animals, a variety of factors appears to enhance susceptibility to myocardial damage, including radiation, malnutrition, corticosteroids, exercise, and previous myocardial injury. Viral myocarditis may be particularly virulent in infants[388] and in pregnant women.

HUMAN IMMUNODEFICIENCY VIRUS (See Chap. 68)

COXSACKIEVIRUS.

Both coxsackieviruses A and B may produce myocarditis, although infection with coxsackievirus B is more common; this agent is the most frequent cause of viral myocarditis, causing more than half the cases.[413] The myocardium appears to be particularly susceptible to the effects of this virus because of the apparent affinity of myocardial membrane receptors for the viral particles. Necropsy often demonstrates a pericardial effusion, pericarditis, cardiac enlargement, and a predominantly mononuclear inflammatory infiltrate, with necrosis of the atrial and ventricular myocardium. In some cases, focal myocardial necrosis simulating myocardial infarction is seen, despite normal coronary arteries.[414]

Although most infections are benign, self-limited, and subclinical, coxsackieviral myocarditis appears to be particularly virulent in the neonate and child (see Chap. 45).[415] In most infections in adults, the other clinical manifestations of viral involvement, such as pleurodynia, myalgia, upper respiratory tract symptoms, and arthralgias, predominate. Severe cases in the adult are characterized by myopericardial involvement with pleuritic or pericarditic chest pain, palpitations, and fever. Many patients

with overt myocardial involvement develop congestive heart failure with cardiomegaly and pulmonary edema.[415]

The *electrocardiogram* is virtually always abnormal, with ST segment and T wave abnormalities and arrhythmias, often ventricular in origin; artrioventricular conduction disturbances are common. *Echocardiography* may reveal diffuse and regional left ventricular wall motion abnormalities that usually improve or disappear over time.

Most patients recover completely within weeks,[415] although the ECG and ventricular function may require months to return to normal. Rarely, coxsackieviral myocarditis is fatal in adults. Some patients become symptomatic after resolution of the infection, and they may present years later with DCM.[416]

Treatment.

This is symptomatic; despite occasional postmortem evidence of intracardiac thrombi, anticoagulation should probably be avoided because of the risk of a hemorrhagic pericardial effusion. Bed rest is indicated during the acute course of myocarditis, but no convincing evidence exists that a period of prolonged rest after apparent resolution of the acute process is useful. Heart failure and cardiac arrhythmias are treated in the usual fashion.

CYTOMEGALOVIRUS.

Unrecognized infection with cytomegalovirus (CMV) is extremely common in childhood, and the majority of the adult population have antibodies to CMV.[417] Primary infection after the age of 35 years is uncommon, and generalized infection usually occurs only in immunosuppressed patients with neoplastic disease, after transplantation, and with HIV infection.[418] The cardiovascular manifestations in adults are generally limited to asymptomatic and transient ECG abnormalities. Symptomatic cardiac involvement is rare, although a hemorrhagic pericardial effusion or myocarditis with left ventricular dysfunction and attendant congestive heart failure may occur.[419] The diagnosis of CMV myocarditis may be suggested by the presence of viral inclusions in myocardial biopsy specimens and confirmed by the detection of viral DNA in the myocardium.[418] Although fatalities are unusual, when they do occur, histological examination of the heart may reveal focal lymphocytic infiltration and fibrosis.

DENGUE.

Although previous dengue epidemics often were associated with symptomatic cardiac involvement, more recent outbreaks have been associated with fewer apparent cardiac complications.[420] [421] The major clinical feature is hypotension due to a capillary leak syndrome. Nonspecific ECG repolarization abnormalities are common but typically benign and transient.[421] Transient ventricular arrhythmias may be seen on occasion.

VIRAL HEPATITIS.

Clinical cardiac involvement in hepatitis is rare; an occasional patient may develop fulminant myocarditis with congestive heart failure, hypotension, and death.[422] There are contested data implicating hepatitis C viral infection as an etiological factor in at least some cases of DCM.[423] [424] [425] The characteristic pathological changes are minute foci of necrosis of isolated muscle bundles, often surrounded by lymphocytes and a diffuse serous inflammation.[422] The ventricles may be dilated, with petechial hemorrhages. Hemorrhage into the myocardium may be a conspicuous finding.[422] Myocardial damage may be produced indirectly through an immune-mediated mechanism or directly by viral invasion of the heart.[422]

Symptomatic myocarditis is generally observed in the first to third week of illness. Patients may have dyspnea, palpitations, and anginal chest pain; fatalities have been reported.[422] ECG changes, including bradycardia, ventricular premature beats, and ST segment and T wave abnormalities, may be seen during the course of hepatitis.[422] These abnormalities are usually transient and asymptomatic, although congestive heart failure, cardiomegaly, and sudden death have been reported.[422]

INFECTIOUS MONONUCLEOSIS.

Cardiac involvement in infectious mononucleosis is extremely rare, although nonspecific ST segment and T wave abnormalities may be seen. In rare cases, pericarditis and myocarditis (even simulating a myocardial infarction) may be present.[426]

INFLUENZA.

Although clinically apparent myocarditis is rare in influenza, the presence of preexisting cardiovascular disease greatly increases the risk of morbidity and mortality.[427] During epidemics, 5 to 10 percent of infected patients may experience cardiac symptoms.[10] Postmortem findings in fatal cases include biventricular dilatation, with evidence of a mononuclear infiltrate, especially in perivascular areas.[427]

Cardiac involvement typically occurs within 1 to 2 weeks of the onset of the illness and may be severe, sometimes contributing to mortality. The clinical manifestations include dyspnea, palpitations, anginal chest pain, arrhythmia, and heart failure; there may be concomitant involvement of the pericardium.[428] Sinus tachycardia or, less commonly, sinus bradycardia may be seen. The ECG may show transient ST segment and T wave abnormalities, conduction defects, and even complete atrioventricular block; death may be associated with massive hemorrhagic pulmonary edema due to viral or bacterial involvement of the lungs.

LASSA FEVER.

Lassa fever, a major cause of death in West Africa that is caused by an arenavirus, often is associated with ECG abnormalities[429] that may represent subclinical myocardial involvement. More than half the patients demonstrate nonspecific repolarization changes and low voltage.[429] Pericardial involvement may occur. Pathological findings include myocardial congestion, edema, and a mononuclear cellular infiltrate. In most cases, however, the putative cardiac involvement does not appear to play a major clinical role.[429]

MUMPS.

Myocardial involvement during the course of mumps is rarely recognized.[430] The hearts of only a few patients with mumps have undergone postmortem examination, and they have been found to be both dilated and hypertrophied. Histologically, there is diffuse

interstitial fibrosis, with infiltration of mononuclear cells and areas of focal necrosis.[430] [430A] There is speculation that prior mumps myocarditis may be involved in the development of endocardial fibroelastosis.[431] Cardiac involvement is usually unrecognized clinically, and the diagnosis of myocarditis is based on nonspecific ECG changes.[430] Transient ST segment and T wave abnormalities are most common, but extrasystoles and atrioventricular conduction block may occur.[430] Tachycardia, a transient apical systolic murmur, and protodiastolic gallop may be present.

POLIOMYELITIS.

Myocarditis occurs in about 5 to 10 percent of epidemic poliomyelitis and is a frequent finding in fatal cases, occurring in half or more of all patients dying with this disease; death may be sudden.[12] Although myocardial involvement is usually focal and minimal in extent, some patients with bulbar disease succumb early in the course of the illness, often with cardiovascular collapse.[432] These patients all have viral infection of the medulla and severe systemic vasoconstriction that leads to pulmonary edema. Myocarditis appears to contribute to the heart failure.[432] The ECG is frequently abnormal, with ST segment and T wave abnormalities, prolongation of the PR and QT intervals, extrasystoles, tachycardia, and atrial fibrillation. Treatment is symptomatic, with aggressive support of pulmonary function; tracheostomy and prolonged mechanical ventilatory support may be required. Fortunately, this disease has been largely eliminated by immunization.

RESPIRATORY SYNCYTIAL VIRUS.

Although respiratory syncytial virus is an important cause of respiratory disease, particularly in children, it rarely results in cardiac involvement.[433] Congestive heart failure, pericardial effusion, arrhythmias, cardiogenic shock, and complete heart block have been seen on occasion.[433] [434]

RUBELLA AND RUBEOLA.

Congenital cardiovascular lesions may develop in the offspring when rubella is contracted by the mother during the first trimester of pregnancy, with persistent ductus arteriosus and pulmonary artery maldevelopment as prominent anomalies. Rare cases of postgestational myocarditis occur, with attendant conduction defects and heart failure.[435]

Overt myocarditis is rare in rubeola, although transient ECG abnormalities, including prolongation of the PR interval, ST segment and T wave changes, atrioventricular conduction abnormalities, and ventricular tachycardia, have been reported.[436] Congestive heart failure occurs on rare occasions, and its appearance is a poor prognostic sign, often indicating a fatal outcome. Histological examination of the heart in fatal cases has revealed evidence of myocarditis characterized predominantly by a perivascular lymphocytic infiltrate.[436]

VARICELLA.

Clinical myocarditis is a rare finding in varicella, although unsuspected myocarditis is common in fatal varicella. Occasionally, a patient may develop overt clinical evidence of myocarditis with congestive heart failure.[437] Histological findings include rare but characteristic intranuclear inclusion bodies within the myocardial cells, along with interstitial edema, cellular infiltrates, and myonecrosis.[437] The ECG may show conduction abnormalities, including complete heart block; sudden death occurs rarely.

VARIOLA AND VACCINIA.

Cardiac involvement after smallpox is rare, although several cases of myocarditis associated with acute cardiac failure and death have been reported. Myocarditis with pericardial effusion and congestive heart failure has also been observed as a complication of smallpox vaccination; an immunological mechanism has been suggested, and dramatic responses to corticosteroids have been reported.[438] The histological changes include a mixed mononuclear infiltrate, with interstitial edema and occasional degenerating or necrotic muscle bundles.

RICKETTSIAL MYOCARDITIS

The rickettsial diseases are frequently associated with evidence of myocardial involvement, but usually it is subclinical. Transient ST segment and T wave alterations are commonly observed. The circulatory collapse that may accompany these diseases is largely a manifestation of abnormalities of the peripheral vascular bed, but a myocardial component may also be present. The basic histopathological process is a vasculitis, with a periarterial interstitial infiltrate.

Q FEVER.

Endocarditis is the most common cardiac manifestation of infection with *Rickettsia burnetii* (Q fever).[439] Myocarditis is not a prominent feature,[439A] although dyspnea and chest pain, perhaps reflecting associated pericarditis, occur frequently. The ECG may demonstrate transient ST segment and T wave changes as well as paroxysmal ventricular arrhythmias. Abnormalities of the immune system have been implicated in the pathogenesis of the disease.

ROCKY MOUNTAIN SPOTTED FEVER.

Clinical evidence of myocarditis is more common than often appreciated in Rocky Mountain spotted fever (caused by *R. rickettsii*), and the heart is often involved in the multisystem damage that occurs as the result of a widespread vasculitis.[440] Unsuspected left ventricular dysfunction is common, and echocardiographic evidence of dysfunction may persist in some patients.

SCRUB TYPHUS.

Myocarditis is common during the course of scrub typhus (tsutsugamushi disease, caused by *R. tsutsugamushi*), especially in fatal cases.[441] The histological findings are those of a focal panvasculitis involving the small blood vessels. Myocardial necrosis is unusual, but hemorrhage into the heart and subepicardial petechiae may occur.[441] Clinical evidence of myocardial involvement typically is not severe and is usually not associated with residual cardiac damage. The ECG may show nonspecific ST segment and T wave abnormalities, as well as first-degree atrioventricular block.[441] A protodiastolic gallop and apical systolic murmur suggestive of mitral regurgitation are occasionally found.

BACTERIAL MYOCARDITIS

BRUCELLOSIS.

Cardiac involvement in the course of brucellosis is uncommon, usually consisting of endocarditis. Myocardial involvement, when it occurs, is manifested by T wave abnormalities and prolongation of atrioventricular conduction. An occasional patient develops fulminant myocarditis, with a lymphocytic and polymorphonuclear infiltrate.[442]

CLOSTRIDIAL INFECTION.

Cardiac involvement is common in patients with clostridial infections with multiple organ involvement. The myocardial damage results from the toxin elaborated by the bacteria, but the precise actions of the toxin remain to be elucidated.[443] The pathological findings are distinctive, with gas bubbles present in the myocardium. Areas of degenerated muscle fibers are apparent, but an inflammatory infiltrate is usually absent.[443] *Clostridium perfringens* may cause myocardial abscess formation, with myocardial perforation and resultant purulent pericarditis.

DIPHTHERIA.

Myocardial involvement is one of the more serious complications of diphtheria and occurs in up to one fourth of cases.[443A] Indeed, myocardial involvement is the most common cause of death in this infection, and half of the fatal cases demonstrate cardiac involvement.[444] Cardiac damage is due to the liberation by the diphtheria bacillus of a toxin that inhibits protein synthesis by interfering with the transfer of amino acids from soluble RNA to polypeptide chains under construction. The toxin appears to have a particular affinity for the cardiac conducting system.

Pathological Findings.

These include a flabby and dilated heart with a myocardium that has a "streaky" appearance. Microscopic examination reveals characteristic fatty infiltration of the myocytes,[444] often with an interstitial inflammatory infiltrate, myocytolysis, and hyaline necrosis of muscle fibers. With time, fibrosis and hypertrophy of the remaining myocardial cells develop. The conduction system is often involved.

Clinical Manifestations.

Signs of cardiac dysfunction typically appear at the end of the first week of the illness. Cardiomegaly and severe congestive heart failure are often present. A protodiastolic gallop and pulmonary congestion may be prominent features. Elevation of the serum transaminase levels may be seen; a high level is associated with a poor prognosis. Sudden circulatory failure and death may occur. Many patients develop ST segment and T wave abnormalities, but atrial and ventricular arrhythmias and conduction defects may also occur.[444] Persistently abnormal ECGs are common after diphtheritic myocarditis, as are cardiomegaly and symptoms of reduced cardiac reserve. Some patients recover fully.

Because of the serious effects of the toxin on the myocardium, antitoxin should be administered as rapidly as possible.[444] Antibiotic therapy is of less urgency. Overt congestive heart failure may be resistant to therapy with cardiac glycosides. The development of complete atrioventricular block is an ominous complication, and mortality is high despite insertion of a transvenous pacemaker.

LEGIONNAIRES DISEASE.

Although pneumonia, rhabdomyolysis, renal failure, and hepatic as well as central nervous system involvement are common with *Legionella pneumophila,* overt cardiac involvement is not.[445] Occasional ECG changes may be noted, consisting primarily of ST segment and T wave abnormalities; ventricular arrhythmias may be seen. Rarely, pericardial effusion, myocarditis with evidence of myocardial necrosis, or congestive heart failure may be seen.[445]

MENINGOCOCCAL INFECTION.

Myocardial involvement is common during the course of fatal meningococcal infections but is less commonly recognized in the usual case. Pathological findings include hemorrhagic myocardial lesions, occasionally associated with intracellular organisms. An interstitial myocarditis composed of lymphocytes, plasma cells, and polymorphonuclear leukocytes may be observed, occasionally with myonecrosis.

Meningococcal myocarditis may result in congestive heart failure as well as in pericardial effusion with tamponade. Death may occur suddenly and be associated with involvement of the atrioventricular node.[446]

MYCOPLASMA PNEUMONIAE INFECTION.

ECG abnormalities are common during the course of atypical pneumonia, although clinically apparent myocarditis is not. When carditis occurs, it may be serious, and, rarely, fatal.[447] Nonspecific ST segment and T wave abnormalities are the most common manifestations of cardiac involvement; a rare patient may develop complete heart block. The ECG findings usually resolve within 1 to 2 weeks. A cell-mediated autoimmune myocarditis has been postulated as the cause of the changes. Pericarditis may be

Figure 48-31 Findings in cardiac tuberculosis. \i\A,\r\ Chest radiograph reveals right-sided pleural effusion, cardiomegaly, and borderline perihilar edema. \i\B,\r\ CT of chest confirmed right-sided pleural effusion and also reveals pericardial effusion and pericardial thickening. \i\C,\r\ Cross section of heart shows thickened pericardium. \i\D,\r\ Close examination of apical myocardium (arrow) reveals myocardial tubercles. \i\E,\r\ Histology shows the presence of granulomas (arrowhead) with giant cells. (From Dhar SC, Hayes S, Cercek B, et al: Images in cardiovascular medicine: Cardiac tuberculosis. Circulation 98:730, 1998. Copyright 1998, American Heart Association.)

a prominent finding, and congestive heart failure is occasionally seen. A protodiastolic gallop and pericardial friction rub may be noted in occasional cases. Complete recovery is the rule in most patients, although occasional patients may have persistent sequelae, including arrhythmias.

PSITTACOSIS.

Myocarditis complicating psittacosis is a relatively common occurrence and is characterized by congestive heart failure and acute pericarditis.[448] Pathological changes include fibrinous pericarditis as well as endocarditis and myocarditis. Fever, chest pain, ECG changes, cardiomegaly, systemic emboli, tachycardia, and hypotension may occur. Although most patients recover completely, fatalities have been reported. The systemic infection may be treated effectively with tetracycline, but the effect of the antibiotic on the myocardium is unknown.

SALMONELLOSIS.

Symptomatic myocardial involvement during *Salmonella* infections is rare, although ECG abnormalities are often seen, suggesting subclinical myocarditis.[449] [450] Other cardiovascular complications include infected mural thrombi, occasionally resulting in pulmonary and systemic emboli, and mycotic aneurysms. Myocardial abscesses may rupture, producing fatal cardiac tamponade. Myocarditis with congestive heart failure occurs most commonly in children who are severely ill with salmonellosis, and it is associated with a high mortality. When myocarditis occurs, it often develops rapidly, with evidence of biventricular failure, tachycardia, a protodiastolic gallop, an apical systolic murmur of mitral regurgitation, and peripheral edema.

ECG abnormalities include ST segment and T wave changes, prolonged PR or QT intervals, and low QRS voltage.[450]

STREPTOCOCCAL INFECTION.

The most commonly detected cardiac finding after beta-hemolytic streptococcal infection is acute rheumatic fever, which is discussed in detail in Chapter 66 .

Involvement of the heart by the streptococcus may produce a myocarditis that is distinct from acute rheumatic carditis.[451] It is characterized by an interstitial infiltrate composed of mononuclear cells with occasional polymorphonuclear leukocytes; the infiltrate may be focal or diffuse and may be localized to the subendocardial or perivascular region. There may be small areas of myocardial necrosis. ECG abnormalities, including prolongation of the PR and QT intervals, occur frequently. Although these abnormalities are rarely associated with other clinical manifestations of myocardial involvement, sudden death, conduction disturbances, and arrhythmias may occur.

TUBERCULOSIS.

Involvement of the myocardium by *Mycobacterium tuberculosis* (not as a complication of tuberculous pericarditis) is rare, particularly since the introduction of drugs effective against tuberculosis (Fig. 48-31) .[452] Most cases of myocardial tuberculosis are clinically silent and are diagnosed only at autopsy. Tuberculous involvement of the myocardium occurs by means of hematogenous or lymphatic spread or directly from contiguous structures; it may lead to arrhythmias, including atrial fibrillation and ventricular tachycardia, complete atrioventricular block, congestive heart failure, left ventricular aneurysms, and sudden death.[452] [453]

WHIPPLE DISEASE

Although overt involvement is rare, intestinal lipodystrophy, or Whipple disease, is not uncommonly associated with cardiac involvement, and periodic acid-Schiff (PAS)-positive macrophages may be found in the myocardium, pericardium, and heart valves of patients with this disorder.[454] [455] Coronary artery lesions, with smooth muscle necrosis, panarteritis, and medial scarring, may be seen. Electron microscopy has demonstrated rod-shaped structures in the myocardium similar to those found in the small intestine, and these represent the causative agent of the disease, *Tropheryma whippelii,* an agent related to the actinomycetes.[454] There may be an associated inflammatory infiltrate and foci of fibrosis. The valvular fibrosis may be severe enough to result in aortic regurgitation and mitral stenosis. Although usually asymptomatic, nonspecific ECG changes are most common; systolic murmurs, pericarditis, complete heart block, and even overt congestive heart failure may occur.[454] The cardiac manifestations of Whipple disease may be overshadowed by the prominent gastrointestinal symptoms that often are present. Antibiotic therapy appears to be effective in treating the basic disease; however, relapses can occur, often more than 2 years after initial diagnosis.

SPIROCHETAL INFECTIONS

LEPTOSPIROSIS (WEIL DISEASE).

Most patients with leptospiral infections have mild or subclinical disease and little evidence of heart involvement. Cardiac involvement in severe or fatal leptospirosis is common, however, with 50 to 100 percent of fatal cases demonstrating evidence of myocarditis.[456] Many patients with clinical systemic disease demonstrate atrial fibrillation, first-degree heart block, and transient ST segment and T wave abnormalities, presumably reflecting myocarditis, although significant left ventricular dysfunction is uncommon.[457] Bradycardia despite fever, ventricular premature depolarizations, congestive heart failure, and pericarditis may be seen as well. The pathological findings in the occasional fatal case include petechiae or large loci of hemorrhage (often located in the epicardium), an interstitial myocardial infiltrate (often subendocardial in location), aortitis, and coronary arteritis.

LYME CARDITIS.

Lyme disease is caused by a tickborne spirochete (*Borrelia burgdorferi*).[458] It usually begins during the summer months with a characteristic rash (erythema chronicum migrans), followed in weeks to months by neurological, joint, or cardiac involvement; some clinical manifestations may persist for years.[458]

About 10 percent of patients with Lyme disease develop evidence of transient cardiac involvement, the most common manifestation being variable degrees of atrioventricular block[459] [460] [461] at the level of the atrioventricular node. Syncope due to complete heart block is frequent with cardiac involvement because often there is an associated depression of ventricular escape rhythms. Ventricular tachycardia occurs uncommonly.[459] Diffuse ST segment and T wave abnormalities and transient, usually asymptomatic, left ventricular dysfunction may be found in some patients, although cardiomegaly or symptoms of congestive heart failure are rare.[460] [462] A positive gallium or indium antimyosin antibody scan may point to suspected cardiac involvement in this disease.[463] The demonstration of spirochetes in myocardial biopsies of some patients with Lyme carditis suggests that the cardiac manifestations are due to a direct toxic effect, although there is speculation that immune-mediated mechanisms may be involved as well.

The value of specific therapy in Lyme carditis remains uncertain, and even without therapy the disease usually is self-limited with complete recovery the rule.[457] Nevertheless, it is thought that treating the early manifestations of the disease may prevent development of late complications.[458] Patients with second-degree or complete heart block should be hospitalized and undergo continuous ECG monitoring. Temporary transvenous pacing may be required for up to a week or longer in patients with high-grade block. Although the efficacy of antibiotics is not established, they are utilized routinely in Lyme carditis. Intravenous antibiotics (ceftriaxone, 2 gm, or penicillin G, 20 million units daily for 14 days) are suggested, although oral antibiotics (doxycycline, 100 mg twice daily, or amoxicillin, 500 mg three times daily for 14 to 21 days) may be used when there is only mild cardiac involvement (first-degree atrioventricular block of less than 40 milliseconds duration).[464] Whether antiinflammatory agents (salicylates, corticosteroids) can ameliorate heart block is not clear.

RELAPSING FEVER.

Many infections are currently observed in Ethiopia. During pandemics, mortality may be particularly high, reaching 70 percent, although sporadic cases are often more benign. Cardiac involvement is said to be a common complication and is often implicated as a cause of death, although one report involving 63 children did not find evidence of cardiac involvement.[465] Atrioventricular conduction

defects occur frequently and may be responsible for sudden death, although tachyarrhythmias have also been implicated. Numerous petechiae are observed with a diffuse histiocytic interstitial infiltrate, particularly around small arterioles in the left ventricle.

SYPHILIS.

Aortitis is the most common manifestation of luetic involvement of the cardiovascular system (see Chap. 40). Aortic regurgitation and coronary ostial narrowing are associated findings. Syphilitic involvement of the myocardium itself in the form of gumma formation is uncommon and usually unsuspected clinically. Involvement of the base of the interventricular septum may result in damage to the conduction system and atrioventicular block. In one case a ruptured left ventricular aneurysm was found as a result of syphilitic endarteritis.[466]

FUNGAL INFECTIONS OF THE HEART

Cardiac fungal infections occur most frequently in patients with malignant disease and/or those receiving chemotherapy, corticosteroids, radiation, or immunosuppressive therapy. Cardiac surgery, intravenous drug abuse, and infection with HIV are also predisposing factors for fungal cardiac involvement.

ACTINOMYCOSIS.

Myocarditis is a rare complication of actinomycotic infection, occurring in less than 2 percent of patients; more commonly, it produces pericardial or endocardial disease.[467] However, cardiac involvement is quite serious when it does occur. Involvement of the heart most commonly is the result of direct extension of disease within the thorax. Initially the pericardium is invaded, with eventual obliteration of the pericardial space. The myocardium may be involved by extension of the pericardial process. Myocardial seeding is less common. The myocardial lesion is a suppurative, necrotizing abscess containing the organism, surrounded by granulation tissue. Both right- and left-sided failure are common manifestations.[467] A pericardial rub may be heard, sometimes associated with clinical evidence of a pericardial effusion or constriction.

ASPERGILLOSIS.

Myocardial involvement is not uncommon in generalized aspergillosis, and when it occurs it is usually fatal.[468] It is being encountered increasingly in the immunocompromised patient.[469] On pathological examination, myocardial necrosis and infarction caused by thrombosis of vessels that contain fungal mycelia are commonly seen, along with myocardial abscesses and pericardial involvement. The ECG may be normal in the face of significant myocardial damage, but T wave changes may be present. The diagnosis of *Aspergillus* infection is often difficult.[469] Identification of *Aspergillus* through open-lung biopsy, aspiration lung biopsy, transtracheal aspiration, or bronchial brush technique may be successful. Treatment is difficult and usually unsuccessful.

BLASTOMYCOSIS.

Involvement of the heart by the fungus is quite uncommon, even in the immunocompromised heart. When involvement occurs, it is most often by direct extension from the pericardium.

CANDIDIASIS.

Disseminated candidal infections are common opportunistic infections, particularly in the compromised host. Endocarditis is the most frequent manifestation of cardiac involvement (see Chap. 47), occurring most commonly in cardiac surgical patients or drug addicts, although multiple abscesses of the myocardium may occur as associated or independent findings. Complete heart block may be caused by microabscesses of the conduction system.

COCCIDIOIDOMYCOSIS.

Involvement of the heart is rare in patients with generalized coccidioidomycosis. The hearts may be grossly normal, although epicardial lesions with resultant pericarditis are common, and progression to constrictive pericarditis may occur (see Chap. 50). A nonspecific, focal interstitial, and perivascular cellular infiltrate with associated muscle fiber degeneration and interstitial edema is commonly found, although granulomas containing fungi are also seen sometimes.

CRYPTOCOCCOSIS.

Cryptococcal infection of the myocardium occurs most commonly in immunocompromised patients with disseminated malignancy or HIV infection. Pathological examination may show cardiac dilatation, with epithelial granulomas, giant cells, and an inflammatory infiltrate.[470] When congestive heart failure occurs, pulmonary congestion and muffled heart sounds may be found on physical examination, and cardiomegaly on the chest roentgenogram. The ECG may show first-degree atrioventricular block and T wave inversions; ventricular arrhythmias have been observed.

HISTOPLASMOSIS.

Cardiac involvement in histoplasmosis is rare and usually is related to mediastinal fibrosis, the most serious complication of histoplasmosis.[471] Pericarditis with effusion may occur (see Chap. 50), and superior vena caval obstruction has been observed.[471] Myocardial involvement is uncommon, although atrial arrhythmias and T wave

abnormalities have been reported.

MUCORMYCOSIS.

Cardiac involvement in the setting of disseminated mucormycosis occurs in about 20 percent of patients and is characterized by fungal invasion of the coronary arteries with resultant areas of myocardial infarction. Valvular and pericardial involvement may be seen as well. Clinical manifestations are nonspecific, and cardiac involvement often is not suspected but may include congestive heart failure, arrhythmias, conduction defects, and endocarditis.[472]

PROTOZOAL MYOCARDITIS

Trypanosomiasis (Chagas Disease)

Chagas disease is caused by the protozoan *Trypanosoma cruzi.* The major cardiovascular manifestation is an extensive myocarditis that typically becomes evident years after the initial infection. The disease is prevalent in Central and South America, particularly in Brazil, Argentina, and Chile, where it is a major public health problem (Fig. 48-32) . Upward of 20 million people are thought to be infected with the parasite, and an estimated 100 million are at risk of infection.[473] In rare cases, the disease may be found in nonendemic areas as a consequence of transfusion with contaminated blood products; somewhat more common is emigration of patients with the disease to nonendemic areas.[474]

The natural history of Chagas disease is characterized by three phases: acute, latent, and chronic. During the *acute phase,* the disease is transmitted to humans (usually below the age of 20 years) through the bite of a reduviid bug (subfamily Triatominae), which harbors the parasite in its gastrointestinal tract.[473] [475] This insect acquires the disease from feeding on infected animals, including the armadillo, raccoon, opossum, and skunk as well as domestic dogs and cats. The reduviid bug, popularly known in Argentina as *vinchuca,* meaning "to let oneself drop," lives in the walls and roofs of houses and, during nocturnal feedings, drops from the ceiling onto the sleeping person below. The bug then often bites the person around the eyes, and infection of the human host occurs when the trypanosomes in the animal's feces gain entry through abraded skin or through the conjunctivae.[473] Occasionally, this results in unilateral periorbital edema and swelling of the eyelid, termed the

Figure 48-32 Distribution of Chagas disease in the Americas. *(From Acquatella H: Chagas' disease. In Abelmann WH, Braunwald E [eds]: Atlas of Heart Diseases. Vol 2. Cardiomyopathies, Myocarditis, and Pericardial Disease. Philadelphia, Current Medicine, 1995, pp 8.1-8.18.)*

Romana sign, whereas entry through the skin may result in a lesion called a *chagoma.* [473] [475] Transmission may occur through blood transfusions; unfortunately, adequate screening to preclude transfusion-related disease is not possible in many areas due to financial and logistic constraints.[473]

ACUTE TRYPANOSOMIASIS.

After inoculation, the protozoa multiply and then migrate widely throughout the body. In less than 10 percent of cases an acute illness occurs; the latter is fatal in about 10 percent of patients.[474] [475] Pathological examination during the acute phase often reveals parasites in the cardiac fibers with a marked cellular infiltrate, particularly around cardiac cells that have ruptured and released the parasites.[475] Involvement may extend into the endocardium, resulting in thrombus formation, and into the epicardium, resulting in pericardial effusion. The pathogenesis of the myocardial lesions of acute Chagas disease appears to relate in large part to immune lysis by antibody and cell-mediated immunity directed against antigens released from *T. cruzi*-infected cells, which become adsorbed onto the surface of infected and noninfected host cells.[473]

Clinical Manifestations.

These include fever, muscle pains, sweating, hepatosplenomegaly, myocarditis with congestive heart failure, pericardial effusion, and, occasionally, meningoencephalitis.[473] [475] Most patients recover, and their symptoms resolve over several months. Young children most commonly develop clinical acute disease and generally are more seriously ill than adults.

LATENT AND CHRONIC TRYPANOSOMIASIS.

The disease then enters a *latent phase* without clinical symptoms; however, there is evidence of early and progressive subclinical cardiomyopathy. ECG changes often appear at this stage and are a marker for the eventual clinical heart disease and increased mortality to become evident later. At an average of 20 years after the initial (and usually unrecognized) infestation, approximately 30 percent of infected individuals develop findings of *chronic Chagas disease,* the manifestations of which cover a wide spectrum from asymptomatic but seropositive patients through those with ECG abnormalities to those with advanced disease characterized by cardiomegaly, congestive heart failure, arrhythmias, thromboembolic phenomena, atypical chest pain, right bundle branch block, and sudden death.[474] In the advanced stage, cardiac dilatation typically involves all the cardiac chambers, although right-sided enlargement may predominate.[474]

The central paradox in the pathogenesis of this disorder is the poor correlation between the level of parasitemia and the severity of disease.[476] It is not unusual to be unable to detect parasites in patients dying of Chagas disease,[477] although evidence of prior infection may be detected more frequently by the much more sensitive polymerase chain reaction technique.[478] *T. cruzi* antigen is frequently found in biopsy specimens of the heart in chronic Chagas heart disease.[479] [480] An autoimmune etiological mechanism has been proposed, and this may explain the lack of correlation of parasitemia with disease severity.[476] [479] [480] Based on animal models, it appears that self-reactive cytotoxic T lymphocytes develop after the initial infection and produce various cytokines.[476] This results in the lysis of normal host cells, perhaps related to cross-reacting antigens of *T. cruzi* and striated muscle.[474] [481] A variety of antibodies against myocyte sarcoplasmic reticulum, laminin, and other constituents have also been implicated in the pathogenesis of Chagas myocarditis.[479] It is thought that the acute phase results in the release from parasite-modified host cells of self-components that are immunogenic.[474] Another hypothesis suggests that cardiac parasympathetic denervation leads to eventual chronic Chagas disease.[474] [477]

Pathology.

Nerves and autonomic ganglia are frequently abnormal, and megaesophagus and megacolon may occur; less commonly, there is dilatation of the stomach, duodenum, ureter, and bronchi. Different strains of *T. cruzi* may account for the geographical differences in the expression of Chagas disease; megaesophagus and megacolon are common in Brazil but quite uncommon in Central America and Mexico, and megaesophagus is unusual in Venezuela.[473] Lesions of the cardiac nerves are routinely found in patients with chronic Chagas disease, with evidence of cardiac parasympathetic denervation.[473] Pathological cardiac findings include cardiac enlargement, with dilatation and hypertrophy of all cardiac chambers. In more than half the patients, the left (and occasionally right) ventricular apex is thin and bulging, resembling an aneurysm.[477] Thrombus formation is frequent and may fill much of the apex; the right atrium also frequently contains thrombus. It has been suggested that these characteristic apical aneurysms (Fig. 48-33) may be the result of intravascular platelet aggregation leading to focal myocardial necrosis.[479]

The microscopic findings are principally those of extensive fibrosis, particularly of the left ventricle.[474] [482] A chronic cellular infiltrate composed of lymphocytes, plasma cells, and macrophages often is present.[473] Increases in arteriole and capillary diameters have been reported.[482] Preferential involvement of the right bundle branch and the anterior fascicle of the left bundle branch by inflammatory and fibrotic changes explains the frequent occurrence of right bundle branch and left anterior fascicular block.[473] The basement membranes of capillaries, vascular smooth muscle cells, and myocytes are thickened.[479] It is unusual to be able to find parasites in the myofibers of autopsied patients.[477]

Clinical Manifestations.

These include anginal chest pain, symptomatic conducting system disease, and sudden death; chronic progressive heart failure, often predominantly right sided, is the rule in advanced cases.[474] Thus, although pulmonary congestion is occasionally noted, the usual findings include fatigue due to diminished cardiac output, peripheral edema, ascites, and hepatic congestion. Tricuspid regurgitation is often present, particularly in patients with severe right-sided heart failure, although mitral regurgitation is frequently present as well. The S_2 is widely split, often with an accentuated pulmonic component, reflecting the combined effects of right bundle branch block and pulmonary hypertension. Autonomic dysfunction is common, with marked abnormalities in the expected reflex changes in heart rate produced by various maneuvers. Deaths result most commonly from pump failure or occur suddenly. Apical aneurysms and left ventricular dilation place patients at high risk for the

latter.[483]

Laboratory Findings.

The chest roentgenogram often demonstrates severe cardiomegaly, with or without pulmonary venous hypertension. The serum aldolase is usually elevated.[484] ECG abnormalities are the rule late in the course of the disease, particularly in patients who are seroreactive to *T. cruzi* antigen. Right bundle branch block, left anterior hemiblock, atrial fibrillation, and ventricular premature depolarizations are the most common findings in patients with chronic Chagas disease.[473] [485] ST segment and T wave abnormalities also are common, as are Q waves; P wave abnormalities and atrioventricular block are seen less frequently.[473] Early in the disease, the ECG may be normal or nearly so. Administration of the antiarrhythmic agent ajmaline may precipitate the appearance of ECG abnormalities and thus identify patients with as yet clinically silent cardiac involvement.[473] Furthermore, electrophysiological testing of asymptomatic patients, even those with normal ECGs, may demonstrate abnormalities of the conducting system in many.

Ventricular arrhythmias are a prominent feature of chronic Chagas disease.[473] [479] [480] Frequent ventricular premature depolarizations, often with multiple morphologies, are seen frequently, and bouts of ventricular tachycardia may occur. Ventricular arrhythmias are particularly common during and after exercise,[473] occurring in the majority

Figure 48-33 Left ventriculogram in the right anterior oblique view of a 55-year-old woman with chronic Chagas disease. Multiple left ventricular aneurysms are noted in anterobasal, anterior, and inferior aspects of left ventricle (circled, right). *(From Venegoni P, Bhatia HS: Chagas' disease and ventricular arrhythmias. Circulation 96:1363, 1997. Copyright 1997, American Heart Association.)*

of patients subjected to stress ECG testing (including some without any clinical evidence of cardiac involvement). Ventricular tachycardia induced by electrophysiological testing is most common in patients with evidence of conduction abnormalities on the ECG, low ejection fraction, and apical left ventricular aneurysm and may predict sudden death.[486] [487] Syncope and sudden death due to ventricular fibrillation are constant threats and may develop even before cardiomegaly or heart failure.[473] [488] [489] Sinus bradycardia may also be seen, even in patients with severe heart failure when a tachycardia would be expected, presumably related to cardiac autonomic dysfunction.[473] Atrial arrhythmias, including atrial fibrillation (often with a slow ventricular response), also may occur.[473] Thromboembolic phenomena are a frequent complication, occurring in more than 50 percent of the patients.[490]

The echocardiographic findings in advanced cases are those of a dilated cardiomyopathy with increased end-diastolic and end-systolic volumes and reduced ejection fraction, often with enlargement of the left atrium and right ventricle.[473] Diastolic filling of the left ventricle is frequently abnormal, even in those without other clinical or echocardiographic evidence of cardiac involvement. In the majority of advanced cases, the echocardiographic appearance is distinctive, with left ventricular posterior wall hypokinesis and relatively preserved interventricular septal motion; an apical aneurysm is often seen on two-dimensional echocardiography. Ten to 15 percent of asymptomatic patients demonstrate apical dyskinesis.

Radionuclide ventriculography may, like echocardiography, demonstrate right or left ventricular wall motion abnormalities in the absence of an overall depression of global ventricular function. Perfusion scanning with thallium-201 may show fixed defects (corresponding to areas of fibrosis) as well as evidence of reversible ischemia.[491] MRI can identify morphological and functional aspects of cardiac involvement; with the use of gadolinium as a contrast medium, it can identify patients with more active myocardial disease.[492]

Left ventricular cineangiography in advanced cases shows a dilated, hypokinetic left ventricle with one large or several apical aneurysms (see Fig. 48-33) containing intracavitary thrombus, often with evidence of mitral regurgitation.[473] Coronary angiography is usually normal, although abnormalities of the coronary microcirculation have been suggested as a cause of the clinical manifestations of Chagas disease.

The complement-fixation test (Machado-Guerreiro test) is useful in diagnosis; it has high sensitivity and specificity for the identification of chronic Chagas disease.[473] Also used in diagnosis are the indirect immunofluorescent antibody, the enzyme-linked immunosorbent assay, and the hemagglutination tests.[473] In endemic areas, perhaps the most widely used test is the detection of parasites in the blood of patients with chronic Chagas disease (which occurs in upward of 50 percent of cases) by means of xenodiagnosis.[493] The patient is bitten by reduviid bugs bred in the laboratory; the subsequent identification of parasites in the intestine of the insect is proof of infection in the human host.

MANAGEMENT.

The treatment of Chagas disease remains difficult; although slowly progressive at first, once cardiac decompensation develops there is usually a rapid and inexorable progression to death, which is usually due to arrhythmia, although congestive failure and systemic thromboembolism account for additional mortality.[474] Patients at greatest risk of mortality are those with left ventricular enlargement and especially those with impaired left ventricular function.[485] [488] Major efforts are aimed at interrupting transmission of the parasite to humans; such vector control methods have been generally successful.[473] They may prevent not only the initial infection but also reinfection that may play a role in determining the severity of the resulting cardiomyopathy.

Amiodarone appears to be effective in controlling the ventricular arrhythmias frequently seen in Chagas disease, although whether this translates into improved survival remains to be established.[494] ICDs are useful, and the indications are similar to those in patients with life-threatening arrhythmias associated with other causes (see Chap. 23).[495] Anticoagulation may be of some benefit in preventing recurrent thromboembolic episodes.[490] Although antiparasitic agents such as nifurtimox, benzimidazole, and itraconazole are effective in reducing parasitemia and are useful in acute

disease, no evidence indicates that they are efficacious in curing the late phases of the disease.[473] [496] A promising avenue of approach appears to be immunoprophylaxis, although a clinically useful vaccine is not yet available. Insertion of an ICD and the latissimus dorsi muscle wrap around the heart (dynamic cardiomyoplasty) have been used sparingly but are not practical options for the vast majority of patients. Similarly, heart transplantation have been performed in a few patients, but the results so far appear to be inferior to those found in other conditions, and episodes of parasitemia and recurrent Chagas disease may be a problem.[497] [498]

AFRICAN TRYPANOSOMIASIS.

African sleeping sickness, caused by *Trypanosoma gambiense* or *T. rhodesiense,* may be associated with myocardial abnormalities, although they are usually of less functional significance than in Chagas disease. *T. rhodesiense,* in particular, may lead to cardiac failure,[499] although the central nervous system findings (excessive somnolence) usually dominate the clinical picture.

Pathological examination often reveals pericardial fluid. The heart is not as greatly dilated and hypertrophied as it is in Chagas disease and may appear to be grossly normal. There is often epicardial thickening with a cellular exudate composed of lymphocytes, plasma cells, and histiocytes. The myocardium typically displays a diffuse interstitial infiltrate, often with zones of patchy fibrosis and interstitial edema.

Nonspecific ECG changes, commonly ST segment and T wave abnormalities and prolongation of the QT interval, are observed in at least half of the patients.[499] Unlike Chagas disease, arrhythmias and conduction disturbances are usually not prominent features, and the arterial pressure is usually normal. Some patients have asymptomatic cardiomegaly, although both pulmonary congestion and peripheral edema have been reported.

TOXOPLASMOSIS.

Toxoplasma infections are caused by an obligate intracellular parasite (*T. gondii*); both congenital and acquired forms may occur. Symptomatic acquired toxoplasmic infections involving the heart are uncommon. They occur most commonly in immunosuppressed patients with malignant diseases and occasionally in patients with the acquired immunodeficiency syndrome and after cardiac or bone marrow transplantation.[500] An inflammatory infiltrate, often with eosinophils and variable degrees of

edema and degeneration of the muscle bundles, and pericardial effusion are often present.

Most adult cases are asymptomatic, but *Toxoplasma* infections may produce a severe, fatal disease with multisystemic involvement. Toxoplasmic myocarditis, often with pericarditis, may occur as an isolated disease process or as part of a multisystemic disseminated disease. Manifestations may include arrhythmias (atrial and ventricular), sudden death, atrioventricular block, pericarditis, and heart failure.[501] Large pericardial effusions may be seen on occasion. Diagnosis may be aided by endomyocardial biopsy.[502]

Treatment is with a combination of pyrimethamine and triple sulfonamides, but the response to therapy is variable; treatment appears to have no effect on the cyst form.[500]

MALARIA.

Although myocardial changes may be demonstrated during the course of malaria, particularly with *Plasmodium falciparum,* clinical findings to indicate cardiac involvement are rare.[503] [504] The heart generally demonstrates few gross abnormalities. The principal findings are histological. The capillaries are often filled and even distended with an accumulation of parasites, sometimes totally occluding the lumen of the vessels. Thrombosis of the capillaries and ischemic myocardial changes may be seen.[504] Focal myocardial damage may be present, along with an interstitial infiltrate composed of lymphocytes, plasma cells, and macrophages. In rare cases, cardiac failure may contribute to or even cause death.[504] ST segment and T wave changes on the ECG may be the only clinical indications of myocardial involvement.[503]

METAZOAL MYOCARDIAL DISEASE

ECHINOCOCCUS (HYDATID CYST).

Echinococcus is endemic in many sheep-raising areas of the world, particularly Argentina, Uruguay, New Zealand, Greece, North Africa, and Iceland, but cardiac involvement in hydatid disease is uncommon, occurring in less than 2 percent of cases.[505] The usual host of *Echinococcus granulosus* is the dog, but humans may serve as intermediate hosts (rather than the sheep, the usual intermediate host) if they accidentally ingest ova from contaminated dog feces.

When cardiac involvement is present, the cysts usually are intramyocardial in the interventricular septum or left ventricular free wall (Fig. 48-34) ; involvement of the right ventricle or atrium may occur.[505] Involvement of the tricuspid valve may be seen on occasion; in most cases, a single cardiac cyst is present.

A myocardial cyst may degenerate and calcify, develop daughter cysts, or rupture. Rupture of the cyst is the most dreaded complication; rupture into the pericardium may result in acute pericarditis, which may progress to chronic constrictive pericarditis.[505] Rupture into the cardiac chambers may result in systemic or pulmonary emboli.[506] Rapidly progressive pulmonary hypertension may occur with rupture of right-sided cysts, with subsequent embolization of hundreds of scolices into the pulmonary circulation. The liberation of hydatid fluid into the circulation may produce profound, fatal circulatory collapse due to an anaphylactic reaction to the protein constituents of the fluid.[505]

Symptoms depend on the location, size, and integrity of the cyst; patients may be asymptomatic or in profound circulatory collapse. It is estimated that only about 10 percent of patients with cardiac hydatid cysts have clinical manifestations.[505] The ECG may reflect the location of the cyst; T wave changes and loss of QRS voltage may occur with left ventricular involvement, whereas atrioventricular conduction defects or right bundle branch block may be seen with involvement of the interventricular septum. Chest pain is usually due to rupture of the cyst into the pericardial space with resultant pericarditis. Large cystic masses may sometimes produce right-sided obstruction.[505]

Diagnosis.

Recognition of an echinococcal cyst of the heart is a relatively simple matter if there is evidence of cysts in other organs, particularly the liver and lung. However, a cardiac cyst may be an isolated, solitary finding. The chest roentgenogram frequently shows an abnormal cardiac silhouette or a calcified lobular mass adjacent to the left ventricle.[505] Although CT and MRI may aid in the detection and localization of heart cysts, two-dimensional echocardiography is thought to be the best choice (see Fig. 48-34). [505] Eosinophilia, present in some patients, is a useful adjunctive finding. The Casoni skin test is not very helpful because both false-positive and false-negative results occur. Serological tests, including hemagglutination and complement fixation, may be more useful, but their predictive accuracy is limited.[505]

Management.

Until recently, treatment for hydatid disease was limited to surgical excision.[507] Experience suggests that the benzimidazole derivatives mebendazole and albendazole may be somewhat useful in the medical management of this disease.[505] [508] Despite the availability of drug therapy, adjuctive surgical excision is generally recommended, even for asymptomatic patients, because of the significant risk of rupture of the cyst and its attendant serious and sometimes fatal consequences.[505] The surgical results have been generally favorable.

VISCERAL LARVA MIGRANS.

People are occasional accidental hosts of the roundworm infestations of dogs due to *Toxocara canis,* but cardiac involvement is rare. Most cases occur in children 1 to 3 years of age.[509] Myocarditis may occur in association with invasion of the myocardium by larvae. The myocardial lesions include granulomas or extensive inflammatory infiltrates (often with eosinophils) with foci of muscle necrosis. Congestive heart failure and death may occur, although asymptomatic cardiac involvement may be seen as well.

SCHISTOSOMIASIS AND RELATED DISEASE.

Direct cardiac involvement

Figure 48-34 Involvement of interventricular septum by a hydatid cyst. *Left,* Transthoracic two-dimensional echocardiogram of parasternal long-axis view showing a 3-cm diameter hydatid cyst (hc) in the upper ventricular septum. *Right,* Transesophageal echocardiography showing a hydatid cyst (hc) having a rounded and well-contrasted capsule. la = left atrium; lv = left ventricle; rv = right ventricle; ao = aorta. *(From Aupetit J, Ritz B, Ferrini M, et al: Images in cardiovascular medicine: Hydatid cyst of the interventricular septum. Circulation 95:2325, 1997. Copyright 1997, American Heart Association.)*

in schistosomiasis, heterophyiasis, and cysticercosis is distinctly unusual. The principal cardiovascular manifestation of schistosomiasis is right-sided heart overload as a consequence of embolization of the ova to the pulmonary vasculature, with attendant pulmonary hypertension.

TRICHINOSIS.

Infestation with *Trichinella spiralis* is a common human finding. Mild myocarditis has been said to be a frequent finding, but recent data suggest that clinically detectable cardiac involvement occurs in a minority of patients.[510] Symptomatic involvement is uncommon and may be responsible for the majority of fatalities.[511] Less frequently, death is due to pulmonary embolism secondary to venous thrombosis or to neurologic complications.

Although the parasite may invade the heart, it does not usually encyst there, and it is rare to find larvae or larval fragments in the myocardium. Nonetheless, pathological findings at autopsy may be impressive. The heart may be dilated and flabby, and a pericardial effusion may be present.[510] A prominent focal infiltrate composed of lymphocytes and eosinophils is commonly found, with occasional microthrombi in the intramural arterioles. Areas of muscle degeneration and necrosis are present.

Clinical Manifestations.

Myocarditis usually is mild and goes unnoticed, but in occasional cases it is manifested by congestive heart failure and chest pain, usually appearing around the third week of the disease, when the general constitutional symptoms are abating. Physical examination may be normal, or there may be gross cardiomegaly with severe congestive heart failure. Sudden death may occur, usually in the fourth to eighth week of the illness.

ECG abnormalities may be detected in about 10 percent of patients with trichinosis and parallel the time course of clinical cardiac involvement, initially appearing in the second or third week and usually resolving by the seventh week of the illness. The most common ECG abnormalities are repolarization abnormalities and ventricular premature complexes.[510] The ECG changes usually resolve completely.

The diagnosis is usually based on the demonstration of a positive indirect immunofluorescent antibody test in a patient with the clinical features of trichinosis. Eosinophilia, when present, is a supportive finding. The skin test is usually but not invariably positive. Treatment is with anthelmintics and corticosteroids; dramatic improvement in cardiac function has been reported after their use.

Braunwald: Heart Disease: A Textbook of Cardiovascular Medicine, 6th ed., Copyright © 2001 W. B. Saunders Company

Toxic, Chemical, Immune, and Physical Damage to the Heart

A wide variety of substances other than infectious agents may act on the heart and damage the myocardium. In some cases, the damage is acute, transient, and associated with evidence of an inflammatory myocardial infiltrate with myocyte necrosis (e.g., with the arsenicals and lithium); in other cases, a hypersensitivity reaction occurs, without prominent evidence of necrosis (e.g., with sulfonamides). Other agents that damage the myocardium may lead to chronic changes with resulting histological evidence of fibrosis and a clinical picture of a DCM. Furthermore, many offending stimuli may be associated with both acute and chronic phases (e.g., alcohol, doxorubicin). The extent of myocardial damage often is related to the dose and rate of exposure to the toxin.

Numerous chemicals and drugs (both industrial and therapeutic) may lead to cardiac damage and dysfunction. Several physical agents (e.g., radiation and excessive heat) may also result in myocardial damage. Furthermore, myocardial involvement may be evident in a variety of systemic disease, which are described in Part V of this book.

Cocaine

The illicit use of this drug has increased dramatically. It may be associated with a variety of cardiovascular complications, including myocardial ischemia and infarction (unassociated with obstructive coronary artery disease in about one third of cases), accelerated atherosclerosis, arrhythmias and sudden death, electrophysiological effects, coronary vasoconstriction, myocarditis, DCM, rupture of the aorta, cerebrovascular events, increased platelet aggregation, arterial thrombosis, and an apparent predisposition to the development of endocarditis.[512] [513] [514] [515] [516] The actual frequency of these complications is in some dispute[517] ; the number of adverse events reported in the literature is far less than the casual impression of medical caregivers in inner-city hospitals would suggest. In one study of cocaine abusers who presented to the hospital with chest pain, the frequency of documented myocardial infarction was low.[518] The effects of cocaine on the myocardium itself include transient depression of ventricular function whether the drug is taken acutely or chronically,[519] [520] scattered areas of myocardial necrosis and myocarditis unrelated to coronary artery disease (which in some cases include contraction band necrosis), and fibrosis.[521] In a some cases there has been evidence of dilated cardiomyopathy.[522] Even asymptomatic cocaine abusers may have myocardial depression, albeit clinically silent.[520]

The cardiovascular effects of cocaine likely are related to its principal pharmacological effects: blocking the reuptake of catecholamines in the presynaptic neurons; blocking sodium channels, leading to local anesthetic, membrane-stabilizing effects; and reducing spontaneous sympathetic activity as a result of effects on the brain stem.[521] It has been speculated that the myocardial damage seen with cocaine relates to excess catecholamines damaging myocytes because their reuptake is blocked; this may lead to calcium overload of the cells, or perhaps to local vasoconstriction with subsequent ischemic damage. Coronary vasoconstriction is mediated by action on alpha-adrenergic receptors and is intensified by cigarette smoking and by beta-adrenergic blockade.[523] The increase in myocardial oxygen needs resulting from tachycardia and hypertension, combined with coronary vasoconstriction, can cause myocardial ischemia and is likely responsible for the observation of more than 20-fold increase in the risk of myocardial infarction in the hour after cocaine use.[519] The monocellular infiltrate (myocarditis) that has been found may merely be a reaction to the associated myocyte death, or it could be a hypersensitivity reaction to the cocaine, a metabolite,[524] or a contaminant.

The Coronary Artery Risk Development in Young Adults (CARDIA) study reported that cocaine use was related to being male, single, unemployed, and black, and to higher levels of other substance use.[525] Patients presenting to the emergency department with chest pain are infrequently asked about cocaine use.[524] Although acute myocardial infarction is a real risk in cocaine users, it may be caused by skeletal muscle injury, with elevation of circulating creatine kinase or CK-MB. Therefore, cardiac-specific troponin T or I is especially useful for detecting myocardial necrosis in these patients.[526] Similarly, myocardial perfusion imaging with technetium-99m sestamibi has been found to be useful in excluding infarction in patients with cocaine-associated chest pain.[527]

Treatment of cocaine-induced myocardial ischemia consists of nitrates, alpha-adrenoceptor blockers, calcium antagonists, and thrombolytic therapy (for acute myocardial infarctions). Beta-adrenoceptor blockers probably should be avoided unless hypertension or tachycardia are present, because they have been shown to further reduce coronary blood flow and increase coronary vascular resistance during cocaine use and may predispose to cocaine-mediated cardiac conduction defects.[513] [514] [521] The ACC/AHA Guidelines for the management of unstable angina listed recommend "... immediate arteriography, if possible, in patients whose

---

ST segments remain elevated after nitroglycerin and calcium channel blocker. Thrombolysis if thrombus is detected." Additional recommendations include thrombolytic therapy if ST segments remain elevated despite nitroglycerine and calcium blockers and coronary arteriography is not possible, as well as coronary arteriography, if available, for patients with new ST depression or T-wave changes, who are unresponsive to nitroglycerin and calcium antagonists.[528]

DAUNORUBICIN AND DOXORUBICIN(See Chap. 69)

INTERFERON-ALPHA(see Chap. 69).

Interferon-alpha is a leukocyte-derived protein used therapeutically to treat malignancies and HIV infections. Cardiotoxicity, usually consisting of hypotension, tachycardia, and transient arrhythmias, occurs in a minority of patients (perhaps up to 10 percent).[522] Several patients have developed congestive heart failure and the clinical picture of a DCM during interferon-alfa therapy; in at least some patients, the cardiomyopathy resolves rapidly with discontinuation of the drug.[522] [529]

INTERLEUKIN-2 (see Chap. 69).

The lymphokine interleukin-2, an antineoplastic agent, has significant cardiovascular toxicity, the most prominent of which is a diffuse capillary leak syndrome with hypotension and tachycardia, although reversible left ventricular dysfunction is seen as well.[529] In about 5 percent of patients, additional cardiotoxicity is seen, consisting of myocardial ischemia, infarction, injury, arrhythmias, and eosinophilic myocarditis.[530]

TRICYCLIC ANTIDEPRESSANTS (see Chap. 70).

Although sinus tachycardia, postural hypotension, disturbances in rhythm, abnormalities of atrioventricular conduction, and even sudden death may be seen with the tricyclic antidepressants, particularly when taken as an overdose, important depression of left ventricular function usually does not occur, even in patients with preexisting heart disease.[529] There has been concern when using tricyclic antidepressants in patients with prior myocardial infarction and/or preexisting ventricular arrhythmias, because these agents have a Class I antiarrhythmic effect, prolong the QT interval, and might be proarrhythmic in these settings. The selective serotonin reuptake inhibitors are remarkably free of cardiovascular toxicity and do not appear to depress ventricular function.[529] They may produce side effects by interacting with the metabolism of drugs mediated through the cytochrome-P450 enzyme system.[530]

PHENOTHIAZINES (see Chap. 70).

The phenothiazines may be associated with a variety of cardiac disturbances, including ECG changes, atrial and ventricular arrhythmias, and sudden death.[531] [532]

Postural hypotension may also be seen. The cardiac effects are largely dose dependent. ECG abnormalities may be observed with as little as 200 mg of thioridazine per day and consist of lengthening of the QT interval and T wave changes. Prolongation of the QT interval may set the stage for the emergence of ventricular arrhythmias, particularly torsades de pointes.[530] [531] Higher doses may lead to frank T wave inversion and increased amplitude of the U wave. Changes in the P wave, QRS complex, and ST segment are usually absent. The ECG abnormalities and arrhythmias resolve with discontinuation of the drug, usually within 48 hours. An occasional patient may require temporary ventricular pacing.

Pathological changes in the hearts of patients who have received phenothiazines and who have died suddenly include the deposition of acid mucopolysaccharide between muscle bundles in periarteriolar regions as well as the conduction system, with myofibrillar degeneration, and endothelial proliferation in the smaller blood vessels, although a direct causal relationship between drug administration and cardiomyopathic changes is only inferential. A variety of explanations have been invoked for the apparent cardiac damage, including direct toxic effects of the phenothiazines on the myocardium, stimulation of higher autonomic centers, and changes in circulating or myocardial levels of catecholamines.

EMETINE.

Cardiovascular changes are said to be common with the chronic use of emetine, a drug often employed in the treatment of amebiasis and schistosomiasis as well as the active ingredient in ipecac syrup (used for childhood poisoning).[533] Myocardial lesions may be observed in some patients at autopsy, and similar cardiac damage is noted in experimental animals given emetine. The myocardial lesions consist of myofibrillar degeneration and necrosis, with an interstitial infiltrate of mononuclear cells and histiocytes.

The ECG, which may be abnormal in 50 percent of treated patients, most commonly shows reduced T wave amplitude or inversion. Prolongation of the QT interval and ST segment shifts may also be seen, although abnormalities of the P wave, PR segment, and QRS complex are infrequent. The ECG changes usually resolve within weeks or months after cessation of treatment. Sinus tachycardia and hypotension may also be seen, as well as transient or permanent left ventricular dysfunction.[534] Only rare fatalities have been reported. Dehydroemetine results in ECG abnormalities similar to those of emetine, but they are less prominent and of shorter duration.

METHYSERGIDE.

The widespread fibrotic reactions seen with this drug can also involve the heart. Up to 1 percent of patients treated long term may develop typically left-sided valvular lesions, resulting in stenosis and regurgitation.[535]

CHLOROQUINE.

This drug has been widely used in the prophylaxis and treatment of a variety of parasitic and other diseases, including collagen and dermatological disorders. ECG changes may be seen with its use, along with conduction disturbances and features of a restrictive cardiomyopathy.[536] In toxic doses, chloroquine may result in depressed cardiac output, bradycardia, arrhythmias, heart block, and death.

ANTIMONY COMPOUNDS.

Various antimony compounds, such as stibophen and tartar emetic, have been widely used in the treatment of schistosomiasis; less toxic agents are now becoming available. The antimony compounds are associated with ECG changes in almost all patients. Typical ECG changes include prolongation of the QT interval with flattening or inversion of T waves. ST segment shifts and P wave changes may be seen, although the QRS complex usually demonstrates no abnormality. The majority of patients do not demonstrate cardiac findings, although chest pain, bradycardia, hypotension, ventricular arrhythmias (including paroxysmal ventricular tachycardia and torsades de pointes), congestive heart failure, and sudden death may occur.[537] [538]

LITHIUM (see Chap. 70).

Lithium carbonate, used in the treatment of bipolar disorders, is associated with T wave changes in one fourth or more of patients who receive the drug.[539] Clinical evidence of myocardial involvement is usually lacking, although intoxication with lithium may be associated on rare occasions with ventricular arrhythmias, symptomatic sinus node abnormalities, atrioventricular conduction disturbances, congestive heart failure, and in rare cases, death.[539] [540] In fatal lithium toxicity, the heart is said to be dilated, with evidence of myofibrillar degeneration associated with a lymphocytic interstitial infiltrate.

HYDROCARBONS.

The fluorinated hydrocarbons, commonly used as aerosol propellants, appear to be cardiac toxins, contrary to their reputation of being inert.[541] In animal models, and occasional humans, the aerosol propellants may cause ventricular tachyarrhythmias, depress myocardial contractility, and lower systemic vascular resistance and arterial pressure.[542] These cardiovascular effects may be involved in the sudden deaths seen in individuals who abuse aerosols for their psychotropic effect.[542]

CATECHOLAMINES.

A severe reversible DCM has been observed in conjunction with pheochromocytoma, and the myocardial damage has been attributed to high levels of circulating catecholamines (see Chap. 64).[543] [544] Similar changes have been demonstrated in experimental animals treated with prolonged infusions of l-norepinephrine.[544] Catecholamines also may produce acute myocarditis, with focal myocardial necrosis, inflammation, epicardial hemorrhages, tachycardia, and arrhythmias.[545] Similar findings have been described with excessive use of beta-adrenoceptor agonist inhalants and methylxanthines in the treatment of decompensated pulmonary disease.[546] The cardiomyopathy associated with pheochromocytoma is one of the conditions that should be considered when heart failure suddenly appears without other obvious explanation.[544]

A variety of mechanisms of myocardial damage have been suggested. A direct toxic effect may be involved, or the damage may be secondary to relative tissue hypoxia because of heightened metabolic demands. Alternatively, the damage may result from changes in autonomic tone, enhanced lipid mobility, calcium overload, damaging effects of catecholamine oxidation products (free radicals), or increased sarcolemmal permeability.[545] Catecholamine-induced vasospasm also may play a role.[544]

LEAD.

The prominent features in lead poisoning generally center on the gastrointestinal and central nervous systems. However, myocardial involvement may contribute to or be the principal cause of death in some cases.[547] ECG changes, atrioventricular conduction defects, and overt congestive heart failure may occur. The ECG and myocardial changes appear to be reversible with chelation therapy.

CARBON MONOXIDE.

Both acute and chronic carbon monoxide toxicity can occur. While central nervous system findings usually dominate the clinical presentation, significant and occasionally fatal cardiac abnormalities have been reported, although some have found no precipitation of arrhythmias following exposure.[548] [549] Because carbon monoxide has a higher affinity for hemoglobin than does oxygen, reduced amounts of oxygen are delivered to the tissues. Thus, the cardiac toxicity may be partially caused by myocardial hypoxia, but a direct toxic effect of the gas on myocardial mitochondria may play an even more important role.[550] The histological features include focal areas of necrosis, most marked in the subendocardium. Focal perivascular infiltrates and punctate hemorrhages are also seen.[550]

Cardiac involvement may appear promptly after exposure, or it may be delayed for up to several days. Palpitations, sinus tachycardia, and various arrhythmias, including ventricular extrasystoles and atrial fibrillation, are common.[551] Bradycardia and atrioventricular block may occur in more severe cases.[551] In patients with ischemic heart disease, angina pectoris and myocardial infarction may be precipitated. ECG ST segment and T wave abnormalities are quite common. Transient right and/or left ventricular wall motion abnormalities may be present.[550] Administration of 100 percent oxygen, bed rest, and surveillance for serious rhythm or conduction abnormalities usually permit rapid recovery.

HYPOCALCEMIA.

In rare patients with chronic hypocalcemia (often

due to hypoparathyroidism), congestive heart failure may occur (see Chap. 16) and resolve only when the serum calcium level is raised.[552] Rapid transfusion of citrated blood can produce hypocalcemia and reversible myocardial depression, as can ambulatory peritoneal dialysis in patients with chronic renal failure.[553]

HYPOPHOSPHATEMIA.

A form of reversible left ventricular dysfunction may be seen with severe hypophosphatemia. Restoration of the serum phosphate level to normal results in hemodynamic recovery.

HYPOMAGNESEMIA.

Focal cardiac necrosis is found in experimental magnesium deficiency and may account for the supraventricular and ventricular arrhythmias and ECG changes that are seen clinically. In addition to arrhythmias, coronary spasm and acute myocardial infarction may be seen.[554] A rare case of fatal cardiomyopathy has been reported.[554] [555]

CARNITINE DEFICIENCY.

Carnitine, an essential cofactor for the oxidation of fatty acids, produces an HCM or DCM in children who have long-standing carnitine deficiency.[556] Carnitine supplementation can lead to symptomatic and functional improvement; determination of carnitine levels therefore is important in children with unexplained cardiomyopathy. Myocardial carnitine levels may be reduced in the hearts of patients with DCM,[557] but the significance of this observation is not known at present.

SELENIUM DEFICIENCY.

Dietary deficiency of the trace element selenium appears to be one of the principal factors responsible for a form of DCM endemic to certain rural areas in China, although the etiological role played by selenium has been questioned.[558] Termed *Keshan disease,* it affects mainly children and young women and apparently is prevented by the prophylactic administration of sodium selenite tablets. A similar cardiomyopathy may be found in westerners subjected to prolonged parenteral hyperalimentation; supplementation with oral selenium may reverse the cardiomyopathy.[559]

SCORPION STING.

The venom of the scorpion is mainly neurotoxic, but cardiac findings may be prominent and even fatal, particularly in children.[560] ECG changes and myocardial damage with elevated serum cardiac enzyme levels are common findings. Hearts are normal on gross examination, with prominent microscopic changes usually but not invariably present, particularly in the subendocardial region and papillary muscles. Degeneration and necrosis of muscle fibers are noted, with interstitial edema and a mononuclear infiltrate. The histological features of scorpion sting suggest high levels of circulating catecholamines and are similar to those seen with experimental catecholamine infusion and in pheochromocytoma.[561]

The ECG often initially shows tall, peaked T waves that progress to inversions and ST segment shifts. Q waves may appear, and the QT interval is usually prolonged. Atrial, junctional, and ventricular arrhythmias may occur. Tachycardia, hypertension, anxiety, diaphoresis, and pulmonary edema--findings resembling those of a massive catecholamine effect--are striking in many patients.[561] A smaller number of patients are seen in shock with peripheral vascular collapse. Most deaths are due to pulmonary edema, presumably the result of left ventricular dysfunction.[560] Occasionally, sudden and unexpected deaths occur in a smaller percentage of patients, presumably as a consequence of arrhythmias. Adrenergic blocking agents and the use of specific antivenom appear to be useful in the management of the cardiovascular manifestation of scorpion stings, although a wide variety of agents has been tried.[561]

WASP STINGS.

Stings by the vespine wasps may lead to anaphylaxis, with hypotension, circulatory collapse, and cyanosis. Occasional patients may have chest pain and clinical findings compatible with acute myocardial infarction.[562] The mechanism of myocardial damage is unclear; perhaps it merely reflects necrosis from profound hypotension, although a direct toxic effect on the myocardium or an indirect effect on the coronary arteries may be involved.[563]

SNAKE BITE.

Cardiac complications are not prominent features of snake bites, and the clinical picture is usually dominated by the neurological, hematological, and vascular damage produced by the snakebite toxin.[564] Myocardial involvement is seen on occasion and may rarely contribute to morbidity and mortality. T wave abnormalities are the most common manifestation of myocardial involvement, although ST segment depression, QRS prolongation, and atrioventricular conduction defects may also be seen.[564] [565] The ECG changes are usually transient, but when persistent they are attributed to direct myocardial damage due to the toxin. Death may occur from circulatory collapse, myocardial depression, or myocardial infarction due to hypotension and coronary artery thrombosis. Coronary artery vasospasm may also be involved.

ARSENIC.

Myocardial involvement may be seen in both acute and chronic arsenical poisoning, usually from pesticides; the heart may be dilated, with accumulation of pericardial fluid.[566] Multiple local and confluent areas of subepicardial and subendocardial hemorrhage are characteristic findings. The myocardium is usually abnormal, with evidence of a perivascular mononuclear infiltrate.[566]

Clinically unrecognized interstitial myocarditis is manifested by T wave inversions and ST segment depression, along with prolongation of the QT interval.[566] The ECG changes usually revert to normal within 2 to 4 weeks. The ECG abnormalities appear to resolve more rapidly when BAL (British antilewisite, dimercaprol) is used in therapy.

CYCLOPHOSPHAMIDE (see Chap. 69).

High doses of cyclophosphamide have been associated with ECG changes, congestive heart failure, and death from hemorrhagic myocarditis.[529] In the majority of treated patients, a reversible decrease of QRS voltage and systolic function is seen, often asymptomatic, although more than 20 percent may succumb as a consequence of myopericarditis. The myocardial damage appears to result from direct endothelial damage and resultant fibrin microthrombi in the capillaries.

5-FLUOROURACIL (see Chap. 69).

This antineoplastic agent has been associated with cardiotoxicity manifested by chest pain, ECG changes, and arrhythmia.[529] Coronary spasm has been implicated but not proven as the mechanism. There is speculation that 5-fluorouracil may also depress left ventricular dysfunction, but this has not been established with certainty.[529]

HYPERSENSITIVITY

Hypersensitivity to a variety of agents may result in allergic reactions that involve the myocardium. A variety of drugs (most commonly the sulfonamides, hydrochlorothiazide, the penicillins, and methyldopa) or other sensitizers may lead to an allergic myocarditis (Table 48-10) , characterized by peripheral eosinophilia and a perivascular infiltration of the myocardium by eosinophils, lymphocytes, and histiocytes; necrosis is seen on occasion.[338] Hypersensitivity myocarditis is rarely recognized clinically and is often first discovered at postmortem examination, although it is occasionally diagnosed on endomyocardial biopsy. Most patients who have hypersensitivity myocarditis are not critically ill, but nevertheless may die suddenly, presumably as a consequence of an arrhythmia. An occasional patient has intense eosinophilic infiltration of the myocardium of no obvious cause, with prominent necrosis evident and findings of hemodynamic collapse; some of these patients may have undiagnosed hypersensitivity myocarditis.[567] [568] Because of the potential for significant deleterious effects, a high index of suspicion for this condition should be maintained. Therapy includes discontinuation of the offending agent and corticosteroids and/or immunosuppression therapy in severe cases.

METHYLDOPA.

Although hepatitis is the most frequently encountered serious adverse reaction to methyldopa, sudden and unexpected death has been reported in a number of patients found at necropsy to have had an unsuspected myocarditis.[568] [569] The histological findings have the characteristics of an allergic myocarditis, showing an interstitial inflammatory infiltrate with abundant eosinophils, vasculitis, and focal myocardial necrosis.[568] ECG changes include sinus bradycardia, sinus pauses, and first- and second-degree AV block.

PENICILLIN.

Allergic reactions to penicillin are fairly common, but myocardial involvement is rare.[570] Histological findings consist of a perivascular and interstitial infiltrate composed of eosinophils and

TABLE 48-10 -- PRINCIPAL DRUGS CAPABLE OF CAUSING HYPERSENSITIVITY MYOCARDITIS

Antibiotics	**AntlInfiammatory**
Amphotericin B	Indomethacin
Ampicillin	Oxyphenbutazone
Chloramphenicol	Phenylbutazone
Penicillin	
Tetracycline	**Diuretics**
Streptomycin	Acetazolamide
	Chlorthalidone
Sulfonamides	Hydrochlorothiazide
Sulfadiazine	Spironolactone
Sulfisoxazole	
	Others
Anticonvulsants	Amitriptyline
Phenindione	Methyldopa
Phenytoin	Sulfonylureas
Carbamazepine	Tetanus toxoid
Antituberculous	
Isoniazid	
Para-aminosalicylic acid	

From Kounis NG, Zavras GM, Soufras GD, Kitrou MP: Hypersensitivity myocarditis. Ann Allergy 62:71, 1989.

mononuclear cells.[568] Both myocardial infarction and pericarditis may occur and account for some of the ECG changes.[570] Transient ECG changes may be the only manifestation of cardiac involvement, with sinus tachycardia, ST segment elevation, and T wave inversion.

SULFONAMIDES.

Sulfonamides may result in myocardial damage owing to a hypersensitivity vasculitis as well as a myocarditis.[570] In fatal cases eosinophilic myocarditis, sometimes with granulomas, can be demonstrated.[568] Although usually clinically silent, myocardial involvement may produce severe and even fatal congestive heart failure. ECG changes are usually absent, but nonspecific ST segment and T wave abnormalities may be seen.

TETRACYCLINE.

Allergic reactions to antibiotics of the tetracycline class include fever, tachycardia, and first-degree atrioventricular block. Postmortem findings include cardiac dilatation, fibrinoid muscle cell degeneration, and a diffuse interstitial and perivascular infiltrate.[568]

GIANT CELL MYOCARDITIS

Giant cell myocarditis is a rare disease of unknown cause characterized by the presence of multinucleated giant cells in the myocardium. (It is included here because of the possibility that it may be of immune or autoimmune origin.) Also called granulomatous myocarditis, this condition is typically a rapidly fatal disease, often of young to middle-aged adults.[571] Pathological findings are usually impressive. The ventricles are dilated, and mural thrombi may be present. A serpiginous area of myocardial necrosis may be seen involving the right as well as the left ventricle. Multinucleated giant cells are found, particularly at the margins of the areas of myocardial necrosis; a lymphocyte infiltrate is present,[572] with helper or suppressor T cells (Fig. 48-35) .[573] [574] [575]

Figure 48-35 Endomyocardial biopsy findings in giant-cell myocarditis. \i\Left,\r\ Active giant-cell myocarditis. Initial pretreatment biopsy showed several giant cells and a mixed lymphocyte-eosinophilic infiltrate (hematoxylin-eosin; original magnification, ;ts250). \i\Right,\r\ Healing giant-cell myocarditis. Biopsy after therapy showed interstitial fibrosis with residual mononuclear cells but no giant cells or myocyte necrosis (hematoxylin-eosin; original magnification, ;ts250). (From Levy NT, Olson LJ, Weyand C, et al: Histologic and cytokine response to immunosuppression in giant-cell myocarditis. Ann Intern Med 128:648, 1998.)

ETIOLOGY.

Giant cell myocarditis occurs on occasion in association with systemic diseases such as sarcoidosis, systemic lupus erythematosus, drug hypersensitivity, infections (especially syphilis and tuberculosis), thyrotoxicosis and malignant thymoma, but the cause of the disease remains obscure.[338] [576] In many ways the clinical features suggest a viral myocarditis except for the rapid and virulent course. Myocardial infection with coxsackievirus B2 has been reported,[574] and an autoimmune reaction to altered cardiac tissue has been suggested based on the histological findings and the association of giant cell myocarditis with other autoimmune disorders, although there is little direct evidence supporting this view.[571]

CLINICAL MANIFESTATIONS AND TREATMENT.

Both sexes are equally affected; the onset typically is rapid, with dyspnea, chest pain, orthopnea, and hypotension. Fever is usually present, with ECG evidence of widespread myocardial involvement. Refractory ventricular arrhythmias, although present in a minority of patients, suggest the diagnosis when present.[571] Overt congestive heart failure and sudden death occur frequently.[571] [572] [573] [574] [575] [576] [577] Medical therapy often is unsuccessful, although corticosteroids and immunosuppressive agents appear to have benefited some patients. Because the prognosis in general is poor, an initial attempt at empirical immunosuppressive therapy is warranted.[578] [579] Occasional patients have had long-term survival after medical therapy,[579A] but cardiac transplantation is considered to be the treatment of choice for most patients; there is a risk of fatal recurrent giant cell myocarditis in the transplanted heart.[580]

PHYSICAL AGENTS

RADIATION (see Chap. 69).

The use of radiation therapy may result in a variety of cardiac complications, which are usually chronic and which include pericarditis with effusion, tamponade, or constriction; coronary artery fibrosis and myocardial infarction; valvular abnormalities; myocardial fibrosis; and conduction disturbances.[581] Although the heart has been regarded as one of the organs more resistant to the effects of radiation, the clinical significance of radiation-induced heart disease is greater than usually thought.[581] Although radiation probably results in some degree of tissue damage in all patients, clinically significant cardiac involvement occurs in the minority of patients, usually long after the radiation treatment has ended.[582] Radiation-induced cardiac damage is related to the dose of radiation, the mass of heart irradiated, and the dose schedule of the radiation.

The late cardiac damage that may follow irradiation appears to result from a long-lasting injury of the capillary endothelial cells, which leads to cell death, capillary rupture, and microthrombi.[581] [583] Because of this damage to the microvasculature, ischemia results and is followed by myocardial fibrosis. In addition to microvascular damage, the major epicardial coronary arteries may become narrowed, especially at the ostia.[582]

Only an occasional patient manifests acute clinical cardiac abnormality with radiation therapy; typically this consists of acute pericarditis. A mild, transient, asymptomatic depression of left ventricular function may be seen early after radiation therapy. The more common clinical expressions of radiation heart disease occur months or years after the exposure. The pericardium is the most common site of clinical involvement, with findings of chronic pericardial effusion or pericardial constriction (see Chap. 50). [581] Myocardial damage occurs less frequently and is characterized by myocardial fibrosis with or without endocardial fibrosis or fibroelastosis. Left and/or right ventricular dysfunction at rest or with exercise appears to be a common, albeit usually asymptomatic, finding 5 to 20 years after radiation therapy, especially in those in whom the now-outmoded technique of a single anteroposterior port was used.[581] Occasional patients may develop usually asymptomatic left-sided (and rarely right-sided) valvular regurgitation (or on occasion stenosis) that rarely requires valve replacement[582] ; often there is a latent period of a decade or more between the radiation exposure and the development of valvular deformity.[583] ECG abnormalities, heart block, and a variety of arrhythmias may be seen months or years after therapeutic radiation, although usually they are of limited clinical significance.[583] [584]

HEAT STROKE

This condition results from failure of the thermoregulatory center following exposure to high ambient temperature. It is manifested principally by hyperpyrexia, renal insufficiency, disseminated intravascular coagulation, and central nervous system dysfunction.[585] However, cardiovascular abnormalities (usually ECG) appear to be common; pulmonary edema, and transient right and/or left ventricular dysfunction may occur, along with hypotension and circulatory collapse. Pathological changes include dilatation of the right side of the heart, particularly the right atrium. Hemorrhages of the subendocardium and the subepicardium are frequently seen at necropsy and often involve the interventricular septum and posterior wall of the left ventricle. Histological findings include degeneration and necrosis of muscle fibers as well as interstitial edema. Factors that have been implicated as possible causes of myocardial damage include direct thermal injury, myocardial hypoxia resulting from circulatory collapse, decreased coronary blood flow, and metabolic abnormalities resulting from widespread injury to other organs.

Sinus tachycardia is invariably present,[585] whereas atrial and ventricular arrhythmias usually are absent. Transient prolongation of the QT interval may be seen, along with ST segment and T wave abnormalities. It may take up to several months for these repolarization abnormalities to resolve. Serum enzyme levels may be elevated and may reflect myocardial damage, at least in part, although comcomitant rhabdomyolysis often is present.

HYPOTHERMIA

Low temperature may also result in myocardial damage. Cardiac dilatation may occur with epicardial petechiae and subendocardial hemorrhages.

Microinfarcts are found in the ventricular myocardium, presumably related to abnormalities in the microcirculation. The lesions are not due to the low temperature per se but appear to be the result of the circulatory collapse, hemoconcentration, capillary slugging, and depressed cellular metabolism that accompany hypothermia. Clinical manifestations of hypothermia include sinus bradycardia, conduction disturbances, atrial (and occasionally ventricular) fibrillation, hypotension, a fall in cardiac output, reversible myocardial depression, and a characteristic deflection of the terminal portion of the QRS pattern (Osborn wave).[586] Treatment includes core warming (often utilizing extracorporeal blood warming), cardiopulmonary resuscitation, and management of pulmonary, hematological, and renal complications.[586] [587] [588]

Chapter 49 - Primary Tumors of the Heart

WILSON S. COLUCCI
FREDERICK J. SCHOEN

With an incidence of 0.002 to 0.3 percent in autopsy series,[1] [2] [3] [4] [5] [6] [7] primary tumors of the heart* are far less common than metastatic tumors to the heart.[8] Benign primary cardiac tumors occur more frequently than malignant ones. The most common cardiac tumor is the myxoma. In a large single-institution series of primary cardiac tumors, comprising 124 cases diagnosed at surgery and autopsy over 40 years (at the University of Minnesota), 42 percent were cardiac myxomas and 16 percent were malignant tumors (sarcomas) (Fig. 49-1) .[9] The proportion of myxomas in comparison with other tumors was increased (to 77 percent) when consideration was limited to surgically excised lesions.[9] [10] Before the advent of modern cardiopulmonary bypass surgical techniques, the correct antemortem diagnosis of an intracardiac tumor was largely academic, because effective therapy was not possible. However, now that many cardiac tumors are curable by operation, it is critically important to establish this diagnosis whenever possible. During the past decade, major advances in noninvasive cardiovascular diagnostic techniques--especially echocardiography (see Chap. 7) , computed tomography (CT), and magnetic resonance imaging (MRI) (see Chap. 10) --have greatly facilitated this task, and it is now possible safely and readily to screen patients suspected of having a cardiac tumor, in many cases arriving at a definitive diagnosis preoperatively. Nevertheless, a high index of suspicion remains the most important element in diagnosing a cardiac tumor.

CLINICAL PRESENTATION

SYSTEMIC FINDINGS.

The cardiac tumor myxoma causes various nonspecific clinical signs and symptoms that often masquerade as many other more common cardiovascular and systemic diseases (Tables 49-1 and 49-2) . Cardiac myxoma can produce a broad array of systemic (i.e., noncardiac) findings including fever, cachexia, malaise, arthralgias, Raynaud's phenomenon, rash, clubbing, and episodic bizarre behavior,[11] [12] as well as systemic and pulmonary emboli. [12A] Various laboratory findings have been reported, including hypergammaglobulinemia, elevated erythrocyte sedimentation rate, thrombocytosis, thrombocytopenia, polycythemia, leukocytosis, and anemia. Systemic signs and symptoms frequently resolve when the tumor is removed.

Role of Interleukin-6.

The association of constitutional symptoms with cardiac myxoma is likely to be due to the tumor's constitutive synthesis and secretion of interleukin-6 (IL-6),[13] [14] [15] [16] [17] [18] [19] [20] [20A] an inflammatory cytokine thought to be a major inducer of the acute phase response, which is associated with fever, leukocytosis, and activation of the complement and clotting cascades.[14] In vitro, IL-6 induces the synthesis of C-reactive protein, serum amyloid A, alpha$_2$ -macroglobulin, and fibrinogen by human hepatocytes.[14] High levels of myxoma production of IL-6 may be accompanied by elevated serum concentration in patients who have cardiac myxoma and symptoms characteristic of autoimmune diseases.[18] In some cases, serum IL-6 levels become undetectable and the immunological features resolve on removal of the tumor.[19] Increased titers of antibodies to myocardium[20] and neutrophils[21] have also been found in patients with myxoma and were shown to decline after removal of the tumor. A case of multiple myeloma has been attributed to continuous immunological stimulation by a left atrial myxoma.[22] Because the cardiac findings are nonspecific and may be subtle or absent, it is not unusual for these systemic findings to lead to a diagnosis of collagen-vascular disease, infection, or noncardiac malignant disease.[23] [24] [25] Rarely, myxomas may be superinfected by bacteria or fungi.[26] [27] [28]

EMBOLIC PHENOMENA.

Embolization of tumor fragments or of thrombi from the surface of a tumor is a frequent and often dramatic clinical occurrence.[29] [30] [31] [32] [33] Although myxomas are the source of most tumor emboli because of the combination of their friable consistency and intracavitary location (Fig. 49-2) , other types of cardiac tumors occasionally may embolize.

The distribution of tumor emboli depends on the location of the tumor and the presence or absence of intracardiac shunts. Left-sided tumors embolize to the systemic circulation, resulting in infarction and hemorrhage of viscera, including the heart,[29] as well as peripheral limb ischemia and vascular aneurysms. The diagnosis of an intracardiac tumor may be made after histological examination of systemic embolic material,[34] [35] and therefore it is of critical importance to make every effort to recover and examine embolic material. In some cases, particularly when petechiae are present, biopsy of skin or muscle[33] can demonstrate intravascular tumor emboli.

Multiple systemic emboli may mimic systemic vasculitis[33] or infective endocarditis, especially when associated with other manifestations of a systemic illness such as fever,

*Tumors arising elsewhere in the body and metastasizing to the pericardium and heart are discussed in Chap. 50 (Pericardial Disease) and Chap. 69 (Hematologic-Oncologic Disorders and Heart Disease).

Figure 49-1 Relative incidence of cardiac tumors. *A,* Incidences of both surgical and autopsy cases are considered. *B,* Relative incidences of only surgical series are considered. Thorac Cardiovasc Surg 38:183, 1990.)

weight loss, arthralgias, elevated erythrocyte sedimentation rate, and elevated serum gamma globulins. The finding at angiography of numerous vascular aneurysms secondary to tumor emboli in the cerebral, renal, femoral, and coronary arteries is not infrequent[36] and may lead to the mistaken diagnosis of polyarteritis nodosa.[23] The neurological consequences of embolization include transient ischemic attacks, seizures, syncope, and cerebral, cerebellar, brain stem, spinal cord, or retinal infarction.[37] The neurological event may occasionally be the first or only clinical manifestation of a cardiac tumor. An embolic stroke in a young person without evidence of cerebrovascular disease, particularly in the presence of sinus rhythm, should raise the suspicion of intracardiac myxoma, as well as infective endocarditis and prolapse of the mitral valve.

Figure 49-2 Photographs of the two most frequent gross appearances of cardiac myxomas. *A,* Polypoid, smooth, round, hemorrhagic left atrial myxoma, noted at autopsy. The tumor mass nearly fills the left atrium and extends into the mitral valve orifice. *B,* irregular gelatinous, friable myxoma mass, surgically removed. The resection margin that surrounds the proximal portion of the stalk is indicated by an arrow. (*A* from Cotran RS, Kumar V, Robbins SL: Robbins' Pathologic Basis of Disease. 5th ed. Philadelphia, WB Saunders, 1994. *B* from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.)

have been noted. [38] Clinically, the findings may be indistinguishable from pulmonary emboli secondary to venous thromboembolism (see Chap. 52) . Although the findings on chest roentgenogram are nonspecific, perfusion lung scanning in such patients may yield results atypical of pulmonary embolism in two respects: (1) The tumor-produced perfusion defects may remain static for long periods, as opposed to typical pulmonary embolic disease in which the defects usually resolve over the course of a few weeks; and (2) flow to one lung may be completely absent while perfusion of the opposite lung is completely normal, a pattern unusual with typical pulmonary emboli.

Cardiac Manifestations

The specific signs and symptoms produced by tumors are more closely related to their precise anatomical location than to their histological types.[39] Thus, it is useful to consider the constellation of findings typical of each location. The presentation of *pericardial tumors* is considered in Chapter 50 and is not discussed here except to

point out that primary tumors of the myocardium and endocardium may extend into the pericardial space and produce many of the clinical manifestations of pericardial tumors, including hemorrhagic pericardial effusion and compression of the heart by the effusion or the tumor itself.

MYOCARDIAL TUMORS.

When clinically apparent, myocardial tumors most commonly result in disturbances of conduction or rhythm,[40] [41] [42] [43] the precise nature of which is determined by the location of the tumor. Thus, tumors in the area of the atrioventricular (AV) node, typically angiomas and mesotheliomas, may produce AV conduction disturbances, including complete heart block, and asystole and can lead to sudden death (see Chap. 26) .[40] [41] [42] [43] A wide variety of arrhythmias may be produced, including atrial fibrillation or flutter, paroxysmal atrial tachycardia with or without block, nodal rhythm, premature ventricular beats, ventricular tachycardia, and ventricular fibrillation (see Chap. 25) .[39] [43] Intramural tumors can also produce symptoms by virtue of their size and location. Impairment of ventricular performance may simulate congestive, restrictive, or hypertrophic cardiomyopathy (see Chap. 48) . Tumor infiltration of the myocardial wall occasionally causes myocardial rupture.[44]

LEFT ATRIAL TUMORS.

Mobile, pedunculated, left atrial tumors may prolapse to various degrees into the mitral valve orifice, resulting in obstruction to AV blood flow and, frequently, mitral regurgitation. The resultant signs and symptoms often mimic those of mitral valve disease[1] [5] [44] (see Table 49-2) , especially mitral stenosis (see Chap. 46) ,[45] and include dyspnea, orthopnea, paroxysmal nocturnal dyspnea, pulmonary edema, cough, hemoptysis, chest pain, peripheral edema, and fatigue. However, weight loss, pallor, syncope, and sudden death--manifestations that are uncommon with mitral valve disease--also occur. It is not unusual for the symptoms to be sudden in onset, intermittent, and related to the patient's body position.[5] [39] Although the majority of symptoms produced by left atrial tumors are nonspecific, the occurrence of paroxysmal symptoms that arise characteristically in a particular body position and are out of proportion to the clinical findings should raise suspicion of a left atrial tumor. The most common primary cardiac tumor presenting in the left atrium is the benign myxoma, which, in the large majority of cases, is solitary.

Physical Examination.

The physical examination may disclose signs of pulmonary congestion; an S_4 ; a loud S_1 , which is often widely split; a holosystolic murmur that is loudest at the apex and resembles mitral regurgitation; and a diastolic murmur resulting from obstruction to flow through the mitral orifice produced by the tumor. The loud S_1 that occurs in patients with left atrial myxoma may be

due to the late onset of mitral valve closure resulting from prolapse of the tumor through the mitral valve orifice.[46] Consequently, the left ventricular-left atrial pressure crossover occurs at a higher pressure, as in patients with mitral stenosis or a short PR interval. It has been suggested that the finding of a loud S_1 in the absence of a short PR interval or a mitral diastolic murmur should raise the suspicion of a left atrial tumor.[46] In many cases, an early diastolic sound, termed a *tumor plop,* can be identified. It is thought to be produced as the tumor strikes the endocardial wall or as its excursion is abruptly halted. Although in most cases the tumor plop occurs later than the opening snap of the mitral valve and earlier than the S_3 , it is not surprising that this sound is frequently confused with the opening snap or the S_3 .

RIGHT ATRIAL TUMORS.

Right atrial tumors frequently produce symptoms of right heart failure, including fatigue, peripheral edema, ascites, hepatomegaly, and prominent *a* waves in the jugular vein pulse.[39] [47] [48] [49] [50] The average time interval from the symptomatic presentation to the correct diagnosis of right atrial tumor may be years. The development of right-sided heart failure can be rapidly progressive and is often associated with new systolic or diastolic murmurs or both. The murmurs are generally the result of tumor obstruction to tricuspid valve flow or of tricuspid regurgitation caused by tumor interference with valve closure or valve destruction caused directly or indirectly by the tumor.[51] It is not surprising that right atrial tumors have been misdiagnosed as Ebstein's anomaly of the tricuspid valve, constrictive pericarditis, tricuspid stenosis, carcinoid syndrome, superior vena caval syndrome, and cardiomyopathy (see Table 49-2) . Pulmonary embolism and pulmonary hypertension occur and may simulate classic thromboembolic disease.[48] Right atrial hypertension may cause right-to-left shunting through a patent foramen ovale, with systemic hypoxia, cyanosis, clubbing, and polycythemia.[50] Whereas myxomas occur much more commonly in the left atrium than in the right atrium, sarcomas occur more commonly in the right atrium.

Physical Examination.

The physical examination can reveal peripheral edema, evidence of superior vena cava obstruction, hepatomegaly, and ascites. An early diastolic rumbling murmur, alone or in combination with a holosystolic murmur secondary to tricuspid regurgitation, may demonstrate respiratory or positional variation. Because of the rarity of *isolated* rheumatic tricuspid valvular disease, the lack of other valvular findings should raise the question of a right atrial tumor. A protodiastolic tumor plop has been described and is thought to be similar in etiology to that produced by left atrial tumors.[52] The jugular venous pressure may be elevated, and a prominent *a* wave and steep *y* descent may be present.

RIGHT VENTRICULAR TUMORS.

Right ventricular tumors often present with right-sided heart failure as a result of obstruction to right ventricular filling or outflow. Clinical manifestations include peripheral edema, hepatomegaly, ascites, shortness of breath, syncope, and sudden death.

A systolic ejection murmur at the left sternal border is usually found on physical examination. A presystolic murmur and a diastolic rumble[39] have been noted and are thought to be due to obstruction of the tricuspid valve. An S_3 may be audible, and a low-pitched diastolic sound that coincides with the maximal anterior excursion of the tumor has been ascribed either to tumor or to late closure of the pulmonary valve.[53] P_2 is often delayed, and its intensity can be normal, decreased, or increased. Tumor emboli to the pulmonary arteries may result in pulmonary hypertension, and the presence of tumor in the pulmonic valve orifice may lead to pulmonary regurgitation. The jugular veins are frequently distended, with a prominent *a* wave, and may demonstrate Kussmaul's sign (see Chap. 4) .

The cardiac findings often lead to a diagnosis of pulmonic stenosis, restrictive cardiomyopathy, or tricuspid regurgitation. Whereas pulmonic stenosis is often asymptomatic and slowly progressive, the symptoms of right ventricular tumors are often rapidly progressive, and there is no poststenotic dilatation or systolic ejection click.

LEFT VENTRICULAR TUMORS.

When left ventricular tumors are predominantly intramural in location, they are often asymptomatic, they can present as conduction disturbances or arrhythmias, or they can interfere with ventricular function. However, when the tumor also has a significant intracavitary component, left ventricular outflow can be obstructed, resulting in syncope and findings consistent with left ventricular failure. Atypical chest pain has also been reported and, in some cases, can reflect obstruction of a coronary artery either directly by tumor involvement or as a result of a tumor embolus to the coronary artery.

Physical Examination.

The physical examination reveals a systolic murmur, and both the murmur and the blood pressure may vary with position. Left ventricular tumors may simulate the findings of aortic stenosis, subaortic stenosis, hypertrophic cardiomyopathy, endocardial fibroelastosis, and coronary artery disease.

Benign Versus Malignant Tumors

The types of benign and malignant mesenchymal tumors that can develop in the heart are typical of those occurring in any mass of striated muscle and connective tissue. Although the exact incidence of each specific tumor type cannot be stated, about 75 percent of all cardiac tumors are benign histologically and the remainder are malignant.[1] The majority of benign cardiac tumors are myxomas, followed in frequency by a wide variety of other tumors (Table 49-3) . Almost all malignant cardiac tumors are sarcomas, and of these the angiosarcoma and rhabdomyosarcoma are the most common forms (Table 49-4) .

Although it is often difficult or impossible to differentiate benign from malignant tumors histologically before operation, certain findings may be helpful. Characteristics

suggestive of malignancy include the presence of distant

metastases, local mediastinal invasion, evidence of rapid growth in tumor size, hemorrhagic pericardial effusion, precordial pain, location of the tumor on the right side of the heart or on the atrial free wall, evidence of combined intramural and intracavitary location, and extension into the pulmonary veins. Benign tumors are more likely to occur on the left side of the interatrial septum and to grow slowly. Although benign tumors do not metastasize, distant tumor emboli can mimic peripheral or pulmonary metastases.[54] The preoperative differentiation between benign and malignant tumors can occasionally be made by examination of peripheral tumor emboli recovered by arteriotomy or by biopsy of skin or muscle.[5] [32] [34] [35]

SPECIFIC CARDIAC TUMORS

Benign Tumors

Myxomas

As already pointed out, myxomas are the most common type of primary cardiac tumor, comprising 30 to 50 percent of the total in most pathological series (or higher, when surgically excised tumors are considered).[1] [2] [3] [4] [5] [8] The mean age of patients with sporadic myxoma is 56 years, and 70 percent are females. However, myxomas have been described in patients ranging in age from 3 to 83 years and are now not infrequently diagnosed in elderly patients, in whom the symptoms and signs of cardiac tumor may have been attributed to other causes for a substantial time. Approximately 86 percent of myxomas occur in the left atrium, and more than 90 percent are solitary[5] [8] (see Fig. 49-2) . In the left atrium, the usual site of attachment is in the area of the fossa ovalis. Myxomas also may occur in the right atrium and, less often, in the right or left ventricle. Several tumors may occur in the same chamber or in a combination of chambers. Although myxomas may occasionally be found on the posterior left atrial wall, tumors presenting in this location should raise the suspicion of malignancy. Myxomas of the mitral and tricuspid valves have been reported.[49] [54]

The clinical signs and symptoms produced by cardiac myxomas include nonspecific manifestations as already discussed, embolization, and mechanical interference with cardiac function (see Table 49-1) . Not surprisingly, the symptoms produced by cardiac myxomas may simulate a wide variety of other cardiac and noncardiac conditions (see Table 49-2) .

FAMILIAL MYXOMAS.

Familial cardiac myxomas constitute approximately 10 percent or less of all myxomas and appear to have an autosomal dominant transmission.[1] [55] [56] [57] Some patients with cardiac myxoma have a syndrome, frequently called "syndrome myxoma" or "Carney's syndrome," that also consists of (1) myxomas in other locations (breast or skin), (2) spotty pigmentation (lentigines, pigmented nevi, or both) (Fig. 49-3), and (3) endocrine overactivity (pituitary adenoma, primary pigmented nodular

adrenocortical disease, or testicular tumors involving the endocrine components).[58] [59] [60] [60A] [60B] Patients with Carney's syndrome tend to be younger (mean age, 20's), are more likely to have myxomas in locations other than the left atrium, sometimes have bilateral tumors, and are more likely to develop recurrences (Table 49-5) .

Although the cause of the syndrome myxoma is unknown, it has been proposed to result from a widespread abnormality resulting in excessive proliferation of certain mesenchymal cells, and excessive glycosaminoglycans production by them, possibly analogous to the neural masses in von Recklinghausen's neurofibromatosis.[61] Patients may have two or more components of this complex, and the first component generally is diagnosed at a relatively young age (mean age, 18 years). Some patients have been said to have the NAME syndrome (*n*evi, *a*trial myxoma, *m*yxoid neurofibroma, *e*phelides) [57] [62] or the LAMB syndrome (*l*entigines, *a*trial *m*yxoma, and *b*lue nevi).[63]

Figure 49-3 Four patients with extensive facial freckling, a finding associated with syndrome myxoma. Patients with this syndrome tend to be younger than patients with sporadic myxoma and have a substantially higher incidence of ventricular, multiple, biatrial, recurrent, and familial myxomas of the heart. In addition, these patients, in contrast to patients with sporadic myxoma, may have noncardiac myxomas and endocrine neoplasms. (From Vidaillet HJ Jr, Seward JB, Fyke FE, et al: "Syndrome myxoma": A subset of patients with cardiac myxoma associated with pigmented skin lesions and peripheral and endocrine neoplasms. Br Heart J 57:247, 1987.)

From Vidaillet HJ Jr, Seward JB, Fyke FE: "Syndrome myxoma": A subset of patients with cardiac myxoma associated with pigmented skin lesions and peripheral and endocrine neoplasma. Br Heart J 57:247, 1987.

Because cardiac myxomas can be familial, routine echocardiographic screening of first-degree relatives is appropriate, particularly if the patient is young or has many tumors. In one study, screening of families of six patients with familial myxoma yielded four close relatives with cardiac myxoma.[64] Moreover, in patients who have a familial history or other components of the previously described syndrome and who are undergoing resection, a careful search should be made preoperatively for several cardiac myxomas. Postoperatively, these patients should be observed closely for the development of other tumors; this occurs in 12 to 22 percent of such patients.[65] The pathological features of familial myxomas do not differ from those occurring sporadically (discussed later).[66]

PATHOLOGY.

Most cardiac myxomas are received by the pathologist as surgically excised specimens that have been removed because of clinical symptoms. Rarely, cardiac myxomas are encountered incidentally at autopsy. The pathological characteristics of myxomas are well described and are independent of location.[1] [54] [67] [68] [69]

Gross Pathology.

Myxomas are gelatinous (often termed myxoid), smooth, and round, with a glistening surface, or they may be variably friable and either irregular or polypoid (see Fig. 49-3). They are either sessile or pedunculated with a distinct stalk, which may be narrow or broad. In approximately 90 percent of cases arising in the atria, the base of attachment is the atrial septum, usually in the region of the limbus of the fossa ovalis. In approximately 10 percent of cases, the point of origin is the posterior or anterior atrial wall or atrial appendage; valvular myxomas are rare. Cardiac myxomas can be multicentric. Areas of hemorrhage are frequent. The tumors average 4 to 8 cm in diameter but range from less than 1 cm to 15 cm or greater.

Histology.

The diagnosis of myxoma is made by the observation of characteristic patterns of cells (often called "lipidic" cells) embedded in a myxoid stroma rich in glycosaminoglycans (Fig. 49-4) .[67] [68] [69] Myxoma cells have a round, elongated, or polyhedral shape; scant pink cytoplasm; and an ovoid nucleus with an open chromatin pattern. They are occasionally multinuclear. Although they may be present individually, myxoma cells are typically present as cords, rings, or florets, sometimes as many layers surrounding vascular structures. Diagnosis of myxoma requires the presence of characteristic isolated or clustered collections of myxoma cells. Hemorrhages; macrophages; often containing iron pigment; lymphocytes; and plasma cells are variably present. Calcification is present in approximately 10 to 20 percent of cardiac myxomas. Extramedullary hematopoiesis, which comprises glandular structures lined by mucin-filled goblet cells,[70] and cellular atypia may be present in a minority of cases; these features may simulate malignancy. Because emboli from myxomas usually derive from the most superficial portions, they may have less definitive histological features than the intracardiac lesion from which they originated.

Ultrastructural and Immunohistochemical Findings.

Myxoma cells have abundant fine cytoplasmic filaments similar to those of smooth muscle cells.[69] The cells most resemble embryonic mesenchymal cells with multipotential capabilities for cellular differentiation, including vasoformative activity and expression of vascular endothelial growth factor,[69A] and are especially similar to embryonic endocardial cushion tissue.[71] *Immunohistochemical studies* demonstrate variable positivity for the endothelial cell markers factor VIII-related antigen and *Ulex europaeus.* More consistent positivity is obtained when myxomas are stained for *vimentin,* indicative of the mesenchymal derivation of the cells, as well as some neuroendocrine markers and smooth muscle cell antigens. Analysis by immunohistochemistry has not been useful for either diagnostic purposes or elucidation of histogenesis.

Embolization.

Although myxomas or other benign cardiac tumors can cause death due to coronary or cerebral embolization,[72] metastatic tumor implantation with wasting is rare. Occasional reports suggest that myxomas may have a malignant counterpart, with local invasion of the interatrial septum, recurrence, or metastasis.[72A] However, some cases of purported malignancy probably represent malignant tumors of other types with extensive areas of myxoid degeneration or of multicentricity that was not appreciated; others may represent inadequate excision or embolization of benign lesions.

Many of the morphological features of organizing mural thrombi resemble those of myxoma, including abundant loose amorphous extracellular matrix, connective tissue cells, and small vascular channels. It is difficult to distinguish between some myxomas and mural thrombi in various stages of organization; indeed, cellular intracardiac thrombi and peripheral thromboemboli occasionally receive an erroneous diagnosis of myxoma. The resemblance to organizing/organized thrombi has

been put forth as evidence that myxomas have a thrombotic origin,[73] but most investigators currently find this notion untenable.[67] [71]

Histogenesis.

The histogenesis of cardiac myxomas is uncertain, but the weight of evidence favors benign neoplasia, with the tumor probably originating from subendocardial nests of primitive mesenchymal cells that may differentiate into several cell types, including endothelial and lipidic cells. Cytogenetic analyses demonstrating clonal chromosomal abnormalities provide the best support for this concept. Sporadic and familial atrial myxomas have been shown to have heterogeneous clonal telomeric rearrangements and other chromosome abnormalities primarily involving chromosomes 2, 12, and 17; a telomeric association between chromosomes 13 and 15, a rearrangement in 1q32, and loss of the Y chromosome have also been reported.[74] [75] [76] [77] [78] [79] [80] Linkage analysis of 11 kindreds affected by Carney's syndrome yielded a chromosomal locus for this disorder mapping to the short arm of chromosome 2 within a 6.4-cM interval (2p16).[74] A gene defect on chromosome 17q (17q2) was associated with Carney's complex in four unrelated families.[76] A most convincing case of clonal structural aberrations was reported by Dijkhuizen and colleagues[80] who found that a cardiac myxoma from a 48-year-old man had normal chromosome number but a complex clonal rearrangement, which included a breakpoint at 12p12, the location of the *Ki-ras* oncogene. The researchers speculated that *Ki-ras* might have a role in the origin of cardiac myxoma. Although myocardial hypertrophy and failure as well as endocrine abnormalities such as pituitary and thyroid tumors have been associated with alterations in the heterotrimeric

Scattered inflammatory cells are also present. *B,* Medium-power view, demonstrating groups of polygonal myxoma cells. *C,* High-magnification view, showing individual variably rounded to elongated myxoma cells, some arranged in cords (arrows). *A,* 50×; *B,* 175×; *C,* 400×; all stained with hematoxylin and eosin.

guanosine triphosphate-binding proteins, activating Gsalpha mutations have not been found in either atrial myxomas or other tumors from patients with Carney's complex.[81] The presence of aneuploidy in some cardiac myxomas provides additional support for the concept of a neoplastic origin.[82]

Before the discussion of nonmyxomatous cardiac tumors is continued later, it should be noted that peculiar microscopic-sized cellular cardiac lesions have been noted incidentally as part of endomyocardial biopsy or surgically removed tissue specimens or at cardiac surgery; these lesions are free floating or loosely attached to a valvular or endocardial mass.[83] [84] Not neoplastic, they have been termed mesothelial monocytic incidental cardiac excrescences (MICE). Histologically, such lesions are composed largely of clusters and ribbons of mesothelial cells and entrapped erythrocytes and leukocytes embedded within a fibrin mesh. Previously considered to be a reactive mesothelial and/or monocytic (histiocytic) hyperplasia, they are now considered to be common artifacts--formed by compaction of mesothelial strips (likely from the pericardium) or other tissue debris and fibrin that are transported via catheters or around an operative site on a cardiotomy suction tip.[85] Such tissue fragments are of importance only in that they should not be confused with metastatic carcinoma.

PAPILLARY TUMORS OF HEART VALVES (PAPILLARY FIBROELASTOMA).

The most common tumors of the cardiac valves, papillary fibroelastomas of the cardiac valves and adjacent endocardium, are not uncommonly found postmortem and may be identified during life by two-dimensional echocardiography.[86] [87] Although many are clinically insignificant, they have the potential to embolize to vital structures [88, 89] or to cause valvular dysfunction, and those on the aortic valve can partially obstruct a coronary arterial orifice.[90] These lesions have a characteristic frondlike appearance resembling a sea anemone. They may be single or numerous; up to 3 or 4 cm in diameter; and occur on any valve or on papillary muscle, chordae tendineae, or endocardium, usually attached by a short pedicle (Fig. 49-5) . Most often, the ventricular surface of semilunar valves and the atrial surface of AV valves are affected. The tricuspid valve is most commonly involved in children, and the mitral and aortic valves in adults. Histologically, the tumor is covered by endothelium that surrounds a core of loose connective tissue rich in glycosaminoglycans, collagen, and elastic fibers and containing smooth muscle cells (often as a fine meshwork surrounding a central collagen or dense elastic fiber core).

Pathogenesis.

The pathogenesis of these lesions is uncertain, but it appears that they may originate secondary to endocardial trauma and/or the organization of mural thrombi.[73] Papillary tumors are generally distinguished from Lambi's excrescences, which are acellular deposits of thrombus and connective tissue covered by a single layer of endothelium and are found on heart valves at the site of endothellal damage in many adults, particularly along the closure margins of the aortic valve cusps. In contrast, papillary fibroelastomas are unusually found at valvular contact areas.

RHABDOMYOMAS.

These are the most common cardiac tumors of infants and children; approximately three-fourths occur in patients younger than 1 year.[91] [92] They occur with equal frequency in the left and right ventricular and septal myocardium; nearly all are multiple. Approximately one-third also involve either one or both atria. In approximately half of affected patients, at least one of the tumors is intracavitary and obstructive. Nonspecific clinical manifestations, including cardiomegaly; right or left ventricular failure or both; and an S_3 , S_4 , and systolic or diastolic murmurs, may mimic mitral stenosis, mitral atresia, aortic stenosis, subaortic stenosis, or infundibular pulmonic stenosis.

Association with Tuberous Sclerosis.

Rhabdomyomas are strongly associated with tuberous sclerosis, a familial syndrome characterized by hamartomas in several organs, epilepsy, mental deficiency, and adenoma sebaceum.[93] [94] [95] One study indicated that at least 80 percent

Figure 49-5 Papillary fibroelastoma. *A,* Gross photograph demonstrating resemblance of this lesion to a sea anemone, with myriad papillary fronds, arising from the chordae tendineae near the mitral leaflet. In this case, many lesions were present, all associated with the mitral valve apparatus. *B,* Histological appearance of papillary fibroelastoma, demonstrating the numerous papillary fronds consisting of a collagen core surrounded by elastic fibers and loose connective tissue, all covered by endocardial endothelium. 100×; stained with elastica van Gieson stain (elastin black).

of patients with cardiac rhabdomyomas have tuberous sclerosis, and 60 percent of patients less than 18 years old with tuberous sclerosis have cardiac rhabdomyomas.[95] Conversely, approximately 50 percent or more of patients having tuberous sclerosis but no signs or symptoms of cardiac disease have been shown to have echocardiographic findings that are consistent with one or more rhabdomyomas. Rhabdomyomas causing significant intracavity obstruction may result in death within the first 24 hours of life, whereas patients with less severe involvement may either remain asymptomatic or have difficulty during infancy or early childhood.

Pathology.

Rhabdomyomas are yellow-gray and range from 1 mm to several centimeters in diameter. They are circumscribed but not encapsulated; microscopically, they are easily distinguished from the surrounding myocardium as clusters of abnormal cells. The microscopic hallmark, termed the *spider cell,* is a large (up to 80-mum diameter) cell containing a central cytoplasmic mass that is suspended by fine fibrillar processes radiating to the periphery, thus giving the appearance of a spider hanging in a net. Such cells are sufficiently characteristic that the tumor may be diagnosed by fine-needle aspiration.[96] The cytoplasm is rich in glycogen and stains positively with periodic acid-Schiff reagent. Electron microscopy demonstrates myofibrils, cytoplasmic and mitochondrial glycogen, and apparent intercellular junctions similar to intercalated discs. Immunohistochemistry reveals diffuse positivity for myoglobin, actin, desmin, and vimentin and the absence of neuroendocrine markers, similar to the staining pattern of the adjacent cardiac muscle. Evidence suggests that rhabdomyomas are actually myocardial hamartomas or malformations rather than true neoplasms. In support of this concept is their multiple occurrence and preponderance in children, especially in those with tuberous scierosis.

FIBROMAS.

Fibromas are benign connective tissue tumors that occur predominantly in children and constitute the second most common type of primary cardiac tumor occurring in

the pediatric age group.[97] The majority occur before the age of 10 years, and about 40 percent are diagnosed in infants younger than 1 year. Males and females appear to be equally affected. Derived from fibroblasts and considered low-grade connective tissue tumors, cardiac fibromas resemble and have the same biological behavior as soft tissue fibromatoses at other sites.

Pathology.

Almost all cardiac fibromas occur within the ventricular myocardium, most frequently within the anterior free wall of the left ventricle or the interventricular septum and much less often in the posterior left ventricular wall or right ventricle. They typically are gray, firm, circumscribed, and not encapsulated and range in size from 3 to 10 cm. Grossly, they exhibit a whoried appearance on cut sections. Microscopically, cardiac fibromas consist of elongated fibroblasts admixed with fibrous tissue consisting mostly of collagen. Their cellularity is variable, and mitotic figures are rarely, if ever, seen. Fibrous tissue is intermingled with adjacent myocardial fibers at the margins of the lesion. Calcification and islands of bone formation may be seen microscopically and occasionally radiographically. The *Gorlin syndrome,* the main features of which are multiple nevoid basal cell carcinomas, cysts of the jaw, and skeletal abnormalities, may be associated in some cases with cardiac tumors, either fibromas or fibrous histiocytomas.[98]

Clinical Manifestations.

Although fibromas may be incidental findings at postmortem examination, approximately 70 percent at some time cause mechanical interference with intracardiac flow, ventricular contraction abnormalities, or conduction disturbances. Clinical manifestations are protean and include murmurs, atypical chest pain, congestive heart failure and signs of subaortic stenosis, valvular or infundibular pulmonic stenosis with right ventricular hypertrophy, tricuspid stenosis, conduction disturbances, ventricular tachycardia, and sudden death. As in the case of rhabdomyomas, the increased use of echocardiography has rarely resulted in the detection of cardiac fibromas in patients without cardiac signs or symptoms. Surgical excision of cardiac fibromas may be possible.[99] [100]

LIPOMAS AND LIPOMATOUS HYPERTROPHY OF THE ATRIAL SEPTUM.

Lipomas occur at all ages and with equal frequency in both sexes. Most range in diameter from 1 to 15 cm, although some have been reported to weigh more than 2 kg. Most tumors are sessile or polypoid and occur in the subendocardium or subpericardium, although about one-fourth are completely intramuscular. Subendocardial tumors with intracavity extension produce symptoms that are characteristic of their location, whereas subepicardial tumors may cause compression of the heart and pericardial effusion. The most common chambers affected are the left ventricle, right atrium, and interatrial septum. Intramural tumors may be asymptomatic or result in arrhythmias, AV or intraventricular conduction disturbances, or mechanical interference. Many tumors are clinically silent, however, and are found only at autopsy or become apparent on a routine chest roentgenogram.

Microscopically, the lesions are usually well encapsulated and composed of typical mature fat cells; they occasionally contain fibrous connective tissue (fibrolipoma), muscular tissue (myolipoma), or vacuolated brown (fetal) fat, resembling a hibernoma.

Whereas lipomas are true neoplasms, a condition termed *lipomatous hypertrophy of the interatrial septum* represents the occurrence

of a nonencapsulated hyperplastic accumulation of mature and fetal adipose tissue within the interatrial septum. These lesions range from 1 to 7 cm in dimension, most often protrude into the right atrium, and are more common in obese, elderly, or female patients.[101] Various atrial arrhythmias have been attributed to these lesions, but a cause-and-effect relationship has been difficult to establish.[101] Because this lesion may occasionally be detected by cineangiography, echocardiography, CT, or other diagnostic techniques, the major clinical dilemma is the differential diagnosis and treatment of an intraatrial filling defect.

ANGIOMAS.

Composed of benign proliferations of endothelial cells, hemangiomas and lymphangiomas are extremely rare.[102] Anatomically, they may occur in any part of the heart, but usually they are intramural, often in the interventricular septum or AV node, where they may cause complete heart block and sudden death. Cardiac tamponade due to hemopericardium may be the presenting clinical syndrome. More commonly found in the right heart chambers, hemangiomas are red, hemorrhagic, generally sessile or polypoid subendocardial nodules, ranging from 2 to 4 cm in diameter. Histologically, the tumors consist of endothelium-lined spaces that may contain blood, lymph, or thrombi; they are classified according to the predominant type of proliferating vascular channel. Dilated, often thrombosed, subendocardial blood vessels (varices) are frequently mistaken for hemangiomas; they are usually found incidentally.

TERATOMAS.

These tumors, which contain elements of all three germ cell layers, occur within the heart less frequently than in the anterior mediastinum.[103] Teratomas are generally observed in children, and when located within the heart, they occur predominantly within the right atrium, right ventricle, or the interatrial or interventricular septum.

CYSTIC TUMOR ("MESOTHELIOMA") OF THE ATRIOVENTRICULAR NODE.

Of controversial histogenesis, these small tumors (usually <15 mm in largest dimension) frequently cause death by complete heart block, ventricular fibrillation,[41] or cardiac tamponade.[104] They occur in patients of virtually any age as poorly circumscribed, often multicystic nodules in the atrial septum, immediately cephalad to the commissure of the septal and anterior leaflets of the tricuspid valve, in the region of the AV node. These lesions are characterized by tubules and cysts lined by flat or cuboidal cells that are devoid of mitotic activity but may have secretory function. Although they are often considered to be derived from mesothelial rests, similar to the adenomatoid tumors of the ovary and testis that they resemble histologically, studies have suggested an endodermal rather than mesothelial origin.[105] [106]

ENDOCRINE TUMORS OF THE HEART.

Approximately 2 percent of *paragangliomas* are intrathoracic, and of these, most are located in the posterior mediastinum. However, these tumors can also occur in close association with the left atrial or left ventricular epicardium, where they are thought to have arisen from sympathetic fibers to the heart or from ectopic chromaffin cells. More rarely still, paragangliomas may arise within the interatrial septum. Tumors in any of these locations may secrete catecholamines and therefore can be associated with signs and symptoms characteristic of pheochromocytoma.[107]

Rarely, benign *thyroid tumors* arise within the heart, presumably from ectopic rests of thyroid tissue.[107A] These tumors most often arise from the interventricular septum and present, not infrequently, as obstruction to right ventricular outflow.

Malignant Cardiac Tumors

About one-fourth of all cardiac tumors exhibit malignant histological characteristics and invasive or metastatic behavior. Nearly all of these are sarcomas, thus making these tumors second only to myxomas in overall frequency. Sarcomas may occur at any age but are most common between the third and fifth decades; they are distinctly unusual in infants and children and show no sex preference. In decreasing order of frequency, the sites involved are the right atrium, left atrium, right ventricle, left ventricle, and interventricular septum.

Sarcomas derive from mesenchyme and therefore may display a wide variety of morphological types, including angiosarcoma, rhabdomyosarcoma, fibrosarcoma, osteosarcoma, and others.[108] [109] [110]

From a clinical viewpoint, sarcomas characteristically display a rapid downhill course. Death most often occurs from a few weeks to 2 years after the onset of symptoms. These tumors proliferate rapidly and generally cause death through widespread infiltration of the myocardium, obstruction of flow within the heart, or distant metastases. About 75 percent of all patients with cardiac sarcomas have pathological evidence of distant metastases at the time of death.[111] [112] The most frequent sites are the lungs, thoracic lymph nodes, mediastinum, and vertebral column; the liver, kidneys, adrenals, pancreas, bone, spleen, and bowel are less often involved.

The cardiac findings are determined primarily by the location of the tumor and by the extent of intracavitary obstruction. Typical presentations include progressive, unexplained congestive heart failure, particularly of the right side; precordial pain; pericardial effusion; tamponade; arrhythmias; conduction disturbances; obstruction of the venae cavae; and sudden death. Tumors limited to the myocardium without intracavitary extension may produce no cardiac symptoms or may cause arrhythmias

and conduction disturbances. Because of the rapid growth potential of sarcomas, they commonly extend into the cardiac chambers, the pericardial space, or both. In about 20 percent of cases, the tumor is sessile or polypoid. When there is extension into the pericardial space, hemorrhagic pericardial effusion is common and tamponade may occur. Because the right side of the heart is most commonly affected, sarcomas frequently cause signs of right-sided heart failure as a result of obstruction of the right atrium, right ventricle, or tricuspid or pulmonic valves. In addition, obstruction of the superior vena cava may result in swelling of the face and upper extremities, whereas obstruction of the inferior vena cava may result in visceral congestion.

ANGIOSARCOMAS.

Included within this category are angiosarcomas and Kaposi's sarcomas.[113] [114] [114A] [114B] All 40 patients in one series were adults. In distinction to most other cardiac sarcomas, in which the sex distribution is equal, there appears to be a 2:1 male-to-female ratio among patients with angiosarcomas. These tumors have a striking predilection for the right atrium (Fig. 49-6) and may be infiltrative or polypoid in nature. Microscopically, angiosarcomas are characterized by ill-defined but variable anastomotic vascular channels lined with atypical, often heaped-up, endothelial cells. By electron microscopy, immature endothelial cells, primitive pericytes, and undifferentiated mesenchymal cells may be identified.[115]

RHABDOMYOSARCOMAS.

These tumors of striated muscle often diffusely infiltrate the myocardium but may also, on occasion, form a

Figure 49-6 Massive pericardial angiosarcoma, with deep myocardial invasion at several sites (arrowheads), particularly at the right atrium (arrow). (From Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.)

polypoid extension into the cardiac chambers and therefore have been clinically mistaken for myxoma.[116] Rhabdomyoblasts (cross-striations by light microscopy; thick and thin filaments and Z-band material by electron microscopy) are the histological hallmark of this tumor, and 20 to 30 percent of the tumors have cross-striations.

FIBROSARCOMAS AND MALIGNANT FIBROUS HISTIOCYTOMAS.

Fibrosarcomas of the heart have a whitish, soft "fish flesh" consistency characteristic of these tumor types elsewhere in the body.[117] Fibroblastic in differentiation, they are composed of spindle-shaped cells with elongated blunt-ended nuclei and frequent mitoses. They may contain areas of hemorrhage and necrosis and extensively infiltrate the heart, often involving more than one cardiac chamber. A thrombus may form in an obstructed pulmonary vein, in the vena cava, or over the mural surface of the tumor.

LYMPHOMAS.

Although cardiac involvement of a systemic lymphoma has been reported in 25 to 36 percent of cases, primary lymphoma involving only the heart or pericardium is much less common.[116] [118] Myocardial infiltration by lymphoma may be nodular or diffuse, and the clinical syndrome of hypertrophic cardiomyopathy has been mimicked. Some of these tumors are predominantly intracavitary.

PULMONARY ARTERY SARCOMAS.

Sarcomas of the pulmonary artery trunk, main branches, or pulmonic valves may present as tumor emboli to the lungs or as right ventricular outflow obstruction.[119] These tumors usually present after the fourth decade, show a 2:1 female predominance, and may originate from undifferentiated tissue of the bulbis cordis. Typical symptoms include dyspnea, chest pain, cough, and hemoptysis and may be associated with radiographic findings of a pulmonary hilar mass or cardiomegaly. Right ventricular injection of contrast material helps to delineate the tumor. Although most reported cases were previously diagnosed at autopsy, it is likely that early diagnosis, surgical resection, and possibly chemotherapy may have an impact on survival of future patients with this tumor.[120]

DIAGNOSTIC TECHNIQUES

Although certain clinical manifestations can be suggestive of a cardiac tumor, no clinical finding or set of findings is pathognomonic. Furthermore, the majority of cardiac tumors produce signs and symptoms typical of the common forms of heart disease. The development of modern diagnostic methods has had a major impact on the diagnosis and hence the natural history of cardiac tumors. It is not unusual for cardiac tumors to be diagnosed and cured in patients who are totally asymptomatic or without signs of cardiovascular disease.[121] Although cardiac catheterization made possible the definitive preoperative diagnosis of cardiac tumors, it was not until the advent of echocardiography that it was feasible to evaluate all patients suspected of having this diagnosis. Both M-mode and two-dimensional echocardiography are effective screening techniques. However, two-dimensional echocardiography, and particularly transesophageal imaging (Fig. 49-7), is more sensitive and provides considerably more information about the site of tumor attachment, pattern of tumor movement, and size. In many centers, the information provided by two-dimensional echocardiography (see Chap. 7) , CT, or MRI (see Chap. 10) (Fig. 49-8) is considered sufficient to proceed directly to surgery without cardiac catheterization and angiography. However, catheterization and angiography should not be omitted in the absence of a technically adequate two-dimensional echocardiographic study, CT, or MRI that has visualized all four cardiac chambers.

It is imperative that noninvasive evaluation, preferably by two-dimensional echocardiography (or CT or MRI), be performed before cardiac catheterization whenever the diagnosis of cardiac tumor is considered. When left atrial myxoma is suspected, it is safest to visualize the left atrium by injecting the contrast agent into the pulmonary artery and film during the levophase. It is particularly important to avoid the transseptal approach, because this risks dislodgement of fragments of tumor that may be attached in the region of the fossa ovalis. Furthermore, because cardiac tumors may be numerous and present in more than one chamber, all four chambers should be visualized noninvasively before cardiac catheterization whenever possible.

Clinical and Noninvasive Methods

CLINICAL EXAMINATION.

When valvular or myocardial disease is suspected on clinical grounds, certain atypical findings can raise the suspicion of cardiac tumor. The intensity of the systolic or diastolic murmur caused by a left atrial myxoma is often exquisitely sensitive to positional change, a finding atypical of valvular heart disease. S_1 may be delayed as a consequence of an elevated left atrial pressure, as in mitral stenosis. It is often intense and widely split, and an early systolic sound may occur, representing tumor movement toward the atrium during systole. In addition, a tumor plop may be present about 100 msec after S_2 ; it appears to result from the sudden tension of the tumor stalk as it prolapses into the left ventricle during diastole or from the tumor striking the myocardium. The tumor plop *precedes* the end of the rapid filling wave of the apexcardiogram and can thereby be differentiated from an S_3 ; as noted, it usually occurs later than an opening snap. Systolic time intervals are usually consistent with a reduced stroke

Figure 49-7 Transthoracic two-dimensional echocardiogram *(A)* and transesophageal two-dimensional echocardiogram *(B)* showing a left atrial (LA) mass prolapsing into and obstructing the mitral valve orifice. Note the superior resolution of the transesophageal echocardiogram. Although not visible here, the myxoma was attached to the midportion of the atrial septum. (From Allard MF, Taylor GP, Wilson JE, McManus BM: Primary cardiac tumors. *In* Goldhaber SZ, Braunwald E [eds]: Cardiopulmonary Diseases and Cardiac Tumors. Atlas of Heart Diseases. Vol 3. Philadelphia, Current Medicine, 1995, pp 15.1-15.22.)

Figure 49-8 Magnetic resonance images illustrating a large tumor in the right ventricular apex, impinging on the apical septum. In the coronal view *(A),* the prominent mass indents the septum. In the

axial views, the tumor shows areas of tissue inhomogeneity *(B)* and indents the ventricular septum *(C).* (From Allard MF, Taylor GP, Wilson JE, McManus BM: Primary cardiac tumors. *In* Goldhaber SZ, Braunwald E [eds]: Cardiopulmonary Diseases and Cardiac Tumors. Atlas of Heart Diseases. Vol 3. Philadelphia, Current Medicine, 1995, pp 15.1-15.22.)

volume. Apexcardiography often shows a deep notch on the upstroke, which occurs at the time of extrusion of the tumor through the mitral valve in early systole.

Right atrial tumors may also result in a widely split S_1 and an early systolic sound. The S_2 may be paradoxically split as a result of early pulmonic valve closure. A tumor plop and systolic and diastolic murmurs, which are increased by inspiration, may also occur with right atrial tumors. The jugular venous pulse tracing may reflect obstruction of the tricuspid orifice, demonstrating an accentuated *a* wave, attenuation of the *x* descent, or an early, broad *v* wave.

RADIOLOGICAL EXAMINATION

Cardiac tumors may display several findings on plain chest roentgenograms. These include alterations in cardiac contour, changes in overall cardiac size, specific chamber enlargement, alterations in pulmonary vascularity, and intracardiac calcification (see Chap. 8) . The cardiac contour may be normal, may display generalized or specific chamber enlargement that mimics virtually any type of valvular heart disease, or may demonstrate a bizarre appearance. Pericardial effusions are rather common and generally indicate invasion of the pericardial space by a malignant tumor. Mediastinal widening, due to hilar and paramediastinal adenopathy, may indicate spread of a malignant cardiac tumor. A bumpy, irregular, or fuzzy cardiac border may be seen when the pericardium is involved. Cardiac enlargement may reflect rapid tumor growth, particularly in the case of sarcomas, whereas specific chamber enlargement is frequently due to intracavitary obstruction, particularly by pedunculated tumors such as myxomas. Thus, left atrial myxoma may produce the radiological pattern characteristic of mitral stenosis. A large tumor mass occasionally displaces the heart and may simulate enlargement of a specific chamber.

Calcification visible by roentgenographic methods may occur with several types of cardiac tumor, including rhabdomyomas, fibromas, hamartomas, teratomas, myxomas, and angiomas. Visualization of intracardiac calcium in an infant or a child is unusual and should immediately raise the question of an intracardiac tumor. Cardiac fluoroscopy and laminography may be helpful in differentiating calcification of cardiac tumor from that of other structures, such as cardiac valves, coronary arteries, pericardium, and mural thrombus. Calcified atrial polypoid tumors may occasionally be seen to prolapse into the ventricle during diastole. Fluoroscopy is also useful in differentiating cardiac tumor from ventricular aneurysm, both of which may result in a localized protrusion on plain chest roentgenograms. However, on fluoroscopic examination, cardiac tumors do not display the paradoxical motion during ventricular contraction that is characteristic of ventricular aneurysm.

ECHOCARDIOGRAPHY.

Two-dimensional echocardiography provides substantial advantages over conventional M-mode echocardiography for the diagnosis and preoperative evaluation of intracardiac tumors.[5] In the majority of cases of cardiac tumors, the information provided by two-dimensional echocardiography provides adequate information about tumor size, attachment, and mobility to allow operative resection without preoperative angiography. This technique is sensitive for detection of small tumors and is especially useful for detection of left ventricular tumors and tumors that do not prolapse through the mitral or tricuspid valve orifices (see Figs. 49-7 and 7-115) .

Left atrial myxomas have been classified by their echocardiographic appearance as follows: Class I tumors are small and prolapse through the mitral valve; class II tumors are small and nonprolapsing; class III tumors are large and prolapse; and class IV tumors are large and nonprolapsing.[122]

The increased sensitivity of two-dimensional echocardiography makes possible the diagnosis of cardiac tumors in neonates and in utero.[123] The improved diagnostic power and widespread use of two-dimensional echocardiography have resulted in an increase in the detection of primary cardiac tumors,[121] in many cases before the onset of clinical signs or symptoms.

Two-dimensional echocardiography may facilitate the differentiation between left atrial thrombus and myxoma, because the former typically produces a layered appearance and is generally situated in the posterior portion of the atrium whereas the latter is often mottled in appearance and rarely occurs in the posterior portion of the atrium. In some atrial myxomas, areas of echolucency may be seen within the tumor mass, corresponding to areas of hemorrhage within the tumor. Because these areas of echolucency are not found in thrombotic or infective lesions, this finding may be of value in the differential diagnosis of an intraatrial mass. Continuous-mode Doppler ultrasonography may be useful for evaluating the hemodynamic consequences of valvular obstruction or incompetence caused by cardiac tumors.[124]

Transesophageal Echocardiography.

This approach provides an unimpeded view of both atria and the atrial septum and appears to be superior to transthoracic echocardiography in many patients.[125] The potential advantages of transesophageal echocardiography include improved resolution of the tumor and its attachment (see Figs. 49-7 and 7-115), the ability to detect some masses not visualized by transthoracic echocardiography, and improved visualization of right atrial tumors. In 17 patients suspected of having a cardiac tumor, transthoracic echocardiography yielded four false positives and two false negatives, whereas transesophageal echocardiography resulted in only one false positive and no false negatives.[126] In the same series, transesophageal echocardiography proved to be superior for visualizing anatomical details such as tumor contour, cysts, and calcification and identified a stalk in 10 of 11 tumors subsequently shown to have a stalk at surgery, whereas transthoracic echocardiography identified a stalk in only 5 of the 11 tumors. Transesophageal echocardiography has been used to guide percutaneous biopsy of a right atrial myxoma.[127] Although transesophageal echocardiography does not appear warranted on a routine basis, it should be considered when the transthoracic study is suboptimal or confusing.

RADIONUCLIDE IMAGING.

Gated blood pool scanning has been used to identify atrial, ventricular, and intramural tumors.[128] Radionuclide ventriculography generally has a lower rate of resolution than does echocardiography or contrast injection angiography and therefore may be less sensitive for detecting small filling defects. In some cases in which the cardiac tumor was not evident by routine static or dynamic radionuclide imaging, it has been possible to delineate the tumor and its movement during a cardiac cycle by use of a computer-generated composite functional image.[128]

COMPUTED TOMOGRAPHY.

CT of the heart has been used to demonstrate cardiac tumors (see Fig. 10-47) .[129] Although more experience will be necessary to establish its role, certain advantages are apparent. These include a high degree of tissue discrimination, which may allow definition of the degree of intramural tumor extension; evaluation of the extracardiac structures; and the ability to construct images in any plane. Resolution appears to be improved substantially by gating the computed tomographic acquisition to the cardiac cycle. CT currently appears to be most useful in the evaluation of suspected tumors of the heart to determine the degree of myocardial invasion and the involvement of pericardial and extracardiac structures. Ultrafast CT, a technique that uses electron beam technology, has a short scanning acquisition time that eliminates the motion artifacts occurring with conventional CT and appears to be useful for assessment of intracardiac masses.[129]

MAGNETIC RESONANCE IMAGING.

MRI may be of considerable value in detecting and delineating cardiac tumors and in some cases may depict the size, shape, and surface characteristics of the tumor more clearly than two-dimensional echocardiography.[130] The larger field of view with MRI (see Figs. 49-8, 10-20, and 10-21) provides better definition of tumor prolapse, secondary valve obstruction, and cardiac chamber size than does two-dimensional echocardiography. Contrast enhancement with gadolinium-diethylenetriaminepentaacetic acid and multislice imaging in the transaxial, sagittal, and long axes can provide precise three-dimensional information. MRI can also provide information about tissue composition that can help to differentiate tumors from thrombi.[131]

Angiography

Cardiac catheterization and selective angiocardiography are not necessary in all cases of cardiac tumors, because as already discussed, in many cases adequate preoperative information may be obtained by echocardiography, CT, or MRI. In several circumstances, however, the risk and expense of cardiac catheterization are outweighed by the supplemental information it may provide. These situations include cases in which (1) noninvasive evaluation has not been adequate in fully defining tumor location or attachment; (2) all four cardiac chambers have not been adequately visualized noninvasively; (3) a malignant cardiac tumor is considered likely; or (4) other cardiac lesions may coexist with a cardiac tumor and possibly dictate a different surgical approach. For instance, when a malignant cardiac tumor is suspected, cardiac angiography may provide valuable information about the degree of myocardial, vascular, and/or pericardial invasion. Likewise, in certain cases, such as the presence of pulmonary hypertension or the coexistence of significant valvular or coronary artery lesions, cardiac catheterization and angiography may provide

information that significantly affects the surgical approach.[132]

The major angiographic findings in patients with cardiac tumors include (1) compression or displacement of cardiac chambers or large vessels, (2) deformity of cardiac chambers, (3) intracavitary filling defects, (4) marked variations in myocardial thickness, (5) pericardial effusion, and (6) local alterations in wall motion. Displacement of the cardiac chambers or the great vessels without deformation of the internal contour may be observed in both benign and malignant tumors, whereas deformation of a cardiac chamber usually indicates an infiltrating malignant lesion. The most frequent angiographic findings are intracavitary filling defects, which may be either fixed or mobile. Fixed defects may be lobulated or appear as a coarse nodularity of the myocardium that is often difficult to distinguish from a mural thrombus. Such defects may reflect endocardial tumors with broad attachments or intramural tumors with intracavitary extension. Mobile intracavitary defects are usually pedunculated tumors, typically myxomas, although the stalk may be difficult to visualize. Such tumors may prolapse into the AV valve orifice during diastole or, in the case of ventricular tumors, into the left ventricular outflow tract during systole. An atrial ball thrombus may mimic a pedunculated tumor but is more likely to be associated with clot in the atrial appendage.

A localized increase in myocardial wall thickness, especially when accompanied by a pericardial effusion, suggests an infiltrating malignant tumor. It is often difficult to differentiate myocardial thickening from pericardial effusion, but this may be aided by observation of the thickness of the right atrial wall. Because the right atrial wall is seldom infiltrated by tumor, the finding of right atrial thickening to greater than 5 mm suggests a pericardial effusion.[132] In myocardial infiltration, localized areas of disordered wall motion may also be noted by cineangiography. Coronary arteriography may in some cases allow visualization of the vascular supply of the tumor, thus demarcating the extent of tumor invasion, the source of its blood supply, and its relation to the coronary arteries.[133] [134] However, the vascular pattern of cardiac tumors has not proved to be a useful sign of malignancy.

False-negative angiographic results generally occur when the diagnosis is not suspected before catheterization. False-positive results

are most often due to thrombus but may also be produced by many entities, such as streaming of nonopaque venous blood, a hematoma in the atrial septum, an aneurysm of the muscular or membranous ventricular septum, Bernheim's syndrome, congenital septal dysplasia, and hydatid cysts of the interventricular septum.

The major risk of angiography is peripheral embolization due to dislodgement of a fragment of tumor or of an associated thrombus. Therefore, thorough evaluation of all cardiac chambers by noninvasive methods before catheterization is recommended for patients suspected of having cardiac tumors so that contrast material can be injected into the chamber proximal (upstream) to the location of the tumor. The transseptal approach to the left atrium is particularly hazardous because of the frequent occurrence of left atrial myxomas in the region of the fossa ovalis.[135]

TREATMENT AND PROGNOSIS

Benign Tumors

Operative excision is the treatment of choice for most benign cardiac tumors and in many cases results in a complete cure.[5] [136] [137] [138] Although many tumors are histologically benign, all cardiac tumors are potentially lethal as a result of intracavitary or valvular obstruction, peripheral embolization, and disturbances of rhythm or conduction. Unfortunately, it is not unusual for patients to die or experience a major complication while awaiting operation; therefore, it is mandatory to carry out the operation promptly after the diagnosis has been established.

Although some epicardial tumors may be removed without the aid of extracorporeal circulation, most intramural and intracavitary tumors must be excised under direct vision, requiring use of a heart-lung machine. Closed approaches are not now recommended because of the increased risk of dislodging tumor fragments. In addition, excision cannot be as complete, and adequate inspection of the other cardiac chambers for additional tumors is not possible.

Dislodgement of tumor fragments constitutes a major risk of operation and can result in peripheral emboli or dispersion of micrometastases, which may seed peripherally. To reduce this risk, manipulation of the heart before cardiopulmonary bypass should be minimized. Some surgeons recommend that venous cannulation for cardiopulmonary bypass be performed via the femoral or azygos vein rather than through the right atrium to avoid dislodging an unsuspected right atrial tumor. In addition, the tumor should be removed en bloc when possible and the chamber then irrigated well with saline.

ATRIAL MYXOMAS.

Numerous reports document complete cure of left and right atrial myxomas with follow-up periods of 10 to 15 years.[139] [140] In about 1 to 5 percent of cases, a recurrence or second cardiac myxoma has been reported after resection of the initial myxoma.[72A] [141] [142] Possible causes of the second tumor include incomplete excision of the original tumor with regrowth; growth from a second "pretumorous" focus, i.e., metasynchronous; or intracardiac implantation from the original tumor. Because of the first two possibilities, some surgeons have advocated excision of the entire region of the fossa ovalis and repair of the resultant atrial septal defect to remove presumably high concentrations of pretumorous cells thought to be located in that region. In one case, the large size of a myxoma, together with its location on the posterior left atrial wall, necessitated complete removal of the heart, which was followed by autotransplantation, i.e., reimplantation of the patient's excised heart.[143] Laser photocoagulation of a 1-cm area around the stalk attachment site has also been suggested as a way of eradicating pretumorous cells without the need for creating an atrial septal defect.[144] Other surgeons have reported equally successful long-term recurrence-free periods with simple excision of the tumor and a small rim at the base. It now appears that in approximately 7 percent of patients with (1) a familial history of cardiac myxoma, (2) features of the complex of lentigines and other abnormalities, or (3) synchronous tumor appearance (i.e., numerous tumors at the time of presentation), the incidence of a second tumor occurring at some time in the future is in the range of 12 to 22 percent, as compared with approximately 1 percent for patients with sporadic atrial myxoma.[142] It is believed that tumor recurrence in these cases is from a second pretumorous focus of cells. In these high-risk patients, a careful search for additional tumors preoperatively and more extensive resection of the underlying endocardium, atrial septum, or both is recommended. Careful echocardiographic follow-up for detection of metasynchronous tumors is recommended[142] for all patients after resection of a myxoma.

OTHER BENIGN TUMORS.

Successful excision has also been reported for ventricular myxomas, as well as most other types of benign cardiac tumor, including rhabdomyoma, hamartoma, fibroma, lipoma, hemangioma, and papillary fibroelastoma.[145] [146] [147] The major surgical considerations in excision of ventricular tumors include preservation of adequate ventricular myocardium, maintenance of proper AV valve function, and preservation of as much of the conduction system as possible. Often, however, papillary muscles, chordae tendineae, or the AV conduction system must be sacrificed during the resection of a tumor, thereby necessitating replacement of the AV valve, implantation of a pacemaker, or both.

Malignant Tumors

Operation is not an effective treatment for the great majority of primary malignant tumors of the heart because of the large mass of cardiac tissue involved or the presence of metastases. The major role for surgery in such cases is to establish a diagnosis in order to preclude the possibility of a curable benign tumor. Nevertheless, in some cases, palliation of hemodynamics and/or constitutional symptoms and extension of life can be achieved by aggressive therapy. Survival for 1 to 3 years has been reported after partial resection, chemotherapy, radiation therapy, orthotopic cardiac transplantation, or various combinations of these modalities.[148] [149] [150] [151] [152] In some instances, localized recurrences have been eliminated by repeated operations. Some success in palliation of symptoms has been reported after the combination of chemotherapy and radiation therapy[153] and after radiation therapy alone.[152] Lymphosarcoma of the heart frequently responds to chemotherapy, radiation therapy, or both.[154] [155] Unfortunately, many other reports indicate a failure to alter the course of cardiac sarcomas despite various combinations of surgery, chemotherapy, and radiation therapy.

Chapter 50 - Pericardial Diseases

DAVID H. SPODICK

PERICARDIAL ANATOMY AND PHYSIOLOGY

Anatomy

Pericardial anatomy is specialized to serve its complex active and passive normal functions (Fig. 50-1) . [1] [2] There are two pericardial layers with nerves, lymphatics, and blood vessels. The *serosa* is a sac lined by a monolayer of mesothelial cells attached by loose connective tissue to the heart surfaces and the inner aspect of the fibrosa, lying on the

Figure 50-1 The opened normal pericardium and heart in situ. The epicardial mesothelium is transparent; the parietal pericardium--mesothelium and fibrosa--is translucent. A curved probe is in the pericardial transverse sinus. (From Spodick DH: Acute Pericarditis. New York, Grune & Stratton, 1959; author's copyright.)

heart like a collapsed rubber glove with finger-like projections over the juxtacardiac great vessels. It contains 15 to 35 ml of serous pericardial fluid, an ultrafiltrate of blood plasma. Externally, it is clasped by the fibrosa and continues upward an average of 6 cm above the aortic root over the aortic arch, where it blends with the deep cervical fascia, and over the venae cavae and pulmonary veins. *Ligaments* attach it to the sternum and the vertebral bodies loosely and to the central tendon of the diaphragm firmly. The serosa directly covering the heart surfaces is the *visceral pericardium* ("the epicardium"; see Fig. 50-1) . The fibrosa with the reflections of the serosal sac internally attached to it is the *parietal pericardium* ("the pericardium"). Parietal pericardial thickness varies from 0.8 to 2.5 mm (up to 3.5 mm on magnetic resonance imaging [MRI] and computed tomography [CT]).

PERICARDIAL SINUSES AND RECESSES.

The pericardial "cavity" is a nonuniform, mainly potential, space. During life most of the normal fluid is undetectable except in the major sinuses and the atrioventricular (AV) grooves and numerous recesses. In front of the atria and superior venae cavae and behind the proximal ascending aorta and pulmonary artery is a short pericardial passage, the *transverse sinus*, where the serosa encloses the terminal portions of the venae cavae and pulmonary veins, with separate recesses surrounding one third to two thirds of the proximal pulmonary artery. With the pulmonary veins it forms an inverted "U", framing a posterior projection, the *oblique sinus.* CT and MRI disclose numerous smaller recesses not detectable in the open pericardium at surgery and post mortem. The pericardial sinuses and recesses increase the pericardial capacity to accommodate increased fluid (or other contents), contributing to the *pericardial reserve volume.*

THE MESOTHELIUM.

Serosal mesothelial cells interdigitate and overlap, maintaining mechanical stability and permitting changes in surface configuration. Projecting *microvilli* presumably reduce friction and facilitate exchange of fluid and ions. *Cytoskeletal filaments* include keratins for structural support and actin. A basal lamina underlies the mesothelium and covers the subepicardial coronary vessels.

THE FIBROSA.

The fibrosa, which is composed mainly of *fibrocollagenous tissue,* is wavy in youth, arranged in fascicular bundles and thicker over thinner parts of the heart. The left atrium is tightly clasped by a dense fibrosal mesh. The fibrosa also contains *elastic fibers.*

NERVES, ARTERIES, LYMPHATICS, AND LYMPH NODES.

The *phrenic nerves* course upward over the anterior parietal pericardium and supply most of it. (They and their nutrient *pericardiacophrenic artery* must be protected during cardiac and pericardial surgery.) The esophageal plexus supplies vagal fibers. Parietal pericardial lymphatics drain to corresponding anterior and posterior mediastinal nodes while the superficial plexus of the cardiac lymphatics drains the visceral pericardium to the tracheal and bronchial mediastinal nodes.

The internal mammary arteries and small aortic twigs contribute the arterial supply.

SUBEPICARDIAL FAT AND CONNECTIVE TISSUE.

Between the heart and the epicardial mesothelium is variable connective tissue and a fat layer that increases with increasing body weight and is disproportionately increased in coronary disease. The fat contains a prostaglandin-like angiogenic factor and important parasympathetic ganglia in a *sinoatrial fat pad.*

Physiology of the Normal Pericardium

PHYSICAL EFFECTS.

Purely mechanical pericardial effects belong mainly to the parietal pericardium and are minimal in euvolemic individuals with normal hearts.[3] [4] [4A] The normal parietal pericardium contributes to resting cavitary diastolic pressures and retracts when incised, indicating it is under stress--indeed it exerts a contact stress. Moreover, by exerting stress[5] (magnified by any increase in pericardial fluid pressure) the normal pericardium restricts overall heart filling with a much greater effect on thinner parts like the right ventricle and atrium that probably depend on pericardial constraint for much of their normal pressures and dimensions (after pericardiectomy right

ventricular [RV] size increases). The pericardium also limits acute cavitary dilation.

Hypervolemia exaggerates all such effects: when cardiac volume is acutely increased, much of the increased ventricular diastolic pressure is borne by the pericardium, ensuring only minimal change in ventricular diastolic transmural

TABLE 50-1 -- ACUTE EFFECTS OF PERICARDIECTOMY/PERICARDIOTOMY

GENERAL EFFECTS
Macrophysiological effects are due to absent/reduced constraint of the heart.
Ventricular interaction:
Pericardium closed: right ventricle dominates
Pericardium open: left ventricle dominates
Experimental results depend on protocol:
Intact conscious closed-chest subjects vs. open-chest anesthetized subjects
Intact vs. blocked autonomic innervation
LA=left atrial; LV=left ventricular; RA=right atrial
SPECIFIC EFFECTS
Decreased
Interactions: ventricular; atrioventricular
Pulmonary volume overload in response to intravascular volume loading:
Excess intravascular volume redistributed from pulmonary to systemic circulation
RA mean pressure Systemic vascular resistance during maximal exercise
LA=left atrial; LV=left ventricular; RA=right atrial
Increased
Cardiac index and stroke work index due to improved LV systolic performance (Frank-Starling response to increased preload) LV end-diastolic diameter LV end-diastolic volume LV stroke volume LV transmural pressure Early LV filling velocity Early LV filling fraction LA booster pump function LA reservoir function Diastolic discharge frequency of LV mechanoreceptors
Increased Exercise Responses
Maximal O_2 consumption
Maximal cardiac output Maximal stroke volume LA pressure LA stroke volume
LV end-diastolic pressure
LA=left atrial; LV=left ventricular; RA=right atrial
Tallest precordial Often conspicuous Never conspicuous

Figure 50-2 Schema of stress-strain and pressure-volume curves of the normal pericardium. After the relatively small *pericardial resolve volume* is exhausted by filling of the pericardial sinus and recesses, the curve at first rises gently, with continued filling at some point more acutely; the time scale and exact proportions are variable depending on the *rate of filling* of the intact pericardial sac. (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

pressures while increasing pericardial constraint. With *euvolemia* the parietal pericardium appears to have minimal direct influence and virtually no effect during *hypovolemia*, probably because decreased preload and reduced heart size free the heart from pericardial constraint. Comparably, nitroglycerin, erect posture, and lower body negative pressure reduce cardiac volume acutely and hence pericardial effects on the myocardium. In contrast, both chronic pericardial effusion and chronic cardiomegaly lead to progressive stretch (time-dependent *stress relaxation* and *creep*) with subsequent hypertrophy of the parietal pericardium increasing its compliance and decreasing its constraining effect on the heart.

Pericardial constraint accounts for most of the resting diastolic right atrial (RA) and RV cavity pressures and contributes substantially to those on the left.
Pericardiotomy augments RV filling and stroke volume with improved systolic function by the Frank-Starling relation. The numerous effects of pericardiectomy or pericardiotomy are summarized in Table 50-1 .

The parietal pericardium is stiffer than cardiac muscle. Its stiffness is related to regional fiber orientations: more parallel fibers yield more pericardial stiffness.[2] Its mechanical functions mainly relate to (1) its contribution to apparent cardiac stiffness, (2) the effects of a chamber filled with fluid at subatmospheric pressure surrounding the heart, and (3) circulatory "feedback" regulation by pericardial neuroreceptors and mechanoreceptors. On stretching, the parietal pericardium initially "gives," due to extension of its elastic fibers and straightening of its wavy collagen. Thereafter, rapidly increasing resistance to increasing stretch produces characteristic "J"-shaped stress-strain and pressure-volume curves (Fig. 50-2) : an initial slow rise in pressure as volume increases--and of strain as stress increases--followed by an angle and a sharp rise. With intact pericardia, ventricular pressure-volume curves are exactly parallel. Acutely increased pericardial fluid or intracardiac volume couple the pericardium to the heart more closely, exaggerating this effect. Removal or opening of the parietal pericardium makes ventricular pressure-volume curves significantly more gentle so that ventricular pressure begins its sharp rise later at a higher cardiac volume and thereafter increases more gradually.

PRESSURE-VOLUME RELATIONSHIPS.

Normal intrapericardial pressure (-5 to +5 mm Hg) is nearly always negative and approximates and varies with pleural pressure during respiration. With early increase in pericardial fluid pressure, changes tend to be small, owing

to the *pericardial reserve volume*--the volume by which the unstressed pericardium exceeds the cardiac volume. Large increases in right-sided heart pressures, as by volume loading, raise pericardial pressure, but the *myocardial transmural pressure* increase is small and well below the change in pericardial pressure.

THE PERICARDIAL HYDROSTATIC SYSTEM.

Normally, pericardial fluid distributes hydrostatic inertial and gravitational (e.g., postural) forces over the cardiac surfaces. This favors approximation of end-diastolic transmural pressure throughout the ventricles and consequently uniform stretch of muscle fibers, tending to balance preload and so permit the Frank-Starling

mechanism to operate uniformly. (Note that pericardial contact pressure measured by flat balloons[5] rather than catheters may better represent baseline pericardial constraint of the heart.)

VENTRICULAR INTERDEPENDENCE AND PERICARDIAL CONSTRAINT OF THE HEART.

Expressed as ventricular interaction, ventricular interdependence represents the effects of pressure and volume changes in one ventricle on the activities of the other, including filling, contraction, and relaxation. Pericardial contributions to ventricular interaction help to explain reduced ventricular compliance when there is increased pressure in the other ventricle. Although the normal right ventricle is much more compliant than the left, the pericardium constrains both similarly and tends to equalize their compliances (nonpericardial interaction also occurs by means of the circumferential and especially the septal myocardial muscles). *Moreover, either ventricle generates greater isovolumic pressure from any diastolic volume when the pericardium is intact than when it is open or removed.* Diastolic cardiac chamber interactions are greatly magnified by the pericardium, which minimally affects systolic interaction. For example, acutely increased RV size (e.g., cardiocirculatory volume overload or RV infarction) raises intrapericardial pressure significantly, imposing a steeper pressure-volume curve (increased stiffness) on both pericardially constrained ventricles.[6] Interaction operates continuously, although minimally, during normal breathing. Inspiration increases RV filling, which slightly reduces left ventricular (LV) filling, and consequently output, and decreases arterial pressure. Respiratory effects are exaggerated by even small increases in pericardial fluid and markedly in cardiac tamponade; this produces pulsus paradoxus.

TRANSMURAL PRESSURES.

Transmural pressures describe the force (related to pressure) balance across a cavity wall. The transmural pressure of the pericardium itself (pericardial pressure minus pleural pressure) approximates zero, although it is usually slightly negative and varies with pleural pressure. *Myocardial transmural pressure* (intracavitary pressure minus intrapericardial pressure) normally is less than 3 mm Hg and depends on pericardial pressure. Transmural pressure at end diastole is a measure of preload (the actual chamber-distending pressure); transmural pressure is thus a true "filling pressure." Therefore, the closed pericardial chamber, normally at slightly subatmospheric pressure, ensures that myocardial transmural pressure stays low relative to even large increases of cavitary diastolic pressures. Myocardial performance is largely determined by end-diastolic fiber length set by end-diastolic chamber volume, which is determined by end-diastolic transmural pressure due to pericardial constraint.

NORMAL RESPIRATORY EFFECTS: RIGHT HEART/LEFT HEART RECIPROCATION(Fig. 50-3) .

Intrapericardial pressure approximates pleural pressure and varies with its respiratory changes: about -3 mm Hg at end expiration to -6 mm Hg at end inspiration. The normal inspiratory fall in pleural pressure reduces pericardial, RA, RV, wedge, and systemic arterial pressures slightly. However, inspiratory pericardial pressure decreases more than atrial pressures so that RA and other central transmural (distending) pressures increase, augmenting systemic venous return and right-sided heart filling and, therefore, RV preload and output (pulmonary artery flow velocity increases). Simultaneously, inspiratory aortic flow decreases as aortic transmural pressure increases (which increases impedance to ejection). Moreover, as the increased RV output crosses the lung any inspiratory "pooling" would reduce the gradient for left atrial (LA) filling. The corresponding slight inspiratory decrease in LV transmural pressure and the increased LV afterload (impedance to ejection) reduce LV stroke output. These are directionally identical, with far greater changes in the same measurements during pulsus paradoxus.

PASSIVE PERICARDIAL FUNCTIONS.

Membranous functions of the pericardium result from its physical presence. It appears to buttress thinner parts of the myocardium, particularly the RA and RV, and to block inflammation from contiguous structures. It reduces friction due to heart movement by means of the pericardial fluid and surfactant phospholipids. *Ligamentous functions* slightly limit cardiac displacement through attachments to adjacent structures.

MICROPHYSIOLOGY OF THE NORMAL PERICARDIUM[2]

Cardiocirculatory feedback regulation by pericardial servomechanisms include (1) *neuroreceptors* in epicardium and fibrosa that detect lung inflation and can alter blood pressure and heart rate through the vagus nerves; (2) *sympathetic efferents* doing the opposite; (3) *mechanoreceptors* sensitive to ventricular stretch, determined by ventricular volume and transmural pressure (myocardial dysfunction is sensed by mechanoreceptors monitoring beat-to-beat changes in cardiac volume, and other mechanoreceptors signal myocardial tension reflexly to match contraction strength with peripheral resistance); and (4) *chemoreceptors* sensitive to substances in the pericardial fluid, which respond to digitalis glycosides and perhaps contribute to their bradycardic effect.

NORMAL PERICARDIAL FLUID.[3]

Serous pericardial fluid (normally 15 to 35 ml) is mainly an ultrafiltrate of plasma including some overflow of myocardial interstitial fluid and lymph. Protein concentration is lower than in plasma but with relatively high albumin. Electrolyte concentrations yield an osmolarity less than plasma, consistent with such an ultrafiltrate.

MESOTHELIAL METABOLIC ACTIVITY.[1] [2] [3]

The mesothelium has cyclooxygenase, prostacyclin synthetase, and lipoxygenase activities; prostaglandin E_1 , eicosanoids, and large amounts of prostacyclin (PGI_2) are continually released into the pericardial cavity in response to hypoxia, pericardial stretch, and increased myocardial work and loading conditions. These prostanoids can alter pericardial sympathetic neurotransmission, myocardial work, loading conditions, and myocardial contractility and modulate the caliber and tone of the coronary vessels with multiple effects on cardiac electrophysiology, possibly including reduction of reperfusion-induced arrhythmias. *Prostacyclin also inhibits*

Figure 50-3 Inspiratory effects on heart and pericardium (reversed in expiration). Inspiration, by means of diaphragm descent, reduces pleural cavity pressure while increasing abdominal pressure. Venous return to the right side of the heart is sharply increased, with filling at the expense of the left side of the heart (atrial and ventricular septa move to the left). This is accentuated by the fall in aortic transmural pressure, which increases impedance to ejection by the left ventricle. This is the normal response pattern; during compressive pericardial disorders (tamponade, constriction) its degree is increased (pulsus paradoxus). See text. LA=*left atrium; LV=left ventricle; RA=right atrium; RV=right ventricle; SVC and IVC=superior and inferior venae cavae.*

platelet aggregation and thrombosis in the major coronary vessels as well as clotting during intrapericardial bleeding, whereas fibrinolytic activity by the mesothelium opposes both intrapericardial clotting and adhesion formation. Small amounts of complement (C3, C4, CH_{50}), other immune factors, myocardial cellular enzymes, and related compounds are continually released into the pericardial fluid.[3] During transmural cardiac injury and necrosis, pericardial fluid "washes" the cardiac surfaces, diluting substrates leaked into it that might adversely affect the superficial myocardial sympathetic nerves. A cell-to-cell interaction between pericardial mesothelium and ventricular myocytes in tissue culture may modulate myocyte structure, function, and gene expression, whereas fibroblast growth factor 2 (FGF_2) in pericardial fluid is a major determinant of myocyte growth and functionally significant angiogenesis. Other growth factors modulate activation of macrophages and coronary endothelial cells so that pericardial fluid analyses may give prognostic information with respect to neoangiogenesis and plaque stability. The effects on the heart, its nerves, and the coronary arteries of intrapericardially injected substances permit the pericardial sac to be used for local delivery of therapeutic agents and gene products. This has been accomplished by catheter through the RA appendage and with an instrument specifically designed for access to the normal pericardium (i.e., the perDUCER). [7] [8]

AUSCULTATORY PHENOMENA (See Chap. 4)

There are five categories of auscultatory phenomena in pericardial disorders: (1) pericardial rubs, (2) abnormal heart sounds, (3) clicks, (4) murmurs, and (5) the effect of pneumohydropericardium.[9] [10]

PERICARDIAL RUB.

The pericardial friction sound (rub, "friction rub"; Fig. 50-4) , a hallmark of acute pericarditis, occasionally audible in subacute and chronic pericardial disease, is ascribed to friction between inflamed, scarred, or tumor-invaded serosal surfaces *(endopericardial rub),* including those after sclerotherapy of effusions, or, infrequently, between parietal pericardium and pleura or chest wall *(exopericardial rub)* or both *(endo-exopericardial rub).* Endopericardial rubs may also be due to destruction of surfactant pericardial phospholipids. The common endopericardial rub, often monotonal, nearly always disappears with resolution of acute inflammation. Exopericardial

rubs sometimes result from penetration by severe acute pericarditis but otherwise are due to direct extension, inflammation, or tumor implants from adjacent structures. They may change radically with respiration, have a musical quality, and seem superficial. Like endopericardial rubs, exopericardial rubs also occur after cardiac surgery and with constrictive and nonconstrictive pericardial scarring; most are from adjacent pleuritis--*pleuropericardial rubs*--due to pleural, or both pleural and pericardial, involvement and have both respiratory and cardiac periodicity. *Conus rubs* accompany pulmonary embolism, thyroid "storm" *(Means-Lerman scratches),* and acute beriberi heart disease; they are ascribed to dilation of the pulmonary conus in a hyperactive heart. In acute pericarditis, rubs usually disappear with accumulation of significant pericardial effusion, but frequently they do not, even during tamponade. Indeed, some rubs, probably exopericardial, "paradoxically" disappear after pericardiocentesis.

Auscultatory Characteristics[9]

Composed of mixed (mainly high) frequency vibrations, most rubs, unlike most murmurs, frequently wax, wane, and transiently disappear. They vary from subtle distant "scrapes" to grating or scratching noises, which may be loud and even palpable. Rubs often give the illusion of "obliterating" or "going through" the heart sounds while seeming superficial. Many change with breathing and body position and do not respect conventional murmur zones of maximum intensity and radiation. Yet, the vast majority of rubs are heard best, or only, along the left mid to lower sternal edge, where palpability is most likely, owing to proximity of the right ventricle to the chest wall. Occasional rubs are sharply localized anywhere along any heart border. Usually loudest in inspiration, particularly with increased pericardial fluid, some rubs have no respiratory predilection; rarely, rubs increase in expiration. Finally, to elicit or accentuate rubs, the examiner should raise all four of the patient's extremities

Figure 50-4 Triphasic pericardial rub: electrocardiogram *(top),* multifilter phonocardiograms *(center)*, and peaks of carotid pulse *(bottom).* S_1 =first heart sound; S_2 =second heart sound. Rub components: DR=diastolic rub; AR=atrial rub; SR=systolic rub. Rub vibrations are mainly high frequency (top two phonocardiograms) and much reduced at lowest frequency (MA/100). This example shows the most common relative intensity: SR louder than AR, louder than DR; only SR remains at lowest filtration. (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

simultaneously to distend the right side of the heart by increased venous return or applying the stethoscope to the precordium while the patient rests on the knee and elbows (Fig. 4-44) .

Components.

Classically described as biphasic ("to-and-fro"), multiobserver investigations revealed, in patients with heart rates less than 120 beats/min, triphasic rub patterns in well over one half of those in sinus rhythm. The rub occurred with atrial systole *(atrial rub),* ventricular systole *(systolic rub),* and early diastole *(early diastolic rub)* (see Fig. 50-4). Only about one third are biphasic (to-and-fro), with some due to absence of atrial systole in rhythm disorders. About 10 percent were monophasic, usually during ventricular systole. At heart rates of more than 100 beats/min the early diastolic and atrial components may fuse *(summation rub).* Some rubs only appear after exercise; others with one or two components may acquire the remaining components on exercise.

HEART SOUNDS.

Pericardial disease can alter heart sounds and their auscultatory appreciation by insulation and particularly by hemodynamic changes.[9] Insulation by pericardial fluid should tend to make heart sounds more distant. Hemodynamic changes common to both tamponade and constriction decrease myocardial compliance and stroke volume, tending to diminish first (S_1) and second (S_2) heart sounds and relatively accentuate the pulmonic component of S_2 . Constrictive pericarditis produces its hallmark, the abnormal early diastolic sound[9] --a variant of the third heart sound (S_3 ; Fig. 50-5) --as well as abnormal splitting of S_2 . Effusive constrictive syndromes (simultaneous scar and fluid) produce mixed pictures.

The early diastolic sound of constriction coincides with the abrupt deceleration of excessively rapid early filling[9] [10] and occurs earlier than an abnormal S_3 of myocardial disease and AV valve regurgitation. The early diastolic sound may be the only loud heart sound (sometimes with an intense "knocking" quality) and misinterpreted as S_1 , especially during rapid heart rates. At bedside, the S_3 appears after the carotid crest and coincides with the trough of the jugular *y* descent.[9] A faint or absent S_3 may be revealed by prompt squatting. Patients with heavy calcification can have a particularly loud and sharp early diastolic sound, owing to markedly reduced compliance. Like its timing, early diastolic sound intensity varies directly with the abruptness with which ventricular expansion halts; that is, louder third sounds correlate with high diastolic pressures and steepness of reascent from the typical early diastolic "dip" of ventricular pressure and chest wall displacement curves. In sinus rhythm, a fourth heart sound (S_4) is occasionally present and ascribable to high resistance to active filling. Lack of impairment of atrial systole explains why the S_4 is more common in *elastic constriction* (see p. 1849).

CLICKS.

Clicks are high-frequency, discrete vibrations resembling opening snaps of stenosed valves. Classically ascribed to pericardial scarring and articulation of calcifications, this remains speculative, because most clicks are due to intracardiac phenomena related to valves and chordae.[9] Indeed, pseudoprolapse and true prolapse of mitral and tricuspid leaflets (due to disproportionate shrinkage of ventricular volume in tamponade and constriction) produce clicks.

MURMURS.

Murmurs arise from turbulent flow across orifices and tubes. In pericardial disease they are epiphenomena--due to related or unrelated coincident heart disease or when pericardial scarring narrows a valve ring or portion of the heart, aorta, or pulmonary artery.

Murmurs with inflammatory cysts, hematomas, or abscesses are due to compression or actual physical disruption of valves. AV groove compression has produced annular mitral and tricuspid stenosis with murmurs indistinguishable in quality, timing, and respiratory behavior from those of AV valve disease.[10] Selective scarring has also produced systolic murmurs of aortic supravalvular and pulmonic supravalvular and infundibular stenosis. In constrictive pericarditis, unexplained mitral and tricuspid regurgitant murmurs are common. Some murmurs appear only postoperatively; others arise from local inequality within a generalized constricting scar. Coexisting cardiac disease independently produces murmurs that may become modified by constriction.

AUSCULTATORY EFFECTS OF PNEUMOHYDROPERICARDIUM.

When air or other gas overlies pericardial fluid, due to trauma, gas-producing organisms, or a fistula from adjacent organs, a metallic tinkle synchronous with systole may be heard if the amount of gas is small. Large amounts produce a churning, splashing, "*mill-wheel sound*" from agitation of the gas-liquid interface by the beating heart.[9]

ELECTROCARDIOGRAPHIC ABNORMALITIES IN PERICARDIAL DISEASE (See Chap. 5)

The pericardium produces no detectable electrical phenomenon, yet pericardial disease can significantly modify the electrocardiogram (ECG).[11] Quasi-specific ST-T wave changes follow spread of pericardial inflammation to the subepicardial myocardium; a superficial myocarditis results.[12] Excess pericardial fluid, fibrin, or dense scar may insulate the heart or short circuit cardiac currents, tending to decrease voltage, although hemodynamic impairment may be as or more important than the size of effusion (unless massive) in reducing voltage. ECG effects of constrictive scarring depend additionally on fibrosis and calcification of the subjacent myocardium; any asymmetry of scarring can mimic disease of a cardiac chamber, valve, or great vessel.

Acute Pericarditis

Acute pericardial inflammation with a superficial shell of myocarditis provokes ST-T abnormalities that, in typical three or four-stage sequence (Table 50-2) , are pathognomonic of acute pericarditis.

STAGE 1.

This stage alone (Figs. 50-6 and 5-47) is quasi-diagnostic. It mimics "early repolarization" and acute

Figure 50-5 Constrictive pericarditis: phonocardiogram showing high-amplitude third heart sound (S_3) larger than S_1 and both components (A_2 and P_2) of well-split second heart sound (S_2). (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

TABLE 50-2 -- ECG: STAGE I PERICARDITIS VS. "EARLY REPOLARIZATION"

	STAGE 1 PERICARDITIS	"EARLY REPOLARIZATION"
Sex	Either	Virtually all males
Age	Any	Usually younger than 40 years
Prevalence in mental institutions	Sporadic	Relatively common
J-ST evolution	Yes	No
PR segment deviations	Frequent	Occasional
	Ubiquitous	Restricted distribution
	Often conspicuous	Never conspicuous
R-S slurring	Uncommon	Nearly always
T waves		
Amplitude	Normal	Usually tall
Summit	May be blunt	Peaked
J height/T apex V6 (PR segment as baseline)	Usually 25%	Usually <25%
Tallest precordial R wave	Usually V_5	Usually V_4

Modified from Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.

infarction with anterior and inferior ST segment elevation. Characteristic evolution involves the ST junction (J) and T wave. Unless there is a deeper involvement, there are no QRS complex abnormalities. The entire subepicardial myocardium is involved in generalized pericarditis so that most ECG leads develop simultaneously "in phase" with each other. The mean J-ST vector (axis) is usually directed left and inferiorly ("southeast"), between +30 and +60 degrees in normal hearts. In the thin-walled atrium, myocarditis cannot be superficial and, at least early in acute pericarditis, exaggerates atrial T waves (Ta wave) that appear early, causing PR segment deviations opposite to P wave polarity. Thus PR segment deviations have a vector (axis) 180 degrees opposite to the P axis--usually at -120 to -150 degrees ("northwest") (see Fig. 50-6) . Stage I is virtually pathognomonic of acute pericarditis when it involves virtually all leads. Minimal lead involvement to be considered typical includes I, II, aVL, aVF, and V_3 through V_6 .[11] Leads theoretically reflecting "endocardial" events show depressed J points and elevated PR segments. Thus, the ST segment is always depressed in lead aVR, very frequently depressed or isoelectric in V_1 , and occasionally depressed in V_2 .

STAGE II.

This stage is evolutionary; in early stage II, all ST junctions return to the baseline more or less "in phase" with little change in the T wave; PR segments may now be deviated if they had not been in stage I. In late stage II, the T waves progressively flatten and invert mainly in leads that had shown ST segment elevations.

STAGE III.

This stage shows generalized T wave inversions in most or all leads. If first recorded in stage III, pericarditis cannot be diagnosed by ECG because stage III is also consistent with diffuse myocardial injury, "biventricular strain," or frank myocarditis. Stage III has become less frequent, presumably due to effective early treatment with antiinflammatory agents.

STAGE IV.

In this stage, the ECG returns to its prepericarditis state. Occasionally, stage IV does not occur and there are permanent, generalized or focal T wave inversions and flattenings.

TYPICAL ECG VARIANTS.

Typical variants[11] include the following:

1. In stage I, the ST segment may be isoelectric or slightly depressed in lead III with a horizontal or semihorizontal QRS axis; with a vertical axis, the ST segment is isoelectric or slightly depressed in lead aVL and isoelectric in lead I.
2. There may be rapid evolution of stage I to normality, that is, return of the elevated J-ST to the baseline with little or no T wave change.
3. Any stage may be absent.
4. Stage II may persist indefinitely or for long periods, with T wave flattening or inversions indicating a more aggressive process or presaging constrictive evolution.

ATYPICAL ECG VARIANTS.

Five atypical variants render the ECG diagnostically nonspecific[11] :

1. There may be no ECG change, either because acute abnormalities are missed (rapid evolution or delayed recording) or because

superficial myocarditis is low-grade or absent. Pericarditis of acute myocardial infarction produces only localized pericardial involvement with no general stage I.
2. PR segment deviations alone are not rare; these are very sensitive (with or without ST deviations) but of undetermined specificity.
3. J-ST changes may be restricted to only a few leads, which is misleading because localized cardiac injury is typical of myocardial ischemia. One may suspect this variant because pericarditic changes lack reciprocal ST deviation.
4. T wave inversions before all ST junctions have returned to the baseline, characteristic of myocardial infarction and myopericarditis (in special cases, patients with preexisting T wave abnormalities, especially digitalis effect, may show J-junction deviation while the original T wave abnormalities persist with or without PR segment deviations) and myopericarditis.
5. In stage III there may be T wave inversions only in some leads (usually V_3 or V_4 to V_6).

Figure 50-6 Acute percarditis: stage 1 ECG. J points are elevated except aVR and V_1 . T waves are essentially normal. PR segments are depressed except aVR and V_1 . Absence of PR deviations in a single limb lead (here, aVL) is common. See text.

Nearly half the ECGs in patients with rubs and corresponding clinical syndromes do not present with or evolve a stage I.[11] The majority with typical ECG changes are always recorded on presentation or the first or second day thereafter. Differentiation from myocardial ischemia is crucial because thrombolytic treatment with unrecognized pericarditis can cause hemopericardium.[11] (see Table 50-5 and Chap. 35) . Differentiation of stage I from the apparently normal variant of "early repolarization" is summarized in Table 50-2.

RATE AND RHYTHM.

Although heart rate is usually rapid (80-130 beats/min), slower rates are noted in patients with autonomic problems--typical of uremic pericarditis. Sinus rhythm is the rule in the absence of heart disease. Indeed, uncomplicated acute pericarditis does not produce significant rhythm disturbances[11] unless there is underlying cardiac disease either preexisting or related through pericardial inflammation, myocardial or pericardial tumor invasion, or associated metabolic abnormality.[11] [12]

PERICARDIAL EFFUSIONS (see pp. 1831, 1838).

ECG effects of pericardial effusion are difficult to assess. Low-amplitude ECGs are seen in many, but certainly not all, cases with detectable effusion. Chronic effusions with compression atrophy or scarring of the myocardium may cause permanent low voltage.[11] Yet large effusions without voltage or other ECG abnormalities are not uncommon, especially in patients with voltage-increasing heart disease. ST-T wave abnormalities during pericardial effusion can persist or disappear after paracentesis. They may be related to superficial myocarditis, but in some cases they seem to depend on presence of fluid, possibly due to myocardial compression or ischemia.[11] ST segment displacements are more common with rapid fluid accumulation (as in hemopericardium). P wave voltage reduction usually requires truly massive effusions. Tamponade can reduce voltage even with smaller amounts of fluid, partly due to reduced cardiac volume (Brody effect). Hemolysis of red cells in fluid can produce excess potassium concentrations that affect the ST segment and T wave, including T wave peaking and reversal of previous T wave polarity. Pleural effusions, particularly on the left, may contribute to voltage reduction, whereas generalized fluid retention (as in cirrhosis and heart failure) can reduce ECG voltage without pericardial disease.[11] Note that the presence of *more than minimally increased pericardial fluid raises the energy required for defibrillation and cardioversion.*[13]

CARDIAC TAMPONADE (see p. 1841).

Unless massively effusive, chronic pericardial effusion and chronic cardiac tamponade have little ECG effect. In acute tamponade, any ECG stage of acute pericarditis can be found but most often ST (J) segment deviations are absent and T waves are low to inverted. Some patients have nearly normal ECGs. Critical acute hemorrhagic tamponade provokes bradycardia, often of AV junctional origin or with preterminal electromechanical dissociation. QRS-T voltage tends to decrease in tamponade, although the degree of change is unrelated to severity. (Note that preexisting heart disease may account for high or low voltage.) Very few patients have microvoltage, and the P waves usually escape. Whereas purely insulating effects of fluid require large effusions, voltage reduction in tamponade probably is mainly due to angulation and especially to compression of the heart, which reduces its size. (Occasional tamponade patients develop left-axis deviation, possibly due to ventricular displacement or greater compression of the thin right ventricle.) Some T wave abnormalities may be due to reduced coronary flow in previously diseased coronary arteries, owing to low aortic pressure in tamponade plus epicardial compression of the coronary vessels as well as obliteration of the normal transmural myocardial pressure gradient. Pre-tamponade T wave inversions may be pseudonormalized.[11]

ELECTRICAL ALTERNATION.

In the appropriate clinical setting this finding is *almost pathognomonic of tamponade,* occurring in up to one third of cases because of periodic (nearly always 2:1) oscillation of the heart swinging within the effusion.[4] Although typical of large effusions, alternation can occur with as little as 200 ml of pericardial fluid with a thick parietal pericardium. It reflects alternation of the spatial axis of the QRS complex and other waves due to cardiac movements while the ECG electrodes remain in place. T wave alternation is less easily seen, whereas P waves and PR segments rarely visibly alternate. Removal of a small fluid aliquot usually abolishes alternation, just as the same initial decrement usually produces the greatest relative hemodynamic improvement. Alternation is critically related to heart rate: beta-adrenergic blocking agents can slow the rate and make alternation disappear.

EARLY REPOLARIZATION (see Table 50-2) .

An ECG almost indistinguishable from the J-point deviations of stage I--found mainly in males younger than age 40 and prevalent in mental institutions--may involve most ECG leads and mimic pericarditis. Unlike stage I, this ECG does not acutely evolve and differentiation is sometimes difficult, requiring clinical correlation.[11] In early repolarization, J-point elevations are usually accompanied by a slur, oscillation, or notch at the end of the QRS just before and including the J point and best seen with tall R and T waves (the largest precordial R wave is usually in V_4 rather than V_5). In general, R wave and T wave voltages are large, and a differential test using the PR segment as a baseline is the height of the J point in lead V_6 . Pericarditis is likely if the J point is more than 25 percent of the height of the T wave apex.[11]

Constrictive Pericarditis

ECG abnormalities in constrictive pericarditis, although often characteristic, are nonspecific. One "typical" ECG would include mildly low voltage QRS and flattened to inverted T waves in all leads of "epicardial" derivation (Fig. 50-7) .[11] (Postoperatively, continued low-voltage predicts reduced survival.) In some patients with chronic and many with acute and subacute constriction, T wave inversions of stage III never improve or regress incompletely. Especially with chronicity, P waves can be wide and bifid (interatrial block), sometimes resembling P-mitrale with P wave axis between +90 and -10 degrees; these predict the future occurrence of atrial fibrillation. The P wave in V_1 may indicate LA enlargement (P-terminal force
4 mV) or RA enlargement (large positive initial component) or both. Yet, many patients have normal ECGs or only nonspecific T wave abnormality. Pleural effusions, ascites, and fluid retention also modify the ECG in constrictive pericarditis. Unlike acute pericarditis, arrhythmias occur in constrictive pericarditis and increase with chronicity (mainly atrial fibrillation and occasionally atrial flutter). Preoperative conversion to sinus rhythm is difficult. Rhythm disturbances are more common with pericardial calcification or an enlarged cardiopericardial silhouette. Arrhythmias always imply cardiac abnormality (see Chap. 25) .

QRS ABNORMALITY.[10] [11]

In chronic constrictive pericarditis, low voltage and myocardial atrophy are common and probably related. In acute and subacute constrictive pericarditis

Figure 50-7 Constrictive pericarditis (chronic form). Low voltage is evident in ten leads and relatively low voltage occurs in V_2 and V_3 , with flat, -+, inverted, and frankly inverted T waves. P waves are wide (interatrial block [IAB]) with P axis=0 degrees: P wave is flat in aVF, inverted in lead III, and upright in lead I (arrows). Wide negative phase of biphasic P wave in V_1 indicates left atrial enlargement (of which IAB is also a strong correlate). (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

(now the prevalent forms) the QRS axis tends to be normal. In classic chronic constrictive pericarditis, the frontal QRS axis tends to be vertical, in many cases more positive than +60 degrees, and sometimes with right-axis deviation; verticalization increases with chronicity. The vertical tendency may represent disproportionate RV injury and strain or perhaps disuse atrophy of the underloaded left ventricle. Electrical alternation may occur in *effusive-constrictive pericarditis* with dominant parietal pericardial constriction and relatively little effusion. QRS abnormalities typical of RV hypertrophy may evolve in patients with unequal constriction or strategically placed postpericardiectomy scarring affecting the pulmonary artery, the right ventricle, the AV groove, or the mitral valve. Other QRS abnormalities, including abnormal Q waves, reflect myocardial penetration by inflammation, scarring, or focal atrophy. T wave abnormalities are variable. After pericardiectomy, QRS voltage nearly always increases with slow or no evolution in patients with myocardial atrophy. Vertical or right-axis orientation may persist, but there is frequently a limited correction. T wave abnormalities may not change and often temporarily worsen.

CONGENITAL ABNORMALITIES

Most congenital abnormalities of the pericardium are discovered accidentally at cardiac surgery, with routine chest radiography, on fetal echocardiography, or while diagnosing unusual, often unrelated, symptoms.[14] Rarest are *pericardial bands* obstructing the superior vena cava. *Pericardial celomic cysts* are most frequent and

usually least important. *Bronchogenic cysts* with congenital partial pericardial defects are important because of potential compression of the heart and vessels.

Congenital Cysts and Diverticula

Cysts occur anywhere on the pericardium (mostly at the right cardiodiaphragmatic angle) and are clinically silent. Usually less than 3 cm in diameter, most are unilocular and smooth and contain clear fluid.[14] Cysts can be associated with chest pain, dyspnea, cough, and significant arrhythmias, probably owing to compression and erosion of adjacent tissues.[15] [16] Rare pedunculated cysts may undergo torsion with chest pain and ischemia-related lesions of the cyst wall. Cysts can become secondarily infected and can complicate related or unrelated pericardial effusion and tamponade. Rapid enlargement is rare, and "spontaneous" resolution is probably due to traumatic rupture.[14] Intrapericardial rupture of large cysts threatens acute tamponade. Indeed, if very large they can mimic pericardial effusion. The principal significance of unilocular and multilocular congenital cysts is simulation of mediastinal tumors (especially when situated away from the diaphragm), loculated pericardial effusions and hematomas, pericardial diverticula, and ventricular pseudoaneurysms.

Diagnosis.

This is usually by appropriate imaging and, rarely, thoracoscopy or thoracotomy and aspiration.[14] Cyst fluid, which may contain hyaluronic acid, is yellowish or crystal clear. On imaging, tumors with central necrosis may simulate cysts, whereas unusually shaped and internally bleeding cysts may simulate tumors. Occasionally, a bronchogenic cyst will be "trapped" in or on the pericardium. Benign teratomas, which may undergo malignant change, and lymphangiomas have the same differential diagnosis. Usually CT (especially electron beam), MRI, and, with some difficulty, two- and three-dimensional echocardiography, especially transesophageal (TEE), can be diagnostic.[17] Treatment by TEE-assisted open, or video-assisted thoracoscopic, excision is required for symptomatic, locally compressive, and hemodynamically compromising cysts. Aspiration with or without ablation by a sclerosant (e.g., alcohol) is an option. *Pericardial diverticula* are rarer and resemble cysts except that a comparable developmental abnormality has left a communication with the pericardial cavity.

Absence of the Pericardium

Complete *pericardial agenesis* is rare, often discovered accidentally at cardiac operation or during evaluation of unrelated symptoms, and demonstrable by negative imaging. [17] [18] [18A] Partial loss of any part of the pericardium can occur with or without a defect in the adjacent pleura and very often with some kind of associated congenital cardiac, pulmonary, or skeletal abnormality. Most common is absence of the entire left side of the pericardium. Partial left absence and absent right pericardium are uncommon. Absence of the inferior pericardium with or without diaphragmatic defect or aplasia is rare in adults. Associated diaphragmatic defects may permit intrathoracic, including intrapericardial, herniation of abdominal organs.

Absence of the entire right or (especially) left pericardium permits homolateral cardiac displacement, which is visible on imaging and increased with the patient lying on the side of the defect (particularly the left), which accentuates cardiac mobility. Small increases in preload cause undue ventricular dilation, especially of the right ventricle.

Partial absence of the left pericardium potentially permits herniation and entrapment of parts of the heart like the left atrium, LA appendage, right atrium, right ventricle, and, with apical defects, protrusion through the defects of large parts of both ventricles. Defect edges may compress cardiac chambers, great vessels, and coronary vessels. The phrenic nerves may be displaced to the edges.[19] [20] [21]

SYMPTOMS.

Acute or chronic symptoms like vague chest pain or dyspnea, including trepopnea, may or may not be related to any pericardial defect, but exacerbation in the left lateral decubitus is typical of left-sided defects.[11] [14] [22] Unusual torsion of the great vessels by unrestrained cardiac mobility may affect filling, ventricular ejection, and coronary flow and has been associated with tricuspic chordal rupture. Ischemic pain and myocardial infarction occur when the edge of a defect critically interrupts a coronary artery.

PHYSICAL FINDINGS.[11]

Physical findings usually only support a diagnosis, especially in left-sided absence, and include basal ejection murmurs, wide split S_2 , as well as apical midsystolic clicks and systolic murmurs accentuated by inspiration. Extensive left defects produce conspicuous precordial impulses; the apex, frequently in the anterior or midaxillary line, is hypermobile with changes in body position.

ELECTROCARDIOGRAM. [11]

Sinus bradycardia is common. Usually, with complete left-sided defects, ECG changes reflect posturally changing anatomical abnormalities and relative volume overload of the right side of the heart. Right-axis deviation and incomplete or complete right bundle branch block are the rule. Leftward displacement of the precordial transition zone is common with poor R wave progression and sometimes QS in leads V_1 to V_3 , mimicking anterior infarction: conspicuous single-peaked P waves reflect RA overload.

IMAGING.

In extensive or complete left pericardial absence chest radiographs show leftward displacement of the heart and aortic knob with the trachea midline. The pulmonary artery "segment" bulges or fills in to straighten ("mitralize") the left heart border; the right border can be so levodisplaced that the spine is clearly seen. "Air" (projections of lung) between the aorta and pulmonary artery or between the left diaphragm and inferior cardiac border are common. Herniation of the LA appendage is virtually diagnostic of partial left defect but must be distinguished from congenital LA aneurysm. CT and MRI show all the features and are most reliable for absence of pericardial tissue. MRI is more sensitive and can show the typical absence of the preaortic pericardial recess (almost always present in normal hearts) in both partial and complete absence of the left pericardium.[14] [17]

TREATMENT.

Treatment, reserved for symptoms (unless herniation threatens) includes partial or complete pericardiectomy, pericardioplasty or extension of the defect to relieve tension on critical structures, and LA appendectomy. Postoperative adhesions help stabilize cardiac position.

ACQUIRED PERICARDIAL DISEASES

Virtually every pathological process, medical and surgical, can involve the pericardium primarily or indirectly.[23] [23A] Thus, freshly diagnosed pericardial disease may or may not be related to other conditions. Classifications in Table 50-3 necessarily overlap; for example, the post-myocardial infarction syndrome belongs both to myocardial/pericardial injury and to the immunopathies. [24] Because of etiopathogenic complexities, protocols for diagnosis and management have been carefully designed and prospectively evaluated.[25]

TABLE 50-3 -- ETIOLOGY/PATHOGENESIS OF ACQUIRED DISEASES OF THE PERICARDIUM*

MAJOR CATEGORIES

I. Idiopathic pericarditis (syndromes)
II. Due to living agents--infectious, parasitic
III. Vasculitis/connective tissue disease
IV. Immunopathies/hypersensitivity states
V. Diseases of contiguous structures
VI. Disorders of metabolism
VII. Trauma--direct, indirect
VIII. Neoplasms--primary, metastatic, multicentric
IX. Of uncertain pathogenesis or in association with various syndromes

Modified from Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.

*Considerable overlap (e.g., categories III and IV, V and VIII).

See corresponding chapter sections for detailed outlines.

PERICARDIAL RESPONSES TO INFLAMMATION AND IRRITATION.

Noxious agents contacting the pericardium set up responses producing clinical disease. For example, microorganisms or antigenic material or immunocytes activated elsewhere can reach the pericardium through the bloodstream, lymphatic vessels, or adjacent organs or by traumatic (including surgical) implantation and set up infective pericarditis. When inflammation is intense, the subjacent myocardium becomes involved, permitting ECG diagnosis; pericardial inflammation is mediated by cytokines, such as tumor necrosis factors and interleukins.[23] Inflamed mesothelium produces increased prostaglandins (inhibition of which may be an effect of antiinflammatory treatment). Intense inflammation involving both myocardium and pericardium produces myopericarditis. Immunopathic mechanisms are increasingly identified in the pathogenesis.[26]

DISEASES OF NEIGHBORING AND CONTIGUOUS STRUCTURES![23]

Diseases of the myocardium, pleura, lungs, diaphragm, esophagus, and mediastinum involve the pericardium by contiguity or by hematogenous or lymphogenous transmission and may or may not become clinically obvious. Sometimes pericarditis is the first clue to disease in a nearby organ. Transmural myocardial infarction virtually always involves the pericardium, but pericardial involvement is diagnosed in fewer than half of patients. Tuberculous pericarditis when not due to hematogenous or lymphogenous implantation can be introduced by adjacent infected mediastinal lymph nodes. Each of the tissues of the pericardium with the exception of the elastic tissue can give rise to primary malignancies and benign tumors, producing irritative (inflammatory) and physical effects that are usually misinterpreted. This is less true for metastatic malignancy. Pericardial fat necrosis is rare, causing nondescript or sharp pain in the left lower chest, often with pleuritic fluctuation suggesting pleuritis or pericarditis. The chest radiograph may show a particularly smudgy pericardial fat pad. Treatment is with antiinflammatory agents or resection.

PERICARDIAL EFFUSION.

Pericardial effusion is identified as any excessive pericardial contents due to inflammatory exudation, systemic fluid retention, bleeding, gas (including air), pus, or any combination of these. Pericardial exudation arises mainly if not entirely from the visceral pericardium. Hydropericardium is a transudate and can result after systemic fluid expansion, as in cardiac failure and other conditions with solute and water retention. Hydropericardium is first recognized as enlargement of the cardiac silhouette. There are no recognized clinical consequences except with rare massive hydropericardia that compress lung and other adjacent structures. Inflammatory/irritative effusion is produced from an exudate, which appears when the rate of inflammatory exudation exceeds the resorptive capacity of the serosa, particularly its lymphatics and veins. They may be obstructed by inflammatory disease and compression by the effusion itself.[12] [23] Because large molecules are poorly transported by the pericardium, the tendency to fluid accumulation may be exaggerated by the oncotic effect of protein-rich exudates. Pericardial effusions induce four functional states[12] : (1) slow production of undetected fluid; (2) effusion without cardiac compression; (3) effusion at a rate appropriate to compress the heart significantly but checked by compensatory mechanisms; and (4) cardiac tamponade. In the first two states, either the normal residual capacity of the pericardium is not significantly exceeded or the fibrosa can stretch. Many effusions become stabilized at some level by compensatory mechanisms. *Tamponade is a continuum,* even in patients who never develop corresponding clinical syndromes; florid tamponade is an emergency. Bleeding, thrombosis, neoplastic tissue, and pus modify clinical and imaging aspects.

POLYSEROSITIS. [23]

Many conditions causing pericarditis can simultaneously or sequentially inflame other serous sacs. Like pericarditis, polyserositis may appear at any inflammatory state from acute to chronic. Symptoms and signs referable to one or another serosa may dominate the picture. Yet pericardial involvement can be the most distressing because of pericardial pain, emergent tamponade, or the steady deterioration of constriction (e.g., tuberculous serositis); physiologically unimportant pericardial adhesions are common. The vasculitis/connective tissue disease group is most likely to produce true polyserositis (exudates) whereas the acquired immunodeficiency syndrome (AIDS) produces a capillary leak syndrome with noninflammatory

transudative effusions much more often than true polyserositis.

HEMOPERICARDIUM.

Hemopericardium is always important because of either frank bleeding into the pericardium as in cardiac wounds, erosion of vessels by tumor, an aggressive inflammatory process, or bleeding diatheses, including administration of thrombolytic agents to patients with pericarditis. Detectable bleeding occurs in effusions of almost every etiology. Unless overwhelmed by the rate of bleeding, the fibrinolytic and anticoagulant properties of the pericardial serosa as well as the beating action of the heart (which defibrinates blood) nearly always keeps most or all of the blood liquid and mixed with other pericardial contents. Frank blood and particularly clots, nearly always indicate major bleeding, which must be dealt with at its source. Indeed, clots, recognizable by echocardiography as hyperechoic objects in a pericardial effusion, usually mandate surgical rather than needle drainage. Moreover, any significant amount of blood in the pericardial fluid, especially in the presence of damaged serosa, is the substrate for adhesions and loculations. Malignancy is a major cause of hemopericardium. Subacute and chronic hemopericardium may be "idiopathic" or due to trauma, bleeding disorders, or vascular anomalies. Increasing fluid may be osmotically affected by split proteins (e.g., fibrolysis) and other molecules.

CHYLOPERICARDIUM.

This condition results from extravasation of chyle owing to a neoplasm, particularly lymphangiomatous hamartoma or cystic hygroma, or abnormal communication between pericardium and thoracic duct.[27] Many cases follow cardiac and thoracic surgery, suggesting damage to lymphatic channels; many others are idiopathic. Chylopericardium tends to be large and chronic, with an element of tamponade, and is only rarely constrictive.[10] The fluid is milky and alkaline with electrolyte, protein, glucose, and cholesterol levels similar to those of blood serum. Fat studies are typical of chyle and include chylomicrons. In neoplasia, the pericardium can refill so rapidly that reaccumulation of chyle may be visible during operation. No visible communication may be demonstrated between the pericardium and the alimentary tract, especially in nonneoplastic patients. Some communication is indicated in chylopericardium by the following tests: (1) intrapericardial appearance of ingested lipophilic dyes, (2) frequent successful treatment by thoracic duct ligation; (3) lymphangiography demonstrating a relationship between thoracic duct and pericardial cavity; and (4) CT or MRI densities consistent with fat (note that if the patient has not eaten for some time, chylous fluid may become clear). "Primary chylopericardium" denotes an unknown cause.[27] Chylopericardium obligates indefinite assessment for constriction. Although chyle is bactericidal, the effusion can become infected. Enhanced CT with lymphangiography should be diagnostic.[28] Conservative management includes pericardial drainage and a low-fat diet with increased medium-chain triglycerides.[23] More often, low thoracic duct ligation plus a pericardial window or resection is required.

CHOLESTEROL PERICARDITIS.

This condition is characterized by high concentrations of cholesterol and other lipids in pericardial fluid and cholesterol crystals in pericardial tissue.[23] Cholesterol effusions tend to be large and subacute or chronic and of multiple etiology. Total pericardial fluid cholesterol approaches or exceeds blood cholesterol (usually normal)

with values often more than 500 mg/dl, accompanied by increased total lipids. Cholesterol in most myxedematous effusions lacks crystal formation and usually is in concentrations below the elevated serum level. Cholesterol effusions are turbid, brown, yellow, orange, amber, purple, or coffee color, with a sheen giving a "gold paint" appearance. There may be evidence of recent or remote hemorrhage and leukocytes (mainly lymphocytes). Specific gravity is nearly always greater than 1.020, whereas electrolyte, total protein, and albumin:globulin ratios approximate those of blood. The pericardium is often thickened by scarring, frequently with variable amounts of fibrin and yellowish nodules, plaques, and papillomatous masses of cholesterol. The epicardium may be visibly inflamed, and constrictive epicarditis is not uncommon. Microscopically, there is often intense fibrosis, with inflammation with many cholesterol clefts and crystals and other lipid crystals. Phagocytes take up considerable lipid and some iron pigment; histocytes have foamy cytoplasm. Crystals and clefts are often surrounded by foreign body giant cells and elements of chronic granulomatous inflammation. Examination under polarized light shows cells containing "Maltese crosses."

Cholesterol effusions occur with pericarditis in tuberculosis, rheumatoid arthritis, and after traumatic hemopericardium, as well as myxedema. In the inflammatory lesions, granulomas are probably a source of the cholesterol as is blood. In "formes frustes" high cholesterol concentration is without crystal formation. Any chronic effusion might result in cholesterol precipitation, particularly with a cholesterol source like blood. Unfortunately, pericardiocentesis frequently results in rapid refilling and sometimes epicardial constriction or unremitting chronic cardiac tamponade.[23] [29] Conservative treatment is drainage, but definitive treatment is pericardial resection and management of any underlying diseases.

LYMPHOPERICARDIUM.

This condition is rare and related to local or, more often, generalized lymphangiectasis. Fluid has characteristics of lymph and may contain a predominance of lymphocytes.[23]

PNEUMOPERICARDIUM AND PNEUMOHYDROPERICARDIUM.

In adults, pneumopericardium may be "spontaneous" and usually occurs in conjunction with hemopericardium or some type of effusion.[23] [3] ° It may follow wounds or fistulous communications due to primary disease[31] or instrumentation of adjacent viscera, which can also produce *pyopneumopericardium.* Pericardial infection by gas-producing organisms duplicates the picture. Some cases may be due to malignant destruction of tissue but also to penetrating and nonpenetrating chest and upper abdominal trauma or after single-lung transplantation. Infants and occasional adults on respirators or with severe asthma develop pneumopericardium from alveolar rupture by high-pressure air or oxygen dissecting into the pericardium through weak points in the pericardial reflections over the great vessels.[1] When due to indirect (blunt) trauma, pneumopericardium occurs by three main mechanisms: (1) direct tracheobronchial-pericardial communication; (2) pneumothorax with a pleuropericardial tear; and (3) penetration along pulmonary venous perivascular sheaths from ruptured alveoli to the pericardium. On chest radiography, air-fluid levels indicate pneumohydropericardium. A chest radiograph may show air in the transverse sinus and often subcutaneous emphysema.

TENSION PNEUMOPERICARDIUM.[30]

This condition is due to increasing air, gas, or fluid, which produces pneumotamponade, often with marked cyanosis and hypotension. Pneumopericardium and hydropneumopericardium can produce audible clicks and splashes and an "air gap" sign on M-mode echocardiograms.

PERICARDIAL DISORDERS DURING PREGNANCY.[23]

There is no evidence that pregnancy affects susceptibility to pericardial disease. However, although tamponade has been observed, the physiological 40 to 50 percent increase in blood volume during pregnancy may moderate its physiological and clinical expression. Many pregnant women normally develop a minimal to moderate clinically silent hydropericardium by the third trimester; this could combine with less than usual exudation by any acute pericarditis to cause cardiac compression. Most pericardial disorders run their accustomed courses during pregnancy and are managed as in nonpregnant patients. Unless contraindicated, treatment with antiinflammatory drugs, antibiotics, and drainage for suppurative pericarditis, drainage of tamponading fluids, and pericardiectomy for constriction, recurrent pericardial effusion, and resistant bacterial pericarditis are indicated.

FETAL PERICARDIAL FLUID.

This can be detected by echocardiography after 20 weeks' gestation and is normally 2 mm or less in depth; more fluid should raise questions of hydrops fetalis, Rh disease, hypoalbuminemia, and immunopathy or maternally transmitted mycoplasmal or other infections. However, "idiopathic" pericardial effusion and tamponade may occur in otherwise normal fetuses (necessitating investigation for infection and neoplasia).[32]

PANCREATITIS.

Acute and recurrent pericarditis, pericardial effusion, and tamponade associated with pancreatitis may be due to simultaneous infection (presumably viral), immunopathy, or chemical

injury by circulating enzymes and rarely by direct pancreatic-mediastinal communication.[23]

BETA-THALASSEMIA.

Acute and recurrent "idiopathic" pericarditis with all its consequences and complications occur in up to one half of children with thalassemia major (most often silent or mild), suggesting more than a casual relation. This may represent viral susceptibility or an immunopathy with a possible element of tissue injury by hemosiderin.[33]

FAMILIAL MEDITERRANEAN FEVER.[34]

Recurrent pericarditis sometimes accompanies pleuritis and/or peritonitis, making familial Mediterranean fever a polyserositis. Constriction is rare. Treatment is with colchicine.

ACUTE PERICARDITIS

"Dry pericarditis," strictly speaking, indicates pericardial inflammation without effusion, that is, with a fibrinous inflammatory exudate (Fig. 50-8) . Because most pericardial irritation evokes at least some fluid clinically, dry pericarditis encompasses cases in which excess pericardial fluid is virtually absent or clinically unimportant.[35] [36] Virtually all etiological forms can present this way (Table 50-4) . In some conditions, such as rheumatoid pericarditis, the acute phase is usually missed or discovered by accident, so that the history is that of the etiological illness, except when acute pericarditis is its first sign. Infectious pericarditis may be preceded by local and systemic signs of infection.[36] The classic example is acute viral pericarditis, which is responsible for most cases of "idiopathic" pericarditis and nearly always preceded by a recent respiratory, gastrointestinal, or "flulike" illness. Moreover, symptoms and signs during acute pericarditis may be modified by or coexist with those of an inciting illness. A specific etiological diagnosis (i.e., nonidiopathic) is more easily discovered in "sicker" patients, including those who develop tamponade.[35]

SYMPTOMS.

The onset may be abrupt or insidious. Bacterial and viral pericarditis often strike dramatically, whereas the uremic or tuberculous pericarditis often goes unnoticed. Diagnosis can be suggested by symptoms with an abrupt onset, but it may depend on objective manifestations after an insidious onset. Viral pericarditis, for example, can declare itself by crescendoing pain over several hours, whereas uremic or tuberculous pericarditis often presents as fever of unknown origin.

PAIN (Table 50-5) .

Over the vast range of causes (see Table 50-4) , pain is the most common symptom, although it often is absent; thus, rheumatoid pericarditis is nearly always silent whereas acute infectious pericarditis only occasionally lacks pain. Pain can be due to inflammation of the pericardium itself, the phrenic nerves, the adjacent pleura,

sympathetic nerves accompanying coronary vessels in the epicardium, or potentiation of the algesic properties of bradykinin by pericardial prostacyclin.[35] Pain can be sharp, "sticking," dull, aching, and pressure-like in individual cases, with intensities varying from 1 to 10. Initially, it tends to be sharp, precordial, and pleuritic and is exacerbated by inspiration, cough, and recumbency; hence, patients sit up for relief. Pain onset, frequently perceived as sudden, particularly when it interrupts sleep, is occasionally related to exertion, which may be coincidental; once established, it worsens with exertion. Characteristic pain relief from sitting up and leaning forward may be related to the biomechanical characteristics of the parietal pericardium. These maneuvers may relieve increased pericardial tissue tension due to inspiration and truncal extension; they also splint the diaphragm.[35] Pain radiation can follow distributions common to angina as well as to the epigastrium, creating problems in differential diagnosis when the pain is not pleuritic or has a pressing quality, and particularly when it radiates to the jaw or one or both shoulders. Shoulder pain must be distinguished from pain in one or both trapezius ridges, usually the left. Trapezius ridge pain

Figure 50-8 Fibrinous pericarditis. Large fibrinous exudate on anterior epicardium. Minimal pericardial fluid permits delineation of fibrin.

transmitted through the phrenic nerves is virtually pathognomonic for pericardial irritation.[35] Indeed, some patients perceive pain only in a trapezius ridge. Note that patients must be asked to point to the areas of pain perception because patients and most physicians confuse the trapezius ridge with the shoulder. Pain can also occur in the midposterior thorax or below the left scapula. Palpation of the chest wall may elicit local tenderness revealing costochondritis, Tietze syndrome, or other chest wall syndromes, including rib fractures in patients with traumatic pericarditis.[37] Finally, some patients do not describe "pain" but rather vague precordial distress with or without inspiratory or postural exacerbation. Some patients with myopericarditis (particularly viral) may have skeletal muscle myalgia.

OTHER SYMPTOMS.

A nonproductive cough is common, exacerbates pleuritic pain, and may antedate chest symptoms. Productive cough is due to associated illnesses. Hiccup is relatively rare. Odynophagia, rarely the only sign of pericarditis, occurs because of apposition of the esophagus and posterior parietal pericardium; odynophagia and dysphagia also result from pericardial inflammation or effusion due to spread from esophageal inflammation, trauma, or malignancy. Faintness and dizziness are uncommon in the absence of tamponade but can occur when there is considerable pain, tachycardia, or constitutional reaction.

SYSTEMIC REACTION.

Fever, usually less than 39°C (102.2°F), is common as a result of pericarditis or accompanying diseases and may herald the clinical onset. Elderly patients lacking mechanisms for cytokine liberation may not be febrile, and some with diseases such as renal failure may be hypothermic. Chills (rigors) are likely to accompany spiking fevers in suppurative pericarditis and some cases of idiopathic (presumably viral) pericarditis. Weakness and depression accompany some cases with marked systemic manifestations. Anxiety is common with very painful or disagreeable precordial sensations, especially in those with preexisting heart disease. Pallor may be a clue to systemic illnesses such as tuberculosis, uremia, neoplasia, and rheumatic carditis. In patients severely ill from antecedent or accompanying disease, symptoms and constitutional reaction

provoked by pericarditis may be submerged in the total picture or suppressed by established treatment.

OBJECTIVE MANIFESTATIONS.

The cardinal sign of pericarditis is the pericardial rub (see Fig. 50-4) --three or fewer friction sounds per cardiac cycle[9] (described earlier). Rubs can be transient or intermittent but often last hours to days. Unusually persistent rubs indicate a tendency to chronicity or continuing pericardial irritation as from malignant

TABLE 50-5 -- PAIN IN ACUTE PERICARDITIS VS. ACUTE ISCHEMIA

	ACUTE PERICARDITIS	ACUTE ISCHEMIA
Onset	More often sudden	Usually gradual, crescendo
Main location	Substernal or left precordial	Same or confined to zones of radiation
Radiation	May be the same as ischemic, also trapezius ridge(s)	Shoulders, arms, neck, jaw, back; not trapezius ridge(s)
Quality	Usually sharp, stabbing; "background" ache or dull and oppressive	Usually "heavy" (pressure sensation) or burning
Inspiration	Worse	No effect unless with infarction pericarditis
Duration	Persistent; may wax and wane	Usually intermittent; <30 min each recurrence, longer for unstable angina
Body movements	Increased	Usually no effect
Posture	Worse on recumbency; improved on sitting, leaning forward	No effect or improvement on sitting
Nitroglycerin	No effect	Usually relief

From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.

infiltration. Rubs are common in the presence of even large pericardial effusions. Echocardiograms in patients with clinically dry pericarditis may show fibrin with or without a small effusion or with a ragged "sunburst" appearance. ECG abnormalities range from normal to nonspecific to typical stage I ST segment deviations, usually with PR segment deviations (see Fig. 50-6, Table 50-6) . Like the pericardial rub, the stage I ECG change is virtually diagnostic of acute pericarditis, always requiring differentiation from certain mimics and particularly when there are typical ECG variants. Occasionally, ECG abnormalities are the only evidence of pericarditis. Finally, any arrhythmias are *not* due to the acute pericarditis itself.[11] Pleural effusions, mainly on the left, are frequent in acute pericarditis. Leukopenia is uncommon and may be due to bone marrow depression by associated disease. Other acute phase reactants,[38] such as the sedimentation rate (ESR) and C-reactive protein (CRP), show mild to marked elevations, the level reflecting the intensity of the process, its inciting disease, or subepicardial myocardial involvement. Serum enzyme elevations derived from myocardium, such as the MB isoenzyme of creatine kinase (CK-MB), aspartate aminotransferase, aldolase, lactate dehydrogenase (LDH), and troponin I, reflect the degree of myocardial involvement by subepicardial myocarditis.[35] Serum myoglobin is usually normal. Patients with the greatest ST segment deviation tend to develop the largest rises, although the correlation is imprecise: some patients do not have significant levels despite ECG changes. Gallium-67 scanning can identify inflammatory and leukemic infiltrations and appears to be superior to scanning with indium-111.[35] [40]

TREATMENT.

Treatment aims to relieve symptoms and eliminate etiological agents. Most patients are hospitalized for complete diagnosis and observation for complications, particularly effusion and tamponade. Antiinflammatory and symptomatic treatments resemble those of other conditions producing comparable pain, fever, and malaise and must be individualized. Nonsteroidal antiinflammatory drugs (NSAIDs) are the mainstay, possibly because many inhibit pericardial synthesis of prostaglandin I_2 . Any effective NSAID may be used. However, indomethacin should be avoided in adults unless all other options fail, because it reduces coronary flow and has marked side effects. Ibuprofen has an excellent side effect profile and increases coronary flow, with the advantage of the largest dose range of the "classic" NSAIDs.[35] [39] Depending on clinical severity and response, treatment may initially require ibuprofen, 300 to 800 mg every 6 to 8 hours, and can be increased. In many mild cases, particularly of "idiopathic" pericarditis, 1 to 4 days of treatment appears adequate. Finally, all patients should be monitored for side effects; because all NSAIDs affect the gastrointestinal mucosa, it is wise to add misoprostol or other mucosal protectants.[41] Anecdotal evidence is increasing that colchicine added to an NSAID or even as monotherapy is effective for the initial attack and to prevent or treat recurrences.[35] It is well tolerated at 0.6 mg every 12 hours with or without a loading dose but must be monitored for side effects. A well-controlled trial is needed. Corticosteroid therapy should be avoided unless required for a specific illness such as a connective tissue disease or when all else fails, and then it should be used in minimally effective doses and carefully tapered. For protracted

TABLE 50-6 -- ECG IN ACUTE PERICARDITIS VS. ACUTE ISCHEMIA

	ACUTE PERICARDITIS	ACUTE ISCHEMIA (AP, MI)
J-ST	Diffuse elevation usually concave, without reciprocal depressions	Localized deviation usually convex (with reciprocals in infarct)
PR segment depression	Frequent	Almost never
Abnormal Q waves	None unless with infarction	Common with infarction ("Q wave" infarcts)
T waves	Inverted after J points return to baseline	Inverted while ST segment still elevated (infarct)
Arrhythmia	None (in absence of heart disease)	Frequent
Conduction abnormalities	None (in absence of heart disease)	Frequent

AP=angina pectoris; MI=myocardial infarction.*From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.*

use of prednisone, ibuprofen or another NSAID should be introduced when tapering; after tapering the prednisone, the NSAID should also be tapered. Colchicine appears to improve therapeutic results and facilitate the "weaning" process.[42] Recovered patients should be observed indefinitely for one or more recurrences or later constriction. If patients require anticoagulants (e.g., those with prosthetic cardiac valves), heparin can be used under strict observation while the pericarditis is in progress.

DIFFERENTIAL DIAGNOSIS.[31]

Acute pericarditis must be differentiated from syndromes producing similar symptoms and signs (Tables 50-5 , 50-6 , 50-7 , and 50-8), bearing in mind that pericarditis may be (1) part of a generalized disease, (2) apparently isolated, or (3) part of a disorder affecting a neighboring organ and (4) occasionally the presenting syndrome of numerous diseases. Pain isolated to or referred to one or both trapezius ridges strongly compels consideration of pericarditis. Central pleuritic chest pain always raises a question of acute pericarditis if pleurisy can be ruled out, but both may occur simultaneously.

When the pain resembles that of cardiac ischemia (see Table 50-8) , it may be longer lasting, sharper, and unresponsive to vasodilator therapy. Purely ischemic pain lacks the frequently pleuritic quality of infarction-related forms of pericarditis. Angina produces ECG changes usually with depressed rather than elevated ST segments. Tables 50-5 , 50-6 , and 50-8 summarize the differentiation of pericarditis from ischemia and infarction. On strictly ECG grounds, up to one third of acute pericarditis cases resemble ischemic heart disease because of atypical ECG evolution (see Chap. 35) . Finally, pulmonary embolism can mimic acute pericarditis, particularly if with pleuritic pain (see Chap. 52) . The ECG is usually nonspecifically altered and the pleural rub, if any, as well as the pain may not be precordial. Rarely, pulmonary embolism provokes a purely pericardial or pleuropericardial rub, pericardial effusion (usually small), or a pericardial response resembling the post-myocardial infarction syndrome.

Monophasic pericardial rubs, particularly the most common one, the ventricular systolic rub,[9] can mimic murmurs of mitral and especially tricuspid regurgitation and also ventricular septal defect, because all rubs tend to be most intense or occur only at the left mid to lower sternal border where some are palpable.[9] Assisting differential diagnosis are the short-term changeable nature of rubs and their occasionally unpredictable precordial distribution, as well as frequently absent heart disease. A typical stage I ECG is virtually diagnostic, although easily confused with the normal variant "early repolarization." The characteristic widespread ST segment changes are distinguishable from most acute myocardial ischemia and infarctions, which nearly always involve "regional" lead groups with reciprocal ST segment deviations in other leads; reciprocal ST segment depressions virtually never occur in uncomplicated acute pericarditis. Abnormal Q waves do not occur without associated

TABLE 50-7 -- CLINICALLY "DRY" ACUTE PERICARDITIS: PRINCIPAL DIFFERENTIAL DIAGNOSES

MANIFESTATION	TO BE DIFFERENTIATED

Electrocardiogram

or preexisting myocardial disease (see Chaps. 5 and 35) .

Myopericarditis/Perimyocarditis

Pericarditis is often accompanied by some degree of myocarditis and vice versa, with one or the other dominating the clinical picture. Most syndromes are primarily myocarditic or pericarditic.

PATHOGENESIS.

Systemic disorders with frequent myocarditis, pericarditis, and myopericarditis include immunopathies, the vasculitis/connective tissue disease group, and drug-related pericarditis. Viral and other infections seem most frequent.[43] [44] Cardiotropic viruses can inflame myocardium and pericardium hematogenously, whereas bacterial and other organisms do so through lymphatics or by extension from pericardial infection. In eosinophilic forms, the destructive nature of the eosinophil is evident with high levels of eosinophilic cationic protein.[43] AIDS frequently involves the myocardium, pericardium, or both[45] (see Chap. 68) . AIDS myopericarditis results from infection with the human immunodeficiency virus (HIV) and viral co-infection, damage by CD5 and CD8 lymphocytes, and myocardial Kaposi carditis.[45] Immunological mechanisms appear necessary for persistent and recurrent myopericarditis even in the absence of a viral genome.

TABLE 50-8 -- "CLINICAL FACTORS": ACUTE PERICARDITIS VS. ACUTE ISCHEMIA*

	ACUTE PERICARDITIS	ACUTE ISCHEMIA (AP, MI)
Myocardial enzymes	Normal or elevated	Elevated (infarct)
Pericardial friction	Rub (most cases)	Rub only if with pericarditis
Abnormal S_3	Absent unless preexisting	May be present
Abnormal S_4	Absent unless preexisting	Nearly always present
S_1	Intact	Often dull, mushy after first day
Pulmonary congestion	Absent	May be present
Murmurs	Absent unless preexisting	May be present

AP=angina pectoris; MI=myocardial infarction.*From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.*

*Electrocardiographic differences in Table 50-6 .

Almost any acute pericardial or myocardial damage can induce an immunopathy with recurrences (especially enteroviral and cytomegaloviral infections). Viruses provoke antibodies to myolemmal and sarcolemmal membranes (ALMABs and ASABs) and may be pathogenetic because of their cytolytic or cytotoxic properties.[46] The AMLABs and ASABs are part of B-cell-driven immune responses; for example, IgG-type AMLABs are diagnostic of perimyocarditis in tuberculous pericarditis. Drug-induced myopericarditis probably is pathogenetically related through "allergic" or hypersensitivity mechanisms. Finally, disease-specific autoantibodies reflect autoimmune involvement, although they correlate poorly with myocardial biopsy.[46] [47]

Many members of the vasculitis/connective tissue disease group (see Chaps. 48 and 67) , classically including acute rheumatic fever, regularly produce myopericarditis.[43] Occasionally, inflammation spreads by contiguity from a primarily pericarditic process to the myocardium or from mediastinitis to the pericardium and myocardium. Pericardial tuberculosis often involves the myocardium, which becomes inflamed and ultimately fibrotic; both active and burned out tuberculosis are evident in tuberculous constriction. In contrast, pure uremic pericarditis may have a brisk inflammatory process in the pericardium and epicardial fat without invading the myocardium.

Evidence of myocardial involvement in pericarditis is summarized in pericarditis (Table 50-9) . During myocarditis, pericardial involvement is mainly recognized by a rub or an effusion.[43] The ECG changes of acute pericarditis, as well as QT prolongation, indicate at least superficial myocarditis even when myocardial involvement is subclinical. Reciprocal and regional J (ST) changes (Fig. 50-9) and abnormal Q waves in the absence of infarction represent significant myocarditis disproportionately involving regions of the myocardium. Arrhythmias or conduction disturbances are absent even in severe pericarditis without independent or related disease of the myocardium or valves; myocarditis qualifies as such a related disease.[38]

After even mild idiopathic (presumably viral) pericarditis, transient myocardial functional and wall motion abnormalities can sometimes be detected for months; in more severe cases, global LV or RV dysfunction or eventual dilated cardiomyopathy are strong evidence of a myocarditic component. Occasional patients who, after drainage of pericardial effusion, develop myocardial dilation and acute cardiac failure ("pericardial shock") in the absence of antecedent heart disease almost certainly have had significant myocarditis.[43] Transient cardiac enlargement, usually recognized by imaging in the absence of increased pericardial fluid, and true dyspnea represents myocarditis. In acute pericarditis, when tachycardia persists after fever and pain subside, a myocarditic component is likely. During acute pericarditis, particularly of viral origin, but also with *Mycoplasma, Leptospira,* and *Borrelia* (Lyme disease) infections and skeletal muscle pain (myalgia)

TABLE 50-9 -- CLUES TO SIGNIFICANT MYOCARDITIS IN PATIENTS WITH ACUTE PERICARDITIS

1. *Any* acute ECG QRS complex change, especially if localized or with atypical evolution. Convex ST segment elevation during acute pericarditis. Atrioventricular or interventricular block.
2. Any significant arrhythmia, especially ventricular (in absence of other heart disease)
3. Evidence of myocardial dysfunction (in absence of other heart disease):

a. Postpericardiocentesis abnormal S_3 (in absence of constrictive pericarditis)
b. Pulmonary edema
c. Postpericardiocentesis cardiac failure, especially pulmonary edema
d. Abnormal imaging and catheterization studies:

(1) Cardiomegaly
(2) Abnormal hemodynamics (in absence of constrictive pericarditis)
(3) Wall motion abnormalities

4. Sinus tachycardia:

a. Out of proportion to fever, anemia, and/or chest pain
b. Persistence after resolution of 6 through 10, below

5. Skeletal muscle myalgias, especially during viral pericarditis (suggests a myotropic organism)
6. Pericarditis with transudative effusion fluid
7. Nonpleuritic substernal chest pain with or without radiation (other than to trapezius ridges)
8. Elevated serum levels of cardiac enzymes, especially in presence of elevated serum myoglobin or troponin
9. Positive antimyosin-indium 111 scintigraphy
10. Myocardial production of tumor necrosis factor in absence of septic shock and congestive heart failure
11. Positive ^{99m} technetium pyrophosphate imaging
12. Positive gadolinium (Gd)-67 scintigraphy; Gd-DTPA-enhanced magnetic resonance imaging
13. Positive fibrinogen polymerization test

Figure 50-9 Perimyocarditis. *Top,* Acute phase with atypical stage III. T wave inversion in inferolateral distribution with J elevation in many leads in (in typical stage III T wave inversions with J on baselines). *Bottom,* Twenty-two days after onset: J on baseline with T wave inversion in inferolateral ("atypical") distribution consistent with myocarditis.

and tenderness, rhabdomyolysis[48] suggests a myotropic organism also involving the myocardium.[43]

Elevations of troponins I and T indicate myocardial damage.[49] Elevated cardiac enzymes with normal myoglobin levels suggest that the pericarditic process has affected only myocardial cell membranes, causing them to leak these substances. This is probably the mildest detectable myopericarditis; elevated serum myoglobin levels may indicate severe (cytoplasmic) damage. Although characteristic ECG changes of acute pericarditis can occur without abnormal enzyme release, in severe cases with significant myopericarditis, CK-MB increases (>10 mug/liter), particularly during ST (J) deviations.[43] Monoclonal antimyosin antibodies labeled with indium-111 are markers of myocarditis,[45] as is detection of proinflammatory cytokine tumor necrosis factor (TNF) in the absence of congestive heart failure and septic shock.

CLINICAL CONSIDERATIONS.

Pericarditis with pericardial effusions that are closer to transudates, particularly with severe dyspnea, suggests significant myocardial involvement, whereas exudates indicate at least a strong pericarditic component.[43] Imaging and cardiac catheterization demonstrate transiently or permanently reduced myocardial function, that is, diffuse or localized abnormal ventricular wall motion. MRI shows focal myocardial edema in such zones of segmental or general wall motion abnormality. Finally, auscultation of a new S_3 ("ventricular gallop") is evidence either for myocardial inflammation or some degree of constriction.[43] [50]

Although cardiac enzymes and markers (troponin I and T) are released in most patients with myocarditis and ECG abnormalities, cardiac enzymes may be normal or only slightly increased and enzyme levels can fall while the ST (J) segment is still elevated.[51] Another clue to a myocarditic component during pericarditis is the occasionally convexly elevated J-ST segment, in contrast to the concave ST segment characteristic of acute pericarditis. Occasional patients have mixed forms of pain of both "myocardial" and pleuritic types, with dominance of one kind suggesting the dominant lesion (e.g., squeezing chest pain during apparent pericarditis suggesting significant myocarditis).

Any cardiac asynergy is due to myocardial abnormality and mimics acute infarction. A biopsy specimen obtained by catheter (endomyocardial biopsy) or by thoracoscope (epimyocardial biopsy) can identify myocardial inflammation, preferably if taken from the left ventricle, from which specimens are more often positive. Epimyocardial biopsies are much more productive.[49] [52] An active immune process will yield major histocompatibility complex Class I expression and tissue binding of IgG, IgA, IgM, and C3.[46] [47] [53] Finally, such evidence of myocardial inflammation sometimes persists in patients with constrictive pericarditis and may contribute to postpericardiectomy cardiac dilation and failure. In constrictive pericarditis with active myocarditis,[50] differentiation from restrictive cardiomyopathy may be difficult.

MANAGEMENT.

In the absence of myocardial failure, management of myopericarditis is the same as for acute pericarditis.[43] (In both, there are no adequate controlled clinical trials.) Patients may respond to antiinflammatory agents. Corticosteroids should be avoided unless all else fails and the patient is severely ill; near the onset of viral illness, they can stimulate virus replication and paralyze immune responses. Immunosuppressive agents seem useful in autoimmune myocarditis but not conclusively and could be injurious; they appear ineffective for viral (lymphocytic) myocarditis.[54] Interferon may be useful in enteroviral forms. Hyperimmune globulin has been used for cytomegaloviral-associated myopericarditis. Captopril may be of benefit in patients with definite heart failure.[55] Pericardial effusions must be drained with special care because they may "splint" a myocarditic heart, which drainage permits to dilate.

Prognosis for recovery is generally good if the myocarditis is not intense (it is often focal in myopericarditis[56]), particularly the infective types, although varying degrees of myocardial damage can produce heart failure and, ultimately, dilated or restrictive cardiomyopathy. Rarely, Dressler syndrome (see Chap. 35) ensues.

PERICARDIAL EFFUSION AND HYDROPERICARDIUM

PATHOGENESIS AND CLINICAL CHARACTERISTICS.

Pericardial fluid is in dynamic equilibrium with the blood serum, including free exchange of water and electrolytes with surprising pericardial permeability to some large as well as smaller molecules. However, inflamed pericardium may obstruct these exchanges. Most pericardial effusions "weep" from the visceral pericardium.[57] Irritative and inflammatory effusions are associated with local production of substances such as cytokines, tumor necrosis factors, and interleukins.[58] Exudation of proteinaceous material and larger molecules and dissolution of intrapericardial thrombi osmotically attract additional fluid and impede reabsorption. Large effusions usually follow venous and lymphatic obstruction in the epicardium and often occur in the subjacent myocardium (myocardial lymph drainage normally occurs by means of the pericardium and probably contributes to effusions). Surprisingly small fluid increments and even the normal 15 to 35 ml can be identified by imaging.[57] Asymptomatic effusions are typically first suggested by relatively insensitive radiography (Fig. 50-10); a minimum of about 250 ml is needed to fill the pericardial reserve volume (see earlier) sufficiently to detectably increase the cardiopericardial silhouette. Increased pericardial fluid is either hydropericardium (transudate), "true" pericardial effusion (exudate; pyopericardium if purulent), hemopericardium, or mixtures of these, collectively termed "pericardial effusion." Exudates characteristically have more cholesterol, protein, and LDH than transudates, with cholesterol greater than 45 mg/dl, protein concentration more than half the serum level, and LDH greater than 200 U/liter or more than 60 percent of the serum LDH (the serum-effusion albumin gradient may be more valid).[57] However, the exudate-versus-transudate characterization may be indistinct. Moreover, with improving congestive failure, more rapid reabsorption of water than protein and LDH may convert hydropericardium to a pseudoexudate.

Figure 50-10 Large pericardial effusion. Chest radiograph shows a large, featureless bilaterally distended cardiopercardial silhouette and left pleural effusion. Lung fields are clear. (Patient had a low voltage ECG.)

Excess pericardial contents is loosely associated with vague *chest symptoms* such as pressure sensations and aches. Rapid exudation can stretch the pericardium, producing "protopathic" pain. Very large effusions can encroach on neighboring structures, manifest as *dyspnea,* especially on exertion, when compression of lung causes a restrictive pulmonary defect; *dysphagia* from esophageal compression; *cough* from bronchial encroachment; *hiccups* from esophageal compression and involvement of the vagi and phrenic nerves; and *hoarseness* from compression of the recurrent laryngeal nerve.[57]

ETIOLOGY.

The causes of exudative pericardial effusion essentially correspond to those of pericardial inflammation and irritation (see Tables 50-3 and 50-4) ; large exudative effusions are most common with tumors, tuberculous pericarditis, cholesterol pericarditis, myxedema, vasculitis/connective tissue disease, uremic pericarditis, and parasitoses.[59] Unusual conditions include the eosinophilic syndromes, endomyocardial fibrosis, and cardiac transplantation (related to chemotherapy, especially cyclosporin or to rejection). Others occur during bone marrow transplant due to graft-versus-host disease.[57] A small to moderate clinically silent hydropericardium develops by the third trimester in many pregnant women (see Chap. 65) . Myopericarditis tends to produce mixed forms, because hydropericardium due to heart failure variably dilutes inflammatory effusions. Drug-related effusions may be difficult to recognize in diseases that can involve the pericardium (e.g., systemic lupus erythematosus [SLE]).

HYDROPERICARDIUM AND CLINICALLY NONCOMPRESSING EFFUSIONS.

Hydropericardium, which is usually small, occurs mainly in conditions of fluid retention but less frequently than pleural effusion. It is usually discovered by accident when imaging the chest or heart. "Noncompressing" exudative effusions due to pericardial lesions produce no significant change in blood pressure or cardiac output and no pulsus paradoxus. They may (1) be asymptomatic, (2) present as pericarditic pain or symptoms and signs of the causative condition, or (3) have asymptomatic but significantly increased respiratory fluctuation in ventricular function. Most have symptoms and signs only of "clinically dry" pericarditis. If the effusion is inflammatory, a pericardial rub usually is audible at some time. Slight exaggeration of the normal inspiratory fall in systolic blood pressure suggests "borderline" tamponade.

The *Bamberger-Pins-Ewart sign* is common with very large effusions and is characterized by a dullness and bronchial breathing between the left (rarely the right) scapula and the spine.[57] Otherwise, physical examination is nonspecific and undependable; even with tamponade, heart sounds may not be muffled and precordial percussion is untrustworthy. The ECG is of little or no direct help, although occasionally very large nontamponading effusions induce *electrical alternation* (see Chap. 5) (otherwise associated with critical tamponade). Reduced ECG voltage is nonspecific and undependable; only massive effusions as in severe myxedema produce true microvoltage that may be equally related to myocardial or hemodynamic abnormality.

IMAGING.

Radiography can only be suggestive. The shape of the heart shadow on fluoroscopy or static films cannot decisively distinguish true cardiomegaly from pericardial effusion. A "water bottle" silhouette or unusually wide mediastinal shadow (see Fig. 50-10) is suggestive, particularly when the lung fields are not congested. Left pleural effusion is common in both "wet" and "dry" pericarditis, whereas bilateral effusion is more common in congestive heart failure.[57] On a well penetrated lateral film, pericardial fluid is suggested by lucent *pericardial fat lines* within the cardiopericardial shadow. Echocardiography, CT, and MRI define heart size; cardiac function can be determined by echo-Doppler, contrast radiography, nuclear scanning, CT, or MRI.

ECHO-DOPPLER CARDIOGRAPHY (see Chap. 7 , Figs. 7-94 7-95 , 7-96 , and 7-97).

Table 50-10 summarizes the results of echo-Doppler investigation of effusions. On the echocardiogram, normal pericardial fluid and small amounts of excess fluid are seen posteriorly, between the LV wall and the parietal pericardium in systole only. With progressive accumulation, posterior fluid appears in both systole and diastole; in larger effusions, fluid appears anterior to the right ventricle. Fluid can be found behind the left atrium (i.e., in the pericardial oblique sinus) but usually with very large often tamponading effusions. *Effusion size* can be estimated by echocardiography: *small:* aggregate echo-free space in systole and diastole less than 10 mm; *moderate:* echo-free space in systole and diastole 10 to 20 mm, at least posteriorly; and *large:* echo-free space or 20 mm or more. As fluid increases, movement of the parietal pericardium decreases. Note that effusion size is a powerful overall predictor of prognosis; large effusions generally mean more serious disease.[57] [58] [59] Anterior fluid is frequently absent after cardiac surgery due to anterior adhesions.[60] With only an anterior echo-free space, posterior adhesions might be present, although epicardial fat is usually more likely; occasionally an infiltrative lesion, often malignant, is responsible. Epicardial fat, occasionally simulating posterior and circumcardiac effusions on echocardiography, must be distinguished by CT or MRI (see Chap. 10) .

With very large effusions, echocardiography may show cardiac oscillation ("swinging") within the pericardium (see Table 50-10) . With some degree of tamponade, often critical, swinging reverses direction on alternate beats instead of on every beat, producing ECG electrical alternation. Large effusions can cause mitral prolapse or pseudoprolapse, as well as midsystolic notching of the aortic or pulmonic valves. TEE is superior to transthoracic echocardiography (TTE), especially for identifying metastases, pericardial thickening, and clots, but it tends to underestimate the volume and distribution of effusions. Three-dimensional echocardiography is promising.[61] Although echocardiography is sufficient in most cases, CT and MRI may be needed if echocardiographic results are equivocal.[57]

MANAGEMENT.

Without tamponade (see p. 1841), hemopericardium, or pyopericardium, there are few absolute indications for drainage. Very large nontamponading effusions can be drained to relieve symptoms due to compression of lung and other structures. Pericardial drainage occasionally may be required for diagnosis through examining fluid; pericardial biopsy can be obtained simultaneously. Pericardiocentesis by needle alone can be unrewarding diagnostically, although modern bacteriological and immunocytochemical methods are improving the results (Table 50-11) . [59] [62] [63] Adequate fluid with an adequate pericardial biopsy is better and more safely obtained by thoracotomy, subxiphoid incision, or video-assisted thoracoscopic resection and drainage, which also permits efficient and relatively inexpensive removal of thrombi, adhesions, and fibrinous material, minimizing chances for recurrence and cicatrization. Percutaneous balloon pericardiotomy may be used but is best for palliation of malignant tamponade. Loculated effusions may require open surgery or thoracoscopic drainage. The decision for operative intervention depends on (1) urgency of diagnosis and a prognosis requiring aggressive management and (2) probable yield of the diagnostic sample. Thus, persistent illness without an etiological diagnosis warrants obtaining tissue as well as fluid surgically. All patients, especially those with underlying cardiac disease, including myocarditis, should be monitored for postdrainage decompensation.[57]

PERICARDIOCENTESIS.

The precise techniques of needle drainage with and without catheter insertion are explained in detail elsewhere.[64] Techniques for nonsurgical drainage for relief of tamponade have been refined over many years, and imaging methods such as echocardiography and CT are now used routinely to locate the effusion and guide needle insertion.[65] Large effusions are more successfully reached; smaller effusions (<5 mm anteriorly) can be missed by the needle, with more frequent complications such as penetration or laceration of cardiac structures. Thick viscous fluids such as pus and partly clotted blood are difficult to aspirate. Patients with severe hemorrhagic disease may tend to bleed. Sites on the chest wall opposite the deepest anterior and inferior fluid collection (determined by imaging) should be used; echocardiographic studies show the apical approach usually to be best.[66] The procedure is best performed in an environment where resuscitation and monitoring

TABLE 50-10 -- ECHOCARDIOGRAPHIC AND DOPPLER EFFECTS OF PERICARDIAL EFFUSION AND CARDIAC TAMPONADE (VARYING SENSITIVITIES AND SPECIFICITIES)

A. Pericardial effusion

1. Echo-free space:

   a. Posterior to LV (small-to-moderate effusion)
   b. Posterior and anterior (moderate-to-large effusion)
   c. Behind left atrium (large-to-very large effusion and/or anterior adhesion

2. Decreased movement of posterior pericardium-lung interface
3. Brisk RV wall movements unmasked with anterior fluid
4. "Swinging heart" (large effusions, usually tamponade)

   a. RV and LV walls move synchronously
   b. Periodicity 1:1 or 2:1 (one or two swings per cardiac cycle); 2:1 is characteristic of definite tamponade
   c. Pseudoparadoxic motion of LV posterior wall
   d. Mitral/tricuspic pseudoprolapse; occasional true prolapse
   e. Mitral systolic anterior motion
   f. Alternating mitral e-f slope and aortic opening excursion
   g. Aortic valve: midsystolic closure movement
   h. Pulmonic valve: midsystolic notch

5. Hemopericardium: clotted blood identifiable
6. Inspiratory decrease in LV ejection time (with effusion; greater with tamponade)

B. Cardiac tamponade--**changes of effusion** plus:

1. RV compression

   a. RV diameters decreased, especially outflow tract (
7 mm)
   b. Early diastolic collapse of right ventricle

2. RA free wall indentation (collapse) during late diastole and/or isovolumic contraction lasting at least one third of the cardiac cycle
3. LA free wall indentation (cases with fluid behind left atrium)
4. LV free wall paradoxic motion
5. SVC and IVC congestion (unless volume depletion); IVC >2.2 cm with <50% inspiratory collapse.
6. Exaggerated inspiratory effects (especially with pulsus paradoxus with reciprocal right-heart/left-heart effects during inspiration and expiration)

   a. Right ventricle expands
   b. Interventricular septum shifts to left
   c. Left ventricle compressed
   d. Mitral

      (1) d-e amplitude decreased
      (2) e-f slope decreased or rounded
      (3) Open time* decreased; delayed mitral opening

   e. Aortic valve: opening decreased*; premature closure*
   f. Echographic stroke volume decreased

7. Notch in RV epicardium during isovolumic contraction
8. Course oscillations of LV posterior wall
9. Pseudohypertrophy: apparent wall thickening due to compression

C. Doppler studies: with any degree of tamponade

1. Major changes on first beats during inspiration and expiration
2. Generally reduced flows/stroke volumes
3. Exaggerated inspiratory augmentation of right-sided and decrease of left-sided flows
4. Respiratory variation in superior and inferior vena caval flow velocities marked in tamponade, less increased with effusion; double-peaked superior vena cava systolic wave. Decreased expiratory diastolic SVC flow.
5. Hepatic vein expiratory effect:

   a. Marked atrial reversal (AR wave)
   b. Marked decrease or reversal of diastolic forward flow
   c. (Occasional) systolic flow reversal

6. (Transesophageal echocardiograms): expiratory increase in pulmonary vein diastolic forward flow
7. Marked inspiratory decrease in LV ejection time; increased RV ejection time
8. Marked inspiratory increase in LV isovolumic relaxation time; decreased RV isovolumic relaxation time
9. Hepatic vein velocity difference between systole and atrial reversal <0 cm/sec

SVC and IVC=superior and inferior venae cavae; LA=left atrial; LV=left ventricular; RA=right atrial; RV=right ventricular.

be a handicap.[57] [64] [67] Right-sided heart and arterial catheterization are optimal and may reveal unanticipated effusive-constrictive pericarditis (see Chap 11) . Pericardial pressure can be measured through the intrapericardial needle or catheter. An intravenous drip containing isotonic saline or dextrose in water can be used to deliver supporting therapy.

Patients are monitored for cardiac decompensation ("pericardial shock") and for recurrent tamponade due to catheter blockage or reaccumulation of fluid (which is particularly important with bloody fluids or frank hemorrhage because of clotting). Residual clots can later dissolve, producing osmotically active fragments, thus renewing effusion or tamponade.

COMPLICATIONS.

The major complications of needle drainage are caused by needle contact with the heart, particularly laceration of a coronary vessel or chamber wall or myocardial

perforation. Injuries to coronary veins, the right atrium, and the right ventricle are most dangerous; these are thin walled and likely to bleed briskly, producing hemopericardium. "Simple" perforation of the myocardium, particularly the left ventricle, without laceration is not rare but is well tolerated. Hypotension, probably reflex, can occur at any point, so that atropine should be on hand. Rare penetrations include stomach, colon, and lung. Arrhythmias occur particularly in patients with preexisting heart disease. Direct contact of the needle with the ventricular surface may produce an injury current or ventricular ectopic beats, and contact with the atrial surface may produce atrial ectopic beats.[57]

CARDIAC TAMPONADE

Pathophysiology

INTERACTION BETWEEN THE PERICARDIUM AND ITS CONTENTS.

To tamponade the heart, pericardial contents must (1) fill the pericardial reserve volume (see Fig. 50-2), then (2) increase at a rate exceeding the rate of stretch of the parietal pericardium, and (3) exceed the rate at which venous blood volume expands to support the small normal pressure gradient for filling the right side of the heart.[68] [69] Increased pericardial fluid causes loss of normal variations in pericardial contact stress (pressures become uniform over all cardiac chambers), increasing both ventricular and AV interaction. Pericardial volume increases partly by reducing cardiac chamber volumes and ultimately equalizes reduced diastolic compliance in all chambers. The resultant operational defect is restriction of cardiac inflows. (Interaction between the rate of fluid accumulation and parietal pericardial stretch determines pericardial stiffness and consequently the shape of the pericardial pressure-volume curve (Fig. 50-11). , With critical tamponade, the heart functions on the steep portion of the pericardial pressure-volume curve so that small fluid increments provoke large pressure increments. With slow fluid accumulation and a yielding pericardium, the initial portion of the pressure-volume curve remains "flat" longer and relatively large fluid volume increases cause relatively little pressure rise (see Fig. 50-11*right*).

Clinically, cardiac tamponade is defined as the decompensated phase of cardiac compression resulting from increased intrapericardial pressure.[68] Physiologically, tamponade is a continuum,[70] because even small increases in pericardial contents couple the pericardium to the heart, producing significantly increased AV and especially ventricular interaction that exaggerates the normal reciprocal respiratory effects on the right and left sides of the heart.[69] If unchecked by compensatory mechanisms, rising pericardial contents, such as effusions, blood, pus, gas, and combinations, ultimately produce critical cardiac compression: florid tamponade.

PATHOPHYSIOLOGICAL CONTINUUM OF TAMPONADE.

The rate of fluid accumulation determines the clinical response. Intrapericardial hemorrhage, as from wounds, rapidly produces "surgical" tamponade in minutes to hours, whereas a low-intensity inflammatory process can require days to weeks before critical cardiac compression ("medical" tamponade). At any rate of accumulation the system is always subject to sudden breakdown of compensation.

PERICARDIAL STRETCH AND PRESSURE-VOLUME RELATIONS.

Pericardial stretch is determined by the rate of increase of its contents and the response of two pericardial "springs": (1) wavy collagen, which tends to be smoothed by expanding pericardial contents, and (2) elastic tissue. Rapid accumulation exhausts these, and the limit of stretch is quickly reached, owing to the pericardium's J-shaped pressure-volume curve (see Fig. 50-11) . The ensuing decompensated tamponade tends to be a "last drop" phenomenon, the last bit of fluid putting the pericardium and consequently the cardiac chambers on the steep portion of their pressure-volume curves. Compression of all heart chambers resists cardiac filling, a form of diastolic dysfunction in which at any diastolic volume excessive intracardiac pressure keeps pace with excessive intrapericardial pressure.

Pericardial drainage has a reciprocal effect: the first decrement usually produces the largest hemodynamic improvement by shifting the stretched pericardium back toward the less steep portion of its pressure-volume curve and consequently shifts the parallel myocardial pressure-volume relations.[68] [71]

RIGHT-SIDED HEART AND VENOUS FACTORS.

The early point of attack of the rising intrapericardial pressure is on the right atrium and ventricle. The pressures of these thinner chambers equilibrate with rising pericardial pressure before the LA and LV pressures. Normal RA and RV pressures are somewhat lower than in the corresponding left chambers, and the RV wall is much thinner. Thus, rising diastolic pressures paralleling rising pericardial pressure occur first in the right and later in the left sides of the heart.[72] Normally, intrapericardial pressure is lower than RA pressure so that RA (transmural) pressure is normally higher than its cavitary pressure; but with tamponade, rising pericardial pressure progressively reduces, and ultimately makes phasically negative, the transmural pressure of first the right and then the left heart chambers. Cardiac filling is maintained by a parallel rise in systemic and pulmonary venous pressure,[68] the venous beds generating enough pressure to keep both sides of the heart filled.[70] A key factor affecting compensation is the rate of venous volume expansion by fluid transfer from the tissues, from the arterial to the venous side of the cardiovascular system; this requires time and is inoperative in rapid "surgical" tamponade. Finally, diastolic suction probably augments filling.[68]

LEFT-SIDED HEART AND ARTERIAL FACTORS.

Pericardial pressure

Figure 50-11 Cardiac tamponade. Schema of pericardial pressure-volume curves (volume increases over time). At left, rapidly increasing pericardial fluid first fills the pericardial reserve volume (initial flat segment) then rises steeply to exceed the limit of parietal pericardial stretch, causing even steeper rise as smaller fluid increments disproportionately increase the pericardial pressure. At the right, a slower rate of pericardial filling takes longer to exceed pericardial stretch limit because of time available for "give." (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

---

equilibrates first with RV diastolic pressure also because pericardial stiffness is inherently greater than RV, but not LV, stiffness. As compensatory mechanisms (Fig. 50-12) are defeated, cardiac filling decreases, pericardial pressure equilibrates with LV diastolic pressure, and cardiac output decreases critically (even the left ventricle ultimately equilibrates due to drastic reduction in volume, producing a very low to phasically negative LV transmural pressure). Eventually, diastolic pressures in both ventricles and the pulmonary artery all equilibrate with mean RA and LA pressures at approximately intrapericardial pressure--the characteristic hemodynamics of "pure" cardiac tamponade.[68] [69] [70] [71] During inspiration, left-right heart pressure differences are least or nil and commonly reversed; circulation is assisted by reciprocal flow changes in inspiration and expiration. During pulsus paradoxus the breathing phases have comparable but exaggerated differential effects; with inspiration, pulmonary wedge pressure falls below pericardial pressure. RA pressure also falls but not below pericardial pressure, enhancing inspiratory RV filling.

Transmural Pressure

The true "filling" (distending) cardiac pressures are the *myocardial* transmural pressures: cavity pressure minus intrapericardial pressure. (Cavity pressures are the sum of transmural pressure and pericardial pressures.) Transient reversal of the transmural pressure gradient (negative transmural pressure) causes RV collapse early in diastole (especially the weak RV outflow tract), and the RA, and sometimes LA, collapse in late diastole[73] (Figs. 50-13 and 50-14 ; see also Figs. 7-95 , 7-96 , and 7-97). (The critical negative transmural pressure buckling pressure for the right ventricle is 0.05 to 0.1 mm Hg; for the left ventricle it is 3.0 mm Hg.[74]) The RV inflow tract continues to fill while the outflow tract collapses, suggesting diastolic suction. The thick left ventricle does not collapse *unless* there is loculated high pressure fluid on its free border, RV hypertrophy, pulmonary artery hypertension, or intrapericardial adhesions. The onset of chamber collapses coincides with a 15 to 25 percent decrease in cardiac output[75] while compensatory mechanisms (see Fig. 50-12) still maintain arterial pressure, mainly due to increased peripheral resistance. Thus, at least in euvolemic and hypervolemic patients, RV collapse tends to occur earlier than pulsus paradoxus.

In tamponade, blood mainly enters the heart when blood is leaving it; pericardial volume and pressure vary continuously during the cardiac cycle, reflecting variations in early cardiac chamber volumes, although pericardial fluid continuously compresses the heart. In early diastole, the peak ventricular filling rate is radically reduced along with the filling fraction, emphasizing the importance of atrial contributions.[68] [69] By end-diastole or earlier, the ventricles are filled and maximally expanded within the

pericardial sac, raising intrapericardial pressure to its maximum. Although atrial expansion by filling would tend to raise pericardial pressure at end systole, ventricular ejection is complete so the ventricles are at minimal volume, permitting intrapericardial pressure to fall. As the ventricles contract to eject blood and the pericardial "space" is increased, the atrial "floors" are pulled downward and pericardial pressure falls, increasing transmural pressure

Figure 50-13 Large pericardial effusion (PE) with tamponade. Arrow indicates right ventricular (RV) collapse. LV=left ventricle.

to enhance atrial filling.[69] Atrial cavitary pressure falls at the same time, producing the *x* descent in atrial pressure curves (Fig. 50-15) . Within these dynamics, the ventricles eject reduced stroke volumes but remain underfilled and therefore operate at the low end of their Frank-Starling curves.

High pericardial pressure prevents normally rapid ventricular filling in early diastole. Moreover, the AV valves tend to close early. These factors progressively amputate the *y* descent of the atrial and venous pressure curves, reflecting curtailed and ultimately absent rapid ventricular filling. (Note that the LA *y* descent may be reduced long after elimination of the RA *y* descent.) Atrial reservoir function has increased importance: in severe tamponade the LA may fill only during expiration and the ventricles only during atrial systole.[69] Decreased filling due to premature AV valve closure exacerbates the reduced ventricular preload (shorter fiber length), further contributing to lower stroke volume and decreased ventricular ejection rate. Ultimately, the aortic valve opens only during expiration. During inspiration,

Figure 50-12 Cardiac tamponade and compensatory mechanisms. Solid arrowheads=tamponade. (From Spodick DH: The Pericarium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

Figure 50-14 Large pericardial effusion with tamponade. Biatrial (RA and LA) collapse (arrows).

leftward shift of the atrial and ventricular septa[68] further reduce LV chamber compliance and obstruct LV filling. Thus, the ventricular pressure curves show an immediate, shallow to barely visible diastolic rise from a slight lowering just after AV valve opening at the high diastolic levels seen with pressure equilibrium--typically 15 to 30 mm Hg in euvolemic patients (see Fig. 50-15) .

CORONARY BLOOD FLOW.

This is reduced primarily by increased subepicardial vascular resistance. Yet with normal coronary arteries coronary blood flow remains adequate to support aerobic metabolism because of proportionate reduction in cardiac work; that is, the ventricles are underloaded.[68] Coronary vasodilator reserve, capacitance, and resistance are not critically impaired. Renal and cerebral blood flow during tamponade, though reduced, are partly supported by autoregulation. However, peripheral vascular resistance is high (response to endogenous angiotensin II) with significant hepatic and mesenteric ischemia.

Despite decreased cardiac output, arterial blood pressure is maintained until relatively late in slowly developing ("medical") tamponade, partly by alpha-adrenergic mechanisms, but thereafter may decline precipitously, owing to falling stroke volume and cardiac output. Good myocardial function permits the ventricles to increase the amount of blood ejected per beat (increased ejection fraction). Diseased or injured left or right ventricles do not maintain compensation as well as normal hearts.[76] [77]

COMPENSATION AND DECOMPENSATION.

Compensatory mechanisms (see Fig. 50-12) include time-dependent pericardial stretch and blood volume expansion, tachycardia, increased ejection fraction, and peripheral vasoconstriction due to intense adrenergic stimulation responding to falling cardiac output. Adrenergic stimulation, including increased serum catecholamines, produces (1) alpha-adrenergically increased systemic resistance, which maintains central blood pressure and supports the gradient for coronary flow (increased systemic resistance is not affected by beta blockade but is decreased by alpha blockade, which is potentially decompensating); (2) a beta-adrenergic contribution, which increases heart rate; (3) rising pressure in the right atrium, which also induces tachycardia to defend the minute cardiac output; (4) beta-adrenergic stimulation, which augments diastolic relaxation; and (5) increased inotropy, which minimizes ventricular and systolic volume and improves the ejection fraction. In decompensated tamponade, the blood pressure fall is strongly influenced by an opioid-dependent mechanism, as demonstrated by naloxone-induced blood pressure increase without increasing cardiac output, that is, a large additional increase in systemic resistance.[75]

Owing to arterial and atrial baroreceptor unloading, arterial pressure is augmented by neurohormonal activation, with a limited late contribution by the renin-angiotensin-aldosterone system. Renin, angiotensin II, arginine vasopressin, and aldosterone decrease urine flow and renal sodium and potassium excretion (after mean blood pressure decreases by about 30 percent), followed by increased adrenocorticotropic hormone.[69] A neurogenic antinatriuresis reflexly increases renal sodium and fluid retention, which, teleologically, defends cardiac filling by increased blood volume and venous pressure. Unlike cardiac failure at comparable central pressures, atrial natriuretic factor does not increase because tamponade prevents myocardial stretch. (Teleologically, this is also favorable because atrial natriuretic factor would increase renal sodium and water elimination and is harmful to myocytes, depressing contractility.[77A]) Finally, tamponade can produce a profound arterial respiratory alkalosis.[67] Mixed venous (pulmonary artery) blood pH, P_{CO_2} , and serum bicarbonate are relatively unchanged, but as cardiac output falls critically the difference between arterial and mixed venous P_{CO_2} increases.

ATYPICAL CARDIAC TAMPONADE.

This occurs in four forms: low pressure, occult, right-sided, and hypertensive.[69] In volume-depleted patients, hypovolemia attenuates compensatory increases in venous blood volume and pressure so that cardiac output falls at lower ventricular diastolic pressure: *Low pressure tamponade* may occur at mean diastolic pressures as low as 6 mm Hg with few symptoms at rest and with or without significant systemic hypotension; yet both RV collapse and pulsus paradoxus may be present. Although pulse contours tend to be abnormal, it may be necessary to expand blood volume by an intravenous saline challenge to produce diagnostic pulse morphology. In *occult tamponade,* pericardial pressure equilibrates with RV and often LV diastolic pressure without a compensatory increase in venous pressure. *Right-sided tamponade,* with right diastolic pressures exceeding left, can occur when LV compliance is very low (e.g., LV hypertrophy) or, more commonly, after cardiac surgery, if fluid is loculated over the right side of the heart. In *hypertensive tamponade,* even with significantly low cardiac output there is unusually high (i.e., normal to even hypertensive) systolic arterial pressure, probably due to excessive adrenergic stimulation.[78]

Figure 50-15 Cardiac tamponade; pressure equilibration. Pulmonary artery (PA) diastolic, right atrial (RA) mean, and right ventricular (RV) diastolic pressures are each approximately 15 mm Hg. Respiratory fluctuation of right ventricular systolic pressure is between 23 mm Hg in maximum expiration and 29 mm Hg at peak inspiration. Right atrial pressure has a single conspicuous drop, the *x* descent; there is no *y* descent. Pulmonary artery systolic pressure changes follow the right ventricular systolic pressures at approximately the same levels. (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

Clinical Features

Pericardial disease of almost any etiology can produce cardiac tamponade, defined as significant compression of the heart by accumulating pericardial contents (liquids, pus, blood, clots, and gas singly or combined).[79] In patients who present with tamponade the great range of pericardial disease requires etiological assessment by probability while anticipating pathogenetic and etiological surprises.[64] Because tamponade is a pathophysiological continuum, patients can have mild to florid tamponade, the latter a form of cardiogenic shock and the former a stage that can progress. Symptoms and signs mirror the rate of physiological impairment. Thus, "medical" and "surgical" tamponade are loose labels conveying relative urgency.[79] "Surgical tamponade," typified by intrapericardial hemorrhage, can quickly overwhelm compensatory mechanisms; with cardiac wounds and intrapericardial rupture of dissecting aortic hematoma as little as 150 ml of blood and clots can be rapidly lethal (see Chap. 51) . In contrast, in primarily inflammatory or irritative bloody effusions, slowly escaping blood is prevented from clotting by the pericardium's fibrinolytic activity and defibrinization by the "whipping" action of cardiac beating. (Note that almost every form of pericarditis can provoke variably bloody effusion.) In

"medical tamponade" fluid exudes at a wide range of rates so that critical cardiac compression may first appear at anywhere from 200 ml to well over a liter. The volume of fluid causing tamponade varies inversely with both parietal pericardial "give" and thickness: disorders that thicken or scar the pericardium such as intense or repeated inflammation can sharply reduce the amount of effusion and bleeding for critical cardiac compression. The clinical onset, ranging from insidious to rapid to sudden, is related to the tempo of physiological impairment. In a patient first discovered to have hundreds of milliliters of fluid, the interplay of exudation rate and pericardial "compliance" permits compensatory responses to keep effusions tolerable longer than in "surgical tamponade."[80]

SYMPTOMS.

Patients may have symptoms of an inciting pericardial disease, notably chest discomfort, but in those presenting unconscious, obtunded, or with convulsions there may be no useful history. Tachypnea and dyspnea on exertion progressing to air hunger at rest (occasionally orthopnea) are common, partly related to increased pulmonary interstitial water increasing lung stiffness. Cough and dysphagia are not uncommon and are deceptive as early complaints. Most patients become weak and anorectic and have symptoms ranging from feeling faint to having syncope. Anemia, common in malignancies, exacerbates dyspnea and weakness. Finally, insidiously developing tamponade may present as signs of its complications, such as renal failure, abdominal plethora, or hepatic (shock liver[81]) and mesenteric ischemia.

PHYSICAL FINDINGS.

Physical examination is of little use in determining the presence of the pericardial effusion itself, although occasional large effusions produce a Bamberger-Pins-Ewart sign. Tachycardia (>100 beats/min) is the rule, although many patients have heart rates of 90 to 100 beats/min and the rate is lower in hypothyroidism and in many uremic patients. During acute pericarditis with tamponade, uremic pericardial rubs often remain and can even be loud. Heart sounds may be distant, owing to insulation by fluid and reduced cardiac function, sometimes with relative accentuation of the pulmonic component of S_2 . The precordium may be quiet and an apex beat not palpable, although, with preexisting cardiomegaly or anterior and apical pericardial adhesions, active pulsations may be palpated. Significant tamponade produces absolute or relative hypotension; indeed, tamponade is part of the differential diagnosis of unexplained hypotension. In "surgical tamponade," shock levels are usual; but in early "medical tamponade," systolic blood pressure is commonly greater than 90 mm Hg. Occasional patients are hypertensive,[78] especially if they have preexisting hypertension; in these patients "normal" blood pressure may be low. (Note that hypertensive blood pressures characterize patients with exaggerated compensatory adrenergic responses and greatly increased peripheral resistance hypertensive tamponade.) Cool extremities, nose, and ears, sometimes with acral cyanosis, are due to vasoconstriction and relative circulatory stasis. Central cyanosis is rare and may be due to a right-to-left shunt, usually through a patent foramen ovale,[82] that disappears after relief of tamponade. Fever is related to etiology, particularly infections. Febrile tamponade may be misdiagnosed as septic shock.

If the patient is not hypovolemic and especially if fluid accumulates sufficiently slowly for expansion of blood volume, jugular venous distention can be anywhere from just visible to striking. Peripheral venous distention can be seen in the forehead, scalp, and ocular fundi. Rapid "surgical tamponade," especially acute hemopericardium, can induce jugular pulsations without distention (i.e., no time for compensatory blood volume expansion). In "medical tamponade," heart rates between 85 and 120 beats/min may yield jugular pulsations slow enough to determine that there is an *x* descent but absent or greatly attenuated *y* descent. Indeed, if a venous pressure level can be discerned, this single definitely negative phase can be timed as midsystolic (between S_1 and S_2). These are not outward pulsations; *x* and *y* in compressive pericardial disease are "collapses" from a high standing level. Neck veins may also show the normal falling pressure level during inspiration. An inspiratory increase or lack of fall, the so-called Kussmaul sign, belongs to constriction; when verified with tamponade, or after pericardial drainage, it indicates underlying epicardial constriction.

Pulsus Paradoxus (See also Chap. 4)

This is defined as a systolic drop in arterial pressure of 10 mm Hg or more during normal breathing. Most patients with cardiac tamponade have some degree of pulsus paradoxus, often palpable in peripheral arteries (Fig. 50-16) . At very low cardiac outputs, however, an arterial catheter may be needed. With a pronounced pulsus paradoxus there may be no Korotkoff sound in inspiration--indeed, the aortic valve may not open in inspiration--with complete inspiratory loss of pulsations in muscular arteries like the radial (the more elastic carotid is less easily evaluated). Pulsus paradoxus may first be appreciated by taking the radial pulse and watching the patient's abdomen during normal breathing. Breathing should not be exaggerated because that can exaggerate the pressure drop. As the abdomen rises, the pulse weakens or disappears.

To quantify the blood pressure difference noninvasively, a cuff is inflated to 15 mm Hg above the apparent highest systolic level and slowly deflated until the first beats are heard and then held at that point during normal respiration (the sequence resembles "bump-bump-bump, silence-silence-silence, bump-bump-bump;" the "bumps"--Korotkoff sounds--are expiratory). Deflation is then continued to where all beats are audible. The difference between the pressures when systolic sounds are first heard and then are continuously heard gives the "size" of the pulsus paradoxus. If a patient is first discovered with pulsus paradoxus, the pericardial variety must be differentiated from other conditions that produce pulsus paradoxus, such as massive pulmonary embolism, profound hemorrhagic shock and other causes of acute hypotension, and obstructive lung disease. In conditions altering tamponade physiology and respiratory mechanisms, pulsus paradoxus may be undetectable.

Figure 50-16 Pulsus paradoxus during early cardiac tamponade. Brachial artery systolic pressure falls excessively during normal breathing (142 to 124 mm Hg); diastolic pressure is steady at 76 mm Hg. ECG shows marked PR segment depression. (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

PATHOPHYSIOLOGY.

Cyclic cardiocirculatory changes during normal breathing alternately favor right- and left-sided heart filling and ventricular performance, with corresponding pulmonary artery and aortic pressures and flows. Pulsus paradoxus is a pulse (pulsus), not a pressure, change.[83] (There were no blood pressure cuffs or catheters; to Kussmaul it was "paradoxic" since the radial pulse disappeared during inspiration while the apex continued to beat.) Pulsus paradoxus is an exaggeration of the normal inspiratory fall in arterial flow and systolic pressure (see Fig. 50-16) (arbitrarily
10 mm Hg). Transmission of pleural pressure variations to the cardiac chambers through the pericardium explains pulsus paradoxus in tamponade whereas their insulation from transmission by scar tends to limit or suppress pulsus paradoxus in constriction. Inspiratory RV volume increase is indispensable for pulsus paradoxus, because when systemic venous return is held constant, tamponade does not cause pulsus paradoxus.[84] Moreover, the right side of the heart is the crux of tamponade dynamics and pulsus can occur in isolated right heart tamponade.[83] [85] Although usually elicited by cuff, pulsus paradoxus is more sensitively revealed by catheter, especially during early tamponade when pericardial pressures are approaching equilibrium with right-sided but not yet with left-sided heart pressures and in low-pressure tamponade. Many such patients have an inspiratory fall in arterial pressure of 10 mm Hg or less that is not quite diagnostic.

Pulsus paradoxus usually signals very large reductions in ventricular volumes and equilibration of mean pericardial and all cardiac diastolic pressures (Fig. 50-17) . [83] Breathing now transiently causes the equilibration pressure level to alternate. *Inspiration* decreases pericardial pressure, favoring right-sided heart filling; *expiration* favors left-sided heart filling. Indeed, pulsus occurs as inspiration depresses pulmonary venous pressure below systemic venous pressure so that pulmonary wedge and LA pressures fall below pericardial pressure and the inspiratory decrease in transmitral flow velocity significantly

Figure 50-17 Physiology of pulsus paradoxus. Complex sequential and simultaneous responses as to inspiratory reduction of pleural pressure produce the inspiratory fall in arterial flow and pressure (see text). (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

exceeds the normal decrease of 15 percent or less. RA atrial pressure falls, but not below pericardial pressure. Inspiration may also transiently reverse pulmonary venous flow in severe tamponade and thus reduce LA flow.

MECHANISMS

Pulsus paradoxus clearly depends on alternate reciprocal exaggeration of ventricular interaction by the respiratory cycle. The inspiratory systolic pressure fall is also related to the pattern and depth of breathing and hence to the degree of pleural pressure fluctuation. Normally, intrapericardial and pleural pressures vary almost equally during breathing, but in tamponade intrapericardial pressure during inspiration decreases somewhat less than pleural pressures; it increases as the right side of the heart fills, partly because the right side of the heart expands into the pericardial fluid, increasing its already high pressure (see Fig. 50-17) . The increased pericardial pressure further compresses the left side of the heart in inspiration, along with a sharp leftward shift of the atrial and ventricular septa, tending to further impede LV filling.[83] The comparable expiratory decreases in right-sided heart filling and cavitary pressures are reflected on echocardiography as maximum RA and RV

diastolic collapses during expiration.

Directional respiratory changes in transmural pressures, flow, and filling remain normal and approximately 180 degrees out of phase, that is, almost perfectly reciprocal for maximal changes. At the low chamber volumes of tamponade, proportional inspiratory pressure increases are very much greater than normal on the right; corresponding left-side inspiratory pressure decreases are relatively less than on the right, although much greater than normal, dramatically reflected by marked respiratory fluctuation of Doppler transvalvular and intravascular flow velocities. Displacement of the ventricular and atrial septa into the underfilled left ventricle and atrium, enlarging the right side of the heart at the expense of the left is a parallel effect due to inspiratory increase in RV transmural pressure and filling. The septal shifts further impede LV filling, which is also opposed by inspiratory reduction of aortic transmural pressure causing the left ventricle to contract against increased aortic impedance. Aortic flow and systolic pressure decrease promptly, within one beat of the onset of inspiration, immediately after inspiratory merging of pulmonary wedge and intrapericardial pressures. Thus, a large component of the change must be left sided, occurring before any series effect of increased RV output can reach the left atrium.[83] Pulsus paradoxus usually disappears with adequate pericardial drainage.

"NONPERICARDIAL" PULSUS PARADOXUS.

Pulsus paradoxus occurs frequently in chronic obstructive airway disease and acute asthma and occasionally in hemorrhagic shock, tension pneumothorax, tracheal compression, RV infarction (possibly due to pericardial constraint), severe pulmonary embolism, restrictive cardiomyopathy, and mediastinal and cardiac compression by mass lesions.

ABSENCE OF PULSUS PARADOXUS.

Tamponade without pulsus paradoxus occurs[83] :

1. When LV diastolic pressures and LV stiffness significantly exceed those of the right ventricle; pericardial pressure may effectively equilibrate only with right-sided heart pressures, a form of RV tamponade.
2. When severe aortic regurgitation damps respiratory fluctuations even without LV dysfunction.
3. With atrial septal defect when inspiratory venous return is balanced by shunting to the left atrium.
4. With extreme hypotension in shock, as in severe tamponade, which can make respiration-induced pressure changes unmeasurable.
5. In some cases of acute LV infarction with tamponading effusion.
6. In local (usually postsurgical) cardiac compression.

7. With pericardial adhesions, especially over the right side of the heart.

RENAL EFFECTS.

Tamponade, like any profound hypotension, induces oliguria because it signals renal sodium and fluid retention. Despite high central circulatory pressures, atrial natriuretic factor cannot increase, owing to the absence of myocardial stretch.

ELECTROCARDIOGRAPHY (see p. 1828 and Chap. 5) .[79]

The ECG can be normal but most often is nonspecifically altered (mainly ST-T wave abnormalities). It may show acute pericarditis at ECG stages 1, 2, or 3. Electrical alternation of the QRS complex, rarely including the T wave, is quasi-diagnostic. P-QRS or P-QRS-T or P-PR segment-QRS-T alternations (panalternation)[86] are seen only in critical cardiac tamponade. Low voltage is usually due to reduced heart size. Significant vagally mediated bradycardia (overriding normal baroreceptor reflexes) and ultimate electromechanical dissociation (pulseless electric activity) occur in end-stage tamponade, especially in rapid hemopericardium in which critical cardiac compression prevents filling (therefore output) while the ECG is continuously generated.

IMAGING.

All imaging methods can demonstrate pericardial effusion. Chest radiographs show an enlarged cardiopericardial silhouette with clear lungs (in the absence of pulmonary disease) (Fig. 50-10 , p. 1838). *Echo-Doppler cardiography,* ideally, although not necessarily, TEE, can eliminate the need for invasive hemodynamic measurement by revealing physiological as well as anatomical abnormalities[87] [88] (see Table 50-10) (Fig. 50-18; see also Figs. 7-95 , 7-96 , and 7-97). Some features are initially blunted in hypervolemic patients.

Echo-Doppler signs are less accurate in patients with pulmonary hypertension and intrapericardial adhesions and of greatly reduced sensitivity after cardiac surgery. If the effusion is large enough, the heart may swing freely in it--the basis of electrical alternation. With large effusions, compression by pericardial fluid permits the entire adult heart to be seen, particularly in the four-chamber scan plane. Cardiac compression may also falsely suggest myocardial hypertrophy (pseudohypertrophy); the left ventricle transiently "remodels."[89]

In the absence of heart disease, systolic function is good, with excellent shortening and ejection fractions, although the ventricles operate at reduced volumes, hence with small stroke outputs. Thus, the heart is underloaded, both "underpreloaded" and "underafterloaded," obviously working hard but prevented by reduced inflow from matching circulatory demand.[79] With hemopericardium, blood and clots are seen, whereas fibrin is common in inflammatory effusions. Collapse of the RV free wall in early diastole (see Fig. 50-13) correlates with obstruction to the atrial *y* descent (i.e., obstruction to rapid filling); it is earliest and most marked in expiration when RV volume is reduced. RA collapse occurs at end diastole and early isovolumic systole; in about 25 percent of cases the left atrium also collapses (see Fig. 50-14). RV diastolic collapse occurs after a 15 to 25 percent drop in cardiac output and before significant decrease in blood pressure in patients who are normovolemic or hypervolemic; it is more specific than RA collapse and more sensitive and specific than pulsus paradoxus in detecting increased intrapericardial pressure, particularly if RV diastolic collapse lasts at least one third of the cardiac cycle. RV diastolic collapse duration is quantitatively related to the pericardial pressure.[73] It may also occur when unilateral or bilateral pleural effusion causes increased pressure in an insignificant pericardial effusion; this is relieved by pleural drainage. Inferior vena cava (IVC) plethora (diameter
 20 mm) and absence of the normal inspiratory IVC collapse (
50 percent) are seen on subcostal echocardiography. Absence of normal inspiratory IVC collapse implies right-sided heart diastolic pressures of 15 mm Hg or more. Respiratory effects parallel pulsus paradoxus reciprocally, with respiration, as shown by atrial and especially ventricular septal shifts from the right into the left atrium and ventricle in inspiration, reversed in expiration. Although total transvalvular blood volume flows are reduced, flow velocity differences between the right and left sides of the heart are enormously magnified during the breathing cycle. Figure 50-18 shows respiratory variation in transmitral flow. Concurrently, respiratory variations of superior vena cava flow velocities are exaggerated in tamponade. Hepatic vein flow velocities increase during inspiration, with retrograde flow in early expiration.

DIAGNOSIS.

Tamponade should be suspected in patients with hypotension and the following findings: elevated systemic venous pressure, falling blood pressure, pulsus paradoxus, tachycardia and dyspnea or tachypnea with clear lungs, chest and abdominal wounds, recent or concurrent evidence of pericarditis, and unexplained "cardiac" enlargement or evidence of pericardial effusion. Moreover, anticoagulant or thrombolytic therapy,[90] certain drugs such as cyclosporine, recent cardiac surgery, blunt chest trauma, malignancies, connective tissue disease, renal failure, and septicemia all precipitate, aggravate, or predispose patients to tamponade. Indwelling instrumentation, particularly of the thin right side of the heart--such as central venous lines, transvenous pacemakers, filtration catheters, and hyperalimentation catheters--can subtly perforate the right atrium or ventricle (see Chap. 11) . Some of these provoke hemopericardium; those delivering parenteral fluids can rapidly fill and overload the pericardial cavity.

Certain conditions inhibit or alter the pattern of chamber collapses and respiratory phenomena[79] [91] just as they limit pulsus paradoxus. These include LV hypertrophy and dysfunction, aortic valve disease, pulmonary hypertension, hypertrophy and reduced compliance of the right ventricle, obstruction of heart valves by intrinsic disease or masses, and intrapericardial adhesions. Finally, LV diastolic collapse occurs with loculated, usually postsurgical, effusions over the left ventricle and, rarely, in circumferential tamponade in patients with intrapericardial adhesions, pulmonary artery hypertension, or RV hypertrophy.[91] [92]

Figure 50-18 Cardiac tamponade. Transtricuspid flow velocity "paradoxus." Marked increase in flow velocity occurs with inspiration.

VARIANT FORMS OF CARDIAC TAMPONADE

LOW PRESSURE TAMPONADE.[83]

Low pressure tamponade occurs in hypovolemia with severe systemic diseases such as tuberculosis and malignancy as well as in chest trauma with bleeding anywhere. Patients are weak, may seem normotensive, and have dyspnea on exertion, with only mild if any jugular venous distention and no diagnostic pulsus paradoxus. However, they have characteristic respiratory changes in Doppler diastolic inflow signals and isovolumic relaxation time (see Table 50-10) . In low-pressure tamponade the low-pressure pericardial effusion equilibrates with RV diastolic pressure only, as in cases of early tamponade, and equilibration occurs first only in inspiration ("inspiratory tracking").

HYPERTENSIVE CARDIAC TAMPONADE.

This condition has all the features of cardiac tamponade except that these exceptional patients have high (rarely very high--
200 mm Hg) blood pressures.[79] Typically, there was antecedent hypertension. Pulsus paradoxus is demonstrable at high pressure. Attempts to reduce the blood pressure may exacerbate the situation and precipitate or greatly exaggerate pulsus paradoxus.[78]

TAMPONADE WITH VENTRICULAR DYSFUNCTION.[85] [90]

RV or LV dysfunction can reduce or eliminate pulsus paradoxus. LV dysfunction, especially reduced compliance, notably in hypertensive or severe coronary artery disease, uremia, or aortic valve disease, may be associated with RA and RV collapses at relatively small volumes of excess pericardial fluid. They essentially produce a right-sided heart tamponade at lower intrapericardial pressures than with a normal left ventricle.

PNEUMOTAMPONADE: TENSION PNEUMOPERICARDIUM OR PNEUMOHYDROPERICARDIUM[79] [93] [94]

Increasing air or other gas in the pericardium with or without excess pericardial fluid, blood, pus, or chyle can easily tamponade the heart. Examples include a check-valve mechanism admitting air from lung structures or intrapericardial gas-producing organisms. Diagnostic and therapeutic principles are the same as in liquid tamponade. There is also a tympanitic precordial percussion and frequently the "mill-wheel sound" of the heart splashing in a fluid-gas interface.

REGIONAL CARDIAC TAMPONADE.[79] [95]

Loculated effusion over any part of the heart can compress that part. Loculation is usually due to localized pericardial adhesions, especially postsurgically, and induces hemodynamic abnormalities consistent with the compressed chambers or zones. For example, after RV infarction, loculated effusion can cause selective RV tamponade with RV diastolic pressure higher than LV diastolic pressure. Loculated effusions compressing the right atrium (often after surgery) may act similarly and can cause a right-to-left shunt through a patent foramen ovale or atrial septal defect. Occasionally, loculated effusion tamponading the right atrium reproduces all the hemodynamic findings of severe generalized tamponade, including pulsus paradoxus.

EFFUSIVE-CONSTRICTIVE PERICARDITIS.

This combination of effusion and constriction with mixed clinical, imaging, and hemodynamic signs can produce tamponade with relatively little fluid when there is a scarred, unyielding parietal pericardium or when a constrictive epicarditis underlies the tamponading fluid.

Cardiac Catheterization

It may be necessary to confirm the diagnosis of tamponade by right heart or complete cardiac catheterization, especially when study of the heart and coronaries becomes desirable. Ideally, catheterization shows high pressures throughout ventricular diastole and near-equilibration (>5 mm Hg) of atrial and ventricular diastolic pressures.[79] [92] Most tamponades equilibrate at 16 to 20 mm Hg (6 to 12 mm Hg in low pressure tamponade). Atrial traces show absent or amputated *y* descent. Arterial and pericardial catheters disclose exaggerated respiratory pressure fluctuations. Absent coronary disease, compression of the epicardial coronary arteries and veins does not result in anaerobic metabolism as measured by coronary sinus lactate level, demonstrating that the tamponaded (consequently underloaded) myocardium has sufficient blood supply to avoid anoxia, despite the usual tachycardia and strong compensatory adrenergic response. Despite very high central circulatory pressures, tamponade does not cause alveolar pulmonary edema.[79] [96] There may be some interstitial lung edema, but neither alveoli nor septa are affected. Subcostal echocardiography shows that the intrahepatic IVC is plethoric--a more reliable sign than jugular venous distention.[87] [88]

Treatment

Definitive treatment is prompt evacuation of pericardial contents. Only in relatively few patients who had dehydration and hypovolemia has it been possible to demonstrate effective cardiocirculatory support by medical measures. Volume infusion may also be diagnostically useful only in hypovolemic patients,[97] by revealing the typical hemodynamics of cardiac tamponade, which are otherwise well concealed in some hypovolemic patients (occult tamponade; low-pressure tamponade (see p. 1841).

MEDICAL TREATMENT.[79] [98] [99]

Experimental evidence favoring a variety of medical agents is conflicting and investigated in models that do not necessarily apply to human tamponade.[98] [99] Medical treatment may appear temporarily effective (partly because tamponade occasionally remits spontaneously) but usually is ultimately ineffective. It is aimed at supporting compensatory and physiological responses, expanding intravascular volume, increasing or decreasing systemic vascular resistance, and supporting inotropy. The latter is almost predictably useless because most tamponaded hearts without preexisting cardiac disease are under effective endogenous inotropic stimulation with an excellent ejection fraction--but at critically low stroke volume. Supporting filling with various intravenous fluids can help hypovolemic patients but otherwise tends to increase heart volume with a subsequent countervailing increase in pericardial pressure, leaving the patient no better and perhaps worse by decreasing transmural pressure. Agents increasing peripheral resistance to support blood pressure have not been demonstrably effective because tamponade evokes maximal endogenous sympathetic stimulation and perhaps because of untoward cardiac effects. Finally, atropine can be given for depressive vagal reflexes during early and late tamponade.[79]

If drainage equipment is not immediately available, medical measures may be attempted for a transiently favorable effect, perhaps permitting additional pericardial stretch. These include isoproterenol, norepinephrine, dobutamine, and similar agents to support blood pressure and flow. Correction of any metabolic acidosis avoids the myocardial depressant effect of that condition and increases responses to endogenous and exogenous catecholamines. Temporary results may also accrue from vasodilators. Nitroprusside plus blood transfusion improved cardiac output in experimental animals.[98] Hydralazine plus volume infusion appears to raise arterial pressure and cardiac output and improve blood flow to myocardium, central nervous system, and kidney, all locations where slightly improving blood flow has not been critical partly due to autoregulation. Positive-pressure breathing of any kind should be avoided at any stage of tamponade because it will further reduce venous return, RV transmural pressure, and cardiac output. Only after the pericardium is incised or the fluid drained may positive-pressure breathing be used safely.

PERICARDIAL DRAINAGE.

Whenever possible, echocardiographically monitored pericardiocentesis or surgical drainage are treatments of choice. Choice of procedure depends on urgency. When death is impending, the quickest method, percutaneous needle paracentesis, can be unavoidable. Yet, with brisk pericardial bleeding, as in wounds, ruptured ventricular aneurysm, or dissecting aortic hematoma, clotting makes needle evacuation impossible. Moreover, bleeding can be slowed by the tamponade pressure so that surgical drainage with suppression of bleeding sources is safer and surer. Drainage should be as complete and prolonged as necessary, whether by catheter or tube or by a window into a neighboring cavity. The choice must be individualized, but a pericardiostomy,[100] with suction drainage for at least 3 to 4 days, is often optimal. Preventing recurrence is important in disorders prone to reaccumulation. Treatment of underlying disease with specific agents may suppress reaccumulation. However, resistant processes such as malignancies and stubborn infections can ultimately require pericardiectomy or obliteration of the pericardial cavity using

tetracycline, minocycline, bleomycin

(installed with a local anesthetic), or other sclerosants; prolonged tube drainage can stimulate obliterative adhesions and is preferable to use of these painful agents.[79] Traditional percutaneous needle pericardiocentesis[77] is usually effective and relatively safe with inferior fluid accumulation at least l cm deep by echocardiogram. Most effusions can be effectively drained with echocardiographic guidance, which has greatly improved its safety, permitting puncture at any reasonable place on the precordium[101] except over the internal mammary arteries, 2.5 cm on each side of the sternum. An apical or, less often, subxiphoid approach is optimal. Fluoroscopic and even CT guidance are also feasible. Contraindications to thoracotomy, such as pleuropulmonary diseases, which make intolerable even temporary compromise of lung tissue, or extensive pleural adhesions may necessitate prolonged tube drainage or even a pericardioperitoneal shunt performed with special equipment.[79]

SURGICAL DRAINAGE.

Subxiphoid surgical incision and thoracoscopic drainage produces little morbidity and can be done in emergencies with only local anesthesia. It permits direct inspection, biopsy of visceral and parietal pericardium, and resection when that is an option. Video-assisted thoracoscopy gives the operator a wide field of view (although a lung, usually the left, must be collapsed). Other chest conditions or failure of thoracoscopic drainage may mandate an open surgical approach.

EFFECTS OF PERICARDIAL DRAINAGE.

After pericardiocentesis, cardiac pressure and volume corrections reflect the presence and degree of cardiac compression and are not predictable from the amount of fluid removed. However, because critically tamponaded hearts operate on the steep portion of their pericardial pressure-volume curve (see Fig. 50-11) , the initial fluid decrement will produce the greatest improvement in stroke volume. After drainage, RV volume usually increases more than LV volume because the more compliant right ventricle was more compressible. Indeed, the right ventricle occasionally dilates and echocardiography shows abnormal ventricular septal motion characteristic of RV volume overload. Especially if there is myocardial disease, RV dilation may initiate congestive failure. LV dilation can also do this with occasional pulmonary edema ("pericardial shock"). Although pulmonary artery pressure usually falls after drainage, it may rise with a temporary mismatch of ventricular output. Such acute right-sided and particularly left-sided heart failure occurs with ventricles unable to accommodate posttamponade increase in venous return exacerbated by continuing high afterload due to continuing increased peripheral resistance from compensatory adrenergic responses. Hemodynamic and clinical improvements are related to increased stroke volume. Effective drainage is characterized by[79] (1) disappearance of pulsus paradoxus; (2) frequent relief of dyspnea; (3) disappearance of signs of venous engorgement paralleling falling RA pressure; (4) reappearance of *y* descents; (5) loss of vena cava plethora; (6) loss of diastolic pressure equilibration; and (7) prompt loss of electrical alternation. A pericardial catheter (rarely necessary) documents normalization of pericardial pressure.

NONEFFUSIVE SEQUELAE OF PERICARDIAL INFLAMMATION

PERICARDIAL ADHESIONS AND FIBROSIS.

Pericarditis can heal without detectable residua or with some scarring of one or both pericardial layers. The plastic fibrinous exudate of acute and subacute pericarditis can be adhesive, but its fate is either fibrinolysis and reabsorption or organization with newly formed collagen fibrils as a matrix for invasion by new blood and lymphatic vessels and later fibrous or fibrogranulomatous adhesions.[102] A common denominator for intense scarring is bleeding; blood, particularly blood lipids and thrombi, and especially combined with pericardial injury and exudate, is thrombogenic.[102] Cicatrization is probably intensified by locally produced interleukins and tumor necrosis factors found in abnormal pericardial fluids and mesothelial production of a chemical promotant for fibroblasts. The most common cause of intrapericardial adhesions is cardiac surgery.[103]

Local thickenings are not rare on CT in patients with healed myocardial infarctions, rheumatic heart disease, sarcoidosis, and other conditions. More destructive inflammation in severe infectious pericarditis may heal without further consequences but frequently provokes constrictive scarring involving the entire heart, any portion of the heart, or the great vessels, distorting or compressing structures it entraps. Compressive syndromes arise from primarily pericardial lesions, differing from primarily myocardial lesions (e.g., myocardial infarction) that are usually associated with adhesions and fibrosis of little or no dynamic significance. In effusive pericarditis, intrapericardial bands on echocardiography predict significant scarring.[104] Some pericardial adhesions may buttress myocardial wounds or infarcts and contribute mural and microvascular support. Some seal an otherwise fatal myocardial rupture to form a pseudoaneurysm (see Chap. 37) .

Clinical Considerations.

Adhesions on the outside of the parietal pericardium even when combined with internal adhesions can be due to inflammatory disease of the mediastinum and pleura. Rarely they affect the cardiac silhouette[102] (unusual configurations can be resolved by imaging methods like spin-gated MRI; and CT is optimal for retrosternal adhesions).[105] External adhesions can produce exopericardial rubs and rarely permit systolic tugging on adjacent organs after pleuritis and mediastinitis. On imaging, intrapericardial adhesions modify some effects of tamponade by shifting chamber collapses to unusual locations and restricting swinging.[106] Adhesions are a major problem in the increasing numbers of second and third thoracotomies. Surgical preventive efforts include intrapericardial absorbable polymer patches, plasminogen activator (rt-PA), and hyaluronic acid. Postoperative pericardial closure decreases adhesions but is usually avoided due to unfavorable hemodynamics.[102]

PERICARDIAL CALCIFICATION (PANZERHERZ: "ARMOR HEART").

Dystrophic calcification (rarely ossification) signifies pericardial injury more destructive than conditions healing without calcification.[102] Yet even extensive calcifications may be well tolerated and asymptomatic. However, any degree of calcification may be found in constrictive pericarditis. Local calcification seems related to involvement of areas of least heart movement and of greatest friction between the epicardium and the parietal pericardium: inferiorly the LV apex, the right atrium, the sternal aspect of the right ventricle, and the AV groove. So many cases, especially those with ECG abnormalities, are associated with constriction that constrictive pericarditis should be ruled in or out when pericardial calcification is discovered. Three-dimensional echocardiography, MRI with tagging, and rapid-acquisition spiral or electron-beam CT can simultaneously map calcifications and indicate any hemodynamic impairment.[107] [108] Calcifications increase the technical difficulties of pericardial resection by requiring special instruments, and where calcification invades the myocardium the procedure is particularly difficult and dangerous.

INFLAMMATORY CYSTS.[98]

These include pseudocysts as well as encapsulated and loculated pericardial effusions. Pericardial scarring may trap portions of an intrapericardial exudate or hemorrhage, producing a pocket or cystlike structure with or without symptoms and signs requiring drainage or resection. Their capsules are scarred parietal and visceral pericardium with persistent inflammatory activity. Chronic inflammatory cysts must be differentiated from ventricular

pseudoaneurysms and true (congenital) pericardial cysts, which tend to be smooth with a predilection for the low right cardiac border, whereas inflammatory pseudocysts, like parasitic cysts, have variable contours and occur anywhere. *Inflammatory diverticula* are related to encapsulated pericardial effusion; they follow exudative pericarditis, especially tuberculous, but acute idiopathic (presumably viral) pericarditis can be a precursor. Unlike inflammatory cysts, only parietal pericardium is primarily involved, and they communicate with the pericardial cavity. Diverticular contents resemble those of inflammatory cysts. Diverticula, for some reason, tend to be right-sided, perhaps because the fibrosa over the right ventricle is particularly thick.

GRANULOMATOUS PERICARDITIS.

Granulomas are characterized by simultaneous inflammation and repair, producing subacute and chronic pericardial disease. These are basically nodules or masses composed mainly of vascular fibrous tissue with variable leukocytic infiltration. They can spread throughout the pericardium to form a static, avascular scar, making etiological diagnosis ultimately progressively more difficult. Many granulomas are rich in cholesterol and represent one source of cholesterol pericarditis. There are four main etiological groups of granulomatous pericarditis: (1) of unknown origin; (2) due to systemic diseases such as rheumatoid arthritis (rheumatoid arthritis causes a great number of pericardial adhesions and even pericardial rheumatoid nodules, sometimes with acute or subacute fibrinous pericarditis); (3) infections, particularly tuberculosis and fungi; and (4) foreign-matter reactions, particularly silicosis and asbestosis, which tend to form static scars with uncertain (usually low) constrictive

potential.

CONSTRICTIVE PERICARDITIS

CLINICAL CONSIDERATIONS.

Constrictive pericarditis "imprisons" the heart.[109] [110] It has important similarities to and differences from cardiac tamponade.[110] Its dominant etiological spectrum has changed (Table 50-12) and its clinical manifestations have changed due to changing tempo of the disease, that is, the aggressiveness of the inciting processes, the point in its development where it becomes significantly compressive or symptomatic and particularly where it becomes diagnosable. With progress in understanding constrictive and restrictive hemodynamics and in testing, diagnosis is only rarely greatly delayed so that most patients are recognized in earlier rather than truly chronic stages. The traditional "*chronic* constrictive pericarditis" is erroneous in most contemporary cases. There remain variably difficult differentiations from restrictive cardiomyopathy, other causes of systemic congestion, particularly RV failure, and hepatic cirrhosis. Sometimes inspection and biopsy of the pericardium and myocardium are required to rule in or out constriction or one of its variants, especially in the presence of systemic diseases that may be related to it. While obliterative adhesions regularly follow cardiac surgery, constrictive scarring is relatively uncommon.[110] Yet, constrictive scarring may follow pericardial resection or pericardiotomy for any condition, including constrictive pericarditis.

PATHOGENESIS.

Currently, most cases are of undetermined etiology--"idiopathic." The initial acute pericarditis can be silent or clinically apparent. The essential pathological process is healing with a thick *or thin* scar that restricts cardiac filling usually by total or near-total obliteration of the pericardial "space," although often with lacunae of fluid, pus, or blood. (Loculated fluid and bandlike constriction can compress any portion of the heart including any chamber, valve rings, and great vessels, mimicking disease in those structures.[109] [110]) Traditionally, constriction has been chronic, sometimes with surprising pericardial thickness; recently, thin constricting pericardia are increasingly evident. Early diagnosis and shift of most processes such as tuberculosis to "idiopathic" pericarditis, viral infections, and cardiac surgery[109] [111] cause most contemporary cases to be *subacute* (arbitrarily, 3 to 12 months after the pericardial insult). *Acute* constriction occurs soon after acute pericarditis; healing can cause constricting cicatrization within days after draining tamponade fluid. *Transient constriction* soon after acute pericarditis, usually with effusion, has been observed by echocardiography, inspection of the jugular

TABLE 50-12 -- CAUSES OF CONSTRICTIVE PERICARDITIS (WESTERN NATIONS)

Great Majority: Unknown or uncertain etiology/"Idiopathic pericarditis"
Relatively Common
Infectious
Viral or probable viral
Tuberculous
Pyogenic
Therapeutic irradiation
Cardiopericardial surgery
Relatively Uncommon (increased incidence in special populations)
Neoplasia
Metastatic
Mesothelioma
Pericardial
Pleural
Uremia (on dialysis)
Vasculitis/connective tissue disease group
Especially rheumatoid arthritis, lupus, scleroderma (including CREST syndrome)
Infectious
Fungal
Parasitic
Myocardial infarct-related
Post hemopericardium (from thrombolysis)
Post-myocardial infarction (Dressler) syndrome
Trauma
Blunt
Penetrating
Drugs
Procainamide (lupus)
Methysergide
Practolol
Hydralazine (lupus)
Hemopericardium/encapsulated hemopericardium in hemorrhagic disorders
Rare
Cholesterol pericarditis
Chylopericardium
Intrapericardial instrumentation
Automatic implantable cardioverter-defibrillator
Epicardial pacemaker
Whipple disease
Wegener granulomatosis
Hypereosinophilic syndromes
Cardiac transplant
Hereditary: mulibrey nanism
Sarcoidosis
Asbestosis
Pericardial amyloidosis
Dermatomyositis
Lassa fever
Chemical trauma: sclerotherapy of esophageal varices

veins, venous pulse, and auscultation (transient abnormal S_3) with or without symptoms and resolving in days to weeks.[110] In *chronic* constriction, pericardial tissue usually shows nonspecific fibrosis with few inflammatory cells and frequent myocardial atrophy.

Both subacute and acute constriction show many more inflammatory cells and lighter connective tissue. Depending on etiology there may be giant cells and granulomas.

PATHOPHYSIOLOGY. [109] [110]

Constricting pericardial scar, like tamponading fluid, sharply accentuates ventricular pressure-volume relations (see Fig. 50-11) and increases ventricular coupling (ventricular interaction). It *progressively* restricts ventricular filling to earlier diastole until 70 to 80 percent of the reduced filling occurs in the first 25 to 30 percent of diastole[109] (in contrast, tamponade *continuously* restricts filling from the beginning of diastole). Elevated

Figure 50-19 Constrictive pericarditis. Dip-plateau of left (LV) and right (RV) pressure curves with diastolic equilibrium are best seen in long diastole (patient with atrial fibrillation).

atrial pressures reflect elevated ventricular diastolic pressures. Moreover, early diastolic filling is at high velocity, owing to (1) high atrial pressure as the AV valves open and (2) diastolic suction,[112] [113] augmented by elastic recoil (conversion of potential to kinetic energy or "rubber bulb" effect[112]), that is, rebound of the ventricular pericardial scar, which had been contracted like a spring by ventricular systole. Such factors produce the "square root" configuration of ventricular diastolic pressure curves (Fig. 50-19) and other findings (see "Cardiac Catheterization," in Chap. 11) .

All cardiac diastolic pressures are nearly equilibrated as in tamponade. Equilibration may be "unbalanced" by vigorous diuretic therapy. Unlike tamponade, venous and atrial pressure waveforms resemble the normal: the *y* descent is preserved, although deep and usually larger than a more or less deep *x* descent (Fig. 50-19) . (In tamponade the *y* descent is eliminated or truncated.) Venous flow toward the heart occurs with the *x* and *y* descents of venous pressure, with the major acceleration during the *y* descent rather than as normally during the *x* descent. There are no systolic abnormalities except with coexisting myocardial lesions, atrophy, or damage, including antecedent or ongoing myocarditis or ischemia. Myocardial atrophy, fibrosis, and calcification are related to chronicity. Ischemia includes intrinsic coronary disease and compression by constricting scar of coronary arteries, veins, or bypass grafts.[114] In uncomplicated constriction, as in tamponade, coronary blood flow is reduced but adequate for aerobic metabolism.

COMPENSATION.

Compensation for constriction resembles compensation in cardiac tamponade. Heart rate is the major mechanism defending cardiac output, because stroke volume becomes nearly fixed by filling halted in early diastole. Increased heart rate mainly amputates the diastolic pressure plateau after the abbreviated filling period, so that tachycardia is relatively less detrimental than in conditions without early filling. Humoral, hormonal, and renal responses are similar to those of cardiac failure and tamponade with electrolyte and water retention.[109] [115] Yet, as in tamponade, restricted atrial distensibility prevents significant rise in atrial natriuretic factors. Sodium and water retention and high systemic venous pressure contribute to high hepatic vein pressure, ascites, and edema. The attendant blood volume expansion is more important than the simultaneously elevated systemic vascular resistance in maintaining arterial pressure.[110]

RESPIRATORY EFFECTS.

Respiratory responses depend on the effects of pericardial scarring: (1) insulation of the heart from intrathoracic pressure changes and (2) increased ventricular interaction. The heart and pulmonary vessels are intrathoracic. Normally they are simultaneously affected by respiratory pressure changes so that pulmonary venous flow to the left atrium is not significantly changed by breathing. But in classic constriction the heart is totally encased; when inspiration decreases intrathoracic pressure, cardiac pressures remain high. Consequently, pulmonary venous blood cannot easily enter the high pressure left atrium; therefore, total pulmonary venous flow and flow velocity are decreased in inspiration, decreasing LV filling and time to peak filling rate. Respiration does not change superior vena cava pressure or flow velocity. Although the IVC is affected by diaphragmatic movements and abdominal pressure fluctuations, there is diminished (<50 percent) to undetectable respiratory change in IVC diameter.[110] [116] Although inspiration does not greatly increase RV filling volume, filling *velocities* sharply increase and pulmonary artery flow velocity increases, with much less effect in decreasing aortic pressure. Yet, in some cases, inspiration decreases systolic blood pressure more than 10 mm Hg, particularly if there is an element of tamponade (effusive-constrictive pericarditis) or other cause for pulsus paradoxus, such as pulmonary disease but especially with marked respiratory shifts of the ventricular and atrial septa. Note that both ventricular and atrial septa are free of constriction and respond to pressure differences across them; thus, they often move sharply with respiration.[110]

The *Kussmaul sign,* inspiratory increased venous pressure with jugular venous distention, eliminates the normal inspiratory fall of 3 to 7 mm Hg in mean RA pressure, because the neck veins are extrathoracic and face an impediment to flow into the high pressure right atrium. The right atrium resists inspiratory acceleration of venous blood toward the heart with little or no respiratory variation in RA mean pressure. Other conditions with markedly increased RA and venous pressures that also produce the Kussmaul sign include RV failure, RV myocardial infarct, restrictive cardiomyopathy, chronic cor pulmonale, and acute pulmonary embolism.[110]

Clinical Aspects

CHEST RADIOGRAPH.

The cardiopericardial silhouette is usually normal or only modestly enlarged. Its shape depends on the configuration of scar tissue and any remaining fluid.[102] [110] The superior vena cava (SVC) and azygos vein are dilated. Pleural effusions are frequent and usually bilateral. Occasional *constrictive pleuritis* may be missed and discovered by CT, at operation, or post mortem. The only chamber enlargement recognized by chest radiography is LA, particularly with heavy scarring on the left ventricle or the left AV groove (functional mitral stenosis). Pulmonary blood flow often redistributes with upper-zone vascular dilation and decreased lower-zone vessel caliber, particularly with LA enlargement. Kerley B lines may be present, but alveolar edema is rare and implies either unequal chamber constriction or concomitant heart or lung disease.[110] Previously, one third to one half of cases, mainly chronic, had obvious pericardial calcification (Fig. 8-23); diagnostic efficiency has reduced its incidence due to earlier surgery. Calcification is best seen on lateral films (see Chap. 8) . With appropriate hemodynamic and clinical findings, calcification strongly favors the diagnosis of constriction but is itself not specific.

CT AND MRI (see Figs. 10-16 and 10-45) . [117] [118]

Pericardial thickening is best demonstrated by cine and gated MRI and CT with and without contrast medium enhancement. Each technique has high time and spatial resolutions that dependably identify and measure pericardial thickening and geometric changes and are more specific than TTE in differentiating scarring from fluid or tumor. CT and MRI demonstrate the frequently deformed ventricles and atria

and enlarged venae cavae that contrast sharply to the aorta, which their diameter normally matches. The atria (particularly the left atrium) may be enlarged and the ventricles narrowed and tubelike. The ventricular septum is frequently sinuous, bowed, or angulated. Pericardial thickness by CT and MRI varies from subtle increase over the normal hairline to 10 to 15 mm (rarely more); any thickening over 3.5 mm helps differentiate constriction from restrictive cardiomyopathy; over 6 mm adds great specificity. However, constricting pericardium may be so thin as not to be recognizable as abnormal by contemporary imaging. CT and MRI permit planning the surgical approach in patients with adequate myocardium by revealing the distribution and varieties of pericardial thickenings and calcifications and any myocardial invasion. Absence of myocardium (especially parts of the LV wall) due to atrophy and fibrosis indicates a poor prognosis, including disastrous postoperative results, particularly irreversible decompensation.[118]

ECHOCARDIOGRAPHY (see Chap. 7) .[109] [110] [119] [120]

In 40 percent of pericardiectomy patients at the Mayo Clinic, the first clue to constriction came from echocardiography, which reflects constricting anatomical changes, accelerated ventricular filling, and restricted diastolic expansion and filling. Transesophageal and three-dimensional echocardiography display pericardial thickening comparably to CT. TTE is not as reliable. Doppler recording is excellent for dynamic changes. No single echocardiographic or Doppler sign is pathognomonic.

The ventricular and atrial septa, which are pliant compared with the constricted walls, shift leftward with inspiration and rightward with expiration. The ventricular septum often shows paradoxic systolic motion: anterior (type A) or flat (type B). It may be accompanied by reduced to absent diastolic ventricular expansion with a "flat" LV posterior wall almost equally distant from the chest wall signals in early and late diastole. This is characteristic but not specific. Normal or paradoxic septal motion is bracketed by the components of septal "bounce" [109] on two-dimensional echocardiography, which can be further analyzed by M-mode. The "atrial" notch begins in the middle of the P wave and is characterized by rapid posterior or anterior motion, or posterior, then anterior, motion after atrial systole. The ventricular notch is often

more abrupt: posterior, posterior-anterior, or, occasionally, an anterior-posterior sequence in early diastole. This "ventricular" septal notch coincides with the early diastolic abnormal S3. The aortic root may show abrupt early diastolic posterior motion. TTE and TEE usually demonstrate enlargement of one or both atria with reduced wall excursion and dimensional change (particularly on the right). Both venae cavae and hepatic veins are dilated with restricted respiratory fluctuations.[109] [110] In the IVC these vary from well under the normal 50 percent of diameter to no change, as in cardiac tamponade and other conditions with 15 mm Hg or more of elevated RA pressure.

ECHO-DOPPLER CARDIOGRAPHY (see Chap. 7) .[109] [110] [117] [121]

Transmitral and transtricuspid Doppler recordings show rapid forward flow in diastole and reverse flow in later systole (Fig. 7-98) . The early-filling and A (late filling) waves are characterized by increased filling velocities and abnormally rapid deceleration from their peaks. Pulmonary venous forward flow velocity is reduced with exaggerated respiratory variation of early diastolic peak velocity and time integral that is even more pronounced than across the mitral valve. Reciprocal respiratory flow changes resemble those in tamponade with decreased left-sided and increased right-sided transvalvular velocities at the very onset (first beat) of inspiration and the reverse at the very onset of expiration. When respiratory variation is blunted or absent due to very high LA pressure, reducing preload by sitting or head-up tilt may unmask it.[122] Doppler tissue imaging shows normal LV expansion velocity and rapid mitral annular velocity. The slope of the color M-mode wave indicates a much more rapid flow from left atrium to left ventricle.

CARDIAC CATHETERIZATION (see Chap. 11) .

Catheterization is required to quantify pressures and identify concomitant cardiac disease if the sum of other findings only suggests constriction. (Diuretics should be withheld because hypovolemia alters the results.) Moreover, coronary angiography should identify atherosclerosis or any unusual distribution of the coronary arteries and minimize operative accidents. Constrictive hemodynamics are "restrictive" and therefore closely resemble those of restrictive cardiomyopathy, often the principal differential diagnosis. The major finding is near equalization (
5 mm Hg) in all diastolic chamber and venous pressures. Both LV and RV traces have a *dip and plateau*, the "*square root*" configuration (see Fig. 50-19), usually more pronounced in the right ventricle, with the sharp short early diastolic fall toward 0 pressure (dip), rising to a restrictive plateau as the relaxing ventricles spring back with and reach the limit of the tight pericardium. Typically, RV and pulmonary artery systolic pressures are 30 to 45 mm (up to 70 mm) Hg with RV end-diastolic pressure at least one third of RV systolic pressure. Negative atrial waves, like negative venous waves, are preserved, with the *y* descent usually deeper than the *x* descent (Fig. 50-20) , although they are often equal. In contrast, when *x* is greater than *y* effusive constrictive pericarditis is suggested. The nadir of the dip of the ventricular "square root" coincides with the atrial *y* nadir, ranging from below 0 to well over 20 mm Hg with fluid-filled catheters. High-fidelity catheters show these to be exaggerated; the nadir is usually 4 to 12 mm Hg. *Angiocardiography* shows normal or decreased LV end-systolic and end-diastolic volumes. The SVC is dilated and continuous with a frequently flat RA border. Coronary arteries are usually well within the cardiopericardial silhouette, that is, deep to their normal superficial location, unless the constricting scar is thin. Epicardial coronaries may display less than normal mobility whereas septal coronaries may appear hypermobile.

HISTORY. [109] [110]

A history of antecedent pericarditis or pericarditis-inducing disease, drugs, or thoracic irradiation may be clues to diagnosis, but absence of any history of a provocative disorder is common. Constriction (especially chronic) may present deceptively as "congestive failure," pleural effusions, RA thrombosis, and even hepatic coma.

Symptoms and Signs.

These reflect the degree of systemic and central venous congestion and fluid retention and may be subtle or overt. Constrictive pericarditis resembles,

Figure 50-20 Constrictive pericarditis. Characteristic right atrial pressure curve has well-formed *x* and *y* descents and *y*>*x*. Mean atrial pressure is approximately 22 mm Hg. Electrocardiogram shows interarterial block. (From Spodick DH: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997.)

but is not, "heart failure": the heart has not failed; it has been prevented from "succeeding." Venous congestion resembles right-sided heart failure with appropriate compensatory responses. Patients have pedal edema, ascites, and abdominal discomfort due to splanchnic engorgement. Ascites may be conspicuous, often without peripheral edema. At higher central diastolic pressures (arbitrarily >15 mm Hg), "central" symptoms are more prominent, including dyspnea, easy fatigability, and occasional orthopnea. Cardiac output cannot rise adequately with exercise because of the relatively fixed stroke volume, so that at any pressure level, dyspnea on exertion is characteristic and exacerbated by any pleural effusions, a diaphragm limited by ascites, or increased lung stiffness from interstitial (not alveolar) edema.[110]

PHYSICAL EXAMINATION.

Mild tachycardia is the rule, even with light exertion. Chronic or aggressive subacute constriction may be accompanied by atrial fibrillation or other atrial arrhythmias. The blood pressure is normal or relatively low, although occasionally hypertensive. Significant (>10 mm Hg; rarely, 15 mm Hg) pulsus paradoxus occurs if there is effusive-constrictive disease or other extracardiac conditions such as lung disease, or if pliant ventricular and atrial septa have exaggerated respiratory mobility. The Valsalva maneuver produces a square wave response, owing to central vascular congestion.[123] Pedal edema may appear early, or there may be ascites with or without edema. Diminished cardiac output may produce pale, cool extremities with peripheral cyanosis. Jaundice in chronic constriction indicates severe congestive or fibrotic liver impairment. Jugular venous distention is a hallmark, although peripheral venous distention is also easily detected in advanced cases. Neck veins are better seen than in most other conditions because of the high level of venous pressure with sharp *x* and *y* descents. These should be sought as collapses from a high standing level. Retinal veins are engorged. Kussmaul sign is common.[110]

Precordial palpation may be "quiet" with no point of maximal impulse or with paradoxical systolic retraction of the chest wall. A sharp early diastolic thrust is common especially in chronic constriction, corresponding to ventricular rapid filling. It coincides with the loud, often palpable, abnormal S_3 (see Fig. 50-5) , which sometimes has a "knocking" quality; it is easily mistaken for S_1 , especially if the simultaneous diastolic thrust is mistaken for the apex beat.[110] If equivocal or faint, the S_3 is enhanced by squatting, sitting up, or standing or during contrast medium injection. It follows S_2 closely; when it mimics S_1 , it follows the carotid pulse peak whereas S_1 precedes it. The jugular *x* descent occurs approximately with the carotid peak, and the *y* descent coincides with the S_3 and any diastolic precordial thrust. The liver is often palpable and may have a double pulsation. Ascites is recognized by abdominal protrusion and fluid wave. The spleen may be palpable if portal hypertension ensues.

LABORATORY FINDINGS.[109] [110]

The hemogram may be normal or show a normocytic normochromic anemia. Otherwise, especially in less chronic constriction, blood counts reflect etiological agents or processes. Rarely, congestive hypersplenism causes selective cytopenia or pancytopenia. Liver function tests are likely to be abnormal due to hepatic congestion and late cardiac cirrhosis, including increased conjugated and unconjugated bilirubin to the point of cutaneous and conjunctival icterus. Ascitic fluid may be an exudate (typically >2.5 gm/dl protein) or a transudate, (rarely chylous); with chronicity, protein concentration and specific gravity decrease. The serum-ascites albumin gradient tends to exceed 10 gm/dl.

Hypoalbuminemia is common due to liver impairment, protein-losing enteropathy or a proteinuric nephrotic syndrome, each related to chronically high venous pressure and more prominent in children.

ELECTROCARDIOGRAPHY [109] (see also Chap. 5) .

The ECG is nearly always nonspecifically abnormal, only rarely within normal limits. T waves are almost always low to flat or have general or local inversions; they are usually symmetrical unless digitalis has been given. QRS complex and T wave voltage may be normal or reduced. Interatrial block is common, especially with chronicity, with P waves wider than 100 milliseconds and usually notched. These can resemble P mitrale (which may be present with AV groove constriction). RA enlargement can accompany a large pointed P wave or dominantly positive "±" P in V_1 . Local or unequal constriction causes changes due to overload of "upstream" cardiac structures, producing ECGs consistent with RV hypertrophy or "strain" and may show right-axis deviation. In chronic constriction, myocardial atrophy probably contributes to reduced voltage, as do fluid retention and pleural effusions. Myocardial calcification and fibrosis, especially with reduced coronary flow, can produce AV blocks, intraventricular blocks, and even abnormal Q waves. Mixed ECG patterns are particularly common in constriction after cardiac operations because of frequently

localized or unequal postoperative scarring and also whatever heart disease required surgery. Finally, constriction can compress even normal coronary arteries sufficiently to produce a positive ECG response to exercise. Subacute and especially chronic constriction is often accompanied by atrial arrhythmias, particularly atrial fibrillation (interatrial block is predictive).

DIFFERENTIAL DIAGNOSIS.[109] [110] [124] [125]

Because of variability in scarring and its many mimics, constriction requires an impressive number of tests. Congestive failure due to heart disease is the principal functional diagnosis. Restrictive cardiomyopathy, often due to myocardial fibrosis or amyloidosis, may be difficult because of frequently identical hemodynamics and impairment. Note that restrictive cardiomyopathy patients are poor thoracotomy risks, whereas constricted patients may become unstable when intubated. The basic problem is to distinguish between abnormal chamber stiffness and abnormal muscle stiffness. The principal differential points are the usual thickness of constricting pericardium on imaging and timing of respiratory changes in ventricular systolic pressures; these are discordant in constriction and concordant in restrictive cardiomyopathy. These Doppler flow changes occur within one beat of the onset of inspiration and expiration in constriction but on later beats, if at all, in restrictive cardiomyopathy. The atrial and ventricular septa, free in constriction, are usually restricted in restrictive cardiomyopathy and therefore unlikely to show respiratory mobility. Meticulous Doppler-echocardiography combined if necessary with CT nearly always makes the diagnosis, and Doppler tissue imaging, slope of the color M-mode wave, and mitral annular velocity give clear separation.[126] [127] Occasional cases, particularly those constricted by a thin pericardium will be sufficiently confusing to require myocardial and/or pericardial inspection and biopsy.

Venous obstructive syndromes (e.g., SVC obstruction and nephrotic syndromes), especially with gross edema and ascites, are usually differentiated by imaging, as is abdominal disease with ascites, such as ovarian carcinoma and hepatic cirrhosis. RA tumors, especially myxomas, can mimic constriction by compressing the tricuspid valve; any ventricular involvement adds to the mimicry. In any unclear syndrome, imaging, hemodynamic data, and liver biopsy can be decisive. However, a few patients have simultaneous restrictive cardiomyopathy and constrictive pericarditis, usually due to radiation therapy, and also occurring in transplanted hearts; biopsy may be necessary. Quite suggestive for differentiation are a history of acute pericarditis of almost any etiology, especially purulent, hemorrhagic, or tuberculous. Finally, all segments of the autonomic nervous system are dysfunctional in constriction; in restrictive cardiomyopathy,

dysfunction is localized to the sympathetic efferent pathway.[128]

Variants of Constrictive Pericarditis

A variety of cases are not "typical" or "classic," owing to the unpredictable pericardial scarring process, particularly in contemporary patients after cardiac surgery with variants that can resemble other conditions.[110]

UNEQUAL/LOCAL CONSTRICTION.

Chambers, valves, and great vessels can be individually or unequally affected by pericardial scarring and calcification, producing murmurs due to locally turbulent blood flow and local ECG and hemodynamic changes. Echocardiography (TEE, TTE, and three-dimensional), MRI, or CT may demonstrate thickened or calcified pericardium. With *LV constriction* the atria, SVC, and IVC are dilated, the right ventricle is normal sized, and the ventricular septum is straight or inclined to the left. With *RV constriction,* the right atrium, IVC, and SVC are dilated and the septum is straight or inclined to the right. *Annular constriction*, mainly in the AV groove, enlarges the atria while the ventricles remain normal or relatively small.

EFFUSIVE-CONSTRICTIVE PERICARDITIS.

This form produces symptoms and objective findings due to variable mixtures of effusion or tamponade accompanied by constriction of the visceral pericardium (*constrictive epicarditis*) or constriction with local tamponade of one or more chambers due to loculated effusion. Physical and laboratory findings usually resemble tamponade more than constriction until after the fluid is drained when a constrictive picture emerges.[110] Occasionally, tamponade is suggested by an abnormal S_3 , which is ruled out by pure, classic tamponade dynamics (i.e., no rapid filling period). In contrast to pure constriction, significant pulsus paradoxus is frequent. A large dominant *x* descent (*x* > *y*) in atrial and venous traces also suggests an element of tamponade. After drainage, pericardial pressure drops to near 0, hemodynamic curves become more typical of constriction, and pulsus paradoxus may disappear. Kussmaul sign in what appears to be dominantly tamponade is a clue to effusive-constrictive pericarditis and may be accentuated after the fluid is drained.

ELASTIC CONSTRICTION.

Thick pericardial fluids particularly rich in blood and fibrin may organize and resemble tamponade, owing to continuous elastic compression, usually by clot. The venous and atrial waveforms may show a predominant *x* descent like tamponade, and there is nearly always no S_3 because there is no early rapid filling; there may be an S_4 . Occasionally, malignancies surround the ventricles, producing a similar picture.

LATENT (OCCULT) CONSTRICTION.

Patients with dyspnea, fatigue, and mild edema with or without a history of acute pericarditis and no specific cardiac findings may show excessive rises in heart rate and venous pressure with exercise, which may also induce an S_3 . Some patients are volume-depleted due to diuretics. Administration of fluids may bring out constrictive dynamics. In this respect the situation is analogous to that in low pressure cardiac tamponade.

TRANSIENT CONSTRICTION.

Transient constriction often follows acute pericarditis.

Management

Medical management does not relieve constriction except if with a dynamic inflammatory component responsive to antiinflammatory agents.[109] [110] [129] Any underlying disease should be treated; for specific infection, therapeutic agents should be given before operation and continued afterward. Surgery is definitive and technically easier early before calcification or myocardial abnormalities. Good surgical results follow in patients in better cardiac and systemic condition as well as with less pericardial scarring, calcification, and hepatic congestion. Although AV valve regurgitation (particularly tricuspid) is common in constriction,[110] postoperative regurgitation is a complication.[130]

Currently, most patients respond well. Some have an immediate postoperative diuresis, others a slower recovery over weeks or months. Removal of pericardium should be as extensive as possible (intraoperatively recorded pressure-volume loops clearly reveal the optimal extent[131]), especially the surfaces contacting the ventricles, always taking care to spare both phrenic nerves. A stubbornly adherent epicardial constriction may need to be scored or "meshed," leaving it in place but loosened. Poorer results are seen[131A] with inadequate resection, uncorrected coronary disease, higher New York Heart Association "heart failure" classifications, and older age; after radiation pericarditis; with chronicity, including peripheral organ failure (particularly renal and hepatic[129] ; ascites, edema, or both are ominous); with severe myocardial atrophy and fibrosis; and with significant arrhythmias reflecting myocardial impairment. Preventive therapy (often unsuccessful) depends on adequate treatment of acute pericarditis and drainage of significant collections of blood or pus. *Corticosteroids usually fail to prevent constriction.* Whether colchicine and NSAIDs have a preventive effect is unknown. In specific cases after drainage of bloody fluid, intrapericardial urokinase or streptokinase and, for purulent fluids, streptodornase, may check these substrates for constriction.

INFECTIOUS PERICARDITIS

Infectious agents that reach the pericardium inflame it directly or by various immune responses.[132] While any pericardial infection can be clinically silent, clinical pictures]conform to some degree to the descriptions below, with differences characteristic of particular causes. Acute viral pericarditis is likely to provoke the entire range of subjective and objective acute findings, whereas tuberculous pericarditis can do so but is often overshadowed by systemic disease or complications such as fever or tamponade.

Viral Pericarditis

Viral pericarditis has a wide etiological range, mainly the viruses causing myocarditis, the degree of involvement of either or both tissues depending on host susceptibility, and the particular agent; inflammatory abnormalities are due to immune complexes, direct viral attack, or both.[132] [133] [134] Early viral replication in pericardial tissue elicits cellular and humoral immune responses against the virus. If inadequate, there is direct tissue damage or a destructive autoimmune reaction. Viral genomic fragments in pericardial tissue may not replicate, yet they serve as a constant source of antigen to stimulate immune responses. Virus-specific IgM, often with IgG and occasionally IgA, can be found in pericardium and myocardium for years.[132] Most cardiotropic viruses involve the pericardium and myocardium hematogenously, although cardiac and thoracic surgery permit direct implantation. A latent period between a recognized viral infection and the onset of acute pericarditis is compatible with both infective and immunopathic induction of pericarditis.

CLINICAL FEATURES.

Most cases of pericarditis of unknown origin, "idiopathic" or "nonspecific," are probably viral; these frequently produce the clinical epitome of acute pericarditis: pain, rub, more or less typical ECG changes, elevated acute-phase reactants (e.g., ESR; CRP), fever, leukocytosis, and variable myocardial enzyme levels. "Variable" ranges from normal to occasionally high levels, reflecting, as does the ECG, variable myocardial inflammation. As with most acute pericarditis, there is a 3:1 to 4:1 male preponderance. Pericarditis may occur during initial viral infection but more often 1 to 3 weeks after an upper respiratory or gastrointestinal syndrome, which is too late to culture the virus.[135] Many patients have pulmonary infiltrates and pleural effusions, often with cough. Any viral pericarditis may be effusive and develop tamponade, although most have little or no effusion.

Clinical illness lasts days to a few weeks, usually resolving within 2 weeks.[132] Complications include unresolved inflammation, particularly recurrent pericarditis due to immunopathy and characterized mainly by pain and often recurrent effusion. One to three recurrences affect up to 50 percent of patients, mainly within 8 months of the initial attack. Typically, recurrences are shorter and milder and usually without ECG changes. They may follow unrelated

infection or physical (rarely mental) stress. Pleural effusions, particularly on the left, are common. Acute effusive viral pericarditis, particularly after tamponade, is associated with eventual classic constriction more often than is "dry" pericarditis. Occasionally, especially in children, with a significant element of myocarditis, heart muscle disease may proceed after the pericardial manifestations become clinically silent. Arrhythmias or conduction defects indicate independent heart disease or significant myocarditis (see Chap. 25) . Differential diagnoses include acute myocardial infarction, particularly with atypical ECGs. Other conditions include traumatic pericarditis, SLE, and nonviral, especially bacterial, pericarditis. Systemic viral disorders (e.g., hepatitis) should suggest a viral etiology. Infectious mononucleosis usually presents as a severe sore throat, adenopathy, and positive serology; a fourfold increase in neutralizing antibody titer is only supporting evidence.

Newer techniques can identify minute amounts of viral nucleic acid; viral genomes can be demonstrated by the polymerase chain reaction (PCR), which amplifies viral DNA along with in situ hybridization.[133]

Reverse immunoassay (RIA) can demonstrate virus-specific immunoglobulins like IgM, IgG, and IgA. It may not be necessary to use these when the diagnosis seems secure in an otherwise healthy patient, especially since, without tamponade, pericardiocentesis and other invasive procedures add little to management and carry risks.[132]

MANAGEMENT.

Effective antiviral agents are not available or even necessary to manage most viral pericarditis. Treatment is for symptoms and complications. Pain, usually pleuritic and limited to the first day or week, is managed by NSAIDs, notably ibuprofen, at doses sufficient to suppress symptoms and fever. Cough can exacerbate pericardial pain and requires antitussive agents. Nontamponading pericardial effusions do not require drainage unless very large. Tamponade requires prompt evacuation of fluid. Usually acute management succeeds. However, virus-specific immunoglobulins are found in many cases of chronic relapsing pericarditis and dilated cardiomyopathy.

Nontuberculous Bacterial (Suppurative) Pericarditis

Acute suppurative pericarditis *(pyopericardium)* simultaneously threatens tamponade and septicemia and is especially serious in children and immunocompromised patients when due to destructive organisms such as staphylococci. Yet, some may be silent, presenting as tamponade or overshadowed by systemic disease and discovered at autopsy. Although many gram-negative organisms such as *Escherichia coli, Salmonella,* other nosocomially acquired infections, and opportunistic organisms have appeared increasingly, the common forms remain streptococcal, pneumococcal, and staphylococcal.[132] Rarely, gasproducing organisms such as *Clostridium* cause pneumopericardium. In adults, pneumopericardium and bacterial pneumopyopericardium are often due to a fistula between the epicardium and a hollow viscus. Invasion from contiguous foci or traumatic implantation include cardiothoracic surgery, mediastinitis, wound infection, myocardial abscess, infective endocarditis, and subdiaphragmatic abscess. Rarely, pericardial invasion spreads along fascial planes from the oral cavity, particularly periodontal and peritonsillar abscesses. Occasionally, infected mediastinal nodes erode the pericardium. Preexisting nonbacterial pericardial effusion as in rheumatoid arthritis, SLE, sarcoid, or uremia can be infected hematogenously. [132] This is probably the pathogenesis of "primary" bacterial pericarditis in which only the pericardium seems to be affected. For example, *Neisseria,* particularly *N. meningitidis* group C, can occur without meningitis, producing "primary" meningococcal pericarditis. Moreover, the *Neisseria* group and other organisms can evoke a sterile, immunopathic effusion, sometimes accompanied by immunopathic or infectious systemic reactions such as arthritis and ophthalmitis.[136] Similarly, *Salmonella* pericarditis, usually due to bacteremia, can occur with or without an enteritic syndrome.

Antimicrobial therapy has decreased the incidence of the common gram-positive infections. Yet there is relative and absolute increase, usually nosocomially acquired, of infections with multiple and gram-negative organisms, especially in immunocompromised patients and after thoracotomy.[132] [133] *Haemophilus influenzae* occurs sporadically in adults, but children are particularly susceptible to it; pericarditis occurs during respiratory illness and even after cellulitis. *H. influenzae* typically provokes a thick, fibrinopurulent exudate similar to cottage cheese or scrambled eggs that can defeat attempts at percutaneous drainage.

CLINICAL FEATURES.[132]

Suppurative pericarditis is most often acute and fulminant, arising over several days with rapid development of tamponade or presenting as tamponade. Effusion is the rule; the fluid is a turbid exudate characterized by polymorphonuclear leukocytes, increased LDH, and decreased glucose. There is typically tachycardia, fever, toxicity, chills, and sweating. Chest pain is variable, and a pericardial rub is audible in most patients. Cough is common, especially with pleuropulmonary involvement. In some older patients, infections have a reduced tempo, are often clinically silent, or are overshadowed by systemic disease. Chest radiographs usually show an enlarged cardiopericardial silhouette. With gas-producing organisms there are lucent "bubbles" or an "air"-fluid interface. Leukocytosis with a marked left shift is typical (although limited to absent in debilitated and immunosuppressed patients). Blood and pericardial fluid cultures should disclose organisms. The ECG frequently shows stage I changes, although it may be nonspecifically abnormal if the lesion is discovered late. Imaging will disclose any effusion. Inflammatory infiltration of the pericardium can be identified by scintigraphy with indium-111 or gallium-67 (also responsive to leukemic infiltrations).[137] There may be a tendency to loculation producing pericardial abscesses that may resemble cysts. (Congenital cysts may become infected.) Etiologyspecific diagnosis depends on smears, cultures, and more sophisticated searches--e.g., antigen detection, especially when treatment appears to sterilize the fluid. The principal differential diagnoses include tuberculous and viral pericarditis.

PERICARDITIS WITH INFECTIVE ENDOCARDITIS.[132]

Pericarditis during endocarditis can be dramatic but is more often found at autopsy. Acute endocarditis may provoke an immunopathic pericardial effusion with immune complex deposition, whereas subacute endocarditis usually causes an infective effusion. Bacterial endocarditis involves the pericardium most often by erosion of a valve-ring abscess or by rupture of an aortic sinus or myocardial abscess. The most common organisms are *Streptococcus viridans* and *Staphylococcus aureus.* Bacteremia can infect both endocardium and pericardium simultaneously. Sterile "sympathetic" (parapericarditic) effusions are not rare,[138] presumably immunopathic. Hemorrhagic effusions follow direct pericardial irritation or bleeding from rupture of a mycotic abscess. Clues to accompanying myocardial and valve-ring invasion include degrees of AV and bundle branch block, each most common with staphylococcal endocarditis.

MANAGEMENT.

Systemically administered antibiotics achieve excellent levels in pericardial fluid.[132] Pericardial drainage and exploration, monitored by TEE,[139] are desirable because infections tend to loculate, form adhesions, and constrict. In critical tamponade, simple drainage may first be used for relief, with exploration postponed. Pericardial fluid

and tissue should be obtained for gram, acid-fast, and

fungal stains, with cultures for aerobes and anaerobes and antimicrobial susceptibility tests.[52] Surgical drainage is preferable over percutaneous drainage, particularly when etiology is uncertain; it permits pericardiectomy when adhesions and loculations predict constriction. With or without definite surgical intervention, urokinase or streptokinase may be used within the pericardium to destroy clots and fibrinous adhesions.[140] Very thick purulent and sanguinopurulent exudates resisting free drainage may require repeated intrapericardial urokinase or streptokinase (to activate the fibrinolytic system) combined with streptodornase (to liquefy viscous nucleoproteins in pus). A clue to loculation and potential constriction is failure to improve after appropriate treatment.[132]

Tuberculous Pericarditis

Pericarditis due to *Mycobacterium tuberculosis* has decreased due to improved public health and effective antimycobacterial treatments. Recently, atypical mycobacteria along with classic tubercle bacilli are increasing in immunocompromised patients, particularly in AIDS due to HIV,[141] lymphocytotrophic, and other viruses. High incidence continues in poorer nations. In the United States its principal importance is differential diagnosis from other syndromes.

PATHOGENESIS. [129]

The pericardium may be infected by hematogenous, lymphatic, peribronchial, or contiguous spread of tuberculosis. (Hematogenous dissemination occurs during all primary tuberculosis.) Lymphatic spread is from lung, bronchi, and mediastinal nodes. Contiguous infection involves intrapericardial inoculation from mediastinal nodal, pleural, and, rarely, myocardial tuberculosis.[141A] Some of the material penetrating the pericardium undergoes proteolytic degradation and antigen processing of individual peptides, with immune responses causing much of the morbidity. These include antimyolemmal antibodies,[133] which are very common in tuberculous pericarditis and probably pathogenic. Protein antigens of the bacillus induce delayed hypersensitivity responses stimulating lymphocytes to release lymphokines that activate macrophages and influence granuloma formation. There are four classic pathological stages of tuberculous pericarditis[129] : (1) fibrinous exudation with initial polymorphonuclear leukocytosis, relatively abundant mycobacteria, and beginning granuloma with loose organizations of T cells and macrophages; (2) serous, usually serosanguineous effusions with a mainly lymphocytic exudate with monocytes and foam cells; (3) absorption of effusion with organization of granulomas caseation, and pericardial thickening due to fibrin, collagenosis, and, ultimately, fibrosis (mycobacteria become difficult to find); and (4) constrictive scarring: replacement of fibrinous and granulomatous matter by fibrosis, which contracts on the cardiac chambers (constriction can develop despite effective antituberculous therapy). Calcification can occur at any stage, tending to form sheets, plaques, hoops, and bands of calcium salts over any part of the heart. Tuberculous pericarditis may surface as an acute or chronic pericardial effusion and occasionally a variant of cholesterol pericarditis with or without overt tamponade and usually with considerable fibrin, adhesions, and loculations demonstrable by imaging. That noneffusive or minimally effusive acute tuberculous pericarditis often heals without treatment is suggested by the appearance of constriction without a recognizable acute state.

CLINICAL FEATURES.[132]

Clinical expression of tuberculous pericarditis depends on the tempo of inflammation, which is typically slow and indolent after an insidious onset and often accidental discovery (especially with large effusions).[142] Occasionally, there is an aggressive course with acute tamponade, often mixed with constrictive components. Children and immunocompromised patients more often present with classic acute pericarditis. Yet most patients have no history of an acute phase and often no history of tuberculosis; evidence of pulmonary tuberculosis is exceptional. However, like tuberculous meningitis, tuberculous pericarditis may erupt during appropriate antimicrobial treatment for tuberculosis elsewhere. When the disease is clinically apparent, patients tend to have lymphocytosis in blood and pericardial fluid with increased proportions of small and T lymphocytes. Tuberculosis may also involve the myocardium, usually without distinctive symptoms unless it is extensive. Eight modes of presentation cover almost any "pericardial" syndrome[132] :

1. Painful acute pericarditis with or without minimal to large effusions and with or without fever, cough, and malaise
2. Silent effusion, often large and chronic
3. Tamponade, usually without other signs except fever
4. Acute constrictive pericarditis (i.e., constriction appearing over a period of days to a month), usually after drainage of an effusion or disappearance of fluid under therapy
5. Subacute constriction (a course of weeks or months) with varying amounts of fluid (i.e., effusive-constrictive pericarditis)
6. Chronic constrictive pericarditis
7. Pericardial calcifications with or without hemodynamic consequences
8. Fever of unknown origin, usually with constitutional symptoms such as anorexia and weight loss

Tuberculous effusions typically increase slowly with few or no symptoms, leading to tamponade or, after reabsorption or drainage, effusive-constrictive or constrictive pericarditis. Yet tuberculous pericarditis may become recognizable at any stage, more often with tamponade,[143] constriction, or combinations of the two or their complications, as when clinically silent constriction causes hepatic congestion and ascites, simulating cirrhosis ("Pick disease"). Those presenting with constriction may have few constitutional signs and symptoms if the inflammatory process has burned out. Moreover, tuberculous etiology may not be clear because so many forms of pericarditis cause constriction. Few patients have rubs and precordial pain; more often there is nondescript precordial discomfort. Dyspnea, particularly on exertion, may follow cardiac compression or pulmonary restriction due to a very large pericardial effusion with pleural effusion. When presenting as fever of unknown origin, the diagnosis is suggested by an enlarged cardiopericardial silhouette, especially if imaging discloses a more or less chronic pericardial effusion. Finally, tuberculous pericarditis must be ruled in or out when any pericarditis does not rapidly resolve on NSAIDs treatment and in tamponade of obscure origin, particularly in immigrants from Third World countries, elderly patients, and immunocompromised patients, in whom pericardial tuberculosis may be the first manifestation[144] (clinically primary tuberculous pericarditis).

DIAGNOSIS.

Identification of *M. tuberculosis* in pericardial fluid or tissue is specific, but negative results do not rule out tuberculous pericarditis.[132] [145] Organisms may be so difficult to find that all fluid drained should be centrifuged and studied by smear, culture, and, if necessary, DNA amplification. Extrapericardial tuberculosis, including lung, pleura, and lymph nodes, indirectly supports the diagnosis, but pericardial tissue should be sampled by subxiphoid incision or pericardioscopy.[52] [132] Yet negative biopsy does not rule out tuberculosis. A positive tuberculin (purified protein derivative [PPD]) skin test can support but not confirm pericardial tuberculosis because it may reflect antecedent extrapericardial tuberculosis, as may positive sputum and gastric aspiration. Negative skin tests imply low risk of tuberculosis but are unhelpful with loss of reactivity in patients with anergy, especially those with severe systemic disease or HIV infection. Early, transiently negative, skin tests may be due to pericardial and pleural sequestration of PPD-reactive T lymphocytes. A "therapeutic test" may be a last diagnostic resort using appropriate antimycobacterial agents for critically ill patients with persistent constitutional signs. Uptake of radionuclides such as gallium-67 and indium-111 indicate pericardial inflammation but are nonspecific because uptake also occurs in purulent and viral pericarditis, leukemic infiltration, and even mesothelioma. High levels (>40 IU/liter) of adenosine deaminase (ADA) activity in pericardial fluid are quasi-specific for tuberculous pericarditis (very high ADA levels appear to predict eventual constriction).[146] Differentiation of neoplastic effusions is virtually absolute, with low levels of ADA accompanying high levels of carcinoembryonic antigen.[132] Complement-fixing antimyolemmal and antimyosin antibodies have been found in most patients with acute tuberculous pericarditis but decrease in late stages and constriction.[52] [133] Mycobacterial antigens have been increasingly detected by enzyme-linked immunosorbent assay (ELISA) with high specificity and sensitivity. Probably optimal is the PCR, which amplifies mycobacterial DNA to "fingerprint" strains of *M. tuberculosis* in pericardial fluid with excellent specificity.[147] [148] It is particularly useful in patients with AIDS/HIV infection who have adenopathy and often atypical mycobacterial infection, especially *M. avium* complex. Moreover, because of 100 percent sensitivity for activity, a negative result excludes *active* tuberculosis. Specificity, virtually 70 percent for active tuberculosis, approaches 90 percent for any tuberculosis infection. False-positive results occur, and blood in pericardial fluid may lead to false-negative results by enzyme inhibition; yet the PCR is superior to bacteriological methods.[147] [148] Cultures should be obtained because of the need for drug susceptibility testing.[132]

MANAGEMENT.

Antimycobacterial treatment has greatly decreased mortality in tuberculous pericarditis, although frequently not preventing constriction.[148A] All isolates of *M. tuberculosis* should be tested for antimicrobial susceptibility. Effective multiple drug therapy is mandatory, and severely ill patients benefit from prednisone or other corticosteroid, which will shorten the course, dramatically decrease symptoms and signs in the acute phase, and reduce the death rate.[132] [149] However, corticosteroids reduce constrictive evolution only modestly if at all.[149] Some atypical mycobacteria resist chemotherapy, requiring efforts to find appropriate combinations. Tamponade should be relieved under chemotherapeutic "cover" to prevent extrapericardial spread. Persistent hypotension warrants adrenal function testing because of possible adrenal tuberculosis. Tendencies to nonresolution or worsening (over 6 to 8 weeks), significant pericardial

thickening, or signs of constriction mandate pericardiectomy as soon as possible. Indeed, patients with tuberculous pericarditis must be observed indefinitely to detect reactivation, constriction, or reconstriction.[132]

Fungal Pericarditis

In the United States, fungal pericarditis is mainly due to two "geographical" fungi, *Histoplasma* and *Coccidioides,* and to "nongeographical" fungi, *Candida* and *Aspergillus* (*Blastomyces* and *Cryptococcus* are comparatively rare, as is *Pneumocystis carinii*). [132] [150] [151] [152] [153] To these are added two "semifungi" (between bacteria and fungi), *Actinomyces* and *Nocardia.* Geographical fungi are locally endemic, whereas nongeographical fungi are largely opportunistic, depending on compromised host defense. All fungi occur preferentially in immunocompromised[153] and severely burned patients, debilitated individuals, infants (especially premature), and those taking corticosteroids that impair antifungal defenses and phagocyte activity. Indeed, apparent cardiac decompensation during fungal infections may be due to tamponade, constriction, or fungal myocarditis.[132] Precise diagnosis is crucial, particularly for the nongeographical fungi, because amphotericin B, a principal antifungal agent, is very toxic. Pericardiectomy is usually crucial for survival.

HISTOPLASMOSIS.

This is the most common "naturally" acquired fungal infection. It is frequent in endemic areas of the Ohio and Mississippi River valleys and western Appalachia. Pericarditis usually occurs late after infection elsewhere. Acute fibrinous pericarditis is usually a noninfectious (irritative or immunopathic) complication of infection in adjacent mediastinal lymph nodes that can penetrate the pericardium, causing granulomatous inflammation and occasionally calcification. Pleural effusions are more common with pericarditis than with pulmonary histoplasmosis. *Histoplasma* pericarditis is relatively common in younger, usually immunocompetent patients, whereas disseminated histoplasmosis, like other fungal infections, is more common with immunosuppression. Pericardial involvement can resemble idiopathic pericarditis, resolving within 2 weeks. However, almost half of *Histoplasma*-induced effusions develop hemodynamic compromise. In contrast to other fungal pericarditides, effusion with or without tamponade can be rapid and massive. The fluid is serous, xanthochromic, or hemorrhagic and predominately leukocytic. Pleuropulmonary involvement produces mixed clinical manifestations: it precedes respiratory illness, pleuritic pain, cough, and dyspnea, resembling viral or tuberculous pericarditis.[151] Only occasionally do patients develop constriction or pericardial calcification (rarely, constriction is the presenting feature). If acute pericarditis resolves, relapses occur variably. The diagnosis must be considered in endemic zones. Rising complement fixation titers and the immunodiffusion test are helpful. Moreover, other causes of pericarditis must also be considered in endemic areas even in seropositive patients.[132] With persistent illness, biopsy of lymph nodes, particularly mediastinal nodes, with cultures and methonium silver stains, may be decisive. *Histoplasma* should be identified, because granulomas alone are nonspecific; indeed, tuberculosis may be associated. The principal differential diagnoses are pericarditis due to viruses, tuberculosis, brucellosis, Hodgkin disease, or sarcoid.

Resolution spontaneously or with antiinflammatory agents without antifungal medication indicates almost certainly "immunopathic" or "irritative" pericardial involvement without infection, even if with tamponade. Unless *clearly* recovering, are in no distress, and have a "dry" pericardium on imaging, patients should be hospitalized because of the (infrequent) possibility of tamponade. Antifungal treatment with amphotericin B or ketoconazole is indicated for disseminated histoplasmosis or severe pericardial inflammation.[132] To reduce chest pain, fever, and effusion and suppress the pericardial rub, NSAIDs usually suffice. Tamponade and constriction require decompression. Corticosteroids predispose to dissemination but may be used for severely ill patients. With disseminated histoplasmosis, adrenal function should be assessed because the adrenals may be involved, requiring corticosteroid treatment.

COCCIDIOIDOMYCOSIS.

This fungal infection is endemic in the southwest, particularly in the San Joaquin Valley. Spores are inhaled from soil. Pericardial coccidioidomycosis is usually a complication of progressive disseminated infection, although it is rarely "primary" (i.e., confined to the pericardium).[132] Hilar node involvement resembles tuberculosis. Infection causes serofibrinous effusion with a potential for adhesion. The clinical spectrum is wide: from classic acute to chronic adhesive pericarditis and rarely to effusive-constrictive pericarditis. Acute pericardial coccidioidomycosis usually accompanies pneumonia from the same organisms, sometimes with systemic adenopathy, osteomyelitis, or meningitis. The main symptoms may be pneumonitic: cough, dyspnea, fever, and pleuritic pain. Patients are usually chronically ill, debilitated, malnourished, and often immunocompromised. Diagnosis requires histological documentation but is suggested by pericarditis in the endemic zone, especially if with disseminated coccidioidomycosis. Pericarditis may resolve without specific therapy, but anticoccidioidal agents such as fluconazole may be necessary, depending on severity and progress.

"NONGEOGRAPHICAL" FUNGAL INFECTIONS.[132] [150] [152] [153]

These related organisms produce similar clinical pictures. Actinomycosis may cause fistulas and sinus tracts to skin and other organs as well as contiguous spread along thoracic and mediastinal tissue planes. Pericarditis tends to be insidious until tamponade or constriction, but acute pericarditis may be followed by chronic effusion with pericardial thickening and adhesions.[154] Acute tamponade may respond to medical and surgical management, only to be followed by rapid constriction. These "semifungi" also cause endocarditis and myocarditis. Although suggested by infection elsewhere, specific diagnosis is by staining and culturing pericardial fluid. Infection is fatal unless treated medically and surgically. *Actinomyces* responds to penicillin and other antibiotics. *Nocardia* responds to sulfonamides, particularly sulfisoxazole. Optimal therapy is combined antimicrobials, surgical drainage, and pericardiectomy as indicated.

PERICARDIAL DISEASE IN AIDS AND AIDS-RELATED COMPLEX (see alsoChap. 68). [132] [155] [156]

Immunocompromised patients with AIDS and AIDS-related complex respond as do other kinds of immunosuppressed patients, such as those receiving corticosteroids and cytotoxic agents, and include mainly patients on cancer chemotherapy or with serious inflammatory disorders or after organ transplants. AIDS predisposes to infection by multiple organisms, many opportunistic, and to malignancies such as Kaposi sarcoma and non-Hodgkin malignant lymphoma. Complications of AIDS and HIV infection affect the endocardium, myocardium, and pericardium; patients with cardiac involvement have lower T4 cell counts. Pericardial disease, particularly effusion, is relatively frequent but more often discovered by imaging or at autopsy. The most frequent cardiac lesion at autopsy is sterile pericardial effusion.[132] In general, late AIDS-related pericardial effusions imply a grave prognosis, suggesting end-stage HIV disease. Patients with pericarditis often also have myocarditis.

Pericardial involvement in AIDS occurs in six forms[132] :

1. *Silent.* Fibrinous and effusive pericarditis with or without adhesions or apparently sterile pericardial effusion occur as part of a generalized serious effusive process, including ascites and pleural effusion ("capillary leak syndrome"). The specific etiology is often uncertain.
2. *Classic acute pericarditis.* Typically there is pain, rub, and often ECG changes. If effusive, the fluid may be clear, purulent or sanguineous. A search for an infectious etiology is often rewarded. Mycobacteria, fungi, and other opportunistic organisms are frequent.
3. *Cardiac tamponade.* This usually is recurrent with chronicity but it may be the presenting syndrome.
4. *Constrictive pericarditis.*
5. *Neoplasia.* This mainly includes Kaposi sarcoma and aggressive Hodgkin or non-Hodgkin lymphoma.
6. *Myopericarditis*. With definite inflammatory signs there tends to be lymphocytic pericardial infiltration. Sterile hydropericardium may be due to uremia or congestive failure from associated myocarditis or cardiomyopathy. Pericardial effusions of any size are associated with shortened survival.[132] Large effusions may be tuberculous or fungal. Nontuberculous *Mycobacterium* infection occurs late.

At least two forms of *malignancy* are related to AIDS: Kaposi sarcoma and non-Hodgkin malignant lymphoma[157] ; Hodgkin and other lymphomas also occur. Kaposi sarcoma involves both visceral and parietal pericardium, with particular predilection for epicardium and subepicardial fat; it produces effusion and occasionally constriction. Although usually disseminated, in AIDS it may appear to be primary in the pericardium with a strong tendency for tamponade.[129] *Malignant lymphoma* is usually multicentric and only rarely primary in the heart, where it typically affects the myocardium more often than the pericardium. Occasionally, an Epstein-Barr viral genome may be discovered.

PARASITIC PERICARDITIS

Pericardial parasitoses appear in endemic areas and in travelers from them in whom mild attacks are often mistaken for idiopathic pericarditis.[132] [158] [159] [160] The acute illness typically resembles suppurative bacterial, or occasionally viral, pericarditis. Parasites frequent in the liver such as *Echinococcus* and amebae may also provoke sterile, presumably immunogenic, ("sympathetic") pericardial effusions, which may cause tamponade.[132] Such parasites usually enter the pericardium from perforation through the diaphragm or from secondary lesions in the lung and pleura. Parasitosis elsewhere suggests the diagnosis. In some patients, fluid may be negative for organisms, requiring biopsy. Blood or pericardial fluid *eosinophilia* always suggests parasitic disease.

may be congenital or acquired. Pericarditis is often found at autopsy in patients with more obvious *Toxoplasma* myocarditis. Pericardial affection is mainly chronic, with often a chronic effusion and rarely constriction. Acute pericarditis with or without tamponade is rare and includes fever, rash, and adenopathy; it can resemble SLE. Pericardial involvement may occur during miliary spread, particularly in patients with leukemia and other disorders treated with chemotherapeutic agents or corticosteroids.

ECHINOCOCCOSIS. [159] [160]

Echinococcus granulosus, an invasive and destructive sporozoan, occurs mainly in sheep-raising countries. It produces hydrated cysts of the myocardium, pericardium, and mediastinum, including great vessels. The pericardium is involved from a ruptured adjacent myocardial cyst or a hepatic cyst penetrating the diaphragm. Chest pain and sharp anaphylactic reactions with eosinophilia are characteristic. Multiple intrapericardial rupture can produce vague to striking symptoms. Pericardial and mediastinal echinococcal cysts also compress the cardiac chambers or great vessels, producing corresponding abnormalities on imaging, which shows well-defined unilocular (occasionally multilocular) cysts with trabeculations due to internal "daughter membranes." Complications include secondary bacterial infection, tamponade, and constriction and even coronary obstruction. Surgical excision (enucleation) may be dangerous due to spillage of active parasites. Evacuation of the cysts and instillation of silver nitrate is usually preferable.

AMEBIASIS. [132]

Amebiasis (caused by *Entamoeba histolytica*) occurs mainly in endemic areas and in travelers from them (in whom the syndrome may appear years later). Although patients may also have intestinal amebiasis, liver abscesses, particularly in the left lobe, typically perforate the diaphragm and involve the pericardium. Mortality is high, especially with missed diagnoses. Serofibrinous ("presuppurative") pericarditis with straw-colored or sanguineous fluid can precede gross rupture into the pericardium and is often suspected to be tuberculous. Frank pericardial rupture can be insidious or dramatic with pain, shock, tamponade, and cyanosis. Fluid is brownish; the pus may simulate anchovy paste, an appearance that is quasi-diagnostic. Secondary bacterial infection must be considered in severely ill patients. Occasionally, there is classic acute pericarditis or subacute effusive-constrictive pericarditis with pericardial thickening. Diagnosis is by fluorescent antibody test or amebic enzyme immunoassay supported by a liver scan with technetium-99m.[132] Medical therapy with antiamebic agents such as metronidazole or dehydroemetine is highly successful in hepatic cases, but pericardial involvement requires drainage and, if necessary, resection.

NEMATODAL PERICARDITIS

Filariasis (caused by *Wuchereria bancrofti*), endemic in Africa and India, produces hemorrhagic effusions in which microfilaria are easily found in nocturnal blood smears.[129] Effusions may be clinically silent or massive with rapid or slow tamponade. Cough and constitutional symptoms are common. Persistent pericardial inflammation produces sanguinopurulent pericarditis with chronic lymphocyte inflammatory changes. Survival may produce rapid constriction, even during chemotherapy. Diagnostic clues include other manifestations of filariasis, such as elephantiasis. *Necator americanus* produces eosinophilic pericardial effusion, possibly an "allergic" effect. *Dracunculus* ("guinea worm") has been found in constrictive pericardial scar.

SPIROCHETAL PERICARDITIS

Except for spirochetes transmitted during Lyme carditis[161] and leptospirosis, spirochetal pericarditis is poorly characterized, owing to extreme rarity of discovery in tissue where its presence may be accidental. *Treponema pallidum* is identified only in the rare involvement of the pericardium by localized or miliary syphilitic gummas with a fibrotic reaction or accompanying a hemorrhagic effusion.[132] *Lyme pericarditis* can produce acute pericarditis, pericardial effusion, and myopericarditis. Fatal myopericarditis may ensue with myocardial and conducting tissue involvements. Silver stains of sampled material may demonstrate the spirochetes. However, ELISA can detect IgM and IgG antibodies. Indium-111 antimyosin scintigraphy may be helpful.[162] Leptospirosis[132] (caused by *Leptospira icterohaemorrhagiae*) is mainly a tropical disease and is reported at all ages. Most cases are subclinical. Conjunctival suffusion is a clue. Myocardial and pericardial involvement, often mild, is seen more frequently in patients who are anicteric. Typical acute pericarditis including friction rub and ECG changes may be due either to the organism itself or to an accompanying uremia. Diagnosis is by *Leptospira* agglutination test.

RICKETTSIAL PERICARDITIS

Rickettsiae, particularly *Rickettsia rickettsii,* can produce pericarditis,[132] [163] [164] myocarditis, and vasculitis in endemic areas, including South America, Africa, and the South Central and Atlantic States (Rocky Mountain spotted fever [RMSF]). In Africa tic-transmitted *boutonneuse fever* is due to *Rickettsia conorii*. Q fever, due to *Coxiella burnetii*, is transmitted by sheep and cattle in milk and is found worldwide. It appears to produce more obvious clinical pericarditis than does RMSF and may present as a pericardial effusion. In RMSF, myocarditis and pericarditis can occur with or without vasculitis, the latter being a "toxic" or immunogenic process. Cross-reactive antimyolemmal antibodies suggest that apericardial involvement can be immunopathic with pericarditis after extension of myocarditis to the epicardium. Diagnosis is by serological test, including Weil-Felix agglutinins and IgM and IgG antibodies.

CHLAMYDIAL PERICARDITIS

Chlamydiae produce classic acute pericarditis and large effusions.[132] Rare until recently, the Chlamydiaceae, especially *C. trachomatis, C. psittaci,* and *C. pneumoniae,* are increasingly found in immunocompromised patients and patients with malignancies, as well as otherwise healthy hosts. They produce pericarditis, myocarditis, pleuritis, and pneumonitis. Psittacosis follows exposure to psittacine and other birds. (Indeed, pericardial effusion is one of the most common forms in affected birds themselves.) Specific diagnosis is by IgG antibody titers.

PERICARDIAL DISEASE IN METABOLIC DISORDERS

Renal Failure (See Fig. 72-6)

Most *uremic pericarditis* is due to chronic renal failure, which produces all morphological forms of acute pericarditis, effusive and noneffusive, and is usually hemorrhagic, with and without tamponade.[165] [166] *Dialysis pericarditis* accompanies prolonged survival due to effective dialysis, and with it uremic constrictive and effusive constrictive pericarditis have appeared. In acute renal failure, acute uremic pericarditis is usually of less serious significance. Although nitrogen retention is necessary for uremic pericarditis, many patients escape pericarditis so that the pathogenesis is uncertain; "toxic metabolites" are often invoked. Pericardial involvement is unrelated to the etiology of renal failure. Although blood urea nitrogen levels are customarily over 60 mg/dl, there is no strict numerical relationship; and echocardiography reveals excess pericardial fluid in many asymptomatic patients. The incidence of acute pericardial disease in chronic renal failure has plummeted, owing to effective dialysis, hemoperfusion, and renal transplantation (although pericarditis follows transplant in 2 to 3 percent of patients[167]). Small pericardial effusions and noninflammatory hydropericardium due to volume overload and congestive failure (see Chap. 17) are common and usually insignificant.

Cardiac tamponade is the main danger, often precipitated by critically increased bleeding. It may appear as an unexplained fall in blood pressure to a level that varies widely between high, but lower than previously, and shock level. A change in mental status may be the first clue. Fever is variable in the absence of infection and more common in dialysis pericarditis than uremic pericarditis. Chest pain varies from severe to absent. Uremic pericardial rubs tend to be loud, are often palpable, and frequently persist after biochemical abnormalities improve. In uremic pericarditis due to acute and chronic glomerulonephritis and in dialysis pericarditis (especially when precipitated by viral infections), complement-fixing antimyocardial antibodies appear, including antimyolemmal autoantibodies that may be pathogenetic as well as diagnostic.

Uremic pericarditis resembles the spectrum of viral pericarditis and its acute complications, including the characteristics noted earlier. Despite comparable degrees of renal failure, only some, usually younger, patients develop uremic pericarditis, acute myocardial infarction, or hyperparathyroidism.[166] [167] A constant exacerbating factor is the uremic hemorrhagic diathesis from hematological impairments that promote bleeding and abundantly vascular granulation tissue due to uremic inflammation. Pericardial effusions usually predict tamponade in proportion to their size. Uremic exudates contain considerable fibrin and inflammatory cells. All are serosanguineous and, with tamponade, hemorrhagic.[168] Despite destruction of the pericardial mesothelium and gross hemorrhage, pure, that is uninfected, uremic

the myocardium, accounting for the customary absence of typical ECG changes. Indeed, if the ECG is typical of acute pericarditis, intercurrent infection must be suspected. Most often, ECGs are grossly unchanged and reflect associated abnormalities such as LV hypertrophy and "strain," coronary disease, and electrolyte abnormalities. Fluid retention and pleural effusion may reduce ECG voltages with or without pericardial effusion.

DIFFERENTIAL DIAGNOSIS.

This may be difficult, especially in mentally confused patients and because nonuremic intercurrent pericarditis of any cause is always possible. For example, when hypertension is not being controlled, dissecting hematoma of the aorta (see Chap. 40) must be considered. Indeed, uremic tamponade may simulate any cardiocirculatory emergency, especially with marked hypotension (often despite fluid overload).[165] [166] [167] [168] Conversely, tamponade may be disguised by a relatively or absolutely high pressure level (high pressure tamponade). Confusion of tamponade with florid heart failure may arise from LV hypertrophy, which is frequent in uremics, and myocardial failure, each of which can prevent pulsus paradoxus. Unexplained worsening renal function may be a clue to tamponade. Sepsis of nonrenal origin may coexist and precipitate tamponade; blood cultures may be positive for organisms and pericardial fluid negative. Hepatic congestion due to tamponade may be confused with viral hepatitis. Finally, in uremic patients, frequent autonomic impairment occurs, even during tamponade, so that the *heart rate may be deceptively slow* (60-80 beats/min) despite fever and hypotension.

TREATMENT.

This consists of drainage, which should be gradual because of possible "pericardial shock" in patients who may have underlying congestive failure or intercurrent myocarditis that predisposes to postdrainage cardiac dilation. A neurogenic element may also contribute to postdrainage collapse because patients are vagotonic; therefore, during pericardial drainage, patients may need to receive atropine.[166] [169] Intrapericardial hydrocortisone, triamcinolone, or equivalent agents may accelerate improvement by suppressing inflammation. For uremia itself, effective dialysis is mandatory, with careful monitoring of intravascular volume, since with excess pericardial fluid rapid vascular volume reduction can precipitate tamponade.

ACUTE RENAL FAILURE.

Patients with hypotension due to shock, sepsis, trauma, or surgery may develop acute renal failure that can be self-limited; but with the blood urea nitrogen of 100 mg/dl or more, uremic pericarditis may appear. This responds to effective treatment of the etiological condition, circulatory support, and acute dialysis. Pericardial involvement is identified by a rub, effusion, or tamponade.

DIALYSIS PERICARDITIS.

Adequate dialysis effectively ends uremic pericarditis within a few months. While classic uremic pericarditis is reversed by dialysis, *dialysis pericarditis,* by definition, appears despite otherwise successful dialysis, even in stable patients with good biochemical control.[166] Its pathogenesis is unknown, although it is much less common during peritoneal dialysis than hemodialysis. Immune complex-like material is found in the dialysate, and this "loss" may retard pericarditis.[168] [169] A pathogenetic role for "middle molecules" has been proposed. Several factors are associated with precipitating dialysis pericarditis and effusion, above all inadequate dialysis. Infection, particularly viral, is frequent, with hepatitis and cytomegaloviruses common in dialysis units. Such infections are often systemic, and the pericardial fluid is sterile. Constitutional symptoms, especially fever, are more severe and more common than in uremic pericarditis, and dialysis pericarditis may be preceded by weight gain and hypotension.[166] Effusion with or without hemorrhage is the most important complication and tends to recur. As in classic uremic pericarditis, larger effusions predict tamponade. Survival due to dialysis has allowed uremic constriction to appear.[166]

Treatment is designed to intensify dialysis while avoiding hypotension. Tamponade calls for drainage with maintenance of an intrapericardial catheter for at least 2 or 3 days. While there are no controlled trials, intrapericardial nonabsorbable corticosteroid-like triamcinolone appears to be effective. A trial of peritoneal dialysis for patients who have been on hemodialysis may be therapeutic. For intractable pericardial effusions, pericardial resection is the only effective approach.[166] [167] [168]

OTHER RENAL CONDITIONS.

Although transplantation is usually successful for renal failure, severe transplant rejection is accompanied by acute pericarditis. [167] Patients with a nephrotic syndrome frequently have pericardial effusions associated with fluid retention (hydropericardium) or actual inflammation. Pericarditis in hepatorenal failure occurs at relatively low blood urea nitrogen levels, does not respond to dialysis, and is almost uniformly fatal.[166]

Hypothyroidism (See also Chap. 64)

Severe hypothyroidism produces large usually clear, high-protein, high-cholesterol, high-specific-gravity pericardial effusions.[165] [166] [170] These are constant in experimental and human myxedema and may precede other signs (especially in primary hypothyroidism). Echocardiography reveals them in 5 to 30 percent. Children with Down syndrome are at special risk for congenital or acquired hypothyroidism, which is often unrecognized because excessive weight, hypotension, and dry skin are classic in Down syndrome and hypothyroidism.[171] With tamponade, dyspnea, fatigue, cardiomegaly, and cyanosis may be attributed to their congenital heart disease.

Many effusions in hypothyroid patients are very large, chronic, asymptomatic, and discovered accidentally by chest radiography.[166] Clinical tamponade[171] is rare because the slow tempo permits pericardial stretch. Three factors may precipitate tamponade: (1) intercurrent acute pericarditis; (2) hemorrhage; and (3) rarely, cholesterol pericarditis with an inflammatory reaction to precipitated cholesterol crystals. Moreover, tamponade can occur with high arterial pressure, presumably due to the increased catecholamines of hypothyroidism.

In severe myxedema, pleural effusion, ascites, and anasarca resemble chronic cardiac failure and constrictive pericarditis.[165] Blood volume is usually increased, whereas in uncomplicated myxedema it tends to be decreased. In some cases, high sedimentation rates suggest an inflammatory component that has been seen on electron microscopy,[166] but the fluid typically has few leukocytes. The ECG may not be altered. However, bradycardia is common, and severely myxedematous patients have distinctly low-voltage to microvoltage QRS.[166] Treatment is thyroid hormone replacement, which is nearly always followed by steady regression of the effusion.[170] [171]

OTHER METABOLIC DISORDERS.

Pericarditis has been repeatedly observed during severe crises in patients with *diabetic ketoacidosis* and *adrenal failure* and in some patients with hyperuricemic *gout*.[165] [166] In each case, although bacterial infection, addisonian crisis, or tuberculosis was ruled out, there has not been convincing evidence that pericarditis did not represent an intercurrent inflammation, usually viral, that precipitated that diabetic or adrenal crisis (rarely, tamponade precedes adrenal insufficiency). In Waterhouse-Friderichsen syndrome an accompanying pericarditis is almost certainly meningococcal.[166] In diabetic ketoacidosis, ECGs resembling stage I acute pericarditis have been repeatedly observed both with and without clinical pericarditis.[166] Purely metabolic cholesterol pericarditis occurs in exceptional patients with high serum cholesterol without the usual inciting causes.

NEOPLASTIC PERICARDIAL DISEASE (See Chaps. 49 and 69)

Three types of neoplastic disease affect the pericardium[172] : (1) primary pericardial tumors, benign or malignant (comparatively rare); (2) secondary malignancies--metastatic and/or from neighboring structures; and (3) nonneoplastic pericardial effusions accompanying malignancy elsewhere. In general, demonstrably malignant effusions imply a prognosis for life of months to a year with breast carcinoma among the "better" prognoses.

SECONDARY MALIGNANCIES: METASTATIC AND INFILTRATIVE

Metastasizing and multicentric malignancies affect the pericardium with or without cardiac involvement, are silent more often and for longer than primary malignancies, and may be the initial sign of malignant disease arising elsewhere.[172] [173] [174] [174A] These can present as a pericardial effusion or deceptively when a strong fibrinous reaction mimics acute pericarditis with pain, pericardial rub, fever, and typical or suggestive ECG changes.[172] [173] Usually the ECG is nonspecific even if typical. The

J-ST elevations sometimes last for days to weeks, implying persistent pericardial and myocardial injury.[172] In metastatic involvement of the heart by discrete tumors, epicardial lymphatics are nearly always involved. Direct extension occasionally occurs from tumors of the lung, chest wall, or esophagus. Solid tumors may be restricted to the pericardium, invade the myocardium, or appear in both. Lymphomas, Hodgkin disease, leukemias, melanomas, and especially multiple myeloma simultaneously infiltrate the myocardium and pericardium, although each can be isolated to the pericardium. Many of these are associated with local production of cytokines, accounting for associated pericardial inflammation.[175] [176] [177] Melanomas, with frequent cardiac involvement often invade the visceral pericardium.[177]

CLINICAL ASPECTS.[172]

Secondary neoplasia tends to be insidious and difficult to diagnose unless cancer is recognized elsewhere. Effusions are usually large, especially in patients with hypoalbuminemia, and may be decompensated to tamponade by intrapericardial hemorrhage. Occasional tumors induce constrictive, especially effusive-constrictive pericarditis, with the constriction due to neoplastic tissue, adhesions, or both. Some tumors encase the heart, producing elastic constriction. Occasional tumors involving the pericardium mimic one of the vasculitis-connective disease group. Neoplastic effusions that

become suppurative suggest infectious pericarditis, especially in patients immunocompromised due to treatment or to AIDS; the organisms are either common or opportunistic pathogens, especially atypical mycobacteria and fungi.[172]

Pericardial malignancy should be suspected, particularly in patients with malignancy elsewhere[172] : (1) with any large or recurrent effusion; (2) apparently refractory "heart failure" with very high venous pressure; (3) superior vena cava syndrome; or (4) unexplained hepatomegaly. Dyspnea, orthopnea (the most common symptom), unexplained chest pain, and nonproductive cough suggest pericardial involvement. Facial edema and persistent jugular venous distention after drainage of a pericardial effusion may be due to SVC syndrome.

DIAGNOSIS.

This may be indicated by chest film, echocardiography, MRI, CT, and radionuclide scanning with indium-111, gallium-67, or technetium.[172] [178] CT and MRI can also reveal tumor contents and texture. For malignant melanoma (over 60 percent with cardiac metastases[177]), MRI is particularly suited because of magnetic scanning. Large effusions or tamponade necessitate studying fluid or tissue, best obtained by video-assisted pericardioscopy, so that samples including *epicardial* biopsy may be obtained safely under direct vision.[52] [179] Cytology, cytometric, and immunohistochemical studies are highly sensitive and specific for most metastatic lesions.[180] [181] False-negative cytology is more common with lymphomas and mesothelioma. Normal mesothelial cells proliferate in response to injury and can show many mitotic figures similar to tumor cells, particularly resembling mesothelioma and adenocarcinoma.[172] [182] Differentiation is by immunohistochemical and ultrastructural methods.[52] [179] Mesothelial cells have keratin and vimentin, whereas carcinoma cells contain carcinoembryonic antigen and LeuM1.[181] [182] [183] The ECG is usually abnormal but nonspecific. Malignant effusions usually with tamponade are a common cause of electrical alternation. Fluid obtained by needle or surgical drainage should be studied for cells, including histochemical staining[181] [182] [183] ; carcinoembryonic antigen and neuron-specific enolase should be sought.[184] Unsatisfactory results require biopsy with the largest possible specimen through the subxiphoid route or by pericardioscopy.

PRIMARY PERICARDIAL NEOPLASM

Benign tumors are found especially in infancy and childhood, whereas *primary malignancies* are discovered mainly in the third and fourth decades.[172] Lipomas and fibromas discovered in mid and later life may grow to giant proportions. Pericardial cysts and particularly hydatid cysts require differential diagnosis, especially if atypically located and if imaging suggests solid tumor.[172] The most important primary malignancies are *mesotheliomas* and *sarcomas* (particularly, *angiosarcoma*), which arise respectively from the pericardial serosa and vasculature and do not metastasize. Pleural mesothelioma can spread to pericardium. They proliferate throughout the pericardium, often invading the myocardium. Mesotheliomas are often related to asbestos or fiberglass exposure, although numerous cases lack either. In general, the signs and symptoms of secondary metastatic and infiltrative malignancies also apply to benign and malignant solid tumors.

CLINICAL FEATURES

Benign tumors usually provoke large effusions even in neonates in whom a cardiorespiratory distress syndrome may appear at or shortly after birth. *Teratomas* are nearly always found in infants with large pericardial effusions; the fluid may be transudate, sanguineous, or, rarely, pyopericardium. [172] Teratomas can compress the right side of the heart and may have detectable calcifications: teeth and bones. Bronchial cysts may resemble teratomas on imaging due to radiopaque contents, but effusions are not common. *Pheochromocytomas* (paragangliomas) and related neurofibromas and neuroblastomas often induce adrenergic hormonal effects, leading to detection by blood and urine tests for catecholamines and localization with iodine-131 metaiodo-benzyl-guanidine. They are hypervascular so that intravenous contrast agents can localize them.[172] *Thymomas* can cause pericardial effusion but may be large enough to be confused with effusion and difficult to identify by imaging if isodense with surrounding structures.[173] [185] Malignant thymomas may present as multisystem disease and autoimmune syndromes as well as cardiac tamponade and SVC obstruction; immunocompromised patients are more susceptible.[172] *Mesotheliomas* may give all the symptoms and signs of metastatic and infiltrate tumors and can mimic idiopathic acute pericarditis with effusion, but with characteristically high levels of hyaluronic acid (hyaluran) in blood and pericardial fluid.[173] [186] They can grow without much exudative reaction to overspread the heart, causing atypical or classic constriction.[173] [181] [182] *Angiosarcomas* grow as blood locules within the pericardial cavity, may or may not deform the cardiopericardial silhouette while enlarging it, and, because of their vascularity, imitate hemopericardium of other origin.[172]

MANAGEMENT

Large refractory and tamponading effusions must be drained. Pericardiocentesis has a high failure rate, except for temporary relief. Percutaneous balloon pericardiotomy[187] [188] or subxiphoid surgical drainage (erroneously termed "window") may be successful in patients with limited survival. Subxiphoid incision permits direct inspection and biopsy; balloon pericardiotomy and pericardiopleural window avoid discomfort and risks of surgery. A pericardioperitoneal shunt may provide prolonged palliation, particularly in children.[172] Extensive pericardial resection is mandatory for persistent recurrence of malignant pericardial constriction; video-assisted pericardio(thoraco)scopic resection is desirable.[172] [173] [179] [189] In patients with very poor prognosis or in whom operation would be hazardous, sclerosing agents have been palliative, although with considerable initial pain.[190] Fortunately, indwelling pericardial drainage tubes act identically, rendering sclerotherapy unnecessary.[172] Yet, there is no convincing evidence that intrapericardial treatment modifies the prognosis for life, which averages 4 months for secondary malignancies except tumors that are unusually sensitive to radiation or systemic chemotherapy.

PERICARDIAL DISEASE IN THE VASCULITIS/CONNECTIVE TISSUE DISEASE GROUP (See Chap. 67)

Diseases causing pericarditis, effusion, adhesions, and constriction include most of the vasculitis/connective tissue disease group--a heterogeneous category of disorders that have in common inflammation of blood vessels. Only specific histological lesions in the pericardium confirm the etiology, although characteristic pericardial fluid constituents may be adequate and characteristic clinical behavior often suggests the diagnosis.[191] The primary pathogenic event leading to vasculitis is probably deposition of immune complexes; group members have immunopathic, including autoimmune, features based on immunoglobulin or complement deposition and/or inflammatory cell infiltration in blood vessels and pericardium.[191] Increased or decreased pericardial fluid complement components with normal serum complement levels suggest local complement activation or consumption. With arthritis, synovial tissue and joint fluid abnormalities may resemble those of pericardium and pericardial fluid.[191] Some heterogeneity relates directly or indirectly to exposure to infectious agents (e.g., streptococcal antigen in acute rheumatic fever; hepatitis B antigen in polyarteritis), to unrelated pericardial trauma (e.g., arthritic manifestations with pericarditis in postpericardiotomy and post-myocardial infarction syndromes), or to hypersensitivity, such as "allergic" reactions (e.g., drug-induced lupus) provoking immunopathic responses. Some, such as Wegener granulomatosis[192] and rheumatoid arthritis,[193] feature granulomas. Sarcoidosis, also granulomatous, is less well understood and not strictly a vasculitis.[191] Many patients develop serological evidence, including hypergammaglobulinemia, cryoglobulinemia, hypocomplementemia, circulating immune complexes, and rheumatoid factor, each of which may also be in pericardial fluid. Most of this group affect a preponderance of females, yet males form a disproportionately large part of those with pericardial involvement, reflecting male preponderance in almost every form of pericarditis.[191]

Laboratory studies (e.g., antinuclear antibodies [ANAs]) may support or confirm some diagnoses but alone are not entirely specific.[194] [195] Some malignancies provoke both vasculitis and pericarditis, and some benign and malignant cardiac tumors, including myxoma, may be associated with systemic syndromes resembling those of members of this group.[191]

Rheumatoid Arthritis

Rheumatoid arthritis and its juvenile and adult variants is probably the largest "generator" of pericardial disease. Pericardial involvement is most common in

middle-aged white men. Almost half of autopsy patients with rheumatoid arthritis have significant pericardial adhesions, and on echocardiography approximately half have excessive pericardial fluid.[190] Rheumatoid arthritis pericarditis is more common

in patients with advanced rheumatoid arthritis with high rheumatoid factor titers.[194] Clinically significant effusions imply a poor prognosis. All morphological forms of pericarditis are associated with rheumatoid arthritis. Acute fibrinous pericarditis, usually subclinical, is demonstrable mainly in patients dying of any reason during arthritis flares. Pericardial effusions, also usually subclinical and small to moderate, can become large, chronic, and even tamponading. Adhesive pericarditis, usually generalized but occasionally localized or with loculated fluid, can provoke all variants of constriction, which tends to occur within 4 to 5 years of the onset of severe rheumatoid arthritis and is comparatively rare with chronicity.[191] Pericardial disease becomes more overt, with severe rheumatoid arthritis particularly in patients with strong serological evidence and only rarely in quiescent disease.[193] [194] [195] [196] The most common presentation is a pericardial rub lasting days to years and accidentally discovered in patients without symptoms or with asymptomatic effusion on echocardiography.[190] Recognition of RA pericarditis is confounded not only by its many variants but also by intercurrent diseases, such as viral pericarditis and drug-induced pericarditis (e.g., by phenylbutazone), possible increased susceptibility to other infections and the excellent substrate for bacterial infection afforded by chronic pericardial effusions. Unilateral or bilateral pleural effusions, pleural rubs, and lung lesions (e.g., Caplan syndrome) are common with active disease. Patients with rheumatoid arthritis and systemic congestion ("right-sided heart failure") raise the question of rheumatoid arthritis constriction or tamponade, although common causes of systemic congestion such as true heart failure are more likely.[191]

DIAGNOSIS.

Although acute, rheumatoid arthritis pericardial effusions may have more fibrin. Acute and chronic effusions resemble arthritic synovial fluid and rheumatoid pleural effusions.[191] [197] They are mainly serous, often serosanguineous, rarely hemorrhagic, and characterized by low glucose (<45 mg/dl) with a mainly neutrophilic leukocytosis (usually >15,000 cells/mm[3]), with many cells showing cytoplasmic inclusions that stain for IgM and soluble immune complexes including IgG; complement levels are very low; latex fixation titers for rheumatoid factor are high and relatively specific. Protein is usually more than 5 gm/dl; cholesterol, including crystals, is frequently increased.[191] [196] [197] ECG changes are nonspecific. Cases must be differentiated from tuberculous and bacterial pericarditis, malignancy and, rarely, other causes of cholesterol pericarditis.

MANAGEMENT.

Treatment is necessary only for symptomatic pericardial disease. Constriction occurs in rheumatoid arthritis patients despite established antiarthritic treatment with corticosteroids, high-dose aspirin, and other antiinflammatory agents.[191] [198]

ACUTE RHEUMATIC FEVER (See also Chap. 66)

Pericarditis in acute rheumatic fever has declined with decreasing rheumatoid factor in the United States.[191] [198] [199] Mainly a disease of children and adolescents, acute rheumatic fever is associated with antecedent streptococcal infection and has features of immunopathies and other connective tissue diseases. Its pericardial lesions include extensive deposition in the pericardium and in vessels of IgG, IgM, and C3. Most patients have at least discrete fibrotic epicardial milk patches; most of those with chronic valve disease have pericardial adhesions, which frequently are obliterative and which do not appear to constrict. Clinically pericardial involvement is mostly minimal or symptomatic; yet manifest pericardial involvement in acute rheumatic fever usually indicates severe and sometimes fatal pancarditis (almost never without valvulitis[199]), especially if with significant effusion, which may be partly or entirely related to rheumatoid factor myocarditis or heart failure.

Acute pericarditis is a sign of active rheumatic carditis.[192] It usually occurs in the first week after fever and arthritis; chest pain varies from mild to severe; there may be a secondary temperature rise. Disproportionate tachycardia and dyspnea are probably related to myocarditis and pulmonary congestion or edema. The pericardial rub may be intense and last several days. Some degree of effusion is the rule with amber fluid, frequently blood tinged, containing considerable fibrin. Tamponade is rare but must be differentiated from congestive heart failure. Differential diagnosis from other vasculitides is essential, particularly juvenile rheumatoid arthritis in adults who have lymphadenopathy, SLE, and also endocarditis, Lyme disease, and sickle cell crisis. Occasionally, pericarditis is the first sign of acute rheumatic fever. In any child with pericarditis, acute rheumatic fever must be ruled in or out, especially if with a rash and arthralgias, which also occur in viral pericarditis and childhood exanthems.

Without definite carditis, the diagnosis of rheumatic pericarditis is circumstantial and includes (1) fever and arthritis usually preceding pericarditis; (2) relative youth in most cases; and (3) serological positivity for beta-hemolytic streptococci. Nonsteroidal agents may be sufficient treatment. Corticosteroid therapy may be used if nonsteroidal agents fail and may be marginally better.

SYSTEMIC LUPUS ERYTHEMATOSUS

Most patients with SLE develop some form of pericarditis, clinical or subclinical.[191] [194] [200] [201] Pericardial effusion, often large, is common, although tamponade and constriction are comparatively uncommon. SLE pericarditis parallels disease activity[202] [203] and is characterized by epicardial microvasculitis and necrosis and a number of antibodies to nuclear components and phospholipids that form pathogenic antigen-antibody complexes. Immune complexes deposited in the pericardium include IgM, IgG, C3, and, rarely, hematoxylin bodies.[191] [200] [201] SLE causes the entire spectrum and all stages (i.e., acute, subacute, chronic and recurrent) of anatomical and pathophysiological pericardial abnormality. This includes pericarditis; exudative pericardial effusion, which can be serous, serosanguineous, or hemorrhagic; pericardial adhesions; and constrictive pericarditis[191] ; any of these may be the first sign.[201] Males are relatively overrepresented, especially among patients who develop constriction.

Pericarditis typically accompanies severe SLE and is often diagnosed during an acute flare that can be painful or painless but virtually always with serological evidence of active disease. Lupus nephropathy is frequent so that uremic pericarditis with effusion may be mistaken for or accompany SLE pericarditis. Increased susceptibility to a range of common and opportunistic bacteria and fungi can be due to the effects of antiinflammatory, immunosuppressive, or cytotoxic treatments and lead to contamination of sterile effusions.[191] Even with infective effusions, blood cultures tend to be negative and some grossly purulent sterile fluids are explained by a very high white blood cell content.

DRUG-INDUCED SLE.

This condition is not rare and produces all the pericarditic forms of idiopathic lupus from acute to constrictive but usually spares the kidney.[191] Acute forms clear after discontinuation of offending drugs such as procainamide, isoniazid, hydralazine, methyldopa, or penicillin. Patients with methysergide lupus may develop constriction or, more often, an imitative fibrosing mediastinitis.

MANAGEMENT.

Therapy is as for SLE. Tamponade requires drainage, and constriction requires pericardiectomy. However, occasional patients with less than critical tamponade respond to high doses of corticosteroids and even a trial of NSAIDs.

PROGRESSIVE SYSTEMIC SCLEROSIS (SCLERODERMA)

Scleroderma provokes uncontrolled fibroblastic activity leading to abnormal collagen deposition in the microvasculature, skin, synovia, gastrointestinal tract, lungs, heart, kidneys, and pericardium occurring diffusely or in limited systemic scleroderma (CREST syndrome).[191] [204] [205] Although myocardial involvement with failure is common, pericardial scleroderma is the most common cardiac form at autopsy.[191] Echocardiography shows pericardial effusion in almost one half of patients. Although relatively few patients have clinical signs of pericardial scleroderma, these extend from acute fibrinous pericarditis to effusions, which may be chronic recurrent or tamponading, to constriction from relentless fibrosis. Rarely, acute and chronic effusions and even tamponade precede the diagnosis.[191] Scleroderma pericardial effusion, frequently bloody, is an exudate contrasting to exudates in other forms of vasculitis because of the absence of autoantibodies, immune complexes, or complement deposition along with very few white blood cells and a variable protein level.[191] [204] Transudates and pleural effusions are more likely to result from heart failure or uremia. Pericardial scarring in scleroderma is typically slow and associated with gradual obliteration of small vessels. Pericardial involvement occurs with or without myocardial scleroderma, but ECGs, almost always nonspecifically abnormal, reflect myocardial involvement. Consequently, a typical stage I ECG of acute pericarditis should raise the question of intercurrent infection. Because scleroderma is systemic, *confounding factors* must be considered. Hemodynamics may be affected by pulmonary lesions with pulmonary hypertension, RV hypertrophy, and systemic congestion. Myocardial scleroderma occasionally produces a restrictive cardiomyopathy masquerading as pericardial constriction. As in radiation pericarditis, constrictive pericarditis and restrictive cardiomyopathy may coexist. Renal

scleroderma can produce uremic pericarditis. Symptomatic pericardial disease is associated with a poor prognosis.

SJOGREN SYNDROME

This "sicca syndrome" (dry eyes and dry mouth due to destructive lymphocytic infiltration of exocrine glands) occurs in isolation or in association with connective tissue disorders such as SLE, rheumatoid arthritis, or scleroderma.[191] [206] Pericarditis is of the types associated with the dominant connective tissue disorder, which is usually severe.

POLYMYOSITIS/DERMATOMYOSITIS

These related chronic inflammatory autoimmune diseases of skeletal muscle and skin also affect the heart and pericardium with or without established skeletal muscle involvement.[191] [207] Cardiac and pericardial involvements are usually asymptomatic. Pericarditis, more common in children, is usually discovered incidentally as an effusion on echocardiography, at autopsy, or, occasionally, as fibrinous pericarditis. As in Sjogren syndrome, pericarditis appears to be more frequent in patients with an "overlap syndrome," that is, complicating manifestations of other connective tissue disorders.[191] Effusions, occasionally large, rarely tamponade; constriction is rare. Like SLE, scleroderma can occur with a predominantly myositic syndrome.[207]

PERICARDITIS IN MIXED CONNECTIVE TISSUE DISEASE

Mixed connective tissue disease is a set of "overlap syndromes" with variably combined features of lupus, scleroderma, and dermatomyositis/polymyositis.[191] Pericarditis is the most frequent cardiac finding, particularly at autopsy with pericardial effusions of all sizes.[190] Acute pericarditis or pleuritis can be a presenting feature. Patients have combinations of polyarthritis, Raynaud phenomenon, lymphadenopathy, esophageal dysmotility, skin and muscle involvement, and frequent pulmonary disease with pulmonary artery hypertension; mitral valve prolapse is frequent, often with mitral regurgitation. There are high titers of speckled fluorescent ANA and especially circulating antibodies against nuclear ribonucleoprotein. Echocardiograms frequently show effusion (usually small), and there may be pericardial thickening consistent with postmortem findings of patchy epicardial fibrosis suggesting recurrent episodes. The ECG is nearly always abnormal, frequently showing characteristic ST segment deviations, which is not surprising because of the relative frequency of acute fibrinous pericarditis.[191] Pericardial fluid is serous or serosanguineous but only rarely causes tamponade. Prognosis is surprisingly good in mixed connective tissue disease because pericardial involvement responds to short courses of low-to-moderate dose corticosteroid therapy.

SERONEGATIVE SPONDYLOARTHROPATHIES

This complex group has in common [191] (1) arthritis with a predilection for sacroiliac apophyseal and lumbosacral joints of the spine and the entheses; (2) absence of rheumatoid arthritis serology; (3) male predominance; (4) extraarticular manifestations, including pericarditis, iritis, uveitis, enteric inflammations, myocarditis, and lesions of the aortic root and valve, often with aortic regurgitation; and (5) association with haplotype histocompatibility antigen B27 (HLA-B27). Iritis and cardiopericardial involvement are found primarily in those with B27 positivity, especially syndromes including particularly ankylosing spondylitis, Reiter disease, and the intestinal arthropathies, all associated with dysentery and sometimes urethritis. Dysentery may be related to specific organisms (not necessarily causative). "Psoriatic arthritis" should be included because it can cause constriction. Ankylosing spondylitis is particularly seen in relatively young males with sacroiliitis. Rubs are discovered, and constriction ensues in those with severe acute toxic polyarthritis episodes. Fibrous pericardial adhesions are seen at necropsy. Some patients have had features of Reiter disease. Cardiac involvement is relatively frequent, particularly acute pericarditis with a friction rub[191] and myocarditis [44] with murmurs, gallop rhythms, and conduction abnormalities, all of which may be accompanied by pericardial effusion with increased complement.

The *intestinal arthropathies* include inflammatory bowel disease. In *Crohn disease* and *ulcerative colitis,* acute pericarditis occurs with or without tamponade. *Whipple disease*, a multisystem disorder, has a high proportion of pericardial lesions at necropsy. Serofibrinous pericarditis, sometimes with pleurisy, may accompany seronegative migratory polyarthritis and gastrointestinal symptoms. Pericardial constriction may precede or follow abdominal complaints but is sufficiently rare to suggest intercurrent primary pericarditis.

SYSTEMIC VASCULITIDES

Giant cell arteritis affects medium and larger arteries in any organ including the heart and pericardium.[191] [208] Concomitant pericarditis with or without effusion is of uncertain pathogenesis and possibly is immunopathic. Infections frequently precede giant cell arteritis so that early pericardial syndromes could be mistaken for viral or other infectious pericarditis.[208] Pericarditis and pericardial lesions accompany *temporal (cranial) arteritis* at necropsy and only occasionally clinically, raising the question of intercurrent infection. *Takayasu arteritis* ("pulseless disease"; aortic arch syndrome) is a chronic, idiopathic inflammation of large vessels occurring in relatively young women, with occasional acute pleuritis and pericarditis, sometimes recurrent; more common is postmortem discovery of pericardial scarring. Tamponade is likely to be due to rupture of a coronary sinus aneurysm. Antiinflammatory, particularly corticosteroid, agents reduce inflammation without effect on ischemia due to arterial lesions.[191]

Polyarteritis (periarteritis nodosa)[209] only occasionally produces acute pericarditis, effusion, or hemopericardium in the absence of uremia. They are more common in patients who are HBsAg positive with associated chronic active hepatitis in some. Patients with coronary arteritis producing myocardial infarcts can develop epistenocardiac pericarditis.

HYPERSENSITIVITY VASCULITIDES

The hypersensitivity vasculitides include *allergic granulomatosis, ChurgStrauss syndrome,* and various *hypereosinophilic syndromes,* all of which have some relation to polyarteritis and produce acute pericarditis, effusion with, or usually without, tamponade and constriction, congestive failure, and acute myocardial infarction.[191] [205] [210] [211] With persistent hypereosinophilia, restrictive cardiomyopathy may result from endocardial involvement. The Churg-Strauss syndrome is a multisystem vasculitis with necrotizing arteritis and eosinophilic infiltrates including extravascular granulomas, particularly in the epicardium. Epicardial and pericardial involvement is relatively frequent, producing all forms of pericarditis and myopericarditis complicated by ischemia due to vasculitis. Characteristically, patients have a history of asthma and allergic rhinitis, which may be transient and episodic. Both blood and pericardial fluid are eosinophilic.

BEHCET SYNDROME.

This is characterized by painful oral and genital ulcers and recurrent hypopyon iritis, sometimes with skin and central nervous system involvement.[191] Arteritis (and venulitis) reveal its relation to the systemic vasculitides. Some patients develop myocarditis, but the *most common cardiac lesion is acute pericarditis.* It is fibrinous or effusive, including pleuropericarditis, each of which may be recurrent but usually self-limited or responding to antiinflammatory agents used for the disease itself. However, Behcet syndrome sometimes provokes thrombosis of major veins, may mimic constriction, and has been associated with chylopericardium and chylothorax.

WEGENER GRANULOMATOSIS.

Wegener granulomatosis is characterized by necrotizing local and systemic granulomatous vasculitis of the upper and lower respiratory tract and glomerulonephritis.[191] [212] It overlaps polyarteritis and both giant cell and hypersensitivity arteritides. Diagnosis often requires biopsies of lung or kidney. Serological testing includes antineutrophil, cytoplasmic antibody, and plasma thrombomodulin, which reflects vascular injury. Cardiac involvement occurs in up to 20 percent, including granulomatous myocarditis, endocarditis (including valvulitis), and aortitis; pericarditis occurs in at least half of these, ranging from acute fibrinous to serous or hemorrhagic effusion and occasional tamponade or constriction.

SARCOIDOSIS.

Cardiac involvement in sarcoidosis is much more common at necropsy than clinically, because granulomas may be microscopic and not strategically located.[191] Widespread active granulomatous myocarditis and pericarditis, fortunately rare, produce serious and often fatal disease. Pericardial effusions with serous or serosanguineous fluid are relatively common, even during corticosteroid therapy. The majority of pericardial effusions are transudates due to myocardial disease, including heart failure. Constriction has been reported.

SERUM SICKNESS.

Serum sickness--with fever, urticaria, lymphadenopathy, myalgia, arthritis, neuritis, vasculitis, and glomulonephritis--can provoke acute pericarditis probably related to pericardial deposition of soluble antigen-antibody complexes when there is an excess of antigen.[191]

MYOCARDIAL INFARCTION-ASSOCIATED PERICARDITIS (See Chap. 35)

Both "early" and "delayed" infarct-associated pericarditis are usually distinct but sometimes without absolute temporal separation, either because one continues into the other or because of the unusually early appearance of pericarditis with characteristics of the delayed form, called *post-myocardial infarction (Dressler) syndrome*.[213] [214] Because the true "early" form is confined to the infarct zone it is known as "infarct pericarditis" or *epistenocardiac pericarditis.*[213] It occurs in almost half of transmural myocardial infarctions but is clinically discovered in many fewer, owing to varying diligence in auscultating a rub, which is usually the only sign. The principal confounding factor in distinguishing epistenocardiac pericarditis from the post-myocardial infarction syndrome is uncertainty as to actual age of any acute infarct; recognition of pericarditis on or near the day

of admission usually means epistenocardiac pericarditis, but behavior of the lesion may reveal post-myocardial infarction syndrome.

Infarct Pericarditis

Myocardial infarction-associated pericarditis occurs with anatomically transmural or nearly transmural infarction and is localized to the infarct's "apex" on the epicardium.[213] [214] [215] Most ECG changes are localized and nearly always overshadowed by myocardial infarction changes. Thus, generalized stage I ECG changes always raise a question of the post-myocardial infarction syndrome. Acute pericarditis accompanying nontransmural infarct is more likely to be early post-myocardial infarction syndrome. The pericardial exudate is fibrinous; late consequence is a collagenized scar overlying the infarct. Because myocardial infarctions causing detectable epistenocardiac pericarditis are transmural and relatively large, ventricular thrombi, especially apical and RV, are relatively common and probably the reason that systemic embolism is more common in patients who have myocardial infarction pericarditis; with RV infarcts, pulmonary embolism can occur. Moreover, there are more ventricular aneurysms in patients with myocardial infarction pericarditis and more thrombi in them. Such complications reflect the strong tendency for myocardial infarction pericarditis to occur with larger myocardial infarctions and, therefore, associated with higher Killip class and more atrial and ventricular arrhythmias than in patients without pericarditis.[213] [215] [216] Atrial and ventricular arrhythmias are related to heart failure and atrial infarction rather than to pericarditis.[212] Temperature exceeds 37.2°C (99°F) more frequently and lasts longer than without pericarditis.

During the first week of acute myocardial infarction, infarct pericarditis is also a common cause of new chest pain, distinguishable from ischemic pain mainly by its respirophasic and positional ("pleuritic") fluctuations. The importance of larger infarct size with easily discoverable (i.e., rub producing) pericarditis is reflected in late mortality. Despite higher Killip classes, the *in-hospital* prognosis is no different from those without pericarditis. However, *late prognosis* (i.e., 6 months and after) is distinctly worse in those who have myocardial infarction pericarditis.[217] [218]

Patients with infarct pericarditis reflect larger myocardial infarction size by greater (1) myocardial enzyme release, (2) number of ECG leads with elevated ST segments, (3) degree of ST segment elevation, (4) number of leads with infarct Q and QRS abnormality, (5) echocardiographic estimate of myocardial infarction size, (6) aggregate wall motion abnormalities, and (7) radiographic score for extravascular lung water.[213] With infarct pericarditis, anterior and multisite myocardial infarctions are more frequent than with the usually smaller inferior myocardial infarctions. With inferior myocardial infarctions, approximately twice as many patients have pericarditis when there is anterior ST segment depression, which is a sign of a more serious process. Patients have lower ejection fractions that continue to fall up to day 10, whereas without pericarditis depressed ejection fractions tend to rise by 6 to 10 days.[129] [213] [215] With pericarditis there are also more frequent signs of heart failure and increased pulmonary wedge pressure.[216] [217] Early thrombolytic therapy has decreased the incidence of epistenocardiac pericarditis; however, pericarditis appearing despite thrombolysis is a marker of greater damage.[218]

PERICARDIAL EFFUSION.[213] [214] [216] [219] [220]

In acute myocardial infarction, pericardial effusions can be irritative (pericarditic) or due to hydropericardium. Effusions tend to develop early, mainly on days 1 to 3, the majority without evidence of pericardial irritation (hydropericardium) and only small to moderate-sized effusions. Larger effusions indicate some degree of heart failure with fluid retention: there is probably increased microvascular permeability associated in some patients with increased extravascular lung water. Increased myocardial interstitial fluid and obstruction of cardiac lymph and venous drainages probably produce the occasional larger irritative effusions that resemble or coincide with hydropericardium.[213] Hydropericardium is more frequent with larger, Q-wave, anterior, and RV myocardial infarctions; they are associated with higher wedge pressures, LV dyssynergy, increased RA pressures, and increased pulmonary alveolar-arterial oxygen difference; reabsorption takes days to weeks.[213] [214] [215] [216] [217]

Although tamponade is rare in the absence of bleeding, hydropericardium presages increased mortality because of its association with the foregoing factors.

Anteriorly loculated effusions may cause isolated right-sided heart tamponade by selectively compressing the right ventricle, AV groove, or right atrium; patients develop new hypotension, but pulsus paradoxus usually is absent. The pericardial fluid may contain increased adenosine[219] and beta-fibroblast growth factor.[221] Hemorrhagic pericardial effusion or frankly bloody hemopericardium occurs "spontaneously" or with antithrombotic therapy and, of course, myocardial rupture.[213] [222] [223] Yet any significant pericardial bleeding with myocardial infarction pericarditis is uncommon. However, rapid "cardiac" enlargement, or a loud or persistent pericardial rub or unexplained drop in hemoglobin or hematocrit, with or without tamponade, should be observed for pericardial hemorrhage due to excessive anticoagulation or subacute ventricular rupture. Patients who survive subacute rupture and echocardiography may show echodense material, owing to organizing blood or clots, simulating the texture of intracardiac thrombi but seen between heart and parietal pericardium. Acute ventricular rupture produces rapid tamponade and death, usually with vagally mediated bradycardia culminating in electromechanical dissociation.[213] [224] Because of the frequency of negative taps due to clots and the need to seal the wound, only immediate pericardiotomy and repair offer any faint hope of survival.

PERICARDIAL FRICTION RUB.

Most rubs occur within 4 days of onset.[213] [216] A persistent loud or widespread rub may indicate the post-myocardial infarction syndrome or unusually intense myocardial infarction pericarditis requiring intensified observation in patients on antithrombotic therapy. With myocardial infarction pericarditis, most rubs are monophasic, are usually systolic, and can resemble or coexist with murmurs of mitral and tricuspid regurgitation or ventricular septal defect.[213] Disappearance followed by recurrence of rubs may indicate onset of the post-myocardial infarction syndrome. Pericardial rubs with inferior myocardial infarctions are more frequent with RV infarction.

ECG.

Infarct pericarditis occurs with transmural (usually Q-wave) myocardial infarction and usually not separately detectable by ECG because it is localized.[11] [213] Failure of evolution of acute ST-T wave changes of myocardial infarction or reversals of ST-T wave evolution in the infarct zone have been associated with infarct pericarditis and impending rupture.[225] [226] Atrial fibrillation is more common after PR segment deviations, a sensitive sign of atrial myopericarditis of unknown specificity and not rare during myocardial infarction pericarditis.[215] Patients with myocardial infarction pericarditis ultimately have more second- and third-degree AV block and more bundle branch and other fascicular blocks, all correlated with larger myocardial infarctions.[213] [216]

THROMBOLYSIS EFFECTS.[213] [218] [224]

Effective antithrombotic therapy, administered sufficiently early, usually reperfuses the culprit artery and produces a smaller myocardial infarction, better LV function, and thus less pericardial involvement. Very early thrombolysis decreases the incidence of myocardial infarction pericarditis by at least one half, reduces heart failure among patients with pericarditis, and decreases the incidence of PR segment depression. The rarity

of significant pericardial bleeding is remarkable, but thrombolysis has increased the incidence of infarct ruptures and made them earlier. Recanalization of an artery supplying a necrotic myocardial infarction can make the infarct hemorrhagic with bloody pericardial effusion and even tamponade.

DIAGNOSIS.

A pericardial rub diagnoses myocardial infarction-associated pericarditis. Pleuritic pain is supporting evidence, whereas pain in one or both trapezius ridges is almost pathognomonic. Stage I ECG changes are uncommon and suggest "early" post-myocardial infarction syndrome,[212] whereas failure to evolve or "resurrection" of previously inverted T waves strongly suggest myocardial infarction pericarditis.[225] [226] Absence of effusion on imaging or a clear pericardial tap exclude subacute ventricular rupture. Dense intrapericardial echoes parallel to the cardiac surfaces suggest subacute rupture.

Conditions to distinguish from myocardial infarction pericarditis (they may coexist) include pulmonary embolism, recurrent ischemia or infarction, acute stress ulcer, mitral and tricuspid regurgitation, ventricular septal rupture, and primary pericarditis without myocardial infarction. "Early" post-myocardial infarction syndrome is distinguished by diffuse ST and PR segment changes and more severe pericarditic symptoms, louder and more persistent rubs, and greater tendency to pericardial effusion and hemorrhage.[213] Primary pericarditis may resemble infarct if the ECG is atypical (see Table 50-5) ; however, in the absence of myopericarditis, any ST segment elevations are not accompanied by reciprocal changes usual with acute myocardial infarction. Pulmonary embolus, which can also accompany an RV myocardial infarction with pericarditis and mural thrombi,[218] may require lung scan or angiography. Recurrent ischemia should respond to nitrates; pain and ST segment changes of pericarditis will not. Acute mitral and tricuspid regurgitation and ventricular septal defects are distinguishable by murmurs, thrills, and imaging. Their murmurs may resemble rubs, but flows should be demonstrable by Doppler imaging.

Tamponade is rare; yet, particularly in patients on antithrombotic therapy, it must be distinguished from circulatory collapse due to shock and myocardial failure. Injured, low-compliance myocardium may prevent pulsus paradoxus. Diagnosing tamponade thus may require imaging or cardiac catheterization. Even if intrapericardial blood is drained, relieving tamponade, pericardial clots seen on imaging presage recurrence and demand special vigilance.[213] New pleuritic pain favors pericarditis, especially after antithrombotic therapy, which usually prevents pulmonary embolus. With large infarcts, unexplained deterioration should suggest tamponade. If the diagnosis of acute myocardial infarction is mistaken, thrombolysis may produce tamponade from inflamed pericardium[227] or aortic dissection, a mimic of both acute myocardial infarction and acute pericarditis (see Chap. 40) .

MANAGEMENT.

Myocardial infarction-associated pericarditis is usually mild and responds to aspirin, up to 650 mg every 4 hours for 2 to 5 days. Other nonsteroidal agents risk thinning an infarct (not conclusively demonstrated in humans); ibuprofen, which increases coronary flow is the agent of choice. Corticosteroid therapy may be used for refractory symptoms (usually post-myocardial infarction syndrome) but should be avoided owing to delayed myocardial infarction healing, possible side effects, and dependency. Although more frequent with thrombolysis, hemopericardium remains uncommon in myocardial infarction pericarditis; therefore, heparin and other antithrombotic treatments may not be contraindicated unless there is a widespread or intense pericardial rub[213] (risk of hemopericardium is probably outweighed by benefits of preventing myocardial infarction extension and ventricular thrombi). Yet the problem is compounded by possible "early" post-myocardial infarction syndrome with diffuse pericarditis and much greater tendency to bleed. Because pericardial bleeding can occur even with clotting indices in the therapeutic range,[222] these must be monitored and the patient watched for tamponade. Finally, any pericardial effusion increases the energy required for defibrillation.[228]

PSEUDOANEURYSM (FALSE VENTRICULAR ANEURYSM)

Pseudoaneurysms represent contained myocardial rupture, most often posterolaterally, limited by the visceral pericardium, with or without adherent parietal pericardium, or by the parietal pericardium alone.[213] [227] They are uncommon and occur with larger infarcts, usually within 5 weeks of onset. They follow ventricular surgery (especially valve replacement), endocarditis, penetrating wounds, and, rarely, tumor infiltration[229] and suppurative pericarditis.[230] Abundant epicardial fat seems to predispose to cardiac rupture[231] but may buttress a pseudoaneurysm.[213] Pseudoaneurysms have a narrow neck communicating with a ventricular cavity; blood flows into the pseudoaneurysm in systole and out in diastole. The neck may be so narrow as to be visible only on color Doppler imaging. Differential diagnosis includes true aneurysm, pericardial cysts, and loculated pericardial effusions.[213]

THE PERICARDIUM AND RIGHT VENTRICULAR MYOCARDIAL INFARCTION

Pericarditis is relatively frequent when inferior myocardial infarction is accompanied by RV myocardial infarction.[213] [229] [232] However, by means of ventricular and AV interaction both the normal and inflamed pericardium constrain the injured right side of the heart, which tends to dilate. RV dilation raises intrapericardial pressure, which decreases LV transmural pressure, thus reducing LV filling, preload, and stroke volume. (Pulmonary embolism can act similarly, with acute right-sided heart dilation imposing acute pericardial constraint.[233]) These represent relative pericardial constriction with constrictive hemodynamics, reduced blood pressure, jugular venous distention, and occasionally an S_3 or Kussmaul sign. Even pulsus paradoxus can appear, related to increased pericardial fluid or septal hyperresponsiveness to the respiratory cycle. These signs may individually depend on the pathophysiological "mix," that is, whether relative constriction due to pericardial tightening or increased intrapericardial pressure dominates. The lungs are usually clear. Thus, the clinical picture usually resembles constriction; with a pericardial rub and pulsus paradoxus it suggests tamponade.[213] Tricuspid regurgitation due to RV myocardial infarction may simulate or obscure a pericardial rub.

POST-MYOCARDIAL INFARCTION SYNDROME (DRESSLER SYNDROME)

This myocardial infarction-associated pericarditis does not require transmural infarction.[213] [234] Most patients have fever, a high sedimentation rate, considerable "pericardial" pain, pleuritis, and sometimes pneumonitis. Its usual onset is from 1 week to several months after clinical onset of myocardial infarction. Some patients have a remote history of pericarditis.[213] Like myocardial infarction pericarditis, the post-myocardial infarction syndrome occurs more often after larger, particularly anterior infarcts, inferior myocardial infarctions with RV myocardial infarction, and complicated myocardial infarctions. Post-myocardial infarction syndrome can appear as an extension of epistenocardiac pericarditis, with persistence or recurrence of rub and fever and with considerable malaise in contrast to myocardial infarction pericarditis, which is mild and transient. The usual gap from onset of myocardial infarction symptoms to the post-myocardial infarction syndrome suggests a necessary latent period. (Because approximately 30 percent of Q-wave myocardial infarctions are "silent," following them, post-myocardial infarction syndrome could appear as "idiopathic pericarditis" because post-myocardial infarction syndrome often resembles viral pericarditis.)

The incidence of post-myocardial infarction syndrome remains uncertain, but it is much less than the originally reported 5 percent of acute myocardial infarction.[235] Post-myocardial infarction syndrome occurs with and without antithrombotic treatment but may be more frequent in patients with pericardial bleeding, which can occur during myocardial infarction with or without an antithrombotic regimen.[234]

The post-myocardial infarction syndrome is often considered autoimmune, based on factors in common with other pericardial injury syndromes. These include a latent period, development of antiheart antibodies, and preceding pericardial injury (most cases have had epistenocardiac pericarditis), although it also occurs in nontransmural infarction and, therefore, without direct pericardial injury. Other factors include frequent recurrence; typical prompt response to antiinflammatory agents; frequent associated pleuritis with or without pneumonitis; changes in cellular immunity suggested by altered lymphocyte subsets compared with control patients; and evidence favoring immune complex formation incorporating antibody combined with myocardial antigen, complement pathway activation, and evidence of cellular as well as humoral immunopathic responses.[213]

CLINICAL FEATURES.

There may be considerable malaise, marked pleuritic pain, and frequently a rub, pericardial and pleural effusions, and fever up to 40°C (104°F). The ECG occasionally shows ST segment and T wave changes suggesting pericarditis superimposed on evolving myocardial infarction, but it is usually dominated by evolutionary myocardial infarction changes.[213] [234] Telltale PR segment deviations are a strong clue. Pericardial and pleural effusions may be serous or hemorrhagic. Leukocytosis is typically polymorphonuclear (occasionally eosinophilic). The ESR is virtually always high. Recurrence can be single or multiple over weeks or even years. Complications are uncommon but include tamponade relatively early. Late constriction is not surprising because of intrapericardial organization of exudate and blood that can also produce loculated effusions. Rarely, effusions can look purulent because of high neutrophil concentration; taken with the customary fever this mimics purulent pericarditis, but pericardial fluid is sterile.

MANAGEMENT.[213] [234]

Patients should be hospitalized and observed for tamponade, differential diagnosis, and adjustments of treatment, including rest and NSAIDs. Recurrences may require

a corticosteroid, which should be a last resort with early tapering to discontinuance.

TRAUMATIC PERICARDIAL DISEASE (See Chap. 51)

Pericardial Reactions to Physical Trauma

The heart and pericardium are only partly protected by the bony thorax.[236] [237] [238] A broad range of pericardial injuries evoke responses due to disruption of pericardial tissue and often adjacent and remote tissues. These may be immediate (cellular and vascular inflammation); delayed, including immunopathic (the post-cardiac--pericardial and myocardial--injury syndrome); and due to healing (adhesions, constriction, effusive-constrictive pericarditis). The inflammatory response may be sterile or infected with or without significant effusion. Traumatic tamponade, the most common cause of early death from cardiac wounds, usually is due to bleeding, producing early or late cardiac compression.[236] [237] [238] Survival with pericardial adhesions can lead to constrictive or effusive-constrictive pericarditis. Blunt (nonpenetrating) trauma, often more complex than penetrating trauma, occasionally causes cardiac and also pericardial rupture with herniation or entrapment of all or part of the heart. Pericardial laceration is not rare with severe blunt trauma, permitting cardiac displacement.

COMPLICATIONS.

Only occasionally does pericardial injury occur in isolation. Concurrent disease or injury of other organs, particularly the heart, modifies the clinical picture, physiological responses, the ECG, and all imaging modalities. These include injuries of the heart, great vessels (especially ascending aorta), conducting system, myocardium, mediastinum, and other chest and abdominal organs. Late pericardial and cardiac sequelae are common, including pericardial effusion, hemopericardium and tamponade, post-cardiac injury syndrome, false aneurysm, congestive failure, and constrictive pericarditis. They require monitoring and long-term follow-up.

Penetrating Trauma

TRAUMATIC AGENTS.

Knives, needles, bullets and high-velocity projectiles, intracardiac instrumentation, and cardiac surgery are the most common causes of penetrating trauma.[236] [238] [239] Bullets and shrapnel cause more damage than lacerating and puncturing instruments, the pathways of which may seal over. However, early tamponade is much more common in cardiac stab wounds than bullet wounds. (Nail gun injuries, a new category, require exploration.[240] [241] [242]) Any chambers can be involved, but the right ventricle is more common in anterior chest wounds. RA, RV, and great vessel wounds are quickest to tamponade and exsanguinate. The left atrium can be penetrated by posterior chest wounds and has been ruptured by external cardiac massage because of the pericardium's tight clasp of the left atrium. These wounds tend to bleed more slowly than wounds of other chambers and may produce hemothorax rather than hemopericardium or be localized to the adjacent oblique sinus (which may be hemodynamically significant). Anterior esophageal penetration by instruments or swallowed foreign objects such as bones and contaminated surgical instruments is likely to cause suppurative pericarditis. All bullet wounds are potentially infected.[243]

CLINICAL FEATURES.

With penetrating trauma the most common causes of immediate death are exsanguination or tamponade and often both. Some patients have rubs, but many do not, or rubs appear with pericardial bleeding and effusion (many patients have serous effusions[244]). ECGs are frequently unhelpful in assessing pericardial damage but may show typical or atypical stage I changes early or late (>24 hours). The principal cause of death--"surgical" tamponade due to hemopericardium or hemopneumopericardium--is difficult to diagnose because of blood loss, vasoconstriction, and frequent hemothorax that are not characteristic of "medical" tamponade. Pulsus paradoxus may be absent or disappear with severe hypotension and shock. There may be tachycardia and abnormal rhythms due to concomitant cardiac injury, or terminal electromechanical dissociation.

TAMPONADE AND HEMOPERICARDIUM.

Paradoxically, tamponade can be a correlate of survival.[245] Patients with tamponade reaching emergency departments appear to survive better than nontamponaded patients. The corollary is that untimely release of tamponade without thoracotomy can cause rapid decompensation because clotting of the pericardial hematoma can be hemostatic for cardiac wounds.[246] Thus, especially in unstable patients, thoracotomy in the emergency department or in the operating room is optimal for wound repair. Pericardiocentesis is a temporizing measure for unstable patients while simultaneously preparing for surgery and administering treatment for shock. In stable patients, thoracotomy, subxiphoid pericardial exploration, or video-assisted thoracoscopy are feasible with the option of extending to a full thoracotomy and, if necessary, laparotomy for abdominal wounds (which can also reach the pericardium).

IATROGENIC PERICARDIAL WOUNDS.

These are produced by cardiac surgery, percutaneous transluminal coronary angioplasty, stenting and pacing instruments, central venous and pulmonary flotation catheters, arrhythmia ablation, and even needles and catheters for pericardial drainage.[247] [248] [249] [250] Pericardial damage during percutaneous transluminal coronary angioplasty can occur with coronary artery dissections, producing local or general pericarditis with or without significant bleeding. Patients may present with new pain, a rub, or tamponade or with hemopericardium. Instruments and pacers may penetrate the right ventricle with or without pericarditic signs or hemopericardium.[246] Central venous catheters tend to penetrate the right atrium and rarely the SVC; fluids administered through them may provoke tamponade or exacerbate tamponade already due to bleeding. *Fetal tamponade* has complicated amniocentesis. Open surgical evacuation is often the optimal management, necessitating rapid transfer to the operating room or thoracotomy in the emergency department.[236]

FOREIGN-BODY AND FOREIGN-SUBSTANCE PERICARDITIS[236]

Smooth-edged foreign bodies less than 1 or 2 cm in diameter may be asymptomatic. Relatively large foreign bodies lying in or near the pericardium, such as metallic fragments, bullets, broken instruments, or needles, are associated with recurrent pericarditis and effusion; they need not penetrate the heart. Asbestos poudrage for coronary disease and cardioverter-defibrillator patches have provoked dense calcification. Silicon-contaminated pacemaker insertion can provoke an exuberant pericardial foreign-body reaction, including giant cells. All can progress to tamponade, adhesions, or constriction. Definitive treatment is removal of the foreign material and any significant adhesions and fluid. Postpericardiotomy syndrome may follow.

SURGICAL PERICARDIAL INFLAMMATION AND EFFUSION[245] [251] [252]

Mild pericarditis and low-grade fever, usually with some bleeding and effusion, are common postoperatively and proportional to the amount of pericardial manipulation, which regularly causes loss of mesothelial cells and provokes fibrinous and leukocyte exudation; significant blood leukocytosis may indicate infection.[245] The ECG tends to reflect

this with minor nonspecific or local ST segment changes, yet often with generalized changes that usually do not evolve beyond stage I. Early pericardial effusions are common, tend to appear by the fifth postoperative day, are usually small (<1 cm echo depth), are usually benign, and are frequently associated with a left pleural effusion. Moderate effusions (1-2 cm) are less common, and large effusions (>2 cm) are uncommon. Large and especially increasing early effusions, usually due to bleeding and more common after valve surgery, are harbingers of tamponade. Late effusions (6-60 days after surgery) may also be due to bleeding, especially in patients taking anticoagulants[253] or with a coagulopathy or due to the osmotic ("hydrophilic") effect of slow intrapericardial clot lysis or to immunopathic responses to cardiopericardial trauma.[236]

POSTOPERATIVE TAMPONADE

Nearly all clinically significant effusions are present by the fifth postoperative day. Circumferential and especially localized tamponade remain challenging diagnostic and therapeutic problems.[236] Anticoagulation is associated with tamponade at any time; its principal importance is in the first 3 to 5 days when hemopericardium is most common. Late tamponade, often associated with postpericardiotomy syndrome, is probably inflammatory or immunopathic.[253] Although classic diagnostic signs of tamponade may be present postoperatively, familiar clinical signs such as pulsus paradoxus are often absent. Similarly, echocardiographic and Doppler signs retain their specificity but their sensitivity is greatly reduced.[219] ECG changes are common and of no help whereas the swinging heart and electrical alternation are

uncommon (probably due to adhesions). Thus, atypical presentations of tamponade should be anticipated by liberal monitoring of vital signs and catheterization data as well as by echocardiography for chamber collapses and other evidence. TEE is superior to TTE for both tamponade and pericardial thickening.[251] [254]

DIFFERENTIAL DIAGNOSIS.

Tamponade must be differentiated from extrapericardial causes of low cardiac output, including[245] (1) ventricular hypokinesis with left, right, or combined ventricular failure; (2) acute LV or RV myocardial infarction; (3) pulmonary embolism; (4) coronary insufficiency; (5) effects of prolonged aortic cross-clamping or inadequate coronary perfusion during cardiopulmonary bypass; (6) severe pulmonary artery hypertension; (7) septic shock; (8) hepatitis (enzyme abnormalities, passive hepatic congestion or injury); or (9) mediastinal hematoma or effusion causing extrapericardial cardiac compression. Apart from elastic constriction[255] by clotted hemopericardium, constrictive pericarditis is not an early consideration but can occur as soon as 2 to 7 weeks (usually much later). Acute cardiac dilatation within a repaired pericardium will have a comparable affect. Each may appear as unexplained dyspnea.[236] [256]

MANAGEMENT. [236]

Operative pericarditis and effusions respond quickly to brief therapy with a corticosteroid or NSAID. Coagulation status and platelet levels should be monitored. Early postoperative tamponade is a surgical emergency usually requiring thoracotomy; later tamponade may respond to drainage and observation. Either type can present as sudden deterioration so that clinically and hemodynamically significant effusions of any size should be drained; urokinase or streptokinase can be instilled to aid drainage and inhibit adhesions if further bleeding is ruled out. Coronary bypass grafts are endangered by any blind procedure. Surgical drainage or video-monitored thoracoscopy may be optimal, as determined by particular fluid loculations disclosed by TEE.

Postoperative Pseudoaneurysm.[236] [257]

False aneurysms occasionally follow cardiac surgery, especially when a chamber has been vented. These resemble pseudoaneurysms after myocardial infarction.

OTHER. [236] [258] [259]

Open-chest *cardiac massage* traumatizes the epicardium, increasing susceptibility to infection, pericardial effusion, tamponade, and ultimate constriction. Removal of *epicardial pacing wires* is usually effected without untoward event, but an epicardial vein or other structure may be traumatized, producing hemopericardium.

CHEMICAL INJURY.

More or less sterile chemical injury to pericardium may follow unusual communications of the biliary tract, pancreas, and esophagus, particularly after sclerotherapy of esophageal varices.[260] Pancreatitis may be accompanied by pericardial irritation and effusion even without communication; this is ascribed to hematogenous and lymphogenous transport of pancreatic enzymes to the pericardium.

ELECTRICAL TRAUMA. [236] [261]

After lightning strikes, with well-known cardiac consequences, occasional survivors have had pericardial effusion with tamponade or recurrent pericarditis. The latter may be a kind of post-cardiac injury syndrome.

Indirect (Blunt/Nonpenetrating) Pericardial Trauma

Indirect injuries to pericardium, heart, and lung are often more complex than those from penetrating trauma.[236] Blunt trauma to the chest and abdomen follows nonpenetrating thoracic impacts, compression (crush), blast, and traumatic deceleration, producing an injury spectrum from contusion to rupture of the heart, the pericardium, or both.[262] Closed-chest cardiac massage even without rib fractures can also traumatize the heart and pericardium.[259] Any cardiac damage, including exacerbation of antecedent heart or pericardial disease, may complicate a range of pericardial injury, including acute, "clinically dry" pericarditis, or hemopericardium with or without tamponade, pneumopericardium, early and late constriction, and recurrent pericarditis.[236] Indirect forces can displace numerous viscera and may cause the heart and great vessels to acutely "trap" more blood than usual, with directional stresses capable of rupturing the pericardium and other structures. A common cause is deceleration forces, characteristic of transportation-associated accidents, acting in any plane or tangentially. Death usually follows cardiac rupture with acute hemopericardium or pericardial rupture and acute extrusion (herniation; luxation) of some or all of the heart. In general, the more serious the cardiac injury, the more serious the pericardial injury. This may occur in the absence of significant external marks. Isolated parietal pericardial rupture with or without cardiac contusion from blunt injury or after cardiac resuscitation is not rare at autopsy. Fibrinous pericarditis often with some hemorrhage is common. Subacute or late constriction may follow hemopericardium or purulent pericarditis from days to years after injury.

PERICARDIAL LACERATION.[236] [262]

Parietal pericardial tears are frequent, especially after falls and other deceleration injuries. Lacerations are rarely isolated or clinically silent; characteristically, cardiac injury accompanies the laceration. The most serious consequence is cardiac herniation: extrusion of all or part of the heart in any direction but usually into the left pleural cavity, frequently with mediastinal and tracheal shift. Herniation is characteristically sudden and nearly always a surgical emergency. (After 72 hours, herniation tends to be restrained by adhesions.) Rupture and laceration of the parietal pericardium occur mainly at either its diaphragmatic or pleural abutments or both.

CLINICAL CONSIDERATIONS.[236] [263] [264]

Symptoms occurring after blunt trauma can be nonspecific or multiple, with and without dyspnea or anterior chest or abdominal pain, and may be overshadowed by injuries elsewhere. In hemorrhaging and other hypovolemic trauma patients, an initial favorable response to fluid administration may obscure and delay recognition and treatment of tamponade. All significant or potentially significant chest injuries require careful monitoring for progression or sudden cardiocirculatory deterioration. Nonpenetrating trauma can produce all of the cardiocirculatory physical findings of penetrating trauma and surgical injuries. A pericardial rub, easily missed, may be the only physical sign. Hypotension is the rule, and pulsus paradoxus must be diligently sought but is often deceptively absent. Free air in the pericardium rises to the upper sac. Cardiac contusions may be identified by indium-111 antimyosin scintigraphy. The ECG commonly shows only ST-T wave changes, which occasionally suggest, but only rarely are typical of, acute pericarditis. With cardiac displacement, the QRS axis may shift and occasionally become unusual; there may be altered precordial R wave progression.

IMAGING.[236] 263a

Chest radiographs, preferably with the patient upright, demonstrate any rib and sternal fractures, gas collections, atelectasis, tracheal shift, and displacement

of a herniated heart. There may be intrapericardial migration of abdominal organs with unilateral (usually left) diaphragmatic elevation and unusual supradiaphragmatic densities, lucencies, and organ shadows. Rarely, patients do not develop symptoms for months, years, or ever. Echocardiography, optimally TEE, is indispensable and so sensitive that a negative high-quality study significantly decreases the likelihood of complications and sequelae. It will disclose pericardial effusion and fibrinous exudate, RV dilation, ventricular (especially RV) thrombi, and traumatic true and false aneurysms.[263] CT or MRI can discriminate hemopericardium by its density and disclose other cardiac and vascular injuries, angulations, and dilations as well as acute hepatic lymphedema due to cardiac or inferior vena cava compression.[236] Video-assisted thoracoscopy is most specific for selecting appropriate sites and extent of thoracotomy incision.[262A]

MANAGEMENT.

Repositioning the patient may permit restitution of a herniated heart's position. Definitive treatment is repair of wounds especially of the heart and vessels and repositioning of displaced organs. The pericardium may have to be sutured, patched, or resected; and some pericardial lacerations may be enlarged to reposition the heart, especially if it dilates.[264]

Post-Cardiac Injury Syndrome; Postpericardiotomy Syndrome

The post-cardiac injury syndrome develops days to months after cardiac and pericardial injury.[236] [253] It so strongly resembles the post-myocardial infarction syndrome that they both appear to be variants of a common immunopathic process. The post-cardiac injury syndrome differs from the post-myocardial infarction syndrome because it acutely provokes a much greater antiheart antibody (AHA) (antiactin and antimyosin) response, probably related to more extensive tissue trauma and more concentrated release of antigenic material.[236] Because even surgery limited to the pericardium can cause the post-cardiac injury syndrome, it is commonly denoted "postpericardiotomy syndrome."

PATHOGENESIS.

Myocardial injury releases cellular constituents, possibly autoantigens provoking an autoimmune antibody reaction by AHAs; complement is activated, C3 and C4 levels fall, and leukocytes are mobilized. In the postpericardiotomy syndrome, AHAs appear to be pathogenic in the presence of a dormant or concurrent viral infection that "permits" them to act.[236] (Some trigger is necessary because AHAs alone may not be pathogenic.) A quantitative effect of AHAs is seen in the proportionality between occurrence of the postpericardiotomy syndrome and extent of surgery; correction of congenital defects and of the Wolff-Parkinson-White syndrome have the highest relative incidences. (Postpericardiotomy syndrome after strictly pericardial surgery may challenge the immunopathic hypothesis because no antipericardial antibodies have been identified.) Evidence that post-cardiac injury syndrome/postpericardiotomy is immunopathic includes the following: preceding latent period; frequent recurrences; stimulation of AHAs and complement activation; prompt response to corticosteroids; and clinical characteristics of fever, pulmonary infiltrates, frequent pleuritis (rarely the only sign),[245] and systemic inflammatory symptoms and signs. The "complete" post-cardiac injury syndrome/postpericardiotomy syndrome correlates well with higher titers of AHAs and is rare in patients younger than age 2, possibly owing to hyporeactivity or carryover protection from the mother's immune defenses. The incidence decreases at advanced ages, possibly related to an immune system that has had more extensive encounters with a variety of microorganisms and/or is senescent and therefore hyporeactive. The extent of myocardial damage is not absolutely correlated with provocation of the post-cardiac injury syndrome/postpericardiotomy syndrome.

CLINICAL ASPECTS.[236] [253]

The post-cardiac injury syndrome and postpericardiotomy syndrome differ from the usually self-limited postoperative or posttraumatic pericarditis in that more patients develop a form of post-cardiac injury syndrome than clinically significant postsurgical pericarditis. The postinjury latent period usually lasts a week to 6 months, with symptoms and signs more severe, disabling, and prolonged (days to weeks per attack) than uncomplicated posttraumatic pericarditis, although few develop tamponade or constriction. Pericardial fluid tends to be serosanguineous. Recurrences are characteristic, mainly within 6 months of the index attack. Among patients without congenital heart disease, the post-cardiac injury syndrome/postpericardiotomy is more frequent in those with a history of either pericarditis or corticosteroid therapy (especially for rheumatoid arthritis), after aortic valve replacement, and in those with B-negative blood. Most patients have tachycardia, malaise, pleuritic pain, new pericardial and sometimes pleural rubs or both, and mild lymphocytosis or granulocytosis; all patients have low-grade fever, which may simulate a continuation of postoperative or postinjury fever.[236] Most postsurgical pericardial rubs should disappear within a week. The post-cardiac injury syndrome/postpericardiotomy syndrome is considered "complete" if fever, pericarditis, and laboratory evidence of inflammation are present and "incomplete" with only two of these.

DIAGNOSIS. [236] [253]

In general, post-cardiac injury syndrome/postpericardotomy syndrome must be considered in patients who after 6 days after surgery or trauma develop fever above 37.8°C (100°F) for over 8 hours with significant pleuritic anterior chest pain and a pericardial rub or two of these, usually with an ESR greater than 40 mm/hr and leukocytosis greater than 11,000 cells/mm[3] . The echocardiogram usually shows a small to moderate pericardial effusion. Chest radiographs show left or bilateral pleural effusion in most patients and right pleural effusion in a few. The cardiopericardial silhouette may be enlarged, and a few patients have pulmonary infiltrates. The ECG usually reflects myocardial abnormalities. Principal differential diagnoses of post-cardiac injury syndrome/postpericardiotomy syndrome include (1) other causes of postoperative fever including infections and pneumonitis, (2) pulmonary embolism, and (3) myocardial infarction. Perhaps half the patients have ECG changes consistent with acute pericarditis. If new changes are inconsistent with infarct or pericarditis, radionuclide scanning or comparable studies may be useful.

MANAGEMENT. [236] [253]

The post-cardiac injury syndrome/postpericardiotomy syndrome usually responds within 48 hours to therapy with aspirin or another NSAID, which should be maintained for 10 days. Corticosteroid therapy is reserved for patients with unresponsive severe symptoms. The unusual tamponading effusion must be drained. Recurrences are often worse than the index attack and should be managed similarly, adding colchicine as tolerated if NSAIDs alone appear ineffective. Pericardiectomy is reserved for intractable effusions that may increase (despite even corticosteroid therapy) and for constriction.

PERICARDIAL SEQUELAE.

Pericardial adhesions are generally proportional to the extent of epicardial and pericardial injury and any residual blood after drainage.[245] Loculated effusion or hemorrhage may become manifest early or months postoperatively. Continued inflammatory activity can induce constrictive pericarditis, usually after months to years. Recurrent pericarditis, probably autoimmune, with or without effusion, may follow any pericardial injury, including radiation pericarditis and even pericardial resection. Pseudoaneurysm is rare.

OTHER PERICARDIAL DISEASES

Aortic Dissection and Intramural Hemorrhage (See Chap. 40)

Aortic dissection, DeBakey types I and II, and aortic intramural hemorrhage often rupture into the pericardium.[213] [265] [266] [267] They are almost indistinguishable clinically; this discussion applies to both. Rupture is the most frequent cause of death due to aortic dissection, usually through tamponade with intrapericardial clotting preventing nonsurgical drainage. There is always over 100 ml of blood and usually 400 to 1500 ml.[235] [266] Subacute and chronic bleeding is tolerated with smaller leaks and mitigation by medical treatment of aortic dissecting and shearing forces.[268] A protracted course may allow dilution by pericardial effusion, owing to pericardial irritation and the osmotic affects of intrapericardial hemolysis.

CLINICAL FEATURES.[213] [266] [267]

The ECG is seldom normal and may show preexisting LV hypertrophy, acute ischemia, or myocardial infarction. Pericardial irritation by blood that first dissects under the epicardium can provoke a rub and occasionally compress coronary arteries, causing myocardial ischemia and infarction. Occasionally, the ECG resembles stage I acute pericarditis. Occlusion of renal arteries combined with hypotension can produce acute uremic pericarditis. Indeed, dissecting hematoma may first present hours to many days before frank rupture as "acute pericarditis" and without pain typical of dissection,[213] [267] suggesting idiopathic pericarditis, which is much more common. In such relatively slow dissections, misleading ST segment elevations can also be due to release of potassium from intrapericardial hemolysis. In older patients with a history of hypertension, acute pericarditis should always be considered part of another syndrome. In younger patients, in whom idiopathic pericarditis is generally more common, signs of Marfan syndrome[267] or other inherited connective tissues disease or aortic coarctation should be sought. Both aortic regurgitation and dissecting aneurysm are more common in patients with bicuspid aortic valves, congenital aortic stenosis, and coarctation with rib notching on the chest film.

Precise diagnosis as in all acute conditions should be as rapid as practical because of the narrow "windows" for aortic rupture and myocardial salvage. Echocardiography, preferably omniplane TEE (as sensitive as CT and MRI) is optimal to detect pericardial effusion, aortic regurgitation, a false lumen, and an aortic intimal flap. If echocardiography is negative or indecisive, CT, especially helical CT, or spin-echo MRI, which is time consuming and logistically difficult, will usually define aortic mural hemorrhages and intimal flaps.[269] They are safer and more sensitive than aortography (which occasionally becomes necessary[270]). All imaging techniques show pericardial effusions due to aortic dissection usually to be anterior.

MANAGEMENT.

The most efficient management when dissection is likely is to do diagnostic procedures in the operating room. Percutaneous pericardial drainage often gives only

temporary or no relief, with increase in blood pressure disrupting sealing clots and accelerating intrapericardial leakage, causing frank hemopericardium, shock, electromechanical dissociation, and death. Definitive treatment is surgical relief of tamponade and repair of the aorta. Rarely, aortic dissection involving the pericardium heals spontaneously. Constrictive pericarditis has resulted as early as 7 months later.

PULMONARY THROMBOEMBOLISM AND PULMONARY HYPERTENSION

Pericardial involvement after pulmonary infarction is uncommon. It can be (1) apparently due to contiguity; (2) a complication of antithrombotic therapy for pulmonary embolism; (3) a simultaneous event in pulmonary embolism after trauma including cardiac or other surgery; and (4) rarely, an apparent immunopathy with a pericardial component closely mimicking the post-myocardial infarction syndrome.[271] [272] Infarction of pulmonary segments adjacent to the pericardium can produce pleuropericardial rubs. These are strictly exopericardial and even classic rubs, which rarely may be the first sign of a pulmonary embolus,[213] with or without pleuritic pain. After blunt or penetrating chest trauma or cardiac surgery the mixed picture may be difficult to unravel. Massive pulmonary embolism, such as primary pulmonary hypertension,[271] has been attended by hydropericardium presumably due to right-sided heart failure; such cases may have a conus rub due to acute cor pulmonale without pericarditis. Finally, since pulmonary embolism can be asymptomatic, signs of acute "idiopathic" pericarditis or effusion should alert physicians to search for it in patients who have risk factors for embolism. In general, disorders dilating the right side of the heart increase pericardial constraint of the entire heart, mimicking constriction, and with hydropericardium suggest tamponade, especially with left-sided chamber collapses,[272] which can also be associated with purely pleural effusions.[273]

POST-PULMONARY INFARCTION SYNDROME.[274]

Rarely after pulmonary embolism, acute pericarditis with or without effusion appears as a syndrome closely resembling post-myocardial infarction syndrome with strictly pericardial rubs, fever, leukocytosis, elevated ESR, frequent pericardial and pleural effusions, and, rarely, tamponade. Like the post-myocardial infarction syndrome and other immunopathies this syndrome responds to antiinflammatory treatment, particularly rapidly to a corticosteroid. NSAIDs should be tried first.

PERICARDIAL INVOLVEMENT IN GASTROINTESTINAL DISORDERS

ESOPHAGEAL DISEASE.[245]

The esophagus overlies the pericardium covering parts of the left atrium and ventricle. Esophageal disorders can involve the pericardium, often catastrophically, frequently with little or no warning, and almost always confusingly because of what appears to be isolated pericardial or cardiac disease or combined esophageal and cardiopericardial signs and symptoms. Most patients who are "candidates" for pericardial involvement include those who have had esophageal surgery and other trauma, gastroesophageal reflux, Barrett esophagus, hiatal hernia, and esophageal strictures. The pericardium is directly involved by fistulas from processes penetrating the esophageal wall such as inflamed esophageal diverticula. These include inflammation (e.g., esophagitis and peptic, bacterial, viral, and fungal ulcers), neoplasms, perforating foreign bodies, corrosive ingestants, and "spontaneous" esophageal rupture. Esophagopericardial fistulas also develop from inflamed surgical and anastomotic suture lines in the esophagus and in patients with colonic interposition for esophageal lesions, resulting in a "thoracic colon"-to-pericardial fistula.

CLINICAL FEATURES.

Symptoms and signs depend on the structures involved, including the pericardium itself. Patients may have acute pericarditis, pericardial effusion, pneumopericardium, pneumohydropericardium, or pneumopyopericardium with or without tamponade; any may be the presenting syndrome, including purulent pericarditis, preceding discovery of the fistula. Effusions are usually small and often loculated by adhesions from chronic inflammation. Esophagopericardial fistulas also follow chemical and physical trauma of the esophagus as well as malignancies, including esophageal, pulmonary, or rarely metastatic, and their radiation therapy. Usually there is a history of chronic peptic esophagitis, esophagogastric surgery, or malignancy. Pain can be retrosternal, in the left chest, or in the shoulders or interscapular. Most patients have fever, many have rubs, and patients with acute cases have shock, dyspnea, and cyanosis, any of which can be the initial symptom. A clue is discovery of a pneumohydropericardium or pneumopyopericardium with a "splashing mill wheel" sound. Whereas polymicrobial pericarditis[276] [277] is common, blood cultures may not be positive.

DRUG- AND TOXIN-RELATED PERICARDIAL DISEASE

Certain medications, toxic substances, and some irritants contacting the pericardium can induce acute or subacute pericarditis and effusion, tamponade, adhesions, fibrosis, or constriction (Table 50-13) .[278] Anticoagulants and thrombolytic agents may cause an inflamed pericardium to bleed with tamponade or eventual adhesions and constriction, but this is not a specific "pericardiotoxic" effect. Drug and toxin responses are mostly acute pericarditis, inflammatory effusion, or, less commonly, hydropericardium. The importance of these relatively uncommon "pericardiopathies" is their diagnosis and its corollary: excluding other pericardial diseases. Most agents in Table 50-13 are used to treat specific diseases, many of which themselves can cause pericarditis or effusions. In general, acute reactions to these agents resolve when exposure ceases, but some can go on to constriction or recurrent pericarditis. Disorders for which many are given include malignancies, infections, and renal failure, each of which can cause pericarditis. Moreover, distinguishing drug- or toxin-induced pericarditis from idiopathic pericarditis is crucial so that exposure to a pericarditis-inducing agent must be considered in the differential diagnosis of idiopathic pericarditis. For every new case of pericarditis, a thorough history includes exposure to any drugs or noxious agents. Mechanisms include lupus reactions,[279] idiosyncracy,[280] "serum sickness," [281]

TABLE 50-13 -- DRUG- AND TOXIN-RELATED PERICARDIAL DISEASE

A.Drug-induced lupus erythematosus
Procainamide
Tocainide
Hydralazine
Methyldopa
Mesalazine
Reserpine
Isoniazid
Hydantoins (phenytoin, dantrolene)
? Quinidine
B. Hypersensitivity reaction (often with eosinophilia)
Penicillins (ampicillin, procaine penicillin)
Cromolyn sodium
? Praziquantel
C. "Idiosyncratic" or hypersensitivity

Methysergide
Minoxidil (?also lupus)
Practolol
Bromocriptine
Psicofuranine
Polymer fume inhalation
Cytarabine
Phenylbutazone
Amiodarone
Streptokinase
p-Aminosalicylic acid
Thiazides
Streptomycin
Thiouracils
Sulfa drugs
Cyclophosphamide
Cyclosporine
Amiodarone
Mesalazine (Rowasa)
5-Fluorouracil
Vaccines
Smallpox
Yellow fever
Granulocyte-macrophage colony-stimulating factor

D. Anthracycline derivatives

Doxorubicin
Daunorubicin

E. Serum sickness

Foreign antisera (e.g., antitetanus)
Blood products

F. Venom

Scorpion fish sting

G. Foreign-substance reactions (direct pericardial application)

Talc (magnesium silicate)
Silicones
Tetracycline and other sclerosants
Asbestos

H. Secondary pericardial bleeding/hemopericardium

Anticaogulants
Thrombolytic agents

---

foreign substance reactions, and immunopathy[282] (see Table 50-13) .

IDIOPATHIC PERICARDITIS: PERICARDITIS OF UNKNOWN ETIOLOGY (NONSPECIFIC PERICARDITIS)

No disease is sui genres (i.e., truly idiopathic); rather, etiology is not demonstrable at the contemporary state of knowledge. "Idiopathic" now means "of unknown etiology," usually a syndrome resembling viral pericarditis.[283] Idiopathic pericarditis, that is, any attack resolving without diagnosis, is the most common form of acute pericarditis. However, many diseases can present first as a pericardial disorder. Examples include the vasculitis/connective tissue disease group in which a pericarditic initial presentation is not recognized, particularly lupus; unrecognized myocardial infarction first becoming symptomatic as myocardial infarction pericarditis or even post-myocardial infarction syndrome; aortic dissection; primary and metastatic malignancies; pulmonary embolism; some forms of acute tuberculous pericarditis; Lyme disease; traumatic pericarditis appearing late after trauma, including radiation pericarditis; the seronegative spondyloarthropathies and intestinal inflammatory diseases; acute pancreatitis first presenting as pericardial effusion. Rare diseases exemplify the extreme etiological range, for example, "yellow-nail syndrome," eosinophilic fasciitis (with pericarditis preceding eosinophilia), and celiac disease with dermatitis herpetiformis[284] (here recurrent pericarditis responds to a gluten-free diet). Whereas undiagnosed acute pericarditis with or without effusion often is safely attributed to viral infection, the remarkable range must be considered. Recurrent "idiopathic" pericarditis tends to follow a pattern seen in viral pericarditis. With a missed, (but nonviral) pathogenesis, the causal disease surfaces after the index pericarditis or during a recurrence.[283] In all large prospective studies of patients with acute pericarditis, the largest single group, often the majority, is "idiopathic," often because there have not been comprehensive searches for evidence of viral infection or systemic diseases such as lupus. Treatment is as usual for acute, clinically dry pericarditis and for effusion and tamponade as needed. Eventual identification of any specific pathogenesis requires adequate follow-up and specific treatment.

RECURRENT AND INCESSANT PERICARDITIS

Perhaps 15 to 20 percent of patients do not recover permanently after an initial attack of acute pericarditis. Although exact incidences and natural histories are uncertain, most patients have had acute idiopathic, presumably or manifestly viral, pericarditis; in them, recurrent pericarditis, or continuously active incessant pericarditis, that is, mainly recurrent or incessant pericardial pain, appear to be immunopathic processses.[285] "Incessant" designates pericarditis (or identical pain) in patients who continuously need treatment to suppress symptoms. This can be extended to those who are free of symptoms for periods of less than 6 weeks, an arbitrary figure because of the usual failure of pericardiectomy to end these painful chronic syndrome. Postoperatively, nearly all patients have a brief, unexplained symptom-free 1- to 6-week period (a few patients either appear to be cured completely or for months to years before symptoms return).[285] It is possible that meticulous removal of nearly all the pericardium (pedestals must be left for the phrenic nerves) may yield improved results, but very long follow-up is needed. Anecdotal evidence suggests better results in the less common cases with recurrent pain who also have recurrent effusions.

INCESSANT PERICARDITIS.

This condition involves continuous activity surfacing when antiinflammatory, usually corticosteroid, therapy is reduced or discontinued. Most such patients may be said to be "steroid hooked," [285] a term of art, more dramatic than "steroid dependent," to reflect their desperation. In a minority, repeated or chronic exposure to the inciting agent or process is clearly responsible for recurrences, such as viral and bacterial reinfection (or reactivation of dormant organisms)[283] [284] [285] and, more commonly, systemic disorders, notably the vasculitis/connective tissue disease group, especially lupus. Certain pathogenetic possibilities may apply to recurrent and incessant pericarditis: (1) inadequate antiinflammatory treatment of the index or subsequent attack; (2) corticosteroid treatment given early during active viral multiplication that promotes and prolongs viral infection; (3) poorly understood cyclic immune or autoimmune responses to specific or nonspecific agents and processes such as respiratory infections or fatigue; and (4) viral RNA sequences in pericardial tissue acting as constant sources of antigen, although not themselves capable of replication.

RECURRENT IDIOPATHIC PERICARDITIS.

"Idiopathic pericarditis" is usually of viral origin because its recurrences are virtually the same syndrome as recurrences after demonstrably viral pericarditis.[262] Recurrent idiopathic pericarditis is perhaps the greatest therapeutic challenge among all pericardial disorders and encompasses both intermittent and incessant forms. Recurrent idiopathic pericarditis and sterile recurrences after viral pericarditis are uncommon without a background of initial or continuing corticosteroid treatment. Characteristically, the incessant form has a threshold level of prednisone below which relapse is certain. Significant effusion is uncommon, and tamponade is rare during recurrences. Constriction appears not to occur in those without effusions.[285] Most recurrent pericarditis seems to represent individual pericardial reactivity to a variety of poorly understood pathogenetic processes and their corticosteroid suppression.

PERICARDIAL IMMUNOPATHY.

Strong evidence that most recurrent pericarditis is immunopathic includes[8] (1) latent period after the index attack lasting days to years but usually months; (2) AHAs in some cases, probably those with significant myopericarditis in the index attack; (3) similarity to illnesses such as the post-myocardial infarction and postpericardiotomy syndromes (related to no. 2); (4) frequent allergic personal and/or family history; (5) rapid response to corticosteroid therapy and relapses with decreasing dose or discontinuance; (6) acute recurrent pericarditis during allergic disorders such as reactions to drugs and in celiac disease and dermatitis herpetiformis to foods with gluten; (7) acute recurrent pericarditis in classic serum sickness, including reactions to immunizations (e.g., for smallpox, yellow fever, hepatitis); (8) recurrent pericarditis in diseases of demonstrably autoimmune pathogenesis such as lupus; (9) occasional occurrence with other serositis, mainly pleuritis and rarely peritonitis; (10) frequent arthralgias especially in the post-myocardial infarction and postpericardiotomy syndromes as well as arthritis in the vasculitides; and (11) occasional eosinophilia.

CLINICAL ASPECTS.

Recurrences vary from one to dozens over periods of weeks to decades. In no individual cases are patterns of recurrence precisely predictable except during corticosteroid weaning with an established threshold level for recurrence. Some patients can predict a relapse, and symptoms are usually stereotyped for each patient. All have pain resembling pain of the index attack often with strong pleuritic components, which is best described as "annoying" and "disabling" making life unpleasant. Objective manifestations are much less uniform and, while frequently detectable in the first recurrence, often become less common.[285] If significant effusion does not accompany the first recurrence, it is less likely subsequently. Exceptional patients have increasing severity in recurrences during which tamponade may first appear.

Recurrent idiopathic pericarditis is frequently of remote viral origin. Enterovirus-specific IgM responses have been found in many patients with chronic relapsing pericarditis, whereas comparable patients after acute enterovirus, mainly coxsackievirus B, infections elsewhere have only transient evidence of viral infection. Yet, among patients with acute pericarditis the level of IgM antibody was significantly higher in those who later experienced relapse. Host genetic factors are suggested by significantly higher levels of HLA-A2 haplotypes in those who were IgM positive (although extracardiac sites of viral persistence could not be excluded).[285] Thus, many patients with recurrent pericarditis experience persistent viral antigenic stimulation. Recurrences frequently follow new exposure to or infection by viral illnesses. It is not clear why constrictive pericarditis can follow a single attack of viral pericarditis while recurrent pericarditis after repeated comparable "idiopathic" attacks appears not to constrict.

NONIDIOPATHIC RECURRENT PERICARDITIS.

Although rare, it is axiomatic that reexposure of susceptible patients to bacterial, particularly tuberculous, and other infections can result in recurrent pericarditis[285] [286] [287] and constriction can ensue. Hemopericardium, particularly with pericardial injury, can be associated with recurrent pericarditis.[285] The post-cardiac injury syndromes are especially prone to recurrence. The most important systemic disorders are the vasculitis/connective tissue disease group, especially lupus. In young patients with beta-thalassemia, the frequency of recurrent pericarditis remains unexplained. Recurrent pericarditis with inflammatory bowel disease is on a fairly firm immunopathic basis, as is that accompanying dermatitis herpetiformis, with immune complex deposition as a common basis of recurrent pericarditis.[285] The recurrent polyserositis of familial Mediterranean fever involves the pericardium less often than other serosae and only rarely constricts. Recurrences are in the group with hypersensitivity and manifest "allergy" usually after exposures to ingestants, inhalants, and injectants.

MANAGEMENT.

For a confirmed etiology there may be specific therapy. For most patients with recurrent "idiopathic" pericarditis, treatment has been difficult. Patients with the incessant form remain corticosteroid dependent. Patients with the intermittent form require treatment only for relapses. Thus the most important preventive consideration is to avoid corticosteroid therapy if possible and to wean patients judiciously from a corticosteroid, relying on aspirin or other NSAIDs, particularly ibuprofen. Immunosuppressive and cytotoxic drugs used in oncology and organ transplantation[288] have not proved effective for recurrent pericarditis. Any effective NSAID may be tried at the lowest adequate dose. Observation is required for gastrointestinal and other side effects, including renal damage particularly in older patients. The largest challenge, requiring high NSAID doses, its to wean "steroid hooked" patients. Without appropriately designed controlled trials, absolute recommendations cannot be given. "Experience" is a potentially useful alternative. It appears that escalating doses of ibuprofen while slowly reducing prednisone gives good results. Treatment must be individually fine tuned. A "standard decrement" of 1 mg of prednisone permits individualized determination of the intervals between dose reductions (e.g. 1 week to 2 months) while introducing colchicine[289] ; and increasing ibuprofen doses beginning with 800 mg every 8 hours, if the patient can tolerate it under careful observation and gastrointestinal mucosal protection.

Recurrent Pericardial Effusion.

If large or with any degree of tamponade, these should be drained by catheter for several days, while maintaining drug therapy.[285] Failure indicates pericardiectomy.

Exercise Restriction.

Personal experience suggests that exercise contributes to exacerbations and recurrences and that restriction of exercise can be a decisive component of treatment in these difficult cases. Absence of appropriately designed controlled trials limits the objectivity of exercise restriction. It is uncertain exactly how to "prescribe" this, but it seems worthwhile.

Radiation Pericardial Disease

Radiation therapy, particularly for Hodgkin disease and other lymphomas and malignancies of the breast, lung or thyroid, involves the pericardium variably, depending on radiation dose, duration of treatment, volume of heart in the field, and radiation source.[236] [290] [291] Incidence increases with survival and follow-up time. (Improved radiation dosing delivery and subcarinal shielding have decreased pericardial involvement.) Peak incidence remains 5 to 9 months after radiation therapy. Prognosis is generally favorable for the pericardial lesion. But, because most significant pericardial involvement is delayed, irradiated patients remain indefinitely susceptible.

PATHOGENESIS.

Of all cardiac structures the pericardium is most susceptible to radiation injury, with pericardial syndromes sometimes complicated by injury of the myocardium, coronary arteries, or valves. Although direct radiation injury can be demonstrated, most patients escape significant involvement, raising questions of triggering latent antigens or viral infections, particularly in the delayed forms. Effusions may be serous, sanguineous, or serosanguineous with high concentrations of protein and lymphocytes resembling malignant effusion.[245] Late thickening is more conspicuous in the parietal pericardium with or without occult or obvious constriction. Microvascular ischemia and collagenization of fibrinous exudates contributes to pericardial fibrosis. Radiation involving more than 50 percent of heart volume and delivering over 2500 rads, or 40 to 60 Gy, increases risk with increasing dose and volume of heart irradiation.

CLINICAL ASPECTS.[236] [290]

Involvement extends from immediate to variably delayed acute, subacute, and especially chronic syndromes. Acute pericarditis, with or without tamponade, is uncommon, but pericardial rubs are frequent during or within weeks of therapy. Oddly, acute syndromes do not correlate with late disease. Echocardiography shows some effusion in all patients with clinical findings. Subacute disease may appear over months, including effusion, constriction, or effusive-constrictive pericarditis. More common are chronic effusion or constriction, even after years of latency, so that other disease must be considered separately or as a precipitant, raising the question of whether radiation injury makes the pericardium more susceptible to infections. Occult constrictive pericarditis (see p. 1853) is relatively common and identified by catheter monitoring of an intravenous saline challenge.

DIAGNOSIS.

Although CT and MRI are more sensitive and specific, TEE is excellent to define the anatomical lesions.[236] Occult constriction may be overlooked in patients with nonspecific complaints (exertional dyspnea, edema, chest pains), which may be attributed to their primary illness. However, radiation therapy is the major cause of combined pericardial constriction and restrictive cardiomyopathy,

with the latter a notorious cause of a poor result from pericardiectomy (see p. 1853).

TREATMENT.

Mild acute pericarditis and noncompressing effusion do not require specific therapy. Usually, there is no reason to discontinue radiation. Prednisone may be needed for intractable pain but does not prevent constriction. Overt constriction necessitates pericardiectomy, always considering the patient's prognosis and quality of life. Radiation constriction presents technical challenges to the surgeon, and severe involvement of the pulmonary vessels and heart may make it unsuccessful.

Chronic Pericardial Effusion and Chronic Cardiac Tamponade

Chronic pericardial effusion represents excessive pericardial fluid remaining, arbitrarily, for at least 3 months.[292] [293] The vast majority are "idiopathic," presumably autoimmune, or follow viral or other burnt out infections and are large to massive. Chronicity with slow fluid formation permits greater relaxation of the parietal pericardium so that chronic effusions present for 6 months to many years can reach 3 or 4 liters, particularly if of inflammatory origin. Few patients give a history of acute pericarditis.

ETIOLOGY.

Pyogenic bacteria have been found in chronic pericardial exudates. Tuberculosis and actinomycosis and other fungi can cause chronic effusions including pericardial cold abscesses.[292] Although pericardial trauma can cause acute tamponade or constriction, it may be followed by chronic hemopericardium[294] and also is occasionally associated with some neoplasms, including primary pericardial sarcoma and Kaposi sarcoma, and various hemorrhagic diseases.[293] [294] The main connective tissue and related disorders associated with chronic effusions include lupus, rheumatic heart disease, scleroderma, polyarteritis, and especially rheumatoid arthritis.[295] *Lymphopericardium* is uncommon and follows lymphatic obstruction, lymphangioma, or rarely communication of thoracic duct and pericardium (usually after cardiothoracic surgery; also implicated in *chylopericardium*). Chronic effusive *cholesterol pericarditis* has multiple causes. *Endomyocardial fibrosis* may be accompanied by and present as a large hydropericardium. Congenital heart lesions, especially atrial septal defect, and *atrial thrombi* rarely are associated with massive chronic effusion. *Irradiation* for thoracic and cervical tumors can produce large, slowly absorbed or nonabsorbed effusions. Metabolic causes include *myxedema* and *uremia.* Hematological disorders associated with chronic pericardial effusion include *polycythemia* and severe, mainly "congenital" anemias--notably *thalassemia* and *pernicious anemia;* rarely, *heterotopic myelopoiesis* in the pericardium provokes a large effusion.[292]

PATHOLOGICAL CHARACTERISTICS.

Structural abnormalities and fluid characteristics largely depend on causative disorders. Pericardial tissue usually shows no acute changes and may be strictly fibrotic with adhesions and loculations, sometimes with cyst formation. Specific histological changes are uncommon even in cases related to known diseases.[296] Yet subacute inflammation and fibrinous pericarditis is occasionally superimposed on chronic changes.[292] The fluid, especially in idiopathic chronic effusion, is usually clear and straw colored with mainly exudative characteristics. However, transudate and exudate borderlines may be indistinct. Inflammatory fluids are more often under pressure, producing chronic tamponade with or without associated constriction. Pericardial calcification is occasional and usually confined to the visceral pericardium. Constriction[292] [296] [297] is not rare with chronic effusions of inflammatory origin. Such effusions may contribute independently to cardiac compression depending on an unyielding scarred parietal pericardium. Moreover, constrictive epicarditis is a principal cause of constriction with chronic effusion (i.e., chronic effusive-constrictive pericarditis). Yet many large chronic effusions, even with pericardial calcification, do not develop significant constriction or tamponade. Constriction sometimes develops rapidly after drainage of long-standing effusions, possibly by exciting previously low-grade inflammation.[292]

PATHOPHYSIOLOGY. [292] [298]

Chronic effusions may have four effects[292] : (1) slow production of small amounts of undetected fluid; (2) demonstrable effusion without symptoms or signs of cardiac compression; (3) smaller or larger effusions compressing the heart but stabilized by compensatory mechanisms; and (4) recurrent or progressive chronic cardiac tamponade. The physiological borderline between a stabilized compressing effusion and progressive tamponade is indistinct; tamponade, acute or chronic, is not "all or none." (In some patients with congestive failure and hydropericardium, drainage decreases both pericardial pressure and cardiac pressures, indicating mild cardiac compression.) If pericardial pressure is elevated but less than RA pressure, drainage reduces only the pericardial pressure. In either case, mean atrial pressures and ventricular diastolic pressures significantly differ from pericardial pressure--in contrast to overt tamponade.[292]

PHYSICAL EFFECTS.[292]

Large effusions may encroach on contiguous structures, causing restrictive pulmonary impairment, dyspnea on exertion, hoarseness, hiccough and dysphagia, and a Bamberger-Pins-Ewart sign.

Chronic Cardiac Tamponade

Chronic tamponade resembles chronic constrictive pericarditis. Diminution of cardiac output is comparable.[292] [293] [294] [295] [296] [297] [298] Compensatory mechanisms resemble acute tamponade, but circulating blood volume is more expanded. Many patients tolerate even massive chronic effusions amazingly well with minimal or no symptoms and signs, at least at rest.[292] [293] Others reach a stage of relentlessly increasing cardiac compression or one of prolonged debility with complications due to chronically diminished cardiac output and congested viscera.

CLINICAL MANIFESTATIONS.

Most symptoms and signs are ascribable to the large pericardial mass, any chronic cardiac compression, and residual pericardial inflammation, modified by any cardiac disease.[272] Chronicity makes symptoms "late" or nil; and such quiet chronic effusions, particularly if "idiopathic," are often accidentally discovered.[292] Symptoms and signs can resemble those of acute effusions or tamponade. However, many patients have vague chest discomfort and chronic fatigue, anorexia, and weight loss.

COURSE. [292] [293] [294] [295] [296]

The course varies according to pathogenetic factors; bland versus actively inflammatory effusion; pure chronic tamponade; or effusive-constrictive pericarditis. With tamponade, patients tend to develop atrial fibrillation as well as myocardial atrophy (with chronicity); liver congestion,[296] which can ultimately induce "cardiac cirrhosis"; the nephrotic syndrome; or protein-losing enteropathy. Complications may also be precipitated by systemic or respiratory infections.

DIAGNOSIS.[292] [293] [294] [295] [296] [297] [298]

Identifying pericardial fluid and tamponade by clinical and graphic methods is the same as for acute effusion and tamponade. The ECG is of little value. Low voltage is probably related to myocardial atrophy, fluid retention, and any pleural as well as pericardial effusion.[292] Etiological diagnosis is not possible in most "idiopathic" cases. Pericardial fluid and tissue obtained surgically, by biopsy or necropsy, may yield evidence from appropriate bacteriological, immunological, and histological techniques; and histologically "nonspecific" tissue may yield evidence of prior infection such as traces of tuberculous or viral RNA sequences.

MANAGEMENT. [296] [297]

Treatment of chronic effusion is individualized considering presence or absence of (1) cardiac compression, (2) a detectable causative disorder, (3) inflammatory manifestations, and (4) symptoms due to encroachment

---

on adjacent structures. In general, inflammatory effusions tend to require surgical intervention sooner or later particularly if with chronic tamponade; noninflammatory

effusions usually respond to treatment of associated disease. Aspiration of pleural effusions and ascites can contribute to symptomatic relief as well as preoperative management. Search for a cause is mandatory, particularly for specific therapeutic targets such as tuberculosis, toxoplasmosis, or myxedema. Management in general is the same as for acute pericardial effusion and tamponade and includes fluid and biopsy for diagnosis and biopsy and drainage for relief. However, drainage without resection is seldom adequate, particularly in idiopathic cases where refilling is common. Signs of persistent inflammation call for antiinflammatory therapy, particularly nonsteroidal agents. Nonabsorbable corticosteroids may be given intrapericardially. In patients for whom complete pericardial resection is not contemplated, chronic systemic congestion calls for sodium restriction and diuretics. Pericardiocentesis should be slow and intermittent to avoid cardiac overloading in patients with poor myocardial function[299] ; expanded blood volume and any myocardial atrophy make overloading more likely than in acute tamponade. After paracentesis, incomplete or tardy improvement in the absence of refilling may be due to myocardial impairment; total failure to improve suggests constrictive epicarditis. While pericardiectomy remains a procedure of choice with or without tamponade, it may be postponed in occasional patients with sustained relief from paracentesis or restricted surgical drainage and appropriate medical measures. However, the tendency of inflammatory chronic effusions to eventually constrict and the morbidity from recurrences favor pericardiectomy.[292] [293] Pleuropericardial fenestration is feasible in patients in whom full thoracotomy or thoracoscopic resection are considered unwarranted, principally because of the patient's general condition. Balloon pericardiostomy has been successful. However, fenestration has important disadvantages, including (1) frequent resealing of the stoma, (2) impossibility of complete dependent drainage, (3) potential constrictive scarring due to irritation by the procedure, (4) inadequate inspection of the epicardium, and (5) incomplete removal of adhesive or inflamed and infected tissue.[292]

Chapter 51 - Traumatic Heart Disease

KENNETH L. MATTOX
ANTHONY L. ESTRERA
MATTHEW J. WALL JR.

The earliest reports of traumatic injury to the heart discouraged operative repair, asserting high mortality and the hopelessness of cardiorrhaphy.[1] This pessimism persisted until the first cardiorrhaphy was performed by Rehn[2] in 1898. Rehn subsequently compiled his series of 124 cases over the next 10 years, with a survival of 40 percent.[3] The first cardiac repair for injury in the United States was performed by Hill[4] in 1902 on a kitchen table. In 1959, Isaacs[5] reported a remarkable survival of 89 percent for stab wounds and 43 percent for gunshot wounds to the heart among 60 patients. Enthusiasm for the surgical intervention in traumatic heart disease grew from these reported successes.

Most of the early reports involving traumatic heart disease involved penetrating injuries. Crynes and Hunter[6] reported the first blunt cardiac injury in 1939. In 1955, Des Forges and associates[7] reported the first successful repair for blunt cardiac injury.

Incidence

In the United States, trauma is the fourth leading cause of death, and it is the leading cause of death in those younger than 40 years of age. Thoracic trauma is responsible for 25 percent of the annual 50,000 deaths from vehicular accidents. As high as one fourth of these deaths are due to traumatic cardiac injury.[8] The actual incidence of cardiac injury from all of the diverse etiologies and classifications (including the confusing "cardiac contusion") is unknown. It has been estimated that cardiac injury may account for 10 percent of deaths from gunshot wounds.[9] Penetrating cardiac trauma is a highly lethal injury, with relatively few such patients reaching the hospital. In a series of penetrating cardiac injuries in South Africa where both those reaching the hospital and those being taken directly to the morgue were included, only 6 percent of 1,198 patients reached the hospital with any signs of life.[10] With improvements in organized emergency medical transport systems, up to 45 percent of those who sustain significant traumatic heart injury may reach the emergency department.[11]

Blunt cardiac injuries have been reported less frequently than penetrating injuries. In a population-based study, which included autopsied patients, the incidence of blunt cardiac injury is 0.1 percent.[12] In hospital-based studies, 10 to 70 percent of motor vehicle fatalities may have been the result of blunt cardiac rupture.[13] [14]

ETIOLOGY AND PATTERNS OF CARDIAC TRAUMA

Categorization of traumatic heart disease is based on mechanism of injury (i.e., penetrating, nonpenetrating [blunt], iatrogenic, metabolic, and other) (Table 51-1) .

PENETRATING CARDIAC TRAUMA.

Penetrating trauma is the most common cause of significant cardiac injury seen in the hospital setting, with the predominant injury being from guns and knives. Penetrating cardiac trauma is secondary to stab wounds in 35 to 96 percent of patients (depending on the instrument used in interpersonal violence in a geographical location), whereas gunshot wounds account for a reported 39 to 66 percent.[15] [16] [17] Both of these etiologies vary according to the year of the report and location in the world. One might also postulate that economic factors influence the availability of a penetrating wounding agent. Other mechanisms such as shotguns, ice picks, and fence impalement have also been reported.

The location of injury to the heart often correlates with the location of injury on the chest wall. Because of their anterior location, the anatomical chambers at greatest risk for injury are the right and left ventricles. In a review of 711 patients with penetrating cardiac trauma, 54 percent sustained stab wounds and 42 percent had gunshot wounds. The right ventricle was injured in 40 percent of the cases, the left ventricle in 40 percent, the right atrium in 24 percent, and the left atrium in 3 percent. One third of

TABLE 51-1 -- ETIOLOGY OF TRAUMATIC HEART DISEASES

I. Penetrating
- A. Stab wounds--knives, swords, ice picks, fence posts, wire, sporting
- B. Gunshot wounds--low-high caliber, handgun, rifles, nail guns, lawnmower projectiles
- C. Shotgun wounds--close range, distant

II. Nonpenetrating (Blunt)
- A. Motor vehicle accident
  - 1. Seat belt
  - 2. Air bag
- B. Vehicular-pedestrian accident
- C. Falls from height
- D. Crushing--industrial accident
- E. Blasts--explosives, grenades
- F. Assault (aggravated)
- G. Sternal or rib fractures
- H. Recreational--sporting events (bull goring), baseball
