Most of the adverse effects of beta blockers occur as a consequence of the known properties of these drugs and include cardiac effects (severe sinus bradycardia, sinus arrest, AV block, reduced left ventricular contractility), bronchoconstriction, fatigue, mental depression, nightmares, gastrointestinal upset, sexual dysfunction, intensification of insulin-induced hypoglycemia, and cutaneous reactions (Table 37-7) . Lethargy, weakness, and fatigue may be caused by reduced cardiac output or may arise from a direct effect on the central nervous system. Bronchoconstriction results from blockade of beta$_2$ receptors in the tracheobronchial tree. As a consequence, asthma and chronic obstructive lung disease are contraindications to beta blockers, even to beta$_1$ -selective agents.[298]

In patients who already have impaired left ventricular function, congestive heart failure may be intensified, an effect that can be counteracted in part by the use of digitalis or diuretics. Beginning therapy with a very low dose (e.g., metoprolol, 12.5 mg daily, for the first week) and then gradually increasing the dose over the course of several weeks has been shown to be beneficial in patients with idiopathic dilated cardiomyopathy and those with heart failure caused by ischemic heart disease (see Chap. 18) .

Beta blockers should be prescribed with great caution in patients with cardiac conduction disease involving either the sinus node or the AV conduction system. In patients with symptomatic conduction disease, beta blockers are contraindicated unless a pacemaker is in place. In patients with asymptomatic sinus node dysfunction or first-degree AV block, beta blockers may be tolerated, but their administration

TABLE 37-7 -- CANDIDATES FOR USE OF BETA-BLOCKING AGENTS FOR ANGINA

Ideal Candidates
Prominent relationship of physical activity to attacks of angina
Coexistent hypertension
History of supraventricular or ventricular arrhythmias
Previous myocardial infarction
Left ventricular systolic dysfunction
Mild to moderate heart failure symptoms (NYHA functional Class II-III)
Prominent anxiety state
Poor Candidates
Asthma or reversible airway component in chronic lung disease patients
Severe left ventricular dysfunction with severe heart failure symptoms (NYHA functional Class IV)
History of severe depression
Raynaud's phenomenon
Symptomatic peripheral vascular disease
Severe bradycardia or heart block
Brittle diabetes
NYHA=New York Heart Association.
Modified from Abrams JA: Medical therapy of stable angina pectoris. In Beller G: Chronic Ischemic Heart Disease. In Braunwald E (ed): Atlas of Heart Disease. Vol 5. Philadelphia, Mosby, 1995, p 7.22. By permission of Current Medicine.

requires careful observation. Pindolol, because of its ISA activity, may be preferable in this situation. Blockade of noncardiac beta$_2$ receptors inhibits catecholamine-induced glycogenolysis, so noncardioselective beta blockers can impair the defense to insulin-induced hypoglycemia. Blockade of beta$_2$ receptors also inhibits the vasodilating effects of catecholamines in peripheral blood vessels and leaves the constrictor (alpha-adrenergic) receptors unopposed, thereby enhancing vasoconstriction. Noncardioselective beta blockers may precipitate episodes of Raynaud's phenomenon in patients with this condition and may cause uncomfortable coldness in the distal extremities. Reduced flow to the limbs may occur in patients with peripheral vascular disease.[299]

Abrupt withdrawal of beta-adrenoceptor blocking agents after prolonged administration can result in increased total ischemic activity in patients with chronic stable angina. This increased ischemia may be caused by a return to the previously high levels of myocardial O_2 demand while the underlying atherosclerotic process has progressed.[300] Occasionally, such withdrawal can precipitate unstable angina and may in rare cases even provoke myocardial infarction. Chronic beta blocker therapy can be safely discontinued by slowly withdrawing the drug in a stepwise manner over the course of 2 to 3 weeks. If abrupt withdrawal of beta blockers is required,

patients should be instructed to reduce exertion and manage angina episodes with sublingual nitroglycerin and/or substitute a calcium antagonist.

Calcium Antagonists (see also Chap. 29)

The critical role of calcium ions in the normal contraction of cardiac and vascular smooth muscle is discussed in Chapter 14 . Calcium antagonists are a heterogeneous group of compounds that inhibit calcium ion movement through slow channels in cardiac and smooth muscle membranes by noncompetitive blockade of voltage-sensitive L-type calcium channels[301] [302] [303] [303A] (see Fig. 14-14) . The three major classes of calcium antagonists are the dihydropyridines (nifedipine is the prototype), the phenylalkylamines (verapamil is the prototype), and the modified benzothiazepines (diltiazem is the prototype). The two predominant effects of calcium antagonists result from blocking the entry of calcium ions and slowing recovery of the channel.[303A] Phenylalkylamines have a marked effect on recovery of the channel and thereby exert depressant effects on cardiac pacemakers and conduction, whereas dihydropyridines, which do not impair channel recovery, have little effect on the conduction system.

MECHANISM OF ACTION.

The efficacy of calcium antagonists in patients with angina pectoris is related to the reduction in myocardial O_2 demand and the increase in O_2 supply that they induce[303A] (see Table 37-3) . The latter effect is particularly important in patients with conditions in which a prominent vasospastic or vasoconstrictor component may be present, such as Prinzmetal (variant) angina (see p. 1324), variable-threshold angina (p. 1276), and angina related to impaired vasodilator reserve of small coronary arteries.[304] Calcium antagonists may be effective on their own or in combination with beta-adrenoceptor blockers and nitrates in patients with chronic stable angina.[301] [305] [306]

Several calcium antagonists are effective for the treatment of angina pectoris (Table 37-8) . Each of these agents is effective in causing relaxation of vascular smooth muscle in both the systemic arterial and coronary arterial beds. In addition, blockade of the entry of calcium into myocytes results in a negative inotropic effect, which is counteracted to some extent by peripheral vascular dilation and by activation of the sympathetic nervous system in response to drug-induced hypotension.[302] However, the negative inotropic effect must be taken into consideration in patients with significant left ventricular dysfunction.

TABLE 37-8 -- PHARMACOKINETICS OF CALCIUM ANTAGONISTS USED COMMONLY FOR ANGINA PECTORIS

CHARACTERISTIC	DILTIAZEM/SR	NICARDIPINE	NIFEDIPINE/SR	VERAPAMIL/SR	AMLODIPINE	FELODIPINE	ISRADIPINE	BEPRIDIL	NISOLDIPINE

CD=combination drug; CR=controlled release; FDA=Food and Drug Administration; IR=immediate release; ND=no data; SR=sustained release.

*Half-life of 4.5 to 12 hours with multiple dosing; may be prolonged in the elderly.

The sustained-release formulation may be preferred for hypertension.

With a rapid onset of action and metabolism by the liver, calcium antagonists have a limited bioavailability of between 13 and 52 percent and a half-life of between 3 and 12 hours. Amlodipine and bepridil are exceptions in that both drugs have long half-lives and may be administered once daily. In the case of some of the other calcium antagonists, sustained-release preparations have been shown to be effective.

ANTIATHEROGENIC ACTION.

Studies in experimental animals, both primates and nonprimates, have suggested that calcium antagonists might have an antiatherogenic effect, and human studies support this conclusion.[307] [308] In multicenter randomized trials using quantitative coronary arteriography, significantly fewer new lesions developed in patients showing mild CAD and taking nifedipine than in patients taking placebo. However, preexisting lesions did not appear to be affected. Prolonged follow-up is necessary to determine whether these angiographic observations are accompanied by clinical benefit. In patients undergoing cardiac transplantation, diltiazem has been reported to be beneficial in reducing the frequency and severity of coronary arteriopathy in the transplanted heart.[309]

First-Generation Calcium Antagonists

NIFEDIPINE.

This dihydropyridine is a particularly effective dilator of vascular smooth muscle and is a more potent vasodilator than either diltiazem or verapamil. Although its in vitro actions on myocardium and specialized cardiac tissue are similar to those of other agents, the concentration required to reproduce effects on these tissues is not reached in vivo because of the early appearance of its powerful vasodilating effects. Thus, in clinical practice, the potential negative chronotropic, inotropic, and dromotropic (on AV conduction) effects of nifedipine are seldom a problem, although even nifedipine can worsen heart failure in patients with preexisting chronic congestive heart failure.[310]

In contrast to beta blockers, which decrease the heart rate and the rate-pressure product at rest and during exercise, nifedipine reduces only systolic pressure.[311] Thus, the beneficial effects of nifedipine in the treatment of angina result from its capacity to reduce myocardial O_2 requirements because of its afterload-reducing effect and to increase myocardial O_2 delivery as a result of its dilating action on the coronary vascular bed (see Table 37-3) . In patients without heart failure, nifedipine causes modest reflex increases in the ejection fraction, velocity of circumferential fiber shortening, heart rate, and cardiac index; these increases can be blocked by beta-adrenoceptor blockade.

The initial dose is 10 mg orally every 8 hours, increased stepwise to 20 mg every 6 hours guided by the blood pressure response, to a maximal daily dose of 160 mg. An extended-release formulation using the gastrointestinal therapeutic system (GITS) of drug delivery (see Table 37-8) is designed to deliver 30, 60, or 90 mg of nifedipine in a single daily dose at a relatively constant rate over a 24-hour period and is useful for the treatment of chronic stable angina, Prinzmetal angina, and hypertension. [312] The efficacy of the extended-release preparation, either alone or in conjunction with beta blockers, in reducing episodes of angina and ischemia on ambulatory monitoring has been documented.[313]

Adverse Effects.

Adverse effects occur in 15 to 20 percent of patients and require discontinuation of medication in about 5 percent. Most adverse effects are related to systemic vasodilation and include headache, dizziness, palpitations, flushing, hypotension, and leg edema (unrelated to heart failure). Gastrointestinal side effects, including nausea, epigastric pressure, and vomiting, are noted in approximately 5 percent of patients. In rare instances, in patients with extremely severe, fixed coronary obstructions, nifedipine aggravates angina, presumably by lowering arterial pressure excessively, with subsequent reflex tachycardia. For this reason, combined treatment of angina with nifedipine and a beta blocker is particularly effective and superior to nifedipine alone.[306] [311] Most of the adverse effects are reduced by the use of extended-release preparations.

Several clinical case-control studies of hypertension and associated reviews have suggested that *short-acting nifedipine* may cause an increase in mortality.[314] [315] [316] [317] These findings have not been confirmed by other case-control studies,[318] [319] and these conclusions have not been accepted universally. No firm data indicate that this risk applies to extended-release nifedipine or to other calcium antagonists.[320] [321] Although insufficient data are available to assess the long-term risks (if any) of calcium antagonists in chronic CAD, *long-acting nifedipine* should be considered an effective and safe antianginal drug for the treatment of symptomatic patients with chronic CAD who are already receiving beta blockers, with or without nitrates. Shortacting nifedipine should ordinarily be avoided.

Because of its potent vasodilator effects, nifedipine is contraindicated in patients who are hypotensive or have severe aortic valve stenosis and in patients with unstable angina who are not simultaneously receiving a beta blocker and in whom reflex-mediated increases in the heart rate may be harmful. Nifedipine (or one of the second-generation dihydropyridines) is the calcium antagonist of choice in patients with mild left ventricular dysfunction, sinus bradycardia, sick sinus syndrome, or AV block (particularly if a beta-adrenoceptor blocking agent is administered concurrently and additional drug therapy for angina is indicated).[306] This recommendation is based on nifedipine having fewer negative effects on myocardial contractility, heart rate, and AV conduction than seen with verapamil or diltiazem in doses used clinically. Nonetheless, in patients with more serious left ventricular dysfunction, all calcium antagonists--even nifedipine--can precipitate heart failure.[310]

Nifedipine interacts significantly with prazosin (resulting in excessive hypotension), cimetidine, and phenytoin (resulting in increased bioavailability of nifedipine and increased quinidine clearance). Nifedipine increases blood levels of propranolol, and use of the two drugs together poses the risk of an added negative inotropic and hypotensive effect.[311] In patients with Prinzmetal angina, abrupt cessation of nifedipine therapy may result in a rebound increase in the frequency and duration of attacks.

VERAPAMIL (see also Chap. 23) .

Verapamil dilates systemic and coronary resistance vessels and large coronary conductance vessels. It slows the heart rate and reduces myocardial contractility. This combination of actions results in a reduction in myocardial O_2 requirement, which is the basis for the drug's efficacy in the management of chronic stable angina. Thrombus formation and thrombin-mediated platelet aggregation are decreased by verapamil,[322] effects also observed with transdermal nitroglycerin. To what extent the clinical benefits of verapamil and nitrates are related to their effects on platelet aggregation and thrombus formation is uncertain.

Verapamil reduces the frequency of angina and prolongs exercise tolerance in patients with symptomatic chronic CAD, and the combination of verapamil and a beta blocker provides clinical benefit that is additive.[323] Despite the marked negative inotropic effects of verapamil in isolated cardiac muscle preparations, changes in contractility are modest in patients with normal cardiac function. However, in patients with cardiac dysfunction, verapamil, like beta blockers, may reduce cardiac output, increase left ventricular filling pressure, and cause clinical heart failure. In clinically useful doses, verapamil inhibits calcium influx into specialized cardiac cells, sometimes causing slowing of the heart rate and AV conduction. Therefore, it is contraindicated in patients with preexisting AV nodal disease or sick sinus syndrome, congestive heart failure, and suspected digitalis or quinidine toxicity.

The usual starting dose of verapamil for oral administration is 40 to 80 mg three times daily to a maximal dose of 480 mg/d (see Table 37-8) . Sustained-release capsules of verapamil are available (60, 90, and 120 mg), and starting doses are 60 to 120 mg twice daily with a usual optimal dose range of 240 to 360 mg/d.

Verapamil interacts significantly with several other drugs. Intravenous verapamil should not be used together with a beta blocker (given intravenously or orally), nor should a beta blocker be administered intravenously in patients

receiving oral verapamil. The bioavailability of verapamil is increased by cimetidine and carbamazepine, whereas verapamil may increase plasma levels of cyclosporine and digoxin and may be associated with excessive hypotension in patients receiving quinidine or prazosin. Hepatic enzyme inducers such as phenobarbital may reduce the effects of verapamil.

Adverse effects of verapamil are noted in approximately 10 percent of patients and relate to systemic dilation (hypotension and facial flushing), gastrointestinal symptoms (constipation and nausea), and central nervous system reactions such as headache and dizziness. A rare side effect is gingival hyperplasia, which appears after 1 to 9 months of therapy.

DILTIAZEM.

Diltiazem's actions are intermediate between those of nifedipine and verapamil. In clinically useful doses, its vasodilator effects are less profound than nifedipine's, and its cardiac depressant action (on the sinoatrial and AV nodes and myocardium) is less than that of verapamil. This profile may explain the remarkably low incidence of adverse effects of diltiazem. This drug is a systemic vasodilator that lowers arterial pressure at rest and during exertion and increases the workload required to produce

myocardial ischemia, but it may also increase myocardial O_2 delivery. Although diltiazem causes little vasodilation of epicardial coronary arteries under basal conditions, it may enhance perfusion of the subendocardium distal to a flow-limiting coronary stenosis[324] ; it also blocks exercise-induced coronary vasoconstriction. In patients with chronic stable angina receiving maximally tolerated doses of diltiazem, the heart rate is significantly reduced at rest, but no effect on peak blood pressure is achieved during exercise, and the duration of symptom-limited treadmill exercise is prolonged.

The dose of diltiazem is 30 to 60 mg four times daily, although higher doses are sometimes needed. Several sustained-release formulations have been approved and are available for once-daily treatment of systemic hypertension and angina pectoris.[325]

Diltiazem is a highly effective antianginal agent. Atenolol and diltiazem have similar efficacy in increasing nonischemic exercise duration in patients with variable-threshold angina and act primarily by slowing the resting heart rate.[326] High doses (mean dose, 340 mg) have been shown to be a relatively safe addition to maximally tolerated doses of isosorbide dinitrate and a beta blocker and cause increases in exercise tolerance and resting and exercise left ventricular ejection fraction.[325] Major side effects are similar to those of the other calcium channel blockers and are related to vasodilation, but they are relatively infrequent, particularly if the dose does not exceed 240 mg/d. As is the case with verapamil, diltiazem should be prescribed with caution for patients with sick sinus syndrome or AV block. In patients with preexisting left ventricular dysfunction, diltiazem may exacerbate or precipitate heart failure.

Diltiazem interacts with other drugs, including beta-adrenergic blocking agents (causing enhanced negative inotropic, chronotropic, and dromotropic effects), flecainide, and cimetidine (which increases the bioavailability of diltiazem), and diltiazem has been associated with increased plasma levels of cyclosporine, carbamazepine, and lithium carbonate. Diltiazem may cause excessive sinus node depression if administered with disopyramide and may reduce digoxin clearance, especially in patients with renal failure.[327]

Second-Generation Calcium Antagonists

The second-generation calcium antagonists (nicardipine, isradipine, amlodipine, and felodipine) are mainly dihydropyridine derivatives, with nifedipine being the prototypical agent. Considerable experience has also accumulated with nimodipine, nisoldipine, and nitrendipine. These agents differ in potency, tissue specificity, and pharmacokinetics and, in general, are potent vasodilators because of greater vascular selectivity than seen with the first-generation antagonists, i.e., verapamil, nifedipine, and diltiazem.

AMLODIPINE.

This agent, which is less lipid soluble than nifedipine, has a slow, smooth onset and ultra-long duration of action (plasma half-life of 36 hours). It causes marked coronary and peripheral dilatation and may be useful in the treatment of patients with angina accompanied by hypertension. It may be used as a once-daily hypotensive or antianginal agent.[328] In a series of randomized placebo-controlled studies in patients with stable exercise-induced angina pectoris, amlodipine was shown to be effective and well tolerated.[329] It has little, if any, negative inotropic action and may be especially useful in patients with chronic angina and left ventricular dysfunction. The Prospective Randomized Amlodipine Survival Evaluation (PRAISE) investigators enrolled 1153 patients with New York Heart Association Class III to IV failure and a mean ejection fraction of 21 percent.[330] When amlodipine versus placebo was added to a full regimen of digoxin, diuretic, and ACE inhibitor therapy, no significant difference in survival was observed in patients with ischemic cardiomyopathy. Although amlodipine did not have a beneficial effect on mortality, these data suggest that in patients with congestive heart failure caused by severe CAD, amlodipine may be safely added for control of hypertension or angina, without an adverse effect on survival.[330]

NICARDIPINE.

This drug has a similar half-life to that of nifedipine (2 to 4 hours), but it appears to have greater vascular selectivity. Nicardipine may be used as an antianginal and antihypertensive agent and requires three-times-daily administration, although a sustained-release formulation is available for twice-daily dosing in hypertension. For chronic stable angina pectoris, it appears to be as effective as verapamil or diltiazem, and its efficacy is enhanced when combined with a beta blocker.

FELODIPINE AND ISRADIPINE.

In the United States, both drugs are approved by the Food and Drug Administration (FDA) for the treatment of hypertension but not for angina pectoris. A recent study documented similar efficacy between felodipine and nifedipine in patients with chronic stable angina.[331] Felodipine has also been reported to be more vascular selective than nifedipine and to have a mild positive inotropic effect as a result of calcium channel agonist properties. Isradipine has a longer half-life than nifedipine and demonstrates greater vascular sensitivity.

BEPRIDIL.

This calcium antagonist interacts with dihydropyridine-binding sites and also has a sodium channel blocking effect. It markedly prolongs the atrial refractory period and may be useful in the treatment of patients with angina and arrhythmias. However, it is also arrhythmogenic and causes QT prolongation and torsades de pointes.[332] Although chemically unrelated to the other calcium channel blockers, bepridil has been shown to be an effective antianginal agent. Nonetheless, because of its potential to prolong the QT interval and to cause torsades de pointes, the drug should be reserved only for patients in whom other antianginal drugs have failed. Interactions with antiarrhythmic agents, tricyclic antidepressants, and cardiac glycosides are potentially hazardous.

Medical Management of Angina Pectoris

RELATIVE ADVANTAGES OF BETA BLOCKERS AND CALCIUM ANTAGONISTS (see Table 37-9) .

The choice between a beta blocker and a calcium channel antagonist as initial therapy in patients with chronic stable angina is controversial because both classes of agents are effective in relieving symptoms and reducing ischemia.[333] Trials comparing beta blockers and calcium antagonists have not shown any difference

TABLE 37-9 -- RECOMMENDED DRUG THERAPY (CALCIUM ANTAGONIST VS. BETA BLOCKER) IN PATIENTS WHO HAVE ANGINA IN CONJUNCTION WITH OTHER MEDICAL CONDITIONS

CLINICAL CONDITION	RECOMMENDED DRUG
CARDIAC ARRHYTHMIA OR CONDUCTION DISTURBANCE	
Sinus bradycardia	Nifedipine or amlodipine
Sinus tachycardia (not caused by cardiac failure)	Beta blocker
Supraventricular tachycardia	Beta blocker (verapamil)
Atrioventricular block	Nifedipine or amlodipine
Rapid atrial fibrillation (with digitalis)	Verapamil or beta blocker
Ventricular arrhythmia	Beta blocker
LEFT VENTRICULAR DYSFUNCTION	
Heart failure	Beta blocker
MISCELLANEOUS MEDICAL CONDITIONS	
Systemic hypertension	Beta blocker (calcium antagonist)
Severe preexisting headaches	Beta blocker (verapamil or diltiazem)
COPD with bronchospasm or asthma	Nifedipine, amlodipine, verapamil, or diltiazem
Hyperthyroidism	Beta blocker

Raynaud's syndrome	Nifedipine or amlodipine
Claudication	Calcium antagonist
Severe depression	Calcium antagonist

COPD=chronic obstructive pulmonary disease. (alternatives in parentheses)

in the rate of death or myocardial infarction,[334] [335] [336] [337] although in some studies beta blockers appeared to have greater clinical efficacy.[334] [336] [337] Because long-term administration of beta blockers has been demonstrated to prolong life in patients after acute myocardial infarction and in the treatment of hypertension, it is reasonable to consider beta blockers over calcium antagonists as the agents of choice in treating patients with chronic stable angina. However, it must be recognized that beta blockers (without ISA) increase serum triglycerides and decrease HDL cholesterol with uncertain long-term consequences.[296] In addition, these drugs may produce fatigue, depression, and sexual dysfunction. In contrast, long-term administration of calcium antagonists has not been shown to improve long-term survival after acute myocardial infarction,[338] although diltiazem is apparently effective in preventing severe angina and early reinfarction after non-Q-wave infarction[339] and verapamil reduces reinfarction rates,[340] whereas nifedipine has been associated with the development of fewer new coronary artery lesions[307] in patients with established CAD.

The choice of drug with which to initiate therapy is influenced by a number of clinical factors (see Table 37-9) .

1. Calcium antagonists are the preferred agents in patients with a history of asthma, chronic obstructive lung disease, and/or wheezing on clinical examination, in whom beta blockers, even relatively selective agents, are contraindicated.
2. Nifedipine (long acting), amlodipine, and nicardipine are the calcium antagonists of choice in patients with chronic stable angina and sick sinus syndrome, sinus bradycardia, or significant AV conduction disturbances, whereas beta blockers and verapamil should be used only with great caution in such patients. In patients with symptomatic conduction disease, neither a beta blocker nor a calcium channel blocker should be used unless a pacemaker is in place. If a beta blocker is required in patients with asymptomatic evidence of conduction disease, pindolol, which has the greatest ISA, is useful. In the case of calcium channel blockers, nifedipine or nicardipine is preferable to verapamil and diltiazem, but careful observation for deterioration of conduction is mandatory.
3. Calcium antagonists are clearly preferred in patients with suspected Prinzmetal (variant) angina; beta blockers may even aggravate angina under these circumstances.
4. Calcium antagonists may be preferred over beta blockers in patients with significant symptomatic peripheral arterial disease because the latter may cause peripheral vasoconstriction.
5. Beta blockers should usually be avoided in patients with a history of significant depressive illness and should be prescribed cautiously for patients with sexual dysfunction, sleep disturbance, nightmares, fatigue, or lethargy.
6. The presence of moderate to severe left ventricular dysfunction in patients with angina limits the therapeutic options. The beneficial effects of beta blockers on survival in patients with left ventricular dysfunction after myocardial infarction,[237] [238] coupled with their beneficial effects on survival and left ventricular performance in patients with heart failure,[341] [342] has established beta blockers as the drug class of choice for the treatment of angina in patients with left ventricular dysfunction, with or without symptoms of heart failure, together with ACE inhibitors, digitalis, and diuretics. If angina persists despite beta blockade and nitrates, amlodipine can be administered.[330] Verapamil, nifedipine, and diltiazem should be avoided.
7. Short-acting nifedipine should not be used as the initial and only agent in patients with unstable angina (see Chap. 36) because the reflex-mediated tachycardia may aggravate unstable angina.[343] However, long-acting nifedipine may be helpful if symptoms persist despite therapy with a beta blocker, aspirin, nitrates, and antithrombotic agents.
8. Hypertensive patients with angina pectoris do well with either beta blockers or calcium antagonists because both agents have antihypertensive effects. However, beta blockers are the preferred initial agent for treating angina in such patients, as noted above, and an ACE inhibitor should be strongly considered for all patients with CAD who have hypertension.[214]

COMBINATION THERAPY.

The combination of a beta blocker, calcium antagonist, and long-acting nitrate is widely used in the management of chronic stable angina.[337] When adrenergic blockers and calcium antagonists are used together in the treatment of angina pectoris, several issues should be considered:

1. The addition of a beta blocker enhances the clinical effect of nifedipine and other dihydropyridines.
2. In patients with moderate or severe left ventricular dysfunction, sinus bradycardia, or AV conduction disturbances, combination therapy with calcium antagonists and beta blockers either should be avoided or should be initiated with caution. In patients with AV conduction system

disease, the preferred combination is long-acting nifedipine or another dihydropyridine and a beta blocker. The negative inotropic effects of calcium antagonists are not usually a problem in combined therapy with low doses of beta blockers but can become significant with higher doses. With such doses, amlodipine is the calcium antagonist of choice, but it should be used cautiously.
3. The combination of a dihydropyridine and a long-acting nitrate (without a beta blocker) is not an optimal combination because both are vasodilators.

Approach to Patients with Chronic Stable Angina

1. Identify and treat precipitating factors, such as anemia, uncontrolled hypertension, thyrotoxicosis, tachyarrhythmias, uncontrolled congestive heart failure, and concomitant valvular heart disease.
2. Initiate risk factor modification, physical exercise, diet, and life style counseling. Initiate therapy with an HMG-CoA reductase inhibitor, as needed, to reduce LDL cholesterol below 100 mg/dl.
3. Initiate pharmacotherapy with aspirin and a beta blocker. Strongly consider an ACE inhibitor as first-line therapy in all patients with chronic CAD.
4. Use sublingual nitroglycerin for alleviation of symptoms and prophylactically.
5. If episodes occur more than two or three times per week, the next step is addition of a calcium antagonist or a long-acting nitrate via eccentric dosing schedules to prevent nitrate tolerance. The decision to add a calcium antagonist or a long-acting nitrate is not based entirely on the frequency and severity of symptoms. The need to treat concomitant hypertension or the presence of left ventricular dysfunction and symptoms of heart failure may be an indication for the use of one of these agents, even in patients in whom episodes of symptomatic angina are infrequent.
6. If angina persists despite two antianginal agents (a beta blocker with either a long-acting nitrate preparation or a calcium antagonist), add the third antianginal agent.
7. Coronary angiography, with a view to considering coronary revascularization, is indicated in patients with refractory symptoms or ischemia despite optimal medical therapy; it should also be carried out in patients with "high-risk" noninvasive test results (see Table 37-2) and in those with occupations or life styles that require a more aggressive approach.

OTHER THERAPIES

An option for patients with refractory angina who are not candidates for coronary revascularization is spinal cord stimulation using a specially designed electrode inserted into the epidural space. The beneficial effects of neuromodulation via this technique on pain are based on the gate theory, in which stimulation of axons in the spinal cord that do not transmit pain to the brain will reduce input to the brain from axons that do so. Irrespective of the mechanism, several observation studies have reported success rates of up to 80 percent in terms of the frequency and severity of angina.[344] What is less easily explained is the apparent antiischemic effect of this technique. Randomized placebo-controlled trials are impossible to perform, and this approach should be reserved for patients in whom all other treatment options have been exhausted.[345]

The use of enhanced external counterpulsation (EECP) is another promising alternative to treatment of refractory angina. The mechanisms underlying the effects of EECP are currently under evaluation and include (1) hemodynamic changes that reduce myocardial O_2 demand in addition to the potential for increased transmyocardial pressure to open collaterals and (2) the possibility that exposure of the arterial bed to the augmented blood flow produced by EECP could lead to the elaboration of various substances that improve endothelial function and vascular remodeling.[346] Irrespective of the mechanism, in a recent multicenter prospective trial in which active counterpulsation was compared with "inactive counterpulsation," the former reduced angina and extended the time to exercise-induced ischemia over a 4- to 7-week period in patients with symptomatic CAD. Moreover, the treatment was relatively well tolerated, so this modality warrants further investigation.[347]

Translaser myocardial revascularization techniques are addressed on p. 1305 .

Percutaneous Coronary Interventions (see also Chap. 38)

Percutaneous coronary interventions (PCIs), which include percutaneous transluminal coronary angioplasty (PTCA), stenting, and related techniques, represent a major therapeutic advance in the management of chronic stable angina.[348] Their importance to the management of CAD in the United States is reflected by the performance of approximately 447,000 procedures in 1997 (52 percent of which were performed on persons younger than 65 years). This figure represents an increase of 190 percent from 1987 to 1997. The dramatic growth in the use of PCI has not eliminated growth in the use of coronary bypass surgery, and in 1997, the latter procedures were performed on 366,000 patients, which reflects an increase of 227 percent in the number of patients treated from 1979 to 1997. The practice of interventional cardiology has changed radically during the last 5 years following the widespread use of stents, the introduction of new platelet inhibitors, and the development of other devices that have a niche in the context of specific technical issues, e.g., rotablator and atherectomy.[349]

PATIENT SELECTION.

Improved technology and increasing operator experience have continued to expand the pool of patients with both single-vessel and multivessel disease who are candidates for PCI (and other catheter-based techniques for revascularization). Factors that need to be considered in patient selection include the following:

1. The need for revascularization (surgical or catheter based) as opposed to medical therapy, including stringent risk factor modification.
2. The likelihood of successful catheter-based revascularization based on the angiographic characteristics of the lesion-type A, B, or C lesions,[350] which characterize complexity as mild, moderate, or severe, respectively (see Chap. 38) . Equally important are factors such as vessel size, extent of calcification, tortuosity, and relationships to sidebranches.
3. The risk and potential consequences of acute failure of PCI, which are a function, in part, of the coronary artery anatomy and underlying left ventricular function.
4. The likelihood of restenosis.
5. The need for complete revascularization based on the extent of CAD, the severity of ischemia, and the presence or absence of left ventricular dysfunction.
6. The presence of comorbid conditions and the suitability of the patient for surgery.
7. Patient preference.

The patient with chronic stable angina who is ideal for PCI, i.e., who is at low risk for complications and in whom the likelihood of technical success is high, is a male with

chronic stable angina who is younger than 70 years and has single-vessel and single-lesion CAD, the anatomical characteristics of a type A lesion with less than 90 percent stenosis, no history of congestive heart failure, and an ejection fraction greater than 40 percent. Although these characteristics define the ideal candidate, excellent technical and clinical results can still be obtained in many patients who do not fulfill these ideal criteria.

Features associated with an increased risk for PCI failure include advanced age, female gender, unstable angina, congestive heart failure, left main coronary artery-equivalent disease, multivessel multi-lesion CAD, and probably recent thrombolytic therapy.[351] Diabetes mellitus in patients with multivessel disease has been associated with increased periprocedural ischemic complications and late mortality in comparison with patients without diabetes. Patients with impaired renal function, particularly those with diabetes, are also at increased risk for periprocedural morbidity and, in particular, contrast agent nephropathy.[351] [352]

The original ACC/AHA criteria for PTCA success based on lesion morphology suggested that the outcome was poorer with type B or C lesions. These data, validated in the early 1990s,[353] were examined more recently in the setting of better guidewires, new devices, and perfusion balloons.[354] In this large study of patients treated between 1994 and 1996, success rates were not shown to differ among patients with A, B1, or B2 lesions, but each was accompanied by higher success rates than seen with type C lesions. Independent predictors of procedural failure were the presence of total occlusion and vessel tortuosity. Predictors of complications were bifurcation lesions, the presence of thrombus, the inability to protect a sidebranch, and degenerative vein graft lesions. The presence of the aforementioned features does not necessarily contraindicate PCI but should certainly raise the threshold for performing the procedure. However, it would appear that in the current era, lesion morphology may be a less powerful predictor of complications than was previously the case.

EARLY OUTCOME.

Continued improvement in the technical aspects of PCI, as well as increasing operator experience, has had a favorable impact on the rate of primary success (usually defined as an increase in diameter of >20 percent and a final diameter obstruction <50 percent) and the rate of reductions in complications, i.e., death, myocardial infarction, and emergency coronary bypass surgery.[355] These improvements have occurred despite broadening of the selection criteria for PCI to include older and sicker patients with more complex anatomy.[349] [351] Current expectations for PCI, particularly with the widespread use of coronary stents, are an overall procedural success rate of at least 90 percent with a mortality of less than 1 percent, rate of Q wave myocardial infarction of less than 1.5 percent, and rate of emergency bypass surgery of 1 to 2 percent.

ABRUPT CLOSURE.

This complication after initially successful PCI has been defined as total or subtotal occlusion of the target lesion, and it is usually recognized before the patient leaves the laboratory. The entity of "threatened" vessel closure is defined by recurrent stenosis of less than 50 percent and Thrombosis in Myocardial Infarction (TIMI) flow less than grade 3.[356]

The treatment objectives of abrupt closure are to establish adequate coronary perfusion as a bridge to coronary bypass surgery or, in some patients, as a definitive strategy.

LONG-TERM OUTCOME.

For the majority of patients undergoing PCI, the intermediate and late outcomes can be characterized by a low mortality or nonfatal myocardial infarction rate.[357] Several recent studies provide reassuring data on the long-term results of PTCA. The 10-year follow-up of the first series of patients undergoing PTCA performed by Gruentzig demonstrated a survival rate of 95 percent in patients with single-vessel disease and 81 percent in those with multivessel disease.[358] In the National Heart, Lung, and Blood Institute (NHLBI) Registry, 5-year survival rates were 93.2, 88.8, and 86 percent in patients with single-, double-, and triple-vessel disease, respectively.[357] Five-year survival rates from 1980 to 1990 in the Emory University data base of over 10,000 patients were 88 and 93 percent, respectively, for patients with and those without diabetes mellitus.[359] Independent correlates of late survival were younger age, preserved left ventricular ejection fraction, and absence of congestive heart failure, multivessel disease, and diabetes.

Restenosis, the Achilles heel of angioplasty, continues to have a major impact on long-term outcome. Also, angina frequently recurs.[349] [357] [360] [361] [362] [363] Restenosis

and, to a lesser extent, progression of disease are the major reasons for repeat revascularization procedures, which in the randomized trials were performed in 30 to 40 percent of patients at 1 to 2 years and, in the Bypass Angioplasty Revascularization Investigation (BARI), in 60 percent of patients at 5 years.[352] Approximately 50 percent of all repeat revascularization procedures are repeat PCIs, with the rest being coronary artery bypass procedures.[352] [364] [365] What is reassuring is that the need for repeat revascularization tapers off rapidly after the second year.

STENTS.

Since their entry into clinical practice in the early 1990s, stents have had an effect on both the early and late results of PCI. In regard to the former, stents have produced a marked reduction in the need for emergency bypass surgery, and in comparison with PTCA, stents have been associated with a significant reduction in the incidence of major cardiac events after discharge.[366] However, these results are not due to any reduction in death or myocardial infarction, but almost entirely to a reduction in the need for and performance of target vessel repeat revascularization, which in turn reflects a reduction in clinical restenosis. The development of newer techniques such as intravascular brachytherapy,[367] techniques for local drug delivery, and new stent coatings may result in a further improvement in long-term results.

COMPARISONS BETWEEN PTCA AND MEDICAL THERAPY.

Only four trials have compared PTCA with medical therapy.[183] [368] [369] [370] The first major randomized trial involving PTCA was the Veterans Administration Comparison of Angioplasty with Medical Therapy in the treatment of single-vessel CAD, reported in 1992.[371] PTCA was distinctly superior to medical therapy in the relief of angina and in improvement in exercise tolerance, although repeat PTCA or CABG surgery was required in 15 percent of patients by 6 months. A conclusion that can be drawn from this study is that a trial of medical therapy followed by PCI in the event of treatment failure is a reasonable initial strategy for patients with stable angina and single-vessel disease. Nonetheless, indices of quality of life, including functional capacity and the patient's perception of well-being, were significantly better among patients treated with PTCA.[372] At 2 to 3 years, although some of the early benefits of PTCA on exercise tolerance and symptoms were sustained, the subsequent use of CABG and PTCA in the two groups was no different.

Another small randomized trial from Brazil, the Medicine Angioplasty or Surgery Study (MASS), compared PTCA with medical therapy and CABG for patients with proximal stenosis of the left anterior descending coronary artery. After 3 years, no difference was seen between medical therapy and PTCA in the combined endpoints of cardiac death, myocardial infarction, and refractory angina requiring revascularization, but the surgical arm was superior to the two other modalities (3 percent incidence in the surgical arm vs. 24 percent after PTCA and 17 percent with medical therapy). Nonetheless, both revascularization arms were superior to medical therapy for the relief of symptoms and reduction in exercise-induced ischemia. At 5 years of follow-up, surgery using the internal mammary artery (IMA) in all patients was superior to PTCA and medical therapy for the combined endpoints of death, myocardial infarction, unstable angina, and treatment failure requiring revascularization, and the only significant difference

between PTCA and medical therapy was in the severity of angina, which was significantly less in the PTCA arm.[369]

The most recent trial of PTCA versus medical therapy and the most relevant to contemporary clinical practice is the Atorvastatin Versus Revascularization Treatment Trial (AVERT).[183] Patients with one- or two-vessel disease who were asymptomatic or had chronic mild to moderate stable angina were randomly assigned to atorvastatin (80 mg/d) or PTCA, followed by usual care, including lipid-lowering therapy in some patients, but this therapy was protocol mandated. The serum LDL cholesterol in the atorvastatin arm exhibited a 46 percent decrease versus an 18 percent decrease in the angioplasty arm. At 18 months, the incidence of ischemic events was 21 percent in the PTCA group in comparison with 13 percent in the atorvastatin group (p=0.024), and among patients with exercise-induced ST segment depression at baseline, the rate of ischemic events was 19 percent versus 8.6 percent in the atorvastatin arm.[183]

The U.K. trial Randomized Intervention Treatment of Angina-2 (RITA-2) enrolled 1018 patients who were generally at low risk in that 80 percent of them had Class 0 to 2 stable angina (patients with unstable angina were excluded), 60 percent had single-vessel disease, 33 percent had double-vessel disease, and only 6 percent had significant left ventricular dysfunction.[370] The rate of death and nonfatal myocardial infarction was 6.3 percent in the PTCA group and 3.3 percent in the medical therapy group (p=NS). The difference was attributable primarily to an excess of periprocedural myocardial infarctions in the PTCA group. The benefits of PTCA over medical therapy in the relief of symptoms occurred primarily in patients who at baseline had much more severe symptoms. The results of this trial are consistent with those of other trials comparing PTCA with medical therapy, which have demonstrated that PTCA is more effective in the relief of symptoms but does not produce any apparent reduction in mortality or late myocardial infarction.

The Duke University data base provides important information on the relative benefits of CABG, PTCA, and medical therapy on survival in 9263 patients referred for cardiac catheterization between 1984 and 1990. Adjusted 5-year survival rates for patients with single-vessel disease were similar--95 percent with PTCA and 94 percent with medical therapy; in patients with two-vessel disease, the rates were 91 and 86 percent, respectively, and in patients with three-vessel disease, they were 81 and 72 percent. These trends suggest that PTCA is superior to medical management in patients with multivessel disease (Fig. 37-5) .

PCI IN PATIENTS WITH LEFT VENTRICULAR DYSFUNCTION.

Several studies of PCI in patients with left ventricular dysfunction have documented a high initial procedural success rate with successful dilatation of at least one lesion in 88 percent and all lesions in 76 percent. Nonetheless, successful dilatation of all lesions is less than the rate in patients with well-preserved ventricular function, probably a reflection of more extensive CAD and total occlusion,[360] and the long-term results are less favorable. Two-year survival rate among patients with an ejection fraction of 0.40 or less and multivessel disease was only approximately 75 percent.[373] In another series, 23 percent of patients with an ejection fraction less than 0.35 died during mean follow-up period of 21 months.[374] In a 1985-1986 report from the NHLBI Registry, the 4-year survival rate for patients with very poor left ventricular function (ejection fraction <25 percent) was only 45 percent.[360] Nonetheless, 87 percent of patients with a mean ejection fraction of 39.6 percent were alive at the latest follow-up, and 77 percent were alive and free of recurrent myocardial infarction or the necessity for bypass surgery.[360] Another study demonstrated similar results with 3-year survival rates of 83 and 92 percent in patients with ejection fractions of 0.31 to 0.35 and 0.36 to 0.40, respectively, but only 69 percent in patients with an ejection fraction of 0.30 or less.[375] To achieve a good outcome in patients with multivessel disease and left ventricular dysfunction, particularly if angina or ischemia is severe, revascularization should be complete. Complete revascularization, however, is often difficult to achieve with PCI, particularly in the presence of chronic total occlusions, which are not infrequent in these patients. This limitation of PCI in the achievement of complete revascularization is an important factor contributing to its relatively disappointing results in patients with significant left ventricular dysfunction and multivessel disease. It is likely that stents and other devices that have the potential to restore and maintain the patency of vessels with chronic total occlusion will expand the pool of patients with multivessel disease which is amenable to complete revascularization, with the potential for better long-term results.

RESTENOSIS (see also Chap. 38)

Although striking improvement has occurred in the initial results of PTCA during the last 20 years, restenosis continues to dominate late events. The most frequently used definition is greater than 50 percent diameter stenosis and/or greater than 50 percent late loss of the acute luminal gain, but no clear consensus has been reached regarding the optimal angiographic definition.[361] From a clinical perspective, restenosis is considered a recurrent ischemic event, usually angina, but restenosis may be clinically silent in approximately 30 percent of patients.[361] Before the introduction of stents, the incidence was 30 to 50 percent.

MECHANISMS OF AND RISK FACTORS FOR RESTENOSIS.

The pathogenesis of restenosis in response to mechanical injury is incompletely understood and multifactorial. Traditionally, restenosis has been considered to be due to the development of neointimal thickening as a result of migration and stimulation of smooth muscle by growth factors. The elastic properties of the vessel undergoing PTCA and its recoil in the development of restenosis have also received attention (Fig. 37-6) . Recent concepts of restenosis suggest that intimal proliferation may account for only about 30 percent of the late loss in lumen diameter 6 months after PTCA. The major mechanism appears

Figure 37-5 Hazard ratios for percutaneous transluminal coronary angioplasty (PTCA) versus medicine calculated from the Cox regression model to evaluate relative survival differences. Points indicate hazard ratios for each level of the coronary artery disease index; bars indicate 99 percent confidence intervals. The horizontal line at ratio 1.0 indicates the point of prognostic equivalence between treatments. Hazard ratios below the line favor PTCA; those above the line favor medicine. Prox LAD=proximal left anterior descending coronary artery; VD=vessel disease. *(From Mark DB, Nelson CL, Califf RM, et al: Continuing evolution of therapy for coronary artery disease: Initial results from the era of coronary angioplasty. Circulation 89:2015, 1994. By permission of the American Heart Association, Inc.)*

Figure 37-6 Possible mechanisms of restenosis after percutaneous transluminal coronary angioplasty (PTCA) and coronary stenting. Serial intravascular ultrasonographic studies suggest that PTCA almost always disrupts plaque without reducing the total intimal area, frequently causes dissections that penetrate into the tunica media through the internal elastic lamina, and transiently enlarges the vessel, measured as the cross-sectional area subtended by the external elastic lamina. Restenosis is caused by pathological arterial remodeling characterized by shrinkage of the area circumscribed by the external elastic lamina and, to a lesser extent, by neointimal thickening. Coronary stenting also enlarges the cross-sectional area of the vessel. The radial force of the stent prevents vessel shrinkage, but neointimal proliferation can be excessive. *(From Bittl JA: Advances in coronary angioplasty. N Engl J Med 335:1290, 1996. By permission of the Massachusetts Medical Society.)*

to be shrinkage of the dilated segment--a maladaptive form of arterial remodeling.[349] [362] This mechanism would explain why stenting, which produces a larger luminal area, is so effective in decreasing the incidence of restenosis. In contrast to the mechanisms of restenosis in native vessels, stent restenosis is accounted for primarily by neointimal proliferation through the stent.[349] Clinical variables that appear to be associated with increased rates of restenosis include diabetes, severe angina, male sex, smoking, and older age. *Anatomical* factors include total occlusion, left anterior descending coronary artery location, saphenous vein graft lesions, long lesions, and multivessel or multilesion PTCA. *Procedural* variables include greater residual stenosis following PTCA, severe dissection, the absence of an intimal tear, the use of inappropriately sized balloons, and the presence of thrombus.

PREVENTION OF RESTENOSIS.

The single major advance in the reduction of restenosis has been the development of stents. In the Belgium Netherlands Stent (BENESTENT) Trial, restenosis rates were 22 percent in the stent group versus 32 percent in the group receiving PTCA alone. This improvement was accompanied by a reduction in clinical events.[376] In the Stent Restenosis Study (STRESS), restenosis rates were 32 and 42 percent in the stent and PTCA groups, respectively. Intracoronary radiation therapy using beta and gamma emitters shows promise in preventing restenosis.[377] [378] Many issues need to be resolved, including cost and logistics, long-term safety, and the potential incidence of "late" restenosis or subacute reocclusion.

MANAGEMENT OF RESTENOSIS.

The incidence of restenosis peaks between 3 and 6 months, and this interval is the period of maximal vigilance for detecting restenosis in asymptomatic patients. The role of "routine" cardiac stress testing, particularly in asymptomatic patients, has not been clarified. Angiography after PTCA should be confined to patients with symptoms or abnormal functional studies because angiographic as opposed to clinical follow-up is associated with a marked increase in repeat revascularization procedures.[379]

Restenosis is amenable to repeat PCI, but it is not entirely clear whether lesions in which restenosis has developed are more prone to the development of restenosis after a subsequent percutaneous intervention.[380] Among patients with stable or unstable angina and restenosis, a 93 percent anatomical success rate after repeat angioplasty has been reported, and most patients experienced significant long-term clinical improvement. However, the likelihood of recurrent angina requiring subsequent bypass surgery was greater than in patients undergoing PTCA for the first time.[381] In patients undergoing a third PTCA for restenosis at the same site, an interval of less than 3 months between the second and third procedures was strongly associated with further restenosis, thus suggesting that such patients should be considered for CABG.[382]

CHRONIC TOTAL OCCLUSION.

Chronic total occlusions are present in 20 to 40 percent of patients with angiographic documentation of CAD[383] and are particularly frequent in patients with multivessel disease and left ventricular dysfunction, in whom a total occlusion is a formidable obstacle to PCI success and the completeness of revascularization. This problem is particularly relevant in the presence of bridging collaterals, an estimated duration of occlusion of more than 3 months, and vessel diameter less than 3 mm.[384] After initially successful elective coronary angioplasty of total occlusions, the restenosis rate was 45 percent in vessels with total occlusion in comparison with 34 percent in those with subtotal obstruction (p0.001), primarily because of an increased number of total occlusions at follow-up angiography[385] (19.2 vs. 5.0 percent for stenoses, p0.001).

Several studies have documented the feasibility of stenting in patients with chronic total occlusions,[386] and the apparent superiority of stenting over PTCA was suggested by the results of small randomized trials in highly selected patients. [387] [388]

PCI IN WOMEN.

The in-hospital mortality among women is slightly higher than among men; however, after a successful procedure, the long-term survival for women is excellent and similar to that for men. Still, women are more likely to experience a recurrence of angina.[389] However, in the BARI Trial, after multivariable adjustments, female gender was shown to be an independent predictor of improved 5-year survival after either form of revascularization.[390]

PCI IN THE ELDERLY.

Catheter-based revascularization is particularly attractive in the elderly because of age-related changes in cognitive function and cerebrovascular events after CABG surgery and because of the adverse effect of coexisting disease (which is frequent in the elderly) on

perioperative outcome.[391] Nonetheless, the increased prevalence of multivessel and diffuse disease and left ventricular dysfunction in the elderly diminishes the proportion of patients likely to have significant long-term benefits in comparison to CABG.[392] The more unfavorable coronary artery anatomy in the elderly population together with left ventricular dysfunction is reflected by the high mortality and periprocedural complication rates in the elderly undergoing PTCA, in addition to greater recurrence of angina in hospital survivors. Still, periprocedural outcomes are improving. Between 1990 and 1992 at the Mayo Clinic, 768 patients 65 years or older had PTCA and were compared with 982 patients who had the procedure between 1980 and 1989.[393] Despite the increased complexity and comorbidity of the latter group, procedural success rates were higher and periprocedural complications lower in the more recent group. However, event-free survival after discharge did not improve and was essentially the same in the two groups, with an overall rate of death from myocardial infarction during the initial hospitalization and 6-month follow-up of approximately 10 percent.[393]

PCI IN CORONARY BYPASS GRAFTS.

CABG and PCI are often considered competitive procedures, but it is more appropriate to view them as complementary. An increasing number of patients who have had CABG and later have recurrent ischemia undergo revascularization with a percutaneous interventional technique. At the Mayo Clinic, approximately 20 percent of all PCIs are in patients who have had previous CABG.[394]

The initial and subsequent success rates of PCI in venous bypass grafts are lower than in native vessels. Success rates are approximately 90 percent, with restenosis rates ranging from 40 to 70 percent. The results are better with dilatation of distal graft lesions.

Innovative approaches to the management of vein graft atherosclerosis include catheter-based aspiration systems, in which the techniques of aspiration and filters are combined to prevent distal emboli,[395] glycoprotein IIb/IIIa platelet receptor inhibitors,[396] and the use of coronary ultrasonography to lyse thrombi.[397] The most encouraging development in patients with vein graft stenoses has been the use of elective stent replacement, which in several initial studies appears to have decreased the long-term incidence of restenosis from 40 to 70 percent after PTCA to 17 to 30 percent with stenting.[398] Long-term results from stenting of saphenous vein grafts are not available but appear to be superior to those after PTCA. An ACC Expert Consensus Document stated that in selected patients with saphenous vein graft disease, stents have resulted in improved initial success rates and larger acute angiographic gain, but restenosis rates and longer-term morbidity are still increased in comparison with stenting in large native coronary arteries.[398] Elective stent placement will probably become the treatment of choice in the management of vein graft stenosis. Whether these results will improve with the adjunctive use of other devices such as transluminal extraction cardiac atherectomy remains to be determined.

COMPARISON OF PCI AND CORONARY ARTERY BYPASS SURGERY. See p. 1319 .

OTHER CATHETER-BASED TECHNIQUES.

Lasers, rotablators, and atherectomy are discussed in Chapter 38 .

CONCLUSIONS.

PCI represents a major advance in the management of CAD, and new developments in interventional cardiology over the last 5 years have had a substantial effect on outcomes and on expanding the pool of patients eligible for these procedures. The practice of interventional cardiology has been revolutionized by coronary stenting, and further advances in coated stents and antithrombotic agents are likely. However, it must be appreciated that restenosis remains a problem, and management of a patient with chronic total occlusion by PCI is suboptimal. The latter is probably the major reason why patients are deemed unsuitable for PCI and referred for CABG. Also, it must be appreciated that a dilatable lesion represents an isolated target whereas atherosclerosis is a diffuse process. Thus, PCI is but one aspect of a comprehensive therapeutic strategy that should vigorously address the risk factors for CAD.

Coronary Artery Bypass Surgery

In 1964, Garrett, Dennis, and DeBakey first used CABG as a "bailout" procedure.[399] Widespread use of the technique by Favoloro and Johnson and their respective collaborators followed in the late 1960s.[400] [401] Use of the IMA graft was pioneered by Kolessov in 1967 and by Green and colleagues in 1970.[402] [403]

The number of coronary bypass operators in the United States increased by 227 percent from 1979 to 1997, and in 1997, approximately 366,000 patients underwent coronary bypass surgery.[5] The advent of PCI may have blunted the growth of CABG. Nevertheless, CABG remains one of the most frequently performed operations in the United States; approximately 1 in every 1000 persons undergoes CABG on an annual basis, and this procedure results in the expenditure of almost $50 billion annually.

The appropriate use of invasive cardiovascular procedures is undergoing increasing scrutiny. It is therefore reassuring to note that in studies of coronary angiography and bypass surgery in New York State and Canada, only 6 and 4 percent of bypass procedures, respectively, were considered inappropriate.[404] In a study from The Netherlands, 84 percent of decisions to perform CABG were rated appropriate, 12 percent uncertain, and 4 percent inappropriate.[405] A recent review of surgical indications from a consortium of academic medical centers demonstrated that only 1.6 percent of operations were considered inappropriate and 7 percent were uncertain.[406]

Technical Considerations

When a decision has been reached to proceed with CABG, administration of beta blockers, nitrates, and calcium antagonists is continued until surgery. It is crucial to minimize perioperative damage and protect the myocardium. The most commonly used method involves a single period of aortic cross-clamping with intermittent infusion of cold cardioplegia solution. A 1994 trial of cold crystalloid versus warm blood cardioplegia in elective bypass surgery in patients with well-preserved preoperative ventricular function demonstrated low mortality and morbidity with both techniques.[407] Cardioplegic solutions may be sanguineous and have high concentrations of potassium with or without added substances, such as O_2 , buffers, and free radical scavengers.[408] Retrograde cardioplegia through the coronary sinus facilitates more uniform distribution of cardioplegic solution. Many surgeons now use a combination of antegrade and retrograde perfusion,[409] as well as topical hypothermia with cold saline or ice slush as an adjunct.

Among patients with satisfactory preoperative cardiac function, a wide range of techniques have produced excellent results. This success is probably a reflection of the extent of myocardial functional reserve in those with well-preserved systolic function. In contrast, among patients with depressed left ventricular function (both acutely and chronically), it is easier to demonstrate a benefit with more

Figure 37-7 Aorticovenous anastomosis in a coronary artery-saphenous vein bypass graft. *A,* Direction of the anastomotic site for left-sided grafts. *B,* Details of aortic orifices. *C,* Direction of right coronary artery (RCA) grafts. *(From Cohn LH: Surgical techniques of emergency coronary revascularization. In Cohn LH [ed]: The Treatment of Acute Myocardial Ischemia: An Integrated Medical-Surgical Approach. Mt Kisco, NY, Futura, 1979, p 87. By permission.)*

specialized protocols, including the use of sanguineous cardioplegic techniques, with or without substrate enhancement,[408] and blood cardioplegia.[410] The theoretical advantages of blood cardioplegic solutions, which may be helpful in patients with severe chronic left ventricular dysfunction, include superior buffering capacity, enhanced flow rates at a capillary level, and a reduction in free radicals.[410]

Renewed interest in coronary bypass surgery without cardiopulmonary bypass has been stimulated by the desire to avoid blood transfusions, by economic issues, and by the wish to avoid the damaging neurological effects of bypass, particularly in the elderly and in patients with heavily calcified aortas.[411] An alternative approach to revascularization using the beating heart is off-pump coronary bypass, which frequently entails a conventional median sternotomy and mechanical suction stabilizing systems. This combination enhances surgical exposure and is particularly useful if multivessel bypass grafting is contemplated. This technique is particularly attractive in patients with diffuse aortic atherosclerosis, and preliminary results are encouraging.[412] [413] [414] [415]

MINIMALLY INVASIVE CABG.

Other approaches are termed "less invasive" or "minimally invasive" and include the use of alternative incisions such as a left thoracotomy with or without cardiopulmonary bypass or fluoroscopic techniques. The ultimate success of these "nontraditional" approaches to CABG will depend on long-term graft patency and the development of new techniques that will increase exposure to allow for more complete revascularization. Initial reports are encouraging in regard to decreasing the number of days spent in the intensive care unit and hospital and reducing neurological complications, but additional large studies are needed.

An innovative approach to coronary revascularization is the "port access" method, which uses small thoracotomy ports for cardiac manipulation; cardiopulmonary bypass is established by groin cannulation. Experience with this technique is limited, although the two largest single-center series and the first report of the Port-Access International Registry, which documented the results of 555 bypass procedures, were encouraging. Nonetheless, follow-up has been short, and the results do not reflect the "learning curve." Limitations to the use of this technique include atherosclerotic involvement of the aortic arch, high cost, long operating times, and the risk of aortic dissection.[415] [416] [417]

A novel approach to coronary revascularization integrates coronary artery bypass with PTCA by combining a minimally invasive coronary bypass surgical procedure on the left anterior descending coronary artery with PTCA on the remaining vessels. Further experience is needed to clarify the selection criteria and long-term strategy and whether it offers any advantages over multivessel bypass surgery alone.[101] [418]

"The learning curve" of minimally invasive coronary bypass surgery has led to numerous reports of early graft failure.[419] In many centers, intraoperative or early postoperative angiography is performed to assess the quality of the anastomosis. It should be emphasized that with conventional surgical techniques, the *early* patency rates of an IMA graft are excellent (98.7 percent in one large series), and less than 50 percent stenosis was noted in 91 percent of grafts. The future of minimally invasive and other techniques will depend on their ability to equal these excellent patency rates.[420]

VENOUS CONDUITS.

The saphenous vein is used mainly for distal branches of the right and circumflex coronary arteries and for sequential grafts to these vessels and diagonal branches (Figs. 37-7 and 37-8) . In emergency situations, many surgeons prefer the saphenous vein, which can be harvested and grafted more rapidly, to the IMA. Arm vein grafts are not as effective as either IMA or saphenous vein grafts.

Eight to 12 percent of saphenous vein grafts become occluded during the early perioperative period. Trauma to the vein during surgical preparation can denude the endothelium, impair the intrinsic fibrinolytic activity of the saphenous vein, and damage the vessel wall, thereby predisposing to early thrombosis.[421] Careful harvesting of the

Figure 37-8 Venocoronary anastomosis to the proximal portion of the arteriotomy. *(From Cohn LH: Surgical techniques of emergency coronary revascularization. In Cohn LH [ed]: The Treatment of Acute Myocardial Ischemia: An Integrated Medical-Surgical Approach. Mt Kisco, NY, Futura, 1979, p 87. By permission.)*

graft, with particular attention to avoidance of overdistention and the use of modified storage solutions, has been shown to improve patency and preserve the integrity of the graft in both animal models and the clinical setting.

INTERNAL MAMMARY ARTERY BYPASS GRAFTS.

The IMA, also known as the internal thoracic artery, is usually remarkably free of atheroma, especially in patients younger than 65 years. When it is grafted to a coronary artery (Figs. 37-9 and 37-10) , it appears to be virtually immune to the development of intimal hyperplasia, which is almost universally seen in aortocoronary vein grafts.[422] Atherosclerotic changes in the IMA develop in only a small percentage of patients after coronary bypass surgery. The IMA is delicate, so great care has to be taken to mobilize the vessel without traumatizing it.[423] The procedure is time consuming, and thus, the IMA is not often used for emergency surgery.

Comparative morphological and angiographic studies of IMA and saphenous vein bypass grafts that have been implanted long-term show that accelerated atherosclerosis occurs commonly in saphenous vein grafts but is extremely rare in IMA grafts. Several potential explanations may be offered for the superiority of the IMA graft.[423] The media of the artery may derive nourishment from the lumen as well as from the vasa vasorum, and the internal elastic lamina of the IMA is uniform. Moreover, the finding that the endothelium of the IMA produces significantly more prostacyclin than that of the saphenous vein may explain why endothelium-dependent relaxation is more pronounced, which may allow flow-dependent autoregulation to occur.[424] The diameter of the IMA graft is usually a closer match to that of the recipient coronary artery than is the diameter of a saphenous vein. The increasing popularity of the IMA as a conduit is reflected in the Society of Thoracic Surgeons data base. Among the patients in the United States who had first operations in 1990, the IMA was used in 48.5 percent, but this figure steadily increased to 79.77 percent by 1997.[425]

In one series, IMA grafts and saphenous vein grafts had patency rates of 95 and 93 percent, respectively, at 1 year,

Figure 37-9 Internal mammary grafting consisting of an in situ left internal mammary artery (IMA) graft to the left anterior descending artery (end to side) and diagonal branch (side to side), with the diamond anastomotic technique used for the latter. The details show the IMA pedicle rolled up over the diagonal coronary artery to facilitate exposure and the use of continuous suture. *(From Jones EL: Extended use of the internal mammary-coronary artery bypass. J Card Surg 1:13, 1986. By permission of Futura Publishing Co.)*

Figure 37-10 Different types of internal mammary artery grafts. A single attached internal mammary artery graft (either the right or left) remains attached proximally to the subclavian artery and is connected to the coronary arteries. Bilateral internal mammary artery grafts (right and left) are joined end to side to coronary arteries. Sequential internal mammary artery grafts consist of an attached or free internal mammary artery with one or more side-to-side anastomoses and one end-to-side anastomosis. The internal mammary artery Y graft has two terminal branches of either the attached or free internal mammary artery sutured to two coronary arteries. A free internal mammary graft is placed by transecting the right or left internal mammary artery near its origin in the subclavian artery and anastomosing the proximal portion of the artery to the aorta and the distal end to the coronary artery. *(From Tector AJ, Schmahl TM, Canino VR: Expanding the use of the internal mammary artery to improve patency in coronary artery bypass grafting. J Thorac Cardiovasc Surg 91:9, 1986. By permission of Mosby.)*

but at 5 and 10 years, the patency rates of the IMA grafts were 88 and 83 percent, superior to the 74 and 41 percent rates for saphenous vein grafts.[426] Excellent long-term results have also been achieved with use of the right IMA as a free or sequential graft.[427] However, fibrointimal proliferation occasionally develops in IMA grafts, and the resultant narrowing may be a factor in late graft closure.[423]

Patients receiving an IMA graft have a decreased risk of late death, myocardial infarction, cardiac events, and reoperations, and this clinical advantage persists for up to 20 years.[428] The contemporary standard for bypass grafting advocates routine use of the left IMA for grafting the left anterior descending coronary artery, with supplemental saphenous vein grafts to other vessels.

Although the benefits of a single IMA graft over a saphenous vein graft alone are not in dispute, the superiority of bilateral IMA grafts over a single IMA graft and one saphenous vein graft is less well accepted.[429] Initial enthusiasm for the use of bilateral IMA grafts was tempered by the higher rate of postoperative complications, including bleeding, wound infection, and prolonged ventilatory support. Subsequent series have shown that bilateral versus single IMA grafting is associated with lower rates of recurrent angina pectoris, reoperation, and myocardial infarction and a trend toward improved survival,[430] but at the cost of a higher rate of sternal wound infections, particularly among patients who are obese or diabetic or require prolonged ventilatory support.

COMPLICATIONS OF ARTERIAL CONDUITS.

Inadequate flow rates with evidence of myocardial ischemia in the perioperative period are rare after IMA grafts to the left anterior descending coronary artery or its

diagonal branches. [423] Perioperative spasm is the presumed cause and can be managed by the administration of sodium nitroprusside or a combination of glyceryl trinitrate and verapamil.[431] Other complications include an increased incidence of sternal wound infections, which is more frequent in obese patients and diabetics and after bilateral IMA implants.

OTHER ARTERIAL CONDUITS.

The success of IMA grafts has stimulated interest in the use of other arterial conduits, particularly in patients who are younger, diabetic, or hyperlipidemic or in whom the saphenous veins are unsuitable or unavailable.[423] Initial enthusiasm for use of the radial artery was blunted by reports of high reocclusion rates. More recent experience, in which attention has been paid to avoiding spasm by minimizing manipulation and the use of calcium channel blockers, has been favorable. Brodman and colleagues reported a 95 percent 12-week patency rate in a large series of patients receiving radial artery grafts.[432] Another recent series reported an 84 percent 5-year patency rate in 100 consecutive recipients of radial grafts versus a 90 percent patency rate for the IMA.[433]

The right gastroepiploic artery can be harvested by extending the median sternotomy incision toward the umbilicus. It is frequently placed as a graft to the right coronary artery, but both the circumflex and the left anterior descending coronary arteries can be grafted with this conduit.[434] Early results demonstrated excellent patency rates, but there is a paucity of data on long-term results. Similarly, the inferior epigastric artery has been used as a free graft for coronary revascularization, with good short-term patency rates but without long-term data.[435] Cryopreserved homologous saphenous vein grafts and glutaraldehyde-treated umbilical veins have been used, but the patency rates are not optimal. These grafts should be used only as a last resort, and this restriction also applies to the use of bovine IMA, Dacron, and polytetrafluoroethylene (PTFE) grafts.[436]

THE DISTAL VASCULATURE.

The state of the distal coronary vasculature is important for the fate of bypass grafts. Late patency of grafts is related to coronary arterial runoff as determined by the diameter of the coronary artery into which the graft is inserted, the size of the distal vascular bed, and the severity of coronary atherosclerosis distal to the site of insertion of the graft. The highest graft patency rates are found when the lumina of the vessels distal to the graft insertion are greater than 1.5 mm in diameter, perfuse a large vascular bed, and are free of atheroma obstructing more than 25 percent of the vessel lumen. For saphenous veins, optimal patency rates are achieved with a

lumen of 2.0 mm or greater.

FLOW RATES.

When measured at the time of surgery, flow rates through saphenous vein grafts average nearly 70 ml/min. Flow rates less than 45 ml/min--and especially less than 25 ml/min--are more frequently associated with graft closure than are flow rates exceeding 45 ml/min.[437] The utility of measuring flow rates is enhanced by taking into account the type of conduit used and the size of the distal vasculature. If flow rates are lower than expected, reassessment of the anastomosis with a probe may be helpful. Possible causes of reduced flow include (1) subcritical obstruction of the coronary artery, (2) a technically poor anastomosis with narrowing of the lumen from kinking of the vessel or pinching at the site of anastomosis, (3) a small myocardial mass perfused by the graft, and (4) a diseased distal vascular bed.[438]

Other Surgical Procedures for Ischemic Heart Disease

Coronary bypass surgery may be combined with surgical procedures aimed at correction of atherosclerotic disease elsewhere in the cardiovascular system, such as correction of mechanical complications of myocardial infarction (mitral regurgitation or ventricular septal defect), left ventricular aneurysms, and concomitant valvular heart disease. Not unexpectedly, morbidity and mortality are correspondingly increased because of the added complexity of the procedure and, in many patients who require these other procedures, the presence of underlying left ventricular dysfunction (see below).

TRANSLASER MYOCARDIAL REVASCULARIZATION.

Translaser myocardial revascularization, an innovative approach to the treatment of ischemic heart disease, is currently under evaluation.[439] [440] The initial assumption was that laser-mediated channels would provide a network of functional connections between the left ventricular cavity and the ischemic myocardium. Subsequent observations demonstrating closure of the channels within hours or days despite apparent relief of symptoms have led to alternative explanations for the apparent clinical success of the procedure. These explanations include improved perfusion by stimulation of angiogenesis, a potential placebo effect, and an anesthetic effect mediated by the destruction of sympathetic nerves carrying pain-sensitive afferent fibers[441] [442] or periprocedural infarction. A recent study evaluated sympathetic innervation with [[11] C]hydroxyephedrine and demonstrated decreased myocardial uptake of this substance in most patients, without significant change in resting or stress myocardial perfusion, which suggests that the improvement in angina after the procedure may be partly due to sympathetic denervation.[442]

Initial clinical studies in patients with severe CAD often amenable to a bypass procedure have been promising in that the majority have demonstrated a clear reduction in anginal severity and improved exercise tolerance. Several small randomized trials of translaser myocardial revascularization have resulted in improvement in comparison with maximal medical therapy.[443] [444] [445] The results of one trial suggested improvement in perfusion as assessed by PET, but such improvement was not shown with thallium scintigraphy in another trial.[444] [445] In contrast to the positive studies, Schofield and associates reported no significant improvement in exercise time and 12-minute walking distance up to 1 year after translaser myocardial revascularization with a carbon dioxide laser,[446] although the laser-treated patients had a modest reduction in the frequency of angina. The subjective improvement in the severity of angina found in this study, in the absence of any measurable effect on myocardial perfusion or exercise tolerance, argues for a placebo effect or denervation. Two other randomized trials from the United States confirmed the improvement in angina in patients receiving surgical translaser myocardial revascularization, but no study has demonstrated a reduction in myocardial ischemia as measured objectively, and laser revascularization was not associated in any of the three randomized trials with long-term improvement in left ventricular systolic function.[447] [448] On the basis of data from the randomized trials, it would appear that the widespread use of translaser myocardial revascularization as a "stand-alone" method cannot be justified, but it may still have a role as an adjunctive procedure during CABG in patients who have some vessels suitable for bypass but others that are unsuitable.

After the FDA approved carbon dioxide laser translaser myocardial revascularization for the sole treatment of Class III or IV angina in August 1998, interest has developed in other sources of laser energy, such as percutaneous myocardial revascularization (PCMR) in association with various techniques of left ventricular mapping (Fig. 37-11) . Initial results have been promising,[449] [450] and the randomized Potential Angina Class Improvement from Intramyocardial Channels (PACIFIC) Trial of 231 patients with Class III or IV angina suggested that the procedure was safe. Moreover, at 6 months the PCMR group had symptomatic improvement in comparison with the maximal medical therapy group (Osterle S, personal communication). Nonetheless, the placebo effect has not been eliminated, and randomized trials in which both patients and investigators are blinded are currently in progress. Because the mechanisms underlying the observed clinical benefits are not well defined, the future of this technique depends on well-designed randomized trials, but it is possible that translaser myocardial revascularization or PCMR may eventually be combined with other interventions such as incomplete bypass surgery or used as an adjunct to PCI. Whether this technique will fulfill its potential as a vehicle for the delivery of angiogenic factors and other forms of gene therapy remains to be determined.[451]

Surgical Outcomes

OPERATIVE MORTALITY.

Risk factors for death following coronary artery surgery may be separated into five categories: (1) preoperative factors related to CAD, including recent acute myocardial infarction, hemodynamic instability, left ventricular dysfunction, extensive CAD, the presence of left main CAD, and severe or unstable angina; (2) preoperative factors related to the aggressiveness of the arteriosclerotic process, as reflected in associated carotid or peripheral vascular disease; (3) preoperative biological factors (older age at surgery, diabetes mellitus, and perhaps female gender); (4) intraoperative factors (intraoperative ischemic damage and failure to use IMA grafts)[452] ; and (5) environmental

Figure 37-11 Schematic demonstrating the mechanism of percutaneous myocardial laser revascularization (PCMR). Left, A ventriculogram and coronary angiogram performed at the beginning of the procedure demonstrate that the left ventricular anatomy is suitable for treatment. A steerable catheter is delivered retrogradely across the aortic valve, and the catheter for energy delivery is advanced through a guiding catheter and placed in the left ventricular chamber. The steerable catheter allows access to the endocardial surface. Right, When the energy delivery catheter is in contact with the endocardium, intramyocardial channels are made by tissue ablation. The channels cause intramyocardial hemorrhage by transecting the microvasculature (bold arrow). A=epicardial artery; v=epicardial vein. *(From Kantor B, McKenna CJ, Caccitolo JA, et al: Transmyocardial and percutaneous myocardial revascularization: Current and future role in the treatment of coronary artery disease. Mayo Clin Proc 74:585, 1999. By permission of Mayo Foundation for Medical Education and Research.)*

or institutional factors, including the specific surgeon and treatment protocols used.[453]

The patient population undergoing CABG has been changing over time, particularly with the wider use of PCI. In comparison with the 1970s, patients undergoing CABG today are older, include a higher percentage of women, and are "sicker" in that a greater proportion have unstable angina, three-vessel disease, previous coronary revascularization with either CABG or PCI, left ventricular dysfunction, and comorbid conditions, including hypertension, diabetes, and peripheral vascular disease.

In-hospital mortality after isolated coronary bypass surgery was characterized by a steady decline from 1967 to the 1980s. Recently, a plateau and perhaps even a slight increase has been noted in morbidity and mortality, findings reflective of the changing demographics toward an older and sicker population of patients undergoing initial surgery and a higher proportion undergoing reoperation.[454] In 1997, perioperative mortality among 174,806 patients undergoing coronary bypass surgery entered into the Society of Thoracic Surgeons data base was 2.8 percent. In patients undergoing an elective first isolated coronary bypass operation, the mortality in 1997 was 1.7 percent.[425]

With increasingly wide scrutiny of procedural results, it has become recognized that absolute rates of morbidity and mortality might not provide a fair basis for comparing institutions and individuals, unless the characteristics of the patients are considered. Several models have been developed and refined with the objective of predicting perioperative mortality.[455] Major determinants are advancing age, poor left ventricular function, and the urgency of surgery, but additional factors such as comorbid conditions and coronary anatomy have added independent predictive value.

A useful perspective of long-term survival after coronary bypass surgery is provided by the most recent follow-up data (mean, 15 years) from the CASS Registry. Ninety percent of patients were alive at 5 years, 74 percent at 10 years, and 56 percent at 15 years. The hazard function for death decreases rapidly after surgery to its nadir at 9 to 12 months, followed by a steady increase with a doubling of the hazard ratio at 15 years in comparison to that at 5 years.

PERIOPERATIVE COMPLICATIONS

Perioperative morbidity (also see Chap. 60) has also increased because of a larger fraction of higher-risk patients.

PERIOPERATIVE MYOCARDIAL INFARCTION.

Perioperative myocardial infarction, particularly if it is associated with hemodynamic or arrhythmic complications or preexisting left ventricular dysfunction, has a major adverse effect on early and late prognosis.[456] The cardiac troponins and myocardial creatine phosphokinase-MB (CK-MB) may be useful as markers of perioperative infarction.[457] Predictors of perioperative myocardial infarction in the CASS Trial were female gender, severe perioperative angina pectoris, severe stenosis of the left main coronary artery, and three-vessel disease.[456] Preconditioning the myocardium with short periods of ischemic stress interspersed with reperfusion increases the resistance to infarction and appears to reduce myocardial damage during cardiac surgery, but the appropriateness of this technique as a routine clinical tool has not been determined.

RESPIRATORY COMPLICATIONS.

Postoperative changes in pulmonary function after CABG are frequent and troublesome, but rarely serious, except in patients with preexisting chronic lung disease or the elderly. A potentially serious complication is phrenic nerve injury, which may be related to cold-induced damage during myocardial protection strategies or possibly to mechanical injury while harvesting the IMA. The pulmonary consequences vary and range from an asymptomatic

radiographic abnormality to severe pulmonary dysfunction requiring prolonged ventilation.[458]

BLEEDING.

Impaired hemostasis and bleeding complications are an inherent risk of CABG. Reoperation for bleeding is required in 2 to 5 percent of patients. Cardiopulmonary bypass causes derangement of the intrinsic coagulation and fibrinolytic systems in addition to platelet function. The risk of bleeding is increased with age, a smaller body surface area, reoperation, bilateral internal thoracic artery grafts, and the preoperative use of heparin, aspirin, and thrombolytic agents. Bleeding is less common in obese patients,[459] but this complication may be reduced with aprotinin and lysine analogs such as aminocaproic acid and tranexamic acid.[460]

WOUND INFECTIONS.

Major perioperative wound complications, especially mediastinitis and/or wound dehiscence, occur in approximately 1 percent of patients.[458] This risk is substantially increased by the use of double IMA grafts, particularly in diabetic patients,[461] and it is markedly increased in obese patients.[459] Preventive measures include careful skin preparation, increased attention to sterility in the perioperative environment, and preoperative use of antimicrobial agents.[458] Other factors that may decrease perioperative infection include the avoidance of unnecessary blood transfusion in view of the immunosuppressive effect of the latter.

PULMONARY INSUFFICIENCY.

In the Society of Thoracic Surgeons data base,[425] postoperative pulmonary insufficiency requiring ventilation for more than 1 day was noted in 5.5 and 10.7 percent of patients undergoing a first operation and reoperation, respectively. The etiology is multifactorial and includes the presence of preexisting pulmonary disease and numerous perioperative factors related directly to anesthesia, cardiopulmonary bypass, incisional pain, chest tube placement, and occasionally, phrenic nerve damage.[458]

Severe chronic obstructive pulmonary disease, as defined by a forced expiratory volume in 1 second (FEV_1) of greater than 50 percent or an FEV_1/forced vital capacity (FVC) ratio less than 0.70, is associated with a high incidence of postoperative pulmonary complications (29 percent).[462] The left ventricular ejection fraction is also an important determinant of prolonged ventilation.[463]

POSTOPERATIVE HYPERTENSION.

Hypertension can occur in up to one-third of patients postoperatively. The mechanisms are unclear but may be related to increased levels of circulating catecholamines and other humoral factors in addition to vasoconstriction secondary to activation of the renin-angiotensin system. Control of postoperative hypertension is important to prevent myocardial ischemia, cardiac failure, perioperative bleeding, and diminished tissue perfusion.[464] Regardless of the cause, sodium nitroprusside is an effective approach to afterload reduction, and other drugs such as calcium antagonists, nitrates, and beta blockers, including short-acting esmolol, are helpful.[458]

CEREBROVASCULAR COMPLICATIONS.

Neurological abnormalities following cardiac surgery are dreaded complications. Postulated mechanisms include emboli from an atherosclerotic aorta or other vessels, emboli possibly from the cardiopulmonary bypass machine circuit and its tubing, and intraoperative hypotension, particularly in patients with preexisting hypertension.[458] [465] [466] Type I injury is associated with major neurological deficits, stupor, and coma, and type II is characterized by a deterioration in intellectual function and memory.[467] In a recent large multicenter series, the incidence of neurological abnormalities was 6.1 percent, and these abnormalities were almost evenly distributed between type I and type II deficits, with mortality rates of 21 and 10 percent, respectively.[467] Intellectual dysfunction in the early postoperative period, as expressed by a battery of neurocognitive defects, was noted in 75 percent of patients. However, major sequelae were unusual.[468] In regard to the neurological sequelae of cardiopulmonary bypass (including stroke, delirium, and neurocognitive dysfunction), older age in addition to other comorbid conditions associated with atherosclerosis is one of the more powerful predictors.[466] In most studies, atherosclerosis of the proximal aorta has also been a strong predictor of stroke.[465]

Intraoperative manipulation of the aorta is a major cause of atheroemboli and neurological complications. Preoperative or intraoperative screening with transesophageal echocardiography or epiaortic echocardiography to detect mobile aortic atheromas is increasingly being used, although the sensitivity and specificity need to be better defined.[469] An aggressive approach to the management of severe aortic atherosclerosis includes changing the cannulation sites based on echocardiographic findings, no-clamp fibrillatory arrest, and replacement of the ascending aorta.

Bypass surgery performed on the beating heart without the use of cardiopulmonary bypass has less potential for generating cerebral emboli,[411] and it appears to produce a lower incidence of cognitive dysfunction in both short- and intermediate-term postoperative follow-up than does conventional coronary bypass surgery with cardiopulmonary bypass.

ATRIAL FIBRILLATION.

Atrial fibrillation is one of the most frequent complications of coronary bypass surgery. It occurs in up to 40 percent of patients, primarily within 2 to 3 days.[470] In the early postoperative period, rapid ventricular rates and loss of atrial transport may compromise systemic hemodynamics, increase the risk of embolization, and lead to a significant increase in duration of the hospital stay and charge and a twofold to threefold increase in postoperative stroke[471] (see also Chap. 60) .

CONDUCTION DISTURBANCES AND BRADYARRHYTHMIAS.

The incidence of postoperative bradyarrhythmias requiring permanent pacemaker implantation was 0.8 percent in a series of 1614 consecutive patients discharged from the hospital after coronary bypass surgery. Predictive factors were preoperative left bundle branch block, concomitant left ventricular aneurysmectomy, and older age. The majority of patients continued to require permanent pacemaker support during follow-up.

SYMPTOMATIC RESULTS.

Coronary bypass surgery is highly effective in the relief of angina and results in improved quality of life. Approximately 80 percent of patients are free of angina at 5 years and 63 percent at 10 years, but by 15 years only about 15 percent are alive and free of an ischemic event.[472] [473] The acceleration in adverse events after 5 to 15 years is due to gradual occlusion of vein grafts in addition to progressive disease in the native coronary vessels. Independent predictors of recurrence of angina are

female gender, obesity, preoperative hypertension, and lack of use of the IMA as a conduit.[474] In patients with triple-vessel disease undergoing coronary bypass surgery, the completeness of revascularization was a significant determinant of the relief of symptoms over a 5-year period.[475]

In the bypass surgery arms of recent randomized trials of PTCA and CABG, recurrent angina pectoris was reported in 21.5 to 34 percent of patients at a follow-up ranging from 2 to 3 years, but (Canadian classification) grade III or IV angina was present in only 6 percent at 2.5 years in the RITA Trial[364] [476] (Fig. 37-12) .

RETURN TO EMPLOYMENT.

Return to full employment has been variable. Among participants in the surgical arm of the Emory Angioplasty Versus Surgery Trial (EAST), whose mean age was 61 years at entry, only 38.5 percent were gainfully employed at 3 years.[364] In contrast, in a study of patients younger than 65 years who were employed at the time of revascularization, 79 percent who had CABG were working at 1 year, and after adjustment for baseline characteristics, 1-year employment rates were the same among patients treated with surgery, PTCA, or medical

Figure 37-12 Prevalence and severity of angina by treatment group for each annual visit up to 7 years in the RITA-1 Trial. The prevalence of severe angina declines markedly from baseline (0-year follow-up) to the first year of follow-up. During the first few years, angina prevalence and severity are greater after percutaneous transluminal coronary angioplasty (PTCA), but no difference is seen at 7 years. CABG=coronary artery bypass graft. *(From Henderson RA, Pocock SJ, Sharp SJ, et al: Long-term results of RITA-1 trial: Clinical and cost comparisons of coronary angioplasty and coronary-artery bypass grafting. Randomised Intervention Treatment of Angina. Lancet 352:1419, 1998. © by The Lancet Ltd., 1998.)*

therapy.[477] Factors that adversely affect the prospects of patients for returning to work include advanced age, postoperative angina, and a period of either unemployment or disability before surgery. Forty-seven percent of patients undergoing bypass surgery in the EAST Trial were able to engage in moderate or strenuous activity 3 years after the procedure.[364]

GRAFT PATENCY.

Experimental studies and observations in patients suggest that the development of disease in venous aortocoronary artery bypass grafts occurs in several phases. The occlusion rate, which is high in the first year, decreases substantially between the first and sixth years. Between 6 and 10 years after surgery, the attrition rate for grafts increases again. Early occlusion (before hospital discharge) occurs in 8 to 12 percent of venous grafts, and by 1 year, 15 to 30 percent of vein grafts have become occluded.[478] After the first year, the annual occlusion rate is 2 percent and rises to approximately 4 percent annually between years 6 and 10. At 10 years, approximately 50 percent of vein grafts have become occluded, and significant atherosclerosis is present in the substantial proportion of grafts remaining patent, with significant stenoses in 20 to 40 percent.[423] [473] [478] Patency rates with IMA grafts are superior.

EARLY PHASE (FIRST MONTH).

Technical factors that may cause thrombotic closure at the proximal or distal anastomoses include kinking because of excessive length, tension from insufficient length, poor graft flow, and inadequate distal runoff. Surgical manipulation of the saphenous vein during harvesting and preparation prior to grafting play key roles in initiating the sequence of endothelial damage with subsequent platelet and fibrin deposition leading to thrombosis.[421]

INTERMEDIATE PHASE (1 MONTH TO 1 YEAR).

Vein grafts that have been implanted in the arterial circulation for 1 month to 1 year are subject to substantial endothelial denudation and proliferation and to migration of medial cells to the intima. Migration of vascular smooth muscle cells through the internal elastic lamina into the intima may also occur.[421] This initial phase of rapid proliferation is followed after several months by a marked increase in the connective tissue matrix, which further increases intimal and medial thickness. This accelerated process of intimal hyperplasia and thickening is an early stage of atherosclerotic plaque formation and is believed to occur because of interaction between platelets and macrophages and endothelial damage. If the proliferation is severe and localized, as may occur at the site of anastomosis between the grafts and the recipient artery, total occlusion can occur within 1 year.

LATE PHASE (BEYOND 1 YEAR).

Some investigators believe that the development of atherosclerosis in vein grafts, as in native arteries, is a continuum starting from platelet deposition and advancing to smooth muscle cell proliferation and finally to lipid incorporation into the plaque. By 10 years, nearly half of venous grafts patent at 5 years have become occluded.[479] Beyond the first year, particularly after 3 to 5 years, the histological appearance of occluded or obstructed coronary bypass grafts is consistent with atherosclerosis. There is clear evidence of mature lipid-laden plaque, foam cells, cholesterol clefts, ulceration, and areas of calcification with disruption of the medial layer.[480] Late coronary atherosclerosis is often characterized by an extensive thrombotic burden and marked friability of the lesions; the resultant intermittent distal embolization in turn complicates repeat revascularization procedures either by percutaneous coronary reintervention or reoperation.[397] [481] [482]

DETERMINATION OF GRAFT PATENCY.

Although angiography is the most frequently used method for the determination of vein graft patency, the diffuseness of the atherosclerotic process, which in many patients decreases the luminal diameter of the entire vessel, may lead to an underestimation of the severity of a more focal lesion. Alternative approaches to the evaluation of vein graft patency that are being investigated include contrast-enhanced CT, phase-contrast magnetic resonance angiography,[483] and transcutaneous [484] and magnetic resonance measurements of angiographic flow (see Chap. 10) .[485]

PROGRESSION OF DISEASE IN NONGRAFTED ARTERIES.

Disease progression, defined as worsening of a preexisting lesion or the appearance of a new diameter narrowing of 50 percent or greater, can occur at a rate of 20 to 40 percent over 5 to 10 years in nongrafted native vessels.[486] The rate of disease progression appears highest in arterial segments already showing evidence of disease,[487] and it is between three and six times higher in grafted native coronary arteries than in ungrafted native vessels. Disease progression is also greater in arteries with patent grafts than in arteries with occluded grafts[488] and usually occurs proximal to the site of graft insertion.[486] [487] These data suggest that bypassing an artery with minimal disease, even if initially successful, may ultimately be harmful to patients, who incur both the risk of graft closure and the increased risk of accelerated obstruction of native vessels.

EFFECTS OF THERAPY ON VEIN GRAFT OCCLUSION AND NATIVE VESSEL PROGRESSION

Measures aimed at enhancing long-term patency are generally directed at delaying the overall process of atherosclerosis, and as such, they may have several additional benefits.[482]

ANTIPLATELET THERAPY.

A meta-analysis of clinical trials conducted before 1990 suggests that antiplatelet or anticoagulant therapy after coronary artery bypass surgery may prevent graft occlusion.[489] Several trials have demonstrated the efficacy of aspirin therapy when started 1, 7, or 24 hours preoperatively, but the benefit is lost when aspirin is started more than 48 hours postoperatively.[490] Aspirin, 100 to 325 mg/d should be continued indefinitely.[491] The addition of dipyridamole or warfarin in conventional doses has not been shown to provide added benefit.[492] Ticlopidine is effective but not superior to aspirin, and its use should be confined to patients who are intolerant of aspirin. Although the effects of clopidogrel on graft patency have not been studied specifically,[493] it is likely to be at least as effective as aspirin.

LIPID-LOWERING THERAPY.

The rationale for lowering lipid levels in patients with CAD was extended to postoperative patients with at least one patent vein graft and LDL cholesterol concentrations between 130 and 175 mg/dl in the Post-Coronary Artery Bypass Graft Trial.[191] Patients who received aggressive treatment with lovastatin and, if needed, cholestyramine to decrease LDL cholesterol to less than 100 mg/dl, in comparison with "moderate" therapy resulting in an LDL cholesterol level of 134 mg/dl, had a

lower rate of progressive atherosclerosis in grafts (27 vs. 39 percent, *p*0.001) and a lower rate of repeat revascularization procedures over a 4-year period. A similar benefit in both native vessels and grafts was noted in the Cholesterol-Lowering Atherosclerosis Study (CLAS), which used combined colestipol and niacin therapy.[494] The Lipid Coronary Angiography Trial (LOCAT) compared gemfibrozil and placebo in patients with LDL cholesterol concentrations of 175 mg/dl or lower and an HDL cholesterol of less than 42 mg/dl. The treated group had a lower rate of progression of native coronary atherosclerosis and a lower incidence of new lesions in the vein graft (2 vs. 14 percent) after an average 32-month follow-up.[194]

SMOKING CESSATION.

Strong evidence from the CASS randomized trial and other series indicates that continued smoking after bypass surgery increases mortality, the recurrence rate of angina, the need for repeat hospitalization, and repeat revascularization procedures.[160] [161] Not unexpectedly, continued smoking has been associated with angiographic progression of graft disease.

Patient Selection

Indications for coronary bypass surgery consist of the need for improvement in the quality and/or the duration of life. Patients whose angina is not controlled by medical management or who have unacceptable side effects with such management should be considered for coronary revascularization. The decision to perform PCI or CABG is based partly on coronary anatomy, left ventricular function, and patient preference. Recent technological developments have enlarged the pool of patients with single-vessel or multivessel disease amenable to PCI. For patients who are suitable for PCI and who do not fulfill the criteria of anatomy requiring surgery (e.g., left main CAD or severe three-vessel disease and left ventricular dysfunction), PCI is generally the procedure of choice. However, if medical therapy has failed, i.e., the symptoms are severe or sufficient to impair quality of life, and the patient is not a good candidate for PCI, CABG should be strongly considered. This procedure is also indicated for patients with CAD, regardless of symptoms, in whom survival is likely to be prolonged**,** [495] and for patients in whom noninvasive testing suggests "high risk," independent of symptoms.[496]

In making the decision about revascularization, it is important to assess the patient's prognosis (Table 37-10) and

TABLE 37-10 -- DETERMINANTS OF ADVERSE PROGNOSIS IN PATIENTS WITH CORONARY ARTERY DISEASE

how it may be affected by surgery. The key initial step is to stratify patients into categories of risk with continued medical therapy based on an analysis of clinical, noninvasive, and, in some patients, angiographic variables. This process defines the *indications* for revascularization over medical therapy and, by implication, the indications for coronary angiography in patients with chronic stable angina. More recent randomized trial data are helpful in finding which *modality* of revascularization (PCI or surgery) is preferable.[496]

The four major determinants of risk in CAD are the extent of ischemia, the number of vessels diseased, left ventricular function, and the electrical substrate (Fig. 37-13) . The major effect of coronary revascularization is on ischemia,

Figure 37-13 Risk stratification in coronary artery disease (CAD). A Venn diagram illustrates factors affecting the prognosis of chronic CAD. Major determinants are the severity of symptoms and/or ischemia, presence of multivessel disease and in particular three-vessel disease, extent of myocardial jeopardy as defined by clinical stenoses in the left main coronary artery and proximal left anterior descending coronary artery, and left ventricular dysfunction. Interactions between an abnormal arrhythmic substrate, evidence of recent plaque rupture (acute coronary syndromes), and general health and coexisting conditions are important.

and the magnitude of the benefit compared with that of medical therapy is enhanced with left ventricular dysfunction, particularly in the presence of reversibly ischemic jeopardized myocardium. In this context, patients can be risk-stratified according to the expected benefit of revascularization versus medical therapy. Patients with more extensive and severe CAD have an increasing magnitude of benefit from CABG over medical therapy (Fig. 37-14 *A* and Table 37-11) . Selection of patients for surgery is based on clinical, angiographic, and noninvasive testing characteristics that may be considered markers or, in some cases, surrogates of the three major predictors--ischemia, left ventricular function, and, to a lesser extent, arrhythmia. Other factors that must always be considered in the decision are general health and noncoronary comorbid conditions.

Natural History of Angina Pectoris

CLINICAL AND ELECTROCARDIOGRAPHIC CRITERIA.

Data from the Framingham Study, obtained before the widespread use of aspirin, beta blockers, and aggressive modification of risk factors, showed that the average annual mortality rate of patients with chronic stable angina was 4 percent.[497] The combination of these treatments has improved prognosis. Nonetheless, a recent study from the United Kingdom of patients evaluated for the first time with typical angina has suggested that the prognosis should be guarded because over a 15-month period, 4 percent mortality and a 7 percent rate of nonfatal myocardial infarction were noted, and only 11 percent had spontaneous remission of angina.[498] Several studies have shown that a composite risk score based on multiple clinical variables (e.g., age, sex, diabetes, previous myocardial infarction, and the nature of the chest pain) may be quite strongly predictive of the presence of severe CAD (triple-vessel or left main CAD) and thus provide a strong indication for angiography[35] [499] (see Fig. 37-14 and Table 37-11) . Numerous studies attest to the adverse prognostic effect of congestive heart failure (based on a clinical history of cardiomegaly on chest radiography), previous myocardial infarction, hypertension, and advanced age in patients with stable angina pectoris.[79] [497] [498] A third heart sound is a useful clinical predictor of an abnormal left ventricular ejection fraction and an adverse prognosis in patients with CAD. The severity of angina, especially the tempo of intensification, is also an important predictor of outcome.

On the other hand, a normal resting ECG in patients with stable angina pectoris speaks in favor of wellpreserved left ventricular function and a favorable long-term prognosis[364] (see p. 1277). Among 14,507 patients with chest pain enrolled in the CASS Registry, 91.8 percent of those with a normal ECG had an ejection fraction greater than 50 percent and only 0.6 percent had an ejection fraction

Survival improved with surgery versus medicine. In the European Coronary Surgery Trial, patients with double-vessel disease and involvement of the paroxysmal left anterior descending coronary artery had improved survival with surgery irrespective of left ventricular function.

less than 35 percent.[500] Left ventricular hypertrophy, as determined on the ECG or echocardiogram, is associated with increased mortality. [501] Although the presence of calcium in the coronary arteries on chest radiography, fluoroscopy, or electron beam CT is associated with an adverse

Figure 37-14 *A,* Adjusted hazard (mortality) ratios comparing coronary artery bypass grafting (CABG) and medical therapy for nine coronary anatomy severity groups (GR) according to the number of vessels diseased (VD), the presence or absence of a 95 percent proximal stenosis (95 percent), and involvement of the left anterior descending coronary artery (LAD). *B,* Adjusted hazard (mortality) ratios comparing CABG and percutaneous transluminal angioplasty (PTCA) for nine coronary anatomy groups according to the number of vessels diseased, the presence or absence of a 95 percent proximal stenosis, and LAD involvement. Among patients with the least severe categories of disease, 5-year survival appears to be better with PTCA (single-vessel disease without proximal stenosis and without LAD involvement), whereas for patients with three-vessel disease and higher-grade, more complex two-vessel disease, a survival benefit is noted with surgery. For other subsets of patients with two-vessel disease, no difference in survival was seen in those treated with CABG or PTCA, and many of these patients are probably similar to those included in the randomized trials. *(Data from the Duke University data base. From Jones RH, Kesler K, Phillips HR III, et al: Long-term survival benefits of coronary artery bypass grafting and percutaneous transluminal angioplasty in patients with coronary artery disease. J Thorac Cardiovasc Surg 111:1013, 1996. By permission of Mosby.)*

prognosis and correlates to some extent with the severity of CAD, the presence and extent of calcification cannot be used at this stage as an indication for angiography or coronary revascularization.[35]

In summary, a comprehensive clinical evaluation provides useful prognostic information in addition to being an indispensable basis for assessing the risk of a procedure and the likelihood of sustained benefits.

NONINVASIVE STRESS TESTING (see p. 1278).

One of the most valuable aspects of noninvasive imaging is the echocardiographic assessment of left ventricular function. Such testing is not necessary for all patients, and among patients with a normal ECG and no previous history of myocardial infarction, the likelihood of preserved left ventricular systolic function is high. In contrast, among patients with a history of myocardial infarction, ST-T wave changes, or conduction defects or Q waves on the ECG, left ventricular function should be measured with echocardiography or an equivalent technique.[35] In patients in whom left ventricular function and coronary anatomy have already been defined, stress testing may provide additional prognostic information about the functional significance of specific angiographic lesions.

The prognostic importance of the treadmill exercise test was determined by several observational studies in the 1980s and early 1990s, and these studies have had a major influence on current indications for coronary revascularization.[35] One of the most important and consistent predictors is the maximal exercise capacity, regardless of whether it is measured by exercise duration or workload achieved or whether the test was terminated because of dyspnea, fatigue, or angina.[35] [502] [503] Other factors with a poor prognosis identified in individual series of patients with chronic stable angina are described in Table 37-2 (see p. 1280).

Prognostic Scores.

The impact of the magnitude of exercise-induced ischemia on prognosis as defined by symptoms or ST segment deviation has led to the development of various prognostic scores that appear to work well in both the inpatient and outpatient settings. Mark and colleagues developed a prognostic score that incorporates exercise duration, the magnitude of ST segment deviation, and exercise-induced angina.[502] Patients were stratified into three groups with an average annual mortality of 0.25, 1.25, and 5.0 percent. Moreover, the score contained incremental information beyond that provided by clinical and catheterization data.[502]

Stress Thallium-201 Myocardial Perfusion Imaging (see also Chaps. 9 and 13 and p. 1278).

A normal stress thallium study is highly predictive of a favorable prognosis in patients with and without documented CAD.[35] [75] [504] In an analysis of 16 studies involving more than 3500 patients, the rate of cardiac death and myocardial infarction over a mean follow-up period of 29 months was only 0.9 percent. In patients with documented CAD, the single most powerful prognostic factor was the magnitude of the perfusion abnormality on SPECT thallium-201 scintigraphy.[505] Pharmacological stress perfusion imaging techniques with dipyridamole, adenosine, or dobutamine have an established place as an alternative to exercise perfusion imaging in establishing the prognosis in patients with stable CAD.[74] [506]

Stress Echocardiography

(see also Chap. 7 and p. 1279). Evidence is increasingly demonstrating that echocardiography with exercise or pharmacological stress (dobutamine, arbutamine, or dipyridamole) is both sensitive and specific for the identification of myocardial ischemia and for risk stratification in patients with chronic stable angina.[98] [507] [508] The presence or absence of inducible regional wall motion abnormalities and the response of the ejection fraction to exercise appear to provide incremental prognostic information in addition to the assessment of cardiac structure and function provided by the resting echocardiogram. Moreover, a negative stress test portends a very low risk for future events.[509] Although most studies demonstrated enhanced diagnostic accuracy for dobutamine stress echocardiography, the prognostic value of dipyridamole and dobutamine may be similar.[510]

The choice of a particular stress testing modality in a patient with chronic stable angina undergoing assessment for coronary revascularization depends on several clinical issues that may limit the technical quality of the echocardiographic images, such as the presence of obesity or chronic obstructive pulmonary disease. Nonetheless, the most vital factor to be considered is probably the level of expertise that an institution has with each technique.

ANGIOGRAPHIC CRITERIA.

The independent impact of multivessel disease and left ventricular dysfunction and their interaction on the prognosis of patients with CAD has been well documented[511] [512] and provides a logical framework for coronary angiography in the assessment of prognosis (Fig. 37-15) . These two risk factors are synergistic in that the adverse effects of impaired ventricular function on prognosis are more pronounced as the number of stenotic vessels increases.[511]

Although several indices have been used to quantify the extent of severity of CAD, the simple classification of disease into one-vessel, two-vessel, three-vessel, or left main CAD is the most widely used and is effective.[511] [513] Additional

Figure 37-15 Graphs showing survival for medically treated CASS patients. *A,* Patients with one-, two-, or three-vessel disease and an ejection fraction of 50 to 100 percent stratified by the number of diseased vessels (DISVES). *B,* Patients with one-, two-, or three-vessel disease and an ejection fraction of 35 to 49 percent stratified by the number of diseased vessels. *C,* Patients with one-, two-, or three-vessel disease and an ejection fraction of 0 to 34 percent stratified by the number of diseased vessels. *(From Emond M, Mock MB, Davis KB, et al: Long-term survival of medically treated patients in the Coronary Artery Surgery Study (CASS) Registry. Circulation 90:2645, 1994. By permission of the American Heart Association, Inc.)*

prognostic information is provided by the severity of obstruction and the location, whether proximal or distal.[35] [514] The concept of the gradient of risk is illustrated in Figure 37-14 , which was derived from the Duke University data base of patients treated medically. Among medically treated patients in CASS, the 12-year survival rate was 91 percent among those with chronic angina and angiographically normal vessels. In the presence of single-vessel disease, it was 86 percent for patients with at least one obstruction of 30 to 50 percent, 79 percent for patients with at least one stenosis of 50 to 70 percent, and 74 percent for patients with single-vessel disease and stenosis of 70 percent or more.[511]

Studies of treated symptomatic patients have revealed that if only one of the three major coronary arteries has more than 50 percent stenosis, the annual mortality rate is approximately 2 percent.[515] The importance to survival of the quantity of myocardium that is jeopardized is reflected in the observation that an obstructive lesion proximal to the first septal perforating branch of the left anterior descending coronary artery was associated with a 5-year survival rate of 90 percent in comparison with 98 percent for patients with more distal lesions.[515] The survival rate of patients with isolated right CAD at 5 years appeared to be higher (96 percent) than for patients with disease of the left anterior descending coronary artery (92 percent). The overall survival of medically treated patients with left anterior descending and left circumflex CAD was not significantly different, but both were less than the survival of patients with isolated right CAD.[515]

The impact of left ventricular dysfunction is illustrated by the 12-year survival rates of unoperated patients in the CASS Registry, which were 73, 54, and 21 percent among patients with ejection fractions of 50 percent or higher, 35 to 49 percent, and less than 35 percent, respectively[511] (Fig. 37-15) .

In the example used in the ACC/AHA guidelines,[35] a 65-year-old man with three-vessel disease and stable angina has a 5-year survival rate ranging from 93 to 58 percent, according to the presence or absence of congestive heart failure and a decreased ejection fraction.

High-grade lesions of the left main coronary artery or its "equivalents," as defined by severe proximal left anterior descending and proximal left circumflex CAD, are particularly life threatening.[516] Mortality among medically treated patients has been reported to be 29 percent at 18 months, 39 percent at 2 years, and 43 percent at 5 years.[516] Survival is better for patients with 50 to 70 percent stenosis (1- and 3-year survival rates of 91 and 66 percent, respectively) than for patients with a left main coronary artery stenosis greater than 70 percent (1- and 3-year survival rates of 72 and 41 percent).[517] Furthermore, a number of characteristics found at catheterization or on noninvasive examination are predictors of an adverse prognosis in patients with 70 percent or greater left main coronary artery stenosis, including chest pain at rest, ST-T wave changes on resting ECG, cardiomegaly on chest radiography, a history of congestive heart failure, findings of left ventricular dysfunction at catheterization, and an increase in the arterial-mixed venous oxygen difference.[517]

Limitations of Angiography.

The pathophysiological significance of coronary stenoses lies in their impact on resting and exercise-induced blood flow, in addition to their potential for plaque rupture with superimposed thrombotic occlusion. It is generally accepted that a stenosis of greater than 60 percent of the luminal diameter is hemodynamically significant in that it may be responsible for a reduction in exercise-induced myocardial blood flow and cause angina and ischemia[518] (see Chap. 34) . The functional significance of obstruction of "intermediate" severity (approximately 50 percent diameter stenosis) is less well established. Coronary angiography is not a reliable indicator of the functional significance of stenosis, nor is it sensitive to the presence of thrombus.[519] Moreover, the coronary angiographic determinants of the severity of stenosis are based on a decrease in the caliber of the lumen at the site of the lesion *relative* to adjacent reference segments, which are considered, often erroneously, to be relatively free of disease. This approach may lead to significant underestimation of the severity and extent of atherosclerosis.[520] Furthermore, assessment of left main stem disease, particularly in vessels with lesser degrees of obstruction, is not optimal.[521]

Another limitation to the routine use of coronary angiography for prognosis in patients with chronic stable angina is its inability to identify which coronary lesions can be considered to be at high risk for future events, such as myocardial infarction or sudden death. Although it is widely accepted that myocardial infarction is the result of thrombotic occlusion at the site of plaque rupture (see Chap. 35) , a growing body of evidence indicates that it is not necessarily the plaque causing the most severe stenosis that subsequently ruptures.[522] Several studies of patients undergoing serial coronary angiography indicate that myocardial infarction often arises from rupture of the plaque that did *not* cause critical obstruction. Lesions causing mild obstructions can rupture, thrombose, and occlude, thereby leading to myocardial infarction and sudden death.[523] [524] [525] In contrast, arteries with severe preexisting stenoses may proceed to clinically silent complete occlusion, often without infarction, presumably because of the formation of collaterals as ischemia gradually becomes more severe.

In summary, angiographic documentation of the extent of CAD is an indispensable step in the selection of patients for coronary revascularization, particularly if the interaction between the anatomical extent of disease, left ventricular function, and the severity of ischemia is taken into account. However, angiography is not helpful in predicting the site of subsequent occlusions that could cause myocardial infarction or sudden cardiac death, particularly in an individual patient.

In the characterization of lesion morphology and severity, intravascular ultrasonography (see Chap. 12) may be helpful, particularly in patients undergoing PCI.[526] Assessment of coronary flow reserve with Doppler techniques and assessment of transstenotic gradients at baseline and during maximal hyperemia (see Chap. 34) are tools that, in an experienced laboratory, may also be helpful in deciding on the flow-limiting significance of a specific lesion and the need for coronary revascularization.[527]

Results

In 1972, a committee of the AHA indicated that the most widely accepted indication for surgical revascularization was "significant disability from moderate to severe angina pectoris, unresponsive to optimal medical care." Three decades later, the realization that CABG prolongs survival in subgroups of patients with either minimal or mild to moderate symptoms has shifted the emphasis toward *ischemia* instead of *symptoms alone* as the target for coronary revascularization. Consequently and appropriately, CABG is currently performed in an increasing number of patients with multivessel disease and/or left ventricular dysfunction (particularly in the face of viable jeopardized dysfunctioning myocardium) and in patients with poor exercise tolerance in the presence of stress-induced ischemia. Severe ischemia and/or reversible left ventricular dysfunction provides a window of opportunity for improving survival (in comparison to medical therapy) that has resulted in an increase in the frequency of CABG in patients with unstable angina and in survivors of acute myocardial infarction. Left ventricular dysfunction, initially a relative contraindication for surgery, has become a major indication. Nonetheless, severe

symptoms or even moderate symptoms that interfere with the quality of life despite adequate medical therapy are still as firm an indication for coronary revascularization (PCI or CABG) as they were for CABG almost three decades ago.

Relief of Angina

CABG is highly effective in providing complete relief from angina in some patients and improvement in the severity of symptoms in most of the rest (Fig. 37-12) . In a series of patients who received saphenous vein grafts alone, approximately 90 percent were free of angina at 1 year. In the following 4 years, the recurrence rate was approximately 3 percent per year and 5 percent per year thereafter. Approximate rates of freedom from angina were 78 percent at 5 years, which decreased to 52 and 23 percent at 10 and 15 years, respectively.[528] The major randomized trials have all demonstrated greater relief of angina, better exercise performance, and a lower requirement for antianginal medications for surgically versus medically treated patients 5 years postoperatively.[495] [529] [530] [531] Beyond 5 years, differences in symptoms between patients initially treated medically and surgically are diminished, in part because of the high "crossover" rate from medical to surgical therapy in patients with continued symptoms and progression of disease in vein grafts and nonbypassed vessels in the surgical group.[529] [530] The 22-year follow-up of the Veterans Administration (VA) Trial demonstrated no difference in the severity of angina between medically and surgically treated groups after 10 years.[532] These results must be tempered by the low rate of initial complete revascularization, absence of the use of an IMA graft, and lack of platelet inhibitor therapy and risk factor reduction in this trial, which reflected the very early part of the "learning curve" of coronary bypass surgery.[533] The reoperation rate for recurrence of symptoms has been reported to be in the range of 6 to 8 percent per year.[534]

For patients with persistent angina despite adequate medical therapy or for patients who do not tolerate medications or who are not suitable candidates for PCI,

coronary bypass grafting provides excellent symptomatic relief.[35] With increasing use of IMA grafts, long-term relief from angina and freedom from subsequent cardiac events are improved in comparison to previous patient populations who received vein grafts alone.

In summary, after 5 years, approximately three-fourths of surgically treated patients can be predicted to be free of an ischemic event, sudden death, occurrence of myocardial infarction, or the recurrence of angina; about half remain free for approximately 10 years and about 15 percent for 15 or more years. Symptomatic improvement is best maintained in patients with the most complete revascularization.[453] [528]

Effects on Survival

Current clinical practice has been shaped by three major randomized trials that enrolled patients between 1972 and 1979: the VA Trial, the European Cardiac Society Study (ECSS), and the National Institutes of Health-supported CASS (Fig. 37-16 and Table 37-12) .[531] [535] [536] [537] [538] [539] These trials antedated widespread use of the IMA for revascularization, as well as the use of aspirin and coronary angioplasty. The extent of the completeness of coronary revascularization, graft patency rates, and perioperative mortality in the VA Trial fall far short of current expectations and reflect, in part, the initial learning experience of coronary bypass surgery.

In the VA Study, no significant difference was found in overall survival between the groups initially assigned to medical or surgical treatment after 11 years of follow-up. However, higher-risk subsets, including patients with left main coronary disease and patients who had three-vessel disease with impaired left ventricular function, initially had a significant survival advantage with surgery, although the magnitude of the difference decreased between 7 and 11 years. On retrospective analysis, a higher-risk subset, those with two or more of the following risk factors--New York Heart Association Class III or IV angina, a history of hypertension, a history of prior myocardial infarction, and ST segment depression on the resting ECG--experienced a survival benefit from surgery.[537]

Patients randomly assigned to an initial surgical approach also experienced an overall survival advantage in the ECSS.[531] Again, the benefits of surgery were greater in patients at higher risk, including those with multivessel disease that included the proximal left anterior descending coronary artery, older patients, those with evidence of ischemia or infarction on the resting ECG, patients with peripheral vascular disease, and those with a markedly positive stress test. No significant difference in survival was seen between medical and surgical treatment in patients with one-vessel disease and those with two-vessel disease without critical stenosis of the proximal left anterior descending coronary artery. In the CASS randomized trial, no difference in overall survival was found between the medically and surgically treated groups.[535] [539] However, survival of patients at higher risk, e.g., those with a left ventricular ejection fraction between 35 and 50 percent, was improved by surgery.[535]

Figure 37-16 Survival curves of the three large randomized trials and four smaller studies combined. *(Reproduced from Eagle KA, Guyton RA, Davidoff, R et al: ACC/AHA Guidelines for coronary artery bypass surgery. J Am Coll Cardiol 34:1262-1347, 1999.)*

LEFT MAIN CORONARY ARTERY STENOSIS.

It is widely agreed that surgical treatment improves survival in patients with left main coronary artery obstruction[540] or its "equivalent." The CASS Registry demonstrated that the superiority of revascularization was equivalent in both symptomatic and asymptomatic patients with disease affecting the left main coronary artery.[516] [541]

Whether a "left main equivalent" anatomy exists that has a natural history similar to that of left main CAD is uncertain. The condition in question may consist of disease in the proximal portions of both the left anterior descending and left circumflex coronary arteries. It is likely that significant left main coronary disease has an ominous nature, because a single event (rupture of a single plaque) can cause infarction of a very large quantity of myocardium. Consequently, although combined disease of the proximal left anterior descending and circumflex coronary arteries does identify a subgroup of high-risk patients, the prognosis is not as poor as it is for patients with left main CAD.[542] Nevertheless, patients with combined stenoses of 70 percent or greater in the left anterior descending coronary artery, before the first septal perforating branch, and in the proximal circumflex coronary artery, before the first obtuse marginal branch, who have impaired ventricular function also have improved survival and less angina following surgical revascularization than if they are treated medically, particularly in the face of left ventricular dysfunction. The median survival of surgically treated patients with left main-equivalent disease is 13.1 years versus 6.2 years for those medically treated.[541]

OVERVIEW OF THE RANDOMIZED TRIALS.

A systematic overview of the seven randomized trials (the three aforementioned large trials and four smaller trials) that compared coronary bypass surgery with medical therapy between 1972 and 1984 yielded 2649 patients (see Fig. 37-16 and Table 37-12) . In interpreting this overview, it must be appreciated that surgical treatment has improved significantly in the past 25 years and that outcomes have been improved, in particular with the widespread use of one or two IMAs. Patients undergoing CABG had a significantly lower mortality at 5, 7, and 10 years, but by 10 years, 41 percent of the patients initially randomly assigned to medical treatment had undergone CABG (so-called crossovers). The advantage for surgery was greatest in patients with left main CAD. An improvement in survival was also noted with surgical treatment in patients with one- or two-vessel disease and stenosis of the proximal left anterior descending coronary artery. Among patients without obstruction of the proximal left anterior descending coronary artery, the reduction in mortality was confined to those with left main coronary artery or three-vessel disease.

To place the relevant and absolute benefits of coronary bypass surgery into perspective, patients were further stratified into high-, moderate- and low-risk subgroups by using criteria developed by the VA Cooperative Study.[537] These criteria were based on clinical findings and included the severity of angina, history of hypertension, prior myocardial infarction, and ST segment depression at rest. Low-risk patients had none of the four risk factors aside from ST segment depression, whereas those with two or three risk factors were considered to be at high risk. In patients at high risk, the mortality reduction was 29 percent at 10 years versus 10 percent for patients at moderate risk. In low-risk patients, a nonsignificant trend was seen toward greater mortality with bypass surgery.

The results of all the trials and registries[538] taken together

From Yusuf S, Zucker D, Peduzzi P, et al: Effect of coronary artery bypass surgery on survival: Overview of 10-year results from randomized trials by the Coronary Artery Bypass Surgery Trialists Collaboration. Lancet 344:563, © by The Lancet Ltd., 1994.

*Systematic overview of the effect of coronary artery bypass graft (CABG) surgery versus medical therapy on survival based on data from the seven randomized trials comparing a strategy of initial CABG surgery with one of initial medical therapy. Subgroup results at 5 years are shown.

indicate that the "sicker" the patient (based on the severity of symptoms or ischemia, age, the number of vessels diseased, and the presence of left ventricular dysfunction), the greater the benefit of surgical over medical therapy on survival (see Table 37-12) .[348] [514] Among low-risk patients and patients with single-vessel disease, no trial has demonstrated any benefit on survival.

Thus, CABG prolongs survival in patients with significant left main CAD irrespective of symptoms, in patients with multivessel disease and impaired left ventricular function, and in patients with three-vessel disease that includes the proximal left anterior descending coronary artery (irrespective of left ventricular function).[495] [543] Surgical therapy has also been demonstrated to prolong life in patients with *two-vessel disease* and left ventricular dysfunction, particularly those with proximal narrowing of one or more coronary arteries and in the presence of severe angina.[544] Although no study has documented a survival benefit with surgical treatment in patients with *single-vessel disease*, some evidence indicates that such patients who have impaired left ventricular function have a poor long-term survival.[511] Such patients with angina or evidence of ischemia at a low or moderate level of exercise, especially those with obstruction of the proximal left anterior descending coronary artery, may benefit from coronary revascularization by either PCI or bypass surgery.

The only randomized data comparing CABG with medical therapy in the current era are from the Asymptomatic Cardiac Ischemia Pilot (ACIP) Study of 558 patients[545] (Fig. 37-17) . This trial of angina-guided versus angina plus ischemia-guided medical therapy (using ambulatory monitoring) in comparison to revascularization by either PTCA (92 patients) or CABG (79 patients) enrolled relatively low-risk patients. After 2 years of follow-up, mortality was significantly lower among the patients assigned to routine revascularization (1.1 vs. 6.6 and 4.4 percent for the two medical groups [*p*0.02]), and rates of death or myocardial infarction were 12.1 (angina-guided medical therapy), 8.9 (ischemia-guided medical therapy), and 4.7 percent following coronary revascularization (*p*0.04). Although this trial was designed as a pilot study and the number of patients was relatively small, the observed risk reductions were statistically significant and suggest that the benefits of revascularization in the context of current revascularization technique may be greater than previously appreciated. The trial was not designed to assess differences between PTCA and bypass surgery but does point to the need for larger, more definitive randomized trials testing contemporary strategies of revascularization with optimal medical therapy and risk factor reduction.

EFFECT OF SURGERY ON SUBSEQUENT MYOCARDIAL INFARCTION.

The major randomized trials of patients with mild to moderate angina suggested that the likelihood of occurrence of myocardial infarction after 5 to 10 years of follow-up was similar in medically and surgically treated patients.[531] [537] [538] [546] [547] In both the VA Study and the CASS, the major benefit of surgery on myocardial infarction does not appear to be mediated by a decrease in the frequency of myocardial infarction but by a decrease in the case fatality rate of patients who subsequently have infarction.[548] Potential explanations are that previous bypass surgery results in smaller infarcts caused by distal occlusions and that the bypass may enhance myocardial perfusion distal to the obstructing lesion.[549]

Patients with Depressed Left Ventricular Function

Depressed *left ventricular function* is one of the most powerful predictors of perioperative and late mortality.[550] [551] [552] [553] In the Society of Thoracic Surgeons data base[425] *(www.ctsnenet.org),* the mean ejection fraction among approximately 161,000 patients undergoing initial coronary bypass in 1997 was approximately 51 percent, and approximately 25 percent had an ejection fraction less than 45 percent. Moreover, as the population ages and the proportion undergoing reoperation increases, the number of patients with preoperative left ventricular dysfunction and clinical heart failure will increase. In the CABG Patch Trial confined to patients with an ejection fraction of 35 percent of less, perioperative mortality was 3.5 percent for patients without clinical signs of heart failure versus 7.7 percent for those with New York Heart Association Class I to IV heart failure.[554] The latter was a powerful independent predictor of increased operative mortality in patients with ventricular dysfunction and a positive signal-averaged ECG[554] (odds ratio, 2.4; *p*=0.01).

Although the effect of a reduced ejection fraction on operative mortality cannot be eliminated, careful attention to intraoperative metabolic, inotropic, and mechanical support, including preoperative intraaortic balloon counterpulsation in some patients, may decrease perioperative mortality in comparison with the mortality rates expected from prediction models.[555]

The powerful effect of the preoperative ejection fraction on late survival emphasizes that in the current era, the presence of left ventricular dysfunction has changed from a relative contraindication to coronary bypass to a very strong indication.[552] This shift in focus has been due to the realization that viable dysfunctioning myocardium may improve after coronary revascularization.[550] [556] Indeed, the

Figure 37-17 Two-year cumulative mortality rates for the three treatment strategies in the Asymptomatic Cardiac Ischemia Pilot (ACIP) study. Significant differences were seen between revascularization and angina-guided strategies *(p* 0.005) and between revascularization and ischemia-guided strategies *(p* 0.05). Angina-guided and ischemia-guided strategies were not significantly different from each other *(p*=0.34). Similar results were noted for the endpoints of cumulative rates of death, myocardial infarction, or cardiac hospitalization. *(From Davies RF, Goldberg AD, Forman S, et al: Asymptomatic Cardiac Ischemia Pilot [ACIP] study two-year follow-up: Outcomes of patients randomized to initial strategies of medical therapy versus revascularization. Circulation 95:2037, 1997. By permission of the American Heart Association, Inc.)*

most striking survival benefits of CABG, as well as symptomatic and functional improvement, are shown by patients with seriously impaired left ventricular function in whom the prognosis of medical therapy is poor.[88] [555] [556] [557] [558] In patients with a history of congestive heart failure and multivessel (particularly three-vessel) disease, coronary bypass surgery may also reduce the incidence of sudden cardiac death.[559] Although preoperative left ventricular dysfunction creates the potential for significant benefit, the perioperative risk should not be underestimated, particularly in the setting of clinical congestive heart failure.[550] In the CASS Registry, operative mortality was 1.97 percent and the 5-year survival rate was 92 percent for patients with normal or nearly normal left ventricular function; operative mortality was 4.2 percent and the 5-year survival rate was 80 percent for those with an ejection fraction of 0.35 to 0.49, and for those with an ejection fraction less than 0.35, operative mortality was 6.2 percent and the 5-year survival rate was 65 percent.[560] A more recent series demonstrated an in-hospital operative mortality of 8.4 percent for patients with an ejection fraction of 0.30 or less.[550]

MYOCARDIAL HIBERNATION.

Improvement in survival and left ventricular function following CABG depends on successful reperfusion of viable, but noncontractile or poorly contracting myocardium

(see Chaps. 13 , 14 , and 34) . Two related pathophysiological conditions have been described to explain reversible ischemic contractile dysfunction[561] : myocardial stunning (prolonged but temporary postischemic ventricular dysfunction without myocardial necrosis) and myocardial hibernation (persistent left ventricular dysfunction when myocardial perfusion is chronically reduced but sufficient to maintain the viability of tissue). The reduction in myocardial contractility in hibernating myocardium conserves metabolic demands and may be protective, but more prolonged and severe hibernation may lead to severe ultrastructural abnormalities, irreversible loss of contractile units, and apoptosis.[562]

Hibernating myocardium can cause abnormal systolic or diastolic ventricular function or both. The predominant clinical feature of myocardial ischemia in these patients may not be angina, but dyspnea secondary to increased left ventricular diastolic pressure. Symptoms of heart failure resulting from chronic left ventricular dysfunction may be inappropriately ascribed to myocardial necrosis and scarring when the symptoms may, in fact, be reversed after the chronic ischemia is relieved by coronary revascularization.[103] [563]

Detection Of Hibernating Myocardium.

Several clinical markers may be used to determine the likelihood that a dysfunctional myocardial segment is viable or nonviable (Table 37-13) . A severe reduction in the diastolic wall thickness of dysfunctional left ventricular segments is indicative of scarring. On the other hand, akinetic or dyskinetic segments with preserved diastolic wall thickness may

TABLE 37-13 -- MARKERS OF VIABLE MYOCARDIUM

CLINICAL INDICATOR	DIAGNOSTIC TEST	ALTERNATIVE TEST
Diastolic wall thickness	Echo	CT, MRI

Figure 37-18 Flow diagram for the practical assessment of noncontractile segments of myocardial wall potentially recoverable by revascularization procedures. An obviously reduced wall thickness is indicative of a postinfarction scar. Absence of contractile function in segments of the ventricular wall with preserved wall thickness may be caused by different mechanisms. An acute ischemic cause can be excluded by the administration of sublingual nitrates. Stunning can be excluded by repeating the ventricular wall motion study several days after the last ischemic episode. Hibernating myocardium should be distinguished from a mixture of scar tissue and viable myocardial cells. *(From Maseri A: Ischemic Heart Disease: A Rational Basis for Clinical Practice and Clinical Research. New York, Churchill Livingstone, 1995. By permission.)*

represent a mixture of scarred and viable myocardium. A useful strategy for the assessment of dysfunctional segments has been developed by Maseri (Fig. 37-18) . Although a number of imaging tools may be used for this assessment (see Chaps. 7 , 9 , 10 , and 13) , the most readily available in most settings is low-dose dobutamine echocardiography.

The term *contractile reserve* describes the ability of hibernating myocardium to exhibit augmented contractility to a suitable temporary stimulus, often causing transient improvement in the global ejection fraction. Contractile reserve underscores the fact that many hypokinetic (and even akinetic) areas of the ventricular wall are composed entirely or in part of viable, hibernating myocardium or a mixture of the latter and fibrous scar. Viable muscle is capable of responding to a sympathomimetic agent. In contrast, necrotic tissue obviously cannot be stimulated to contract by any pharmacological or hemodynamic intervention or by improved perfusion. The most common method of identifying contractile reserve is echocardiographic imaging during infusion of a low dose of dobutamine.[561] Numerous studies have demonstrated that the finding of contractile reserve by low-dose dobutamine echocardiography identifies dysfunctional, but viable myocardium with the potential to improve in function after myocardial revascularization.[89] [102] [103] [561] [564]

PET (see Chap. 9) has emerged as an excellent method for demonstrating viable myocardium in patients with impaired left ventricular function.[89] [561] [563] [564] [565] [566] In comparative studies, PET has yielded the highest predictive accuracy of all imaging modalities in detecting dysfunctional myocardium that will improve after revascularization.[89] [564] However, the high cost, technical difficulty, and need for a cyclotron continue to limit this technique's widespread applicability.

Important advances in the assessment of myocardial viability with thallium-201 include rest-redistribution imaging to determine whether regions with hypoperfusion at rest manifest filling in of the resting defect with time and stress-redistribution-reinjection imaging, in which a second injection of thallium is administered to determine whether defects that do not redistribute after exercise represent fibrotic

myocardium or myocardium that is severely ischemic[88] [89] [102] [561] [567] (see Chap. 9) .

Prognostic Implications of Identifying Viable Myocardium.

A growing body of evidence indicates that the detection of viable myocardium in patients with CAD and left ventricular dysfunction not only identifies those in whom improvement in cardiac function is likely after revascularization but also identifies a group of high-risk patients in whom revascularization improves survival (Fig. 37-19) . Studies with PET, thallium-201, and dobutamine echocardiography have uniformly demonstrated that patients with left ventricular dysfunction and evidence of hibernating myocardium have a high mortality rate during medical therapy and appear to have a better outcome with revascularization.[103] [568] [569] [570] [571] All these studies have limitations, including a small number of patients, the retrospective nature of the analysis, and lack of a randomized control group. However, the consistency of the findings has been striking. Recent data point out that viability assessment is also helpful in the selection of patients for revascularization because patients selected for revascularization on the basis of an imaging study demonstrating myocardial viability have lower operative mortality and a higher long-term survival rate than do those who have no evidence of important myocardial viability or those in whom a viability assessment is not performed.[88] [103] [572] Perioperative mortality in the latter patients approaches 10 percent.[88] [103] [572]

The mechanisms for improved survival after revascularization in patients with hibernating myocardium may be related to improvement in left ventricular function, but it is likely that other important factors are also operative. Revascularization of viable myocardium may also reduce left ventricular remodeling, the propensity for serious arrhythmias, and the likelihood of a future fatal acute ischemic event.[89] In this manner, patients with left ventricular dysfunction and hibernating myocardium may be viewed as other high-risk patients with left ventricular dysfunction, multivessel CAD, and jeopardized myocardium, in whom outcome is improved by revascularization. In this regard, survival may be enhanced by revascularization in such patients, even if left ventricular function does not improve after the procedure.

Surgical Treatment in Special Groups

WOMEN (see also Chap. 58) .

It is clear that CABG use is much lower in women than in men.[573] [574] However, what has not been established is whether these differences represent underutilization in women, overutilization in men, or both.[458] [575] In comparison with men, women who undergo coronary bypass surgery are "sicker," as defined by age, comorbid conditions, the severity of angina, and history of congestive heart failure.[574] [576] Many series have demonstrated higher morbidity and mortality in coronary surgery in women. The 1997 Society of Thoracic Surgeons data base showed that approximately 30 percent of isolated CABG procedures in the United States were performed in women, with a perioperative mortality of 3.9 percent versus 2.3 percent for men.[425]

Among patients 70 years or older in the Toronto Hospital experience, operative mortality in men in comparison with women was 5.4% vs 11.8% from 1982-1986, 3.8%

vs 5.8% from 1987-1991 and 3.8% vs 6.3% from 1992-1996.[577] Perioperative morbidity, including myocardial infarction, respiratory failure, and stroke, was also significantly higher in women. A higher incidence of sternal wound infections may be related to obesity.[458] Most of the differences between men and women are the consequence of age, the "sicker" preoperative status of women, a higher rate of nonelective procedures, and the presence of more diffuse disease and left ventricular dysfunction in women reaching surgery,[578] but the presence of smaller distal vessels (as a function of a smaller body surface area) and lower use of IMA grafts may also be contributing factors.[390] [579] However, a small independent detrimental effect of female gender persists in most multivariate analyses. Despite the increased perioperative mortality and morbidity in women, late survival is similar in men and women,[580] but the relief of anginal symptoms appears to be less in women.[577] [580] [581]

Independent risk factors for long-term prognosis in women are similar to those in men, including older age, previous coronary bypass surgery, previous myocardial infarction, and diabetes.[580] In the BARI Trial, in-hospital mortality was similar for men and women, as were the unadjusted 5.4-year mortality rates of 12.8 percent in women and 12 percent in men (*p*=NS). After adjustment for the higher risk profiles in women, including age, symptom severity, and comorbid conditions, the relative risk of death in women versus men was actually lower, 0.60 (95 percent confidence intervals, 0.43 to 0.84; *p*=0.003). However, these data may not be generalizable outside the confines of a randomized trial.

YOUNGER PATIENTS.

Patients 35 years or younger who undergo CABG usually have hyperlipidemia and other major risk factors for CAD.[582] Despite the severity of the underlying disease and the rapidity of the atherosclerotic process, CABG is associated with excellent actuarial survival rates of 94 percent at 5 years and 85 percent at 10 years.[582] Nonetheless, in the CASS Registry, patients younger than 35 years had markedly impaired survival over a 15-year period in comparison with an age- and sex-matched U.S. population.[581] This impaired survival is probably the result of progression of premature atherosclerotic disease, the presence of multiple risk factors, and the development of progressive vein graft disease. The latter underlies the current trend for the use of bilateral IMA grafts and other arterial conduits in younger patients.

THE ELDERLY (see also Chap. 57) .

A demographic tide in combination with marked improvement in perioperative care and in the outcomes of CABG has resulted in

Figure 37-19 Survival among 58 patients with coronary artery disease, left ventricular dysfunction, and contractile reserve detected by low-dose dobutamine echocardiography. Patients treated with revascularization have a significantly higher survival rate than those treated medically. EF=ejection fraction. *(From Chaudhry FA, Tauke JT, Alessandrini RS, et al: Prognostic implications of myocardial contractile reserve in patients with coronary artery disease and left ventricular dysfunction. J Am Coll Cardiol 34:730, 1999. Reprinted with permission from the American College of Cardiology.)*

a burgeoning population of elderly patients with extensive disease undergoing such surgery. In 1997, the median age of patients undergoing an initial coronary bypass procedure was approximately 65 years in the United States and 64 years in Canada.[425] In 1997 in the United States, among 17,806 patients undergoing isolated CABG, 34 percent of patients were older than 70 years, 8872 operations were performed on octogenarians, and 106 new patients were in their 90s.[425] Between 1987 and 1990 in the Medicare population, the number of patients older than 80 years undergoing coronary bypass surgery increased by 67 percent.[583]

Older patients are "sicker" than their younger counterparts in that they have a greater frequency of comorbid conditions, including peripheral vascular and cerebrovascular disease, more extensive triple-vessel and left main CAD, and a higher frequency of left ventricular dysfunction and history of congestive heart failure.[392] Not unexpectedly, these differences are translated into higher perioperative mortality and complication rates, with a sharp increase in the slope of the curve relating mortality to age seen in patients older than 70 years.[425] [458] [577] [581] [584] More encouraging data were recently presented from the Toronto Hospital: Over a 15-year period, despite an increase in the prevalence and severity of risk factors, operative mortality in patients 70 years or older declined from 7.2 percent to less than 5 percent overall, with a mortality of 3 percent for patients defined as "low" or "medium risk." [577]

Perioperative morbidity is also increased in the elderly, with high rates of low-output syndrome, stroke, gastrointestinal complications, wound infection, and postoperative atrial fibrillation.[458] [471] The major predictors of perioperative mortality in the elderly are similar to those in younger patients, but with an increasing emphasis on the number of associated comorbid conditions, including the presence of peripheral and cerebrovascular disease. Although chronological age is not the most powerful independent predictor for perioperative mortality, it is an *independent* predictor, which suggests that other less tangible factors associated with older age increase operative risk.[392] In addition, from an examination of Medicare data from 1987 to 1990, patients older than 70 years, in comparison with those 65 to 70 years old, had longer postoperative hospital stays (mean of 14.3 vs. 10.4 days), higher charges, and greater costs.[583]

Despite the difficulties and expense of performing coronary bypass surgery in the elderly, excellent *long-term* survival rates can be achieved in addition to having the elderly return to an active functional status.[581] [585] [586] [587] In the CASS Registry, among patients 65 and 75 years old at the time of surgery, 74 and 59 percent, respectively, were alive 10 years after surgery and 54 and 33 percent 15 years after surgery (now 90 years old).[581] The survival of these patients exceeded that of the average age- and sex-matched U.S. population, which probably reflects in part the benefit of coronary revascularization in addition to selection bias. Similarly, octogenarians who survived the perioperative period had a long-term survival rate similar to that of the general octogenarian population of the United States.[583]

Predictors of late outcome in the elderly are similar to those in younger patients, including left ventricular dysfunction, but the number of associated comorbid conditions in addition to chronological age has a major effect.[588] Although no randomized trials have compared surgical and medical therapy in patients older than 65 years, a nonrandomized analysis of the CASS Registry demonstrated a significant benefit from surgery over medical therapy in the majority of patients who were considered to be at "high risk," whereas among the approximately 15 percent of low-risk patients who had mild angina, relatively good ventricular function, and no left main CAD, no survival differences were seen between those treated medically and those treated surgically. Therefore, the results in this registry are consistent with the randomized trials conducted during the same time in a younger population.[538]

Fundamental to successful performance of coronary bypass surgery is meticulous assessment of the patient, with mandatory attention to comorbid conditions, which can have a major detrimental effect on both perioperative morbidity and mortality and long-term survival. Evaluation of the elderly for coronary bypass surgery should take into account other less tangible factors related to quality of life and the potential ability to benefit from the operation. These factors include not only the chronological age of the patient but also the estimated physiological age, the patient's attitude, including understanding of the risks and expectations of the procedure, and an assessment of the patient's level of activity and current life style.

END-STAGE RENAL DISEASE.

Cardiovascular disease is the major predictor of mortality in patients with end-stage renal disease (ESRD) and accounts for 54 percent of deaths[589] (see Chap. 72) . Patients with ESRD have numerous risk factors that not only accelerate the development of CAD but also complicate its medical management. These risk factors include diabetes, hypertension with left ventricular hypertrophy, both systolic and diastolic dysfunction, abnormal lipid metabolism, anemia, and increased homocysteine levels.[458] Coronary revascularization with PCI or CABG is feasible and well documented in patients with ESRD, but the mortality and complication rates are increased.[458] [590] It has been suggested that for chronic dialysis patients, CABG is preferred for revascularization over PCI.[590] In one series, the 30-day mortality was 9 percent, but CABG produced a substantial improvement in the quality of life.[591] Another series reported a 68 percent cumulative survival rate over a 5-year period in patients with New York Heart Association Class II to III symptoms, which supports a policy of operating on symptomatic patients receiving dialysis but before the onset of severe congestive heart failure.[592] In the only randomized trial of surgical and medical therapy for insulin-dependent diabetic candidates for renal transplantation, 10 of 13 medically managed patients and 2 of 13 surgically treated ones had a major cardiovascular event during approximately 8 months of follow-up (*p*0.01).[593]

In summary, coronary bypass surgery can be performed with an acceptable risk and a reasonable expectation of long-term benefit in carefully selected patients with ESRD. As for all high-risk situations, careful attention to patient selection is essential.

PATIENTS REQUIRING REOPERATION.

Currently, approximately 10 percent of coronary artery procedures are reoperations, and in some centers, particularly tertiary care centers, the proportion is increasing rapidly and accounts for 15 to 18 percent of all CABG operations.[458] The major indication for reoperation is late disease of saphenous vein grafts. Moreover, the patient population is elderly, and an added factor underlying recurrent symptoms is progression of disease in native vessels between the first and second operations. Several series have emphasized the "sicker" preoperative status of patients undergoing reoperation, including older age, more extensive comorbidity, associated valvular heart disease, and a greater prevalence of left ventricular dysfunction and greater extent of ischemic jeopardized myocardium.[594] Not unexpectedly, the mortality associated with reoperation is significantly higher than that of initial bypass procedures. In the 1997 data base of the Society of Thoracic Surgeons, the mortality among 99,810

patients undergoing an elective first CABG procedure was 1.7 percent versus 5.2 percent for elective reoperations. For patients undergoing first operations, mortality was 2.6 percent for urgent and 6 percent for emergency procedures in comparison with 7.4 and 13.5 percent, respectively, among patients undergoing repeat bypass surgery. Virtually every large series has demonstrated higher morbidity and twofold to threefold greater mortality for reoperation.[594] [595] The determinants of perioperative mortality are similar to those for a first operation, although a short time interval between the first operation and the repeat procedure is an added major predictor of increased mortality. Third- and even fourth-time coronary reoperations are increasing in frequency and are associated with substantial increases in perioperative complications, including bleeding and myocardial infarction.[595]

More encouraging are the late survival rates of approximately 77 to 90 percent at 5 years and 48 to 83 percent at 10 years.[594] [596] Although in one series 73 percent of patients were free of angina at 5 years, relief of angina is generally less complete than after an initial operation.

Indications for reoperation have not been defined by randomized trials, but in general, the same principles that apply to patients with initial disease should be followed. Information about the effect of graft stenosis on late survival

was recently provided by a large retrospective study of patients who had postoperative coronary angiography and in whom a stenosis of 20 percent or more was present in at least one graft (Fig. 37-20) . Stenoses in a vein graft to the left anterior descending coronary artery were associated with a reduction in survival, and the major improvement in survival after reoperation was particularly evident for patients in this category. Among these patients, survival rates were 84 and 74 percent for the reoperation group 2 and 4 years after catheterization versus 76 and 53 percent for the medically treated group (p=0.004). [597] Nonetheless, the greater risk and the less favorable outcome after reoperation than after the initial procedure need to be considered, and the indications should probably be more stringent than for patients with native vessel disease alone.

OTHER HIGH-RISK SUBGROUPS.

Patients with *familial hyperlipidemia* have long been considered to be at particular risk for an adverse late outcome after CABG. More encouraging results have been reported with the use of an IMA or other arterial conduit in conjunction with aggressive lipid-lowering therapy.[598] In comparison with age-matched nondiabetic patients, elderly *diabetic* patients with angiographically proven CAD are more likely to be female with evidence of peripheral vascular disease and a higher number of coronary occlusions.[599] In a cohort of CASS Registry patients, diabetes was an independent predictor of mortality. However, the relative survival benefit of CABG versus medical therapy was comparable in diabetic and nondiabetic patients, with a significant (44 percent) reduction in mortality provided by surgery over medical therapy in diabetics.[599] Other large studies have emphasized the independent adverse effect of diabetes on mortality after CABG. In the Duke data base, the 5-year unadjusted survival rate was 74 percent among diabetic patients and 86 percent among nondiabetic patients treated surgically.[363] In a diabetic population undergoing coronary revascularization, insulin dependence is an added adverse predictor of 5- and 10-year survival rates.[600]

Summary of Indications for Coronary Revascularization

1. Certain anatomical subsets of patients are candidates for CABG, regardless of the severity of symptoms or left ventricular dysfunction. Such patients include those with significant left main CAD and most patients with three-vessel disease that includes the proximal left anterior descending coronary artery, especially those with left ventricular dysfunction.
2. The benefits of coronary bypass surgery are well documented in patients with left ventricular dysfunction and multivessel disease, regardless of symptoms. In patients whose dominant symptom is heart failure without severe angina, the benefits of coronary revascularization are less well defined, but this approach should be considered in patients who also have evidence of severe ischemia (regardless of angina symptoms), particularly in the presence of a significant extent of potentially viable dysfunctioning (hibernating) myocardium.
3. The primary objective of coronary revascularization in patients with single-vessel disease is relief of significant symptoms or objective evidence of severe ischemia. For the majority of these patients, PCI is the revascularization modality of choice.
4. In patients with angina who are *not* considered to be at high risk, survival is similar for surgically and medically treated groups.
5. All the indications discussed above relate to the potential benefits of surgery over medical therapy on *survival*. Coronary revascularization with PCI or CABG is highly efficacious in relieving symptoms and may be considered for patients with moderate to severe ischemic symptoms who are dissatisfied with medical therapy, even if they are not in a high-risk subset. For such patients, the optimal method of revascularization is selected on the basis of left ventricular function and arteriographic findings and the likelihood of technical success.

Comparisons Between PTCA and CABG

OBSERVATIONAL STUDIES.

Since the catheter-based revascularizations in these comparative studies were limited largely to PTCA, this term instead of PCI is used in this section. Among the many comparative studies of PTCA and CABG in patients with multivessel disease, several included patients with single-vessel disease,[514] [601] [602] but in only five studies were the groups matched for differences in baseline characteristics.[514] [601] [603] [604] [605] Regardless of the limitations of these series and the differences in baseline characteristics, the results are quite consistent. Over a period of 1 to 5 years, the rates of mortality and nonfatal infarction were not significantly different between the two groups but recurrent events, including angina pectoris and the need for repeat revascularization procedures, were significantly more frequent in the PTCA than the CABG group. Among patients with left ventricular dysfunction, survival after CABG appears to be better than after PTCA, probably because of the ability to achieve more complete revascularization with the former.[606] Indeed, complete revascularization is achieved by PTCA in only 25 to 50 percent of patients with two-vessel disease and in 10 to 25 percent of those with three-vessel disease.[607] In the future, improvements in transcatheter techniques, particularly in the ability to treat chronic total occlusions, may improve the results of this approach in patients with left ventricular dysfunction.

Outcome data 1 year after PTCA in patients (most of

Figure 37-20 Survival of patients with late stenoses in saphenous grafts to the left anterior descending coronary artery. In this subgroup, patients undergoing reoperation had improved survival when compared with those receiving medical therapy. *(Data obtained from the Cleveland Clinic Series. From Lytle BW, Loop FD, Taylor PC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein bypass grafts to coronary arteries. J Thorac Cardiovasc Surg 105:605, 1993. By permission of Mosby.)*

Figure 37-21 Hazard ratios for coronary artery bypass graft surgery (CABG) versus percutaneous transluminal coronary angioplasty (PTCA). Points below 1.0 favor CABG. Circulation 89:2015, 1994. By permission of the American Heart Association, Inc.)*

whom had single-vessel disease) indicate that recurrence of symptoms and/or the need for repeat revascularization procedures is high (approximately 40 percent) and that approximately 20 percent actually undergo CABG. In one report, after approximately 2 years, 49 percent of patients had had one repeat cardiac catheterization and approximately 25 percent had undergone multiple cardiac catheterizations.[603] These results need to be modified by a reduction in the rate of repeat revascularization procedures and recurrent angina in patients currently treated with stents instead of PTCA alone.[366] [608] CABG provided a clear survival benefit over PTCA in the Duke University data base in patients with two-vessel disease that included 95 percent or greater obstruction of the proximal left anterior descending coronary artery and in all forms of three-vessel disease (Fig. 37-14 *B*, p. 1310; and Fig. 37-21) . However, the effect of the method of revascularization on survival was equal in patients with two-vessel disease who did not have obstruction of the proximal left anterior descending coronary artery. The New York State procedure registries of PTCA and CABG from 1993 to 1995 demonstrate an approximately 37 percent rate of repeat revascularization after PTCA over a 3-year period in comparison with 3.3 percent after surgery.[608] Hazard ratios for mortality are shown in Figure 37-22 (Figure Not Available) , which illustrates that the anatomical extent and specific site of the disease influence the results of the treatment chosen, whether PTCA or CABG.

RANDOMIZED TRIALS

PTCA Versus CABG in Patients with Single-Vessel Disease.

In the RITA Trial, 45 percent of patients had single-vessel disease, and both the Lausanne Trial and the MASS Trial from Brazil, which included a medical arm, were limited to patients with isolated disease of the proximal left anterior descending coronary artery.[369] [476] [609] The results of these small trials were consistent in that over 2 to 3 years the rates of mortality and myocardial infarction were similar in the two strategies, as was improvement in symptoms, but at the cost of more frequent reintervention in patients treated with PTCA. At 5 years in the Lausanne Trial, mortality rates and functional status were similar for the two groups; however, an excess incidence of nonQ-wave myocardial infarction was noted in patients treated with PTCA, but this complication did not affect vital status or symptomatic outcome.[610]

In summary, the results suggest that PTCA and CABG are highly effective in preventing symptoms in patients with single-vessel disease. Moreover, no difference in mortality is seen between these two methods of revascularization.

Figure 37-22 (Figure Not Available) Differences in adjusted percent survival at 3 years with percutaneous transluminal coronary angioplasty (PTCA) and coronary artery bypass graft surgery (CABG) in the New York State data base (1993 to 1995). Data are stratified according to the number of vessels diseased and whether the left anterior descending (LAD) coronary arteries are involved and according to whether the stenoses are proximal. Note the better survival with CABG among patients with three- or two-vessel disease in combination with proximal LAD involvement. *(From Hannan EL, Racz MJ, McCallister BD, et al: A comparison of three-year survival after coronary artery bypass graft surgery and percutaneous transluminal coronary angioplasty. Figure 37-23 Cumulative risk of death or myocardial infarction after percutaneous transluminal coronary angioplasty (PTCA) and bypass surgery in the RITA-1 trials (-----, PTCA; CABG). No significant difference was found in either death or the combined endpoint of death or myocardial infarction. *(From Henderson RA, Pocock SJ, Sharp SJ, et al: Long-term results of RITA-1 trial: Clinical and cost comparisons of coronary angioplasty and coronary-artery bypass grafting. Randomised Intervention Treatment of Angina. Lancet 352:1419, 1998. © by The Lancet Ltd., 1998.)*

Multivessel Disease.

Seven published studies have compared PTCA with CABG in patients with multivessel disease. Another study, the Arterial Revascularization Therapy Study (ARTS), has recently been presented.[611] One of these trials (RITA) included patients with single-vessel disease.[352] [364] [476] [612] [613] [614] [614A] Despite the heterogeneity of the trials in regard to design, methods, and the patient population enrolled, the results are generally comparable and provide a consistent perspective of CABG and PTCA in selected patients with multivessel disease. A major limitation is that these trials, except for ARTS and ERACI-II,[620] were conducted before the widespread use of stents and other advances in PCI technology and adjunctive therapy, such as ticlopidine and glycoprotein IIb/IIIa platelet inhibition. Also, these trials lacked an aggressive approach to lipid lowering in both groups of patients. In the RITA, the ERACI-I, ARTS, and the French Monocentric trials, the ability to achieve "equivalent" degrees of revascularization in the two groups was an inclusion criterion.[364] [476] Moreover, the majority of patients entered into the trials had well-preserved left ventricular function and a mean ejection fraction exceeding 50 percent. In the main, patients enrolled in these trials were at relatively low risk, with predominantly two-vessel disease and well-preserved left ventricular function, i.e., a high proportion of patients in whom CABG surgery had *not* been previously shown to be superior to medical therapy in regard to survival. Thus, one would not expect a significant mortality difference between PTCA and CABG, particularly with the relatively small sample size of the trials (Fig. 37-23) .[365] [615]

The BARI Trial, initiated by the NHLBI, enrolled 1829 patients with multivessel disease in the United States and Canada. This trial is the largest of the randomized trials of PTCA and bypass surgery and the only trial with sufficient statistical power to detect a substantial mortality difference. At 5 years, overall survival rates were not different between the two groups (89.3 percent with CABG and 86.3 percent with PTCA [p=0.19]), nor was any difference noted in the incidence of Q wave myocardial infarction.[352] [616] An initially unexpected finding--but one that is also evident as a trend in the Coronary Angioplasty Versus Bypass Revascularisation Investigation (CABRI) and EAST trials (Rickards A, personal communication; King SB III, personal communication)--was that patients with previously treated diabetes who underwent PTCA had a mortality of 34.5 percent versus 19.4 percent for those who underwent CABG (p=0.003) (see also Chap. 63) .

Because of the heterogeneity among the trials, it is reassuring that the results are highly consistent within the trials and with observational studies. In these highly selected patients, neither procedure has demonstrated, after 1 to 5 years of follow-up, a clear superiority over the other for primary outcomes of mortality and Q wave myocardial infarction (Fig. 37-23) .[617] Although a meta-analysis by Pocock and colleagues demonstrated a trend in favor of bypass surgery, this trend did not reach statistical significance.[618]

CABG is initially associated with greater improvement in angina, which appears to be proportional to the more complete revascularization in patients with multivessel disease (Fig. 37-12) .[619] Moreover, as anticipated from the observational data, repeat revascularization procedures are more frequent after PTCA, although it is likely that more widespread use of stents will reduce the magnitude of the difference in repeat revascularization rates. In the RITA Trial, for example, after 5 years, repeat PTCA was performed in 27 percent of patients in the angioplasty group and CABG was performed in 26 percent; in comparison, among the patients treated initially with surgery only, 3 percent underwent reoperation and 9 percent subsequently required PTCA. What is encouraging among patients assigned to PTCA is the striking decrease in the need for reinterventions after the first 2 years, with a repeat revascularization rate of only 3 percent per year during years 3 to 5 of follow-up. In patients assigned to CABG, the reintervention rate remains steady at 2 percent per year, but it might be expected to increase after approximately 7 to 8 years of follow-up.[617] In the ARTS Trial, which compared multivessel stenting with CABG, repeat revascularization was performed in only 16.9 percent of patients in the stented group. This figure is lower than the repeat procedural rates noted in trials of angioplasty alone. Preliminary results from this study also suggested that 1-year costs were lower in the stented than in the bypass surgery group.[611] In the ERACI-II Study, preliminary results were similar to those in the ARTS Trial, with only 16 percent of patients who had PCI with stenting requiring repeat revascularization in follow-up versus 4.4 percent of bypass surgical patients (mean follow-up, 14.7 ± 6.4 months).[620]

Another consistent, but not unexpected finding was the lower in-hospital cost for patients undergoing PTCA.[364] However, the need for recurrent hospitalization and repeat revascularization procedures over the long term contributed to an increase in postdischarge cost in the PTCA

arms, which resulted in similar overall cost over 3 to 5 years.[364] [373] [374] [621] A major determinant of lower cost is the presence of two-vessel disease; in comparison, patients with congestive heart failure, comorbid conditions, or diabetes are likely to accrue higher cost regardless of the procedure.[621] Other measures of procedural success, including indices of the quality of life, cognitive function, and return to employment, were similar between PTCA and CABG.[621] [622]

Indications for Revascularization: The Choice Between PCI and CABG (Fig. 37-24 and Table 37-14)

Medical management of chronic CAD as outlined on pp. 1282 , 1283 , 1284 , 1285 , 1286 , 1287 , 1288 , 1289 , 1290 , 1291 , 1292 , 1293 , 1294 , 1295 , 1296 , 1297 , and 1298 involves a reduction in reversible risk factors, life style alteration counseling, treatment of conditions that intensify angina, and pharmacological management of ischemia. When an unacceptable level of angina persists or the patient has troubling side effects from the antiischemic drugs, the coronary anatomy should be defined to allow selection of the appropriate technique for revascularization. In patients in whom the angina is controlled, noninvasive testing is carried out and coronary arteriography performed in those with a "high-risk" result[365] (see p. 1280). After elucidation of the coronary anatomy, selection of the technique of revascularization is made as follows:

SINGLE-VESSEL DISEASE.

Among patients with single-vessel disease in whom revascularization is deemed necessary and the lesion is anatomically suitable, PCI is generally preferred over bypass surgery.

MULTIVESSEL DISEASE.

The first step is to decide whether a patient falls into the category of those who were included in randomized trials comparing PTCA and CABG. The majority of patients included in these trials were at lower risk, as defined by two-vessel disease and well-preserved ventricular function. Moreover, three trials required that equivalent degrees of revascularization be achievable

Figure 37-24 Indications for coronary revascularization with bypass surgery (CABG) or percutaneous coronary intervention (PCI) in patients with multivessel disease. The combination of triple-vessel disease and left ventricular (LV) dysfunction and/or left main coronary artery (LMCA) disease is primarily surgical, whereas the majority of the patients entered into the randomized trials were suitable for angioplasty on the basis of double-vessel disease, preserved left ventricular dysfunction, and suitable anatomy. Diabetics should be treated individually.

TABLE 37-14 -- COMPARISON OF REVASCULARIZATION STRATEGIES IN MULTIVESSEL DISEASE

ADVANTAGES	DISADVANTAGES
PERCUTANEOUS CORONARY INTERVENTION	
Less invasive	Restenosis
Shorter hospital stay	High incidence of incomplete revascularization
Lower initial cost	Relative inefficacy in patients with severe left ventricular dysfunction
Easily repeated	Uncertain long-term outcome (>10 yr)
Effective in relieving symptoms	Limited to specific anatomical subsets
CORONARY ARTERY BYPASS GRAFT SURGERY	
Effective in relieving symptoms	Cost
Improved survival in certain subsets	Increased risk of a repeat procedure because of late graft closure
Ability to achieve complete revascularization	Morbidity
Wider applicability	

Modified from Faxon DP: Coronary angioplasty for stable angina pectoris. In Beller G (ed): Chronic Ischemic Heart Disease. In Braunwald E (ed): Atlas of Heart Disease. Vol 5. Philadelphia, Current Medicine, 1995.

by both techniques. Most patients with chronically occluded coronary arteries were excluded, and of those who were clinically eligible, approximately two-thirds were excluded for angiographic reasons. The lack of any difference in late mortality and myocardial infarction between the two groups in such patients indicates that PCI is a reasonable *initial* strategy, provided that the patient accepts the distinct possibility of symptom recurrence and need for repeat revascularization. Patients with a single localized lesion in each affected vessel and preserved left ventricular function fare best with PCI.

NEED FOR COMPLETE REVASCULARIZATION.

Complete revascularization is an important goal in patients with left ventricular dysfunction and/or multivessel disease. The major advantage of CABG surgery over PCI is its greater ability to achieve complete revascularization, particularly in patients with three-vessel disease. In the majority of such patients, particularly those with chronic total coronary occlusion, left ventricular dysfunction, or left main CAD, CABG is the procedure of choice.[348] [475] Among patients with borderline left ventricular function (ejection fraction between 40 and 50 percent) and milder degrees of ischemia, PCI may provide adequate revascularization, even if it is not complete anatomically.

In many patients, either method of revascularization is suitable. Other factors that come into consideration include (1) access to a high-quality team and operator with an excellent record of success; (2) patient preference--some patients are made anxious by the idea that after PCI they remain at risk for symptom recurrence and may require reintervention (such patients are better candidates for surgical treatment); (3) advanced patient age and comorbidity--frail, very elderly patients and those with comorbid conditions, such as cancer or serious liver disease with a limited life expectancy, but who have disabling angina--are often better candidates for PCI; and (4) younger patient age--PCI is also often preferable in younger patients (<50 years) with the expectation that they may require CABG at some time in the future and that PCI will postpone the need for surgery; this sequence may be preferable to two operations. Patient preference is a pivotal aspect of the decision to perform PCI or CABG in these patient groups.

PTCA AND CORONARY BYPASS SURGERY IN DIABETIC PATIENTS (see also Chap. 63) .

The poorer outcomes after PTCA than after CABG in treated diabetic patients in the BARI Trial, together with similar trends in the EAST and CABRI trials, have raised concern about whether all diabetic patients with multivessel disease should be treated surgically. This important issue has significant economic implications, but further analysis suggests that treatment of diabetic patients can be individualized, as in nondiabetic patients. Despite the use of stents for multivessel PCI in the ARTS Trial, preliminary data suggest that the 1-year mortality in diabetic patients who received PCI and stenting was double that of those undergoing bypass surgery (6.3 vs. 3.1 percent).[623]

One explanation for the difference in outcomes may be an altered vascular biological response in diabetic patients to balloon injury and progression of disease in nondilated segments. The diabetic atherosclerotic milieu is characterized by a procoagulant state, decreased fibrinolytic activity, increased proliferation, and inflammation.[624]

Restenosis is more frequent in diabetic patients, as is disease progression. In a study of patients referred for diagnostic angiography 1 month or more after successful PTCA, the number of new narrowings in the arteries of diabetic patients increased by 22 percent, particularly at other sites in the artery that initially underwent PTCA.[625] Thus, CABG, which bypasses the majority of the vessel instead of a specific lesion, may offer a better long-term outcome.[626]

Another explanation for the results of PTCA and CABG is related to the patient selection criteria for enrollment into the trials. In the BARI Registry, in which patients were treated according to the preference of the individual physician, and in two large data base studies, poorer outcomes were noted for both CABG and PTCA in diabetics versus nondiabetics, but *among diabetics*, no survival difference was noted between PTCA and CABG.[627] Similar trends were noted in two large community studies.[363] [600] Diabetic patients as a group in BARI had a greater prevalence of three-vessel disease, left ventricular dysfunction, and a history of congestive heart failure. It is noteworthy that in the Emory University Study of diabetic patients, approximately 85 percent of those with three-vessel disease underwent bypass surgery, whereas the use of PTCA and CABG was similar among those with two-vessel disease.[600] A plausible explanation for the differences in results in the registry and data base studies and the randomized trials is that in the latter, sicker diabetic patients with three-vessel disease and left ventricular dysfunction, by design, were treated equally with bypass surgery and PTCA, whereas in clinical practice, such patients are referred appropriately for surgery, and earlier data base studies suggest that 3- to 5-year survival after CABG in the higher-risk subgroups is superior to that obtained with PCI.

The therapeutic implications of these observations are evident. The revascularization strategy in diabetic patients should be based on the number of vessels diseased, lesion-related technical factors, the caliber of the distal vessels, and the presence or absence of left ventricular dysfunction.

Coronary Bypass Surgery in Patients with Associated Vascular Disease

Management of patients with combined CAD and peripheral vascular disease involving the carotid arteries, the abdominal aorta, or the vessels of the lower extremities presents many challenges.[32] Combined disease is becoming increasingly frequent as the population of patients under consideration for CABG ages and as technical improvements allow the application of coronary revascularization to ever more complex cases.

IMPACT OF CAD IN PATIENTS WITH PERIPHERAL VASCULAR DISEASE.

Clinically apparent CAD occurs frequently in patients with peripheral vascular disease.[32] The prevalence of clinically unrecognized CAD, as documented by angiographic studies, is even higher.[628] Among patients undergoing peripheral vascular surgery, late outcomes are dominated by cardiac causes of morbidity and mortality.[628] [629] Conversely, in patients with CAD, the presence of peripheral vascular disease, even if asymptomatic, is associated with an adverse prognosis, presumably because of the greater total atherosclerotic burden borne by these patients.[33] [630]

If coronary revascularization is performed before vascular surgery in patients with combined peripheral vascular disease and CAD, the perioperative mortality of the vascular procedure is reduced.[32] In seven series totaling 1237 patients undergoing vascular surgical procedures, the mean operative mortality was 1.5 percent among patients with prior CABG surgery, similar to the 1.3 percent mortality rate in patients without clinically apparent CAD and substantially lower than the 6.8 percent mortality rate in patients with clinically suspected but uncorrected CAD.[32] Late mortality in patients with peripheral vascular disease is also reduced among those who have undergone prior CABG.[631] However, because patients with CAD and peripheral atherosclerosis tend to be older and have more widespread vascular disease and end-organ damage than do patients without peripheral atherosclerosis, the perioperative mortality and morbidity consequent to CABG are high and the late outcome not as favorable.[32] [628] [632] In the Northern New England Cardiovascular data base, in-hospital mortality after bypass surgery was 2.4-fold greater in patients with peripheral vascular disease than in those without it, particularly for patients with lower extremity disease.[633] In the BARI Trial, approximately one-third of patients had peripheral vascular disease, among whom the risk of major complications after both bypass surgery and PTCA was markedly increased in comparison to those without peripheral vascular disease, even after controlling for baseline differences.[634] *Diffuse atheroembolism* is a particularly serious complication of coronary bypass surgery in patients with peripheral vascular disease and aortic atherosclerosis. It is a major cause of perioperative death, stroke, neurocognitive dysfunction, and multiple organ dysfunction after CABG.

Not only is perioperative morbidity and mortality increased in patients with peripheral vascular disease, but the latter is also a strong marker of an adverse long-term outcome. At any point during a 10-year period, patients in either the medical or surgical group in the CASS Registry who had peripheral vascular disease had a 25 percent greater likelihood of mortality than did those without this condition.[33] Similarly, in the Northern New England Cardiovascular data base, the 5-year mortality remained approximately twofold greater in patients with peripheral vascular disease than in those without it, even after adjusting for comorbid conditions, which are more frequent in patients with peripheral vascular disease.[633] [635] In the BARI Trial, patients with asymptomatic lower extremity disease, as defined by the ankle-arm index, had an almost fivefold greater mortality than did those without lower extremity arterial disease. Indeed, mortality was similar for patients with symptomatic and patients with asymptomatic lower extremity disease.

It is important to identify CAD and to estimate its severity in patients who are candidates for peripheral vascular surgery. The diagnostic problem is intensified because these patients often have limited walking capacity and may not develop effort angina. Pharmacological stress myocardial perfusion scintigraphy or echocardiography can be used. Identification of "high-risk" patients by these techniques (Table 37-2, p. 1280) should lead to coronary angiography in these patients even if they have no or only mild angina and, depending on the anatomical findings, should lead to coronary revascularization, often before peripheral vascular surgery.

Thus, the presence of peripheral vascular disease suggests that the patient may also have high-risk CAD, with potential benefit from CABG in the long term. In the ECSS, patients with CAD and peripheral vascular disease receiving CABG had a much better survival rate than did those who were treated medically.[531] In the CASS Registry, patients with peripheral vascular disease and three-vessel CAD who received surgical treatment also exhibited a major reduction in late mortality and morbidity in comparison

---

with those who were managed medically.[32] Observations such as these argue for *consideration* of CABG in patients with peripheral vascular disease who have significant CAD. The major indication for coronary revascularization before vascular surgery in patients with known chronic CAD is the intention of improving the *long-term* prognosis. A randomized trial of prophylactic coronary artery revascularization in patients undergoing elective vascular surgery is in progress.[636]

CAROTID ARTERY DISEASE.

In patients with stable CAD and *carotid artery disease* in whom coronary endarterectomy is planned, exercise stress testing and consideration of coronary revascularization can ordinarily be performed after the carotid surgery.[32] CAD is significantly associated with an increased risk of stroke after bypass surgery, and this association is also strongly correlated with age.[467] [637] However, many strokes are not ipsilateral to the site of stenosis, and the association most likely reflects the presence of diffuse aortic atherosclerosis. [638] The prevalence of significant carotid disease in an increasingly elderly population coming to CABG is high--approximately 17 to 22 percent have a stenosis of 50 percent or greater, 6 to 12 percent have a stenosis of 80 percent or greater, and the percentage is higher in patients with left main CAD.[458] [639] In patients for whom surgical treatment is considered for both carotid artery disease and CAD, the merits of a combined versus a staged approach are debated.[640] [641] Neither strategy has been demonstrated to be unequivocally superior to the other, and an individualized approach, depending on the patient's initial condition, the severity of symptoms, the anatomy of the coronary and carotid vessels, and individual institutional experience, is most appropriate.[458] [642]

MANAGEMENT.

Patients with severe or unstable coronary disease requiring revascularization can be categorized into two groups according to the severity and instability of the accompanying vascular disease.[32] When the noncoronary vascular procedures are elective, they can generally be postponed until the cardiac symptoms have stabilized, either by intensive medical therapy or by revascularization. A combined procedure is necessary in patients with both unstable CAD and an unstable vascular condition, e.g., frequent recurrent transient ischemic attacks or a rapidly expanding abdominal aortic aneurysm.[640] [643] In some patients in this category, PCI offers the potential for stabilizing the patient's cardiac condition before proceeding with a definitive vascular repair.[644]

Other Manifestations of Coronary Artery Disease

PRINZMETAL (VARIANT) ANGINA

In 1959, Prinzmetal and associates described an unusual syndrome of cardiac pain secondary to myocardial ischemia that occurs almost exclusively at rest, is not usually precipitated by physical exertion or emotional stress, and is associated with ECG ST segment elevations[645] (Fig. 37-25) . This syndrome, now known as *Prinzmetal,* or *variant, angina*, may be associated with acute myocardial infarction and severe cardiac arrhythmias, including ventricular tachycardia and fibrillation, as well as sudden death. A prevailing clinical impression, at least in North America, is that Prinzmetal angina has become less frequent for reasons that are unclear, perhaps because of the more widespread use of calcium antagonists, better nitrate regimens, or alterations in pathophysiology of the coronary disease process.[646] It appears to remain more common in Japan.

Mechanisms

The original hypothesis of Prinzmetal and colleagues, that variant angina was the result of transient increases in coronary vasomotor tone or vasospasm, was convincingly demonstrated by coronary angiography.[647] Vasospasm causes a transient, abrupt, marked decrease in the diameter of an epicardial (or large septal) coronary artery that results in myocardial ischemia. This event occurs in the absence of any preceding increases in myocardial O_2 demand, as reflected in an increased heart rate or blood pressure. The decrease in diameter can usually be reversed by nitroglycerin, sometimes requiring large doses, and can occur in either normal or diseased coronary arteries. Although the sites of vasospasm may correspond to areas of severe focal stenosis, in some patients with apparently normal vessels at angiography, the vasospastic segments appear to occur at sites of at least minimal atherosclerotic change, as detected by intravascular ultrasonography.[648] Measurements of great cardiac vein flow and left anterior descending coronary artery diameter in patients with vasospastic angina suggest that not only epicardial but also the coronary resistance arteries are affected by the coronary vasomotion disorder.[649] This focal severe vasospasm should not be confused with vasoconstriction of both the large and small coronary vessels, a *normal* response to stimuli such as cold exposure. The latter response is much less intense and occurs diffusely throughout the coronary vascular bed.

In patients with Prinzmetal angina, basal coronary artery tone may be increased. Although responses to various vasoconstrictor substances, including catecholamines, thromboxane A_2 , serotonin, endothelin, and arginine vasopressin, are greater in spastic segments of the coronary arteries, hypersensitivity to vasoconstrictor stimuli also occurs throughout the entire coronary tree,[650] perhaps as a manifestation of a more generalized response to vasoactive stimuli.[651] The precise mechanisms have not been established, but a systemic alteration in NO production or an imbalance between endothelium-derived relaxing and contracting factors has been suggested.[650] [652]

In other patients, the sites of spasm in Prinzmetal angina may be adjacent to atheromatous plaque. It has been suggested that in this subgroup of patients, the basic abnormality may be hypercontractility of the arterial wall associated with the atherosclerotic process itself. Other suggested mechanisms include endothelial injury (which reverses the dilator response to a variety of stimuli, e.g., acetylcholine [see Chap. 34]) and hypercontractility of vascular smooth muscle as a result of vasoconstrictor mitogens, leukotrienes, serotonin, endothelin, angiotensin II, histamine,[653] [654] and higher local concentrations of blood-borne vasoconstrictors in areas adjacent to neovascularized atherosclerotic plaque.

The sequelae of coronary spasm may, but do not consistently, accelerate atherosclerosis and predispose to further spasm. One mechanism may involve the release of potent

Figure 37-25 Electrocardiogram (ECG) before an episode of Prinzmetal angina *(A)* and during an episode of Prinzmetal angina *(B)*. ST segments are now markedly elevated in the inferior leads, with reciprocal depression in the anterior leads. After nitroglycerin was given, the ECG returned to baseline. *(From Berman ND, McLaughlin PR, Huckell VF, et al: Prinzmetal's angina with coronary artery spasm. Angiographic, pharmacologic, metabolic and radionuclide perfusion studies. Am J Med 60:727, 1976. By permission of Excerpta Medica.)*

vasoconstrictor substances such as platelet-derived growth factors, in addition to activation of the coagulation system.[655] [656] The combination of a reduction in blood flow and an increase in platelet activation and local thrombosis may accelerate the process of atherosclerosis.[655] Histological findings in patients undergoing coronary atherectomy suggest that repetitive coronary vasospasm may provoke vascular injury and lead to the formation of neointimal hyperplasia at the initial site of spasm. In this respect, coronary spasm may have a key role in the rapid progression of coronary stenosis in some patients.[657] Ergonovine stimulation has been demonstrated to provoke platelet aggregation and an increase in beta-thromboglobulin levels before ECG changes and chest pain in patients with coronary vasospasm.[658]

Imaging with iodine-123-labeled metaiodobenzylguanidine ([123] I-MIBG) has demonstrated regional myocardial sympathetic dysinnervation, which was not observed in patients with significant obstructive CAD and in subjects with normal coronary arteries.[659] The region of myocardial sympathetic dysinnervation is usually in the area of distribution of the vessel in which vasospasm developed.[659] [660]

Coronary spasm in patients with variant angina may induce stasis and result in the conversion of fibrinogen to fibrin in the coronary vessels, with elevated levels of plasma fibrinopeptide A, an index of fibrin formation.[661] The latter displays significant circadian variation in plasma concentration, with peak levels occurring from midnight to early morning, in parallel with the frequency of ischemic attacks in these patients.[662] In patients with variant angina, a significant variation in fibrinolytic activity (lowest in the early morning) corresponds with the occurrence of anginal episodes, which are most frequent in the early morning. The possibility that vasospasm may induce leukocyte adhesion in the coronary circulation at an early stage in the initiation of an inflammatory process has been suggested.[663]

Cigarette smoking is an important risk factor for Prinzmetal angina.[664] It has been reported that hypomagnesemia predisposes to variant angina,[665] and magnesium sulfate has been shown to terminate cold pressor-induced anginal attacks and the induction of future attacks[666] and to suppress attacks induced by hyperventilation[667] and exercise in these patients. [668]

Clinical Manifestations

Patients with variant angina tend to be younger than patients with chronic stable angina or unstable angina secondary to coronary atherosclerosis, and many do not exhibit classic coronary risk factors except that they are often heavy cigarette smokers. The anginal discomfort is often extremely severe, is generally referred to as "pain," and may be accompanied by syncope. Associated features in patients with syncope include inferior ST segment elevation and serious arrhythmias, either AV block and asystole or ventricular tachyarrhythmias[669] [670] [671] [672] (Fig. 37-26) .

Attacks of Prinzmetal angina tend to be clustered between midnight and 8 A.M.[662] Attacks sometimes occur in clusters of two or three within 30 to 60 minutes.[45] Patients studied by means of ambulatory ECG, even those without clinically apparent angina pectoris, show more frequent abnormalities in the morning. In contrast to

patients with unstable angina, the pain at rest in patients with Prinzmetal angina has not usually progressed from a period of chronic stable angina. Although exercise capacity is generally well preserved in patients with Prinzmetal angina, some patients experience typical pain and ST segment elevations not only at rest but during or after exertion as well. Acute myocardial infarction in patients with spasm and angiographically normal coronary arteries has been well documented.[673] [674]

Clinical features do not reliably differentiate patients with Prinzmetal angina and normal or mildly abnormal coronary arteriograms from those with this syndrome and severe coronary obstruction.[669] However, the latter may have a combination of fixed-threshold, exertion-induced angina with ST segment depression, as well as episodes of angina at rest with ST segment elevation. In rare cases, Prinzmetal angina develops after coronary artery bypass surgery,[675] and occasionally it appears to be a manifestation of a generalized vasospastic disorder associated with attacks of migraine and Raynaud's phenomenon; it has also been reported in association with aspirin-induced asthma.[676] Coronary spasm with ventricular fibrillation has been observed in thyrotoxicosis.[677] Some patients appear to demonstrate a distinct relationship between emotional distress and episodes of coronary vasospasm, which is consistent with studies suggesting that a sympathovagal imbalance may precipitate spasm in patients with variant angina.[672] Alcohol withdrawal may precipitate variant angina,[678] and conversely, alcohol ingestion may prevent coronary spasm.[679] Variant angina has been reported to be provoked by 5-fluorouracil[680] and by cyclophosphamide [681] (see Chap. 69) .

The results of cardiac examination are usually normal in the absence of ischemia (unless the patient has suffered a previous myocardial infarction), but signs of dyskinesia and impaired left ventricular function during episodes of myocardial ischemia are often revealed.

Figure 37-26 Arrhythmia during silent ischemia and reperfusion. Selected strips from a 2.5-minute continuous recording (lead II) in patient during an angiographically documented spasm of the right coronary artery are shown. Tracing A began 24 seconds after the onset of ST segment elevations (arrows) and demonstrates premature ventricular contractions and salvos. The top strip of tracing B was recorded 70 seconds after onset, immediately after the sublingual administration of nitroglycerin (1/150 grain); the bottom strip of tracing B was recorded 36 seconds later. Tracing C was recorded 130 seconds after onset and shows spontaneous reversion (asterisk) and atrial fibrillation. *(From Myerburg RJ, Kessler KM, Mallon SM, et al: Life-threatening ventricular arrhythmias in patients with silent myocardial ischemia due to coronary-artery spasm. N Engl J Med 326:1451, 1992. By permission of The Massachusetts Medical Society.)*

Electrocardiographic Studies

The key to the diagnosis of variant angina lies in the detection of ST segment elevation with pain (see Fig. 37-25) . In a series of patients with variant angina and normal coronary arteries monitored with a computerized 24-hour, 12-lead ECG recording and analysis system, approximately 90 percent of episodes were associated with ST segment elevation, with accompanying arrhythmias in 19 percent, but no arrhythmias were noted in the small proportion of patients with ST segment depression.[669] In some patients, episodes of ST segment depression follow episodes of ST segment elevation and are associated with T wave changes, including peaking of T waves or pseudonormalization of previously depressed segments. ST segment and T wave alternans[682] and increased QT dispersion[683] are the result of ischemic conduction delay and may be associated with potentially lethal ventricular arrhythmias.[684] R wave "growth" may also be associated with the occurrence of ventricular arrhythmias.[685] Many patients exhibit multiple episodes of asymptomatic ST segment elevation (silent ischemia). ST segment deviations may be present in any leads; the concurrent presence of ST segment elevations in both the inferior and anterior leads (reflecting extensive ischemia) is associated with an increased risk of sudden death.[686] A pattern of *alternating* ST segment elevation between the precordial and inferior leads is associated with angiographically documented multivessel spasm involving both the left anterior descending and right coronary systems.[687]

Transient conduction disturbances may occur during episodes of ischemia.[670] [672] [685] Ventricular ectopic activity is more frequent during longer episodes of ischemia, is often associated with ST segment and T wave alternans,[685] and is of ominous prognostic import. In survivors of out-of-hospital cardiac arrest without flow-limiting coronary stenoses, spontaneous or induced focal coronary spasm has been found to be associated with life-threatening ventricular arrhythmias. In some patients, reperfusion rather than ischemia itself correlates with the onset of ventricular arrhythmias[688] (Fig. 37-26) . Myocardial cell damage, as reflected by the release of small quantities of CK-MB, may occur in the absence of persistent ECG changes in patients with prolonged attacks of variant angina; transient Q waves have been observed, which may be explained by a transient loss of normal cell membrane electrical activity during spasm.[689] Transmural myocardial infarction caused by coronary artery spasm in the absence of angiographically demonstrable obstructive CAD has been described.[673] [674]

Exercise testing in patients with variant angina is of limited value because the response is so variable. Approximately equal numbers of patients show ST segment depression, no change in ST segments during exercise, or ST segment elevation, which reflects the presence of underlying fixed CAD in some patients, the absence of significant lesions in others, and the provocation of spasm by exercise in the rest. Ambulatory ECG monitoring or the use of a telephone transmitter may be helpful in capturing ST segment elevation during symptomatic episodes.[690]

Hemodynamic and Arteriographic Studies

Spasm of a proximal coronary artery with resultant transmural ischemia and abnormalities in left ventricular function has been convincingly documented arteriographically and is the diagnostic hallmark of Prinzmetal angina.[691]

Significant fixed proximal coronary obstruction of at least one major vessel occurs in the majority of patients, and in these patients spasm usually occurs within 1 cm of the obstruction. The remainder have normal coronary arteries in the absence of ischemia. The process almost always involves large segments of the epicardial vessels at a single site, but at different times other sites may be involved (Fig. 37-27) . The right coronary artery is the most frequent site, followed by the left anterior descending coronary artery.[690] Among the 45 percent of patients in one series with multivessel spasm, three different patterns were noted: (1) spasm at a different site on different occasions (migratory spasm), (2) spasm that sequentially affected two different sites, and (3) simultaneous spasm at more than one site. The duration of ST segment elevation was greater in patients with sequential and simultaneous spasm than in those with single-vessel spasm, as was the frequency of arrhythmias.[669] Patients with Prinzmetal angina and normal coronary arteriograms in the absence of pain are more likely to have purely nonexertional angina and ST segment elevations involving the inferior leads during pain. In contrast, patients with Prinzmetal angina who have fixed obstructive lesions with superimposed coronary artery spasm often have associated effort-induced angina and ischemia in the anterolateral leads. Patients with no or mild fixed coronary obstruction tend to experience a more benign course than do patients with associated severe obstructive lesions.[692]

PROVOCATIVE TESTS

THE ERGONOVINE TEST.

Several provocative tests for coronary spasm have been developed. Of these, the ergonovine test is the

Figure 37-27 Angiograms of the left coronary artery in patients with variant angina (left anterior oblique projection). Infusion of 10^{-4} M acetylcholine into the left coronary artery *(top panel)* induced spasm at three focal sites in the left anterior descending artery (arrows). Spasm was reversed after intracoronary nitroglycerin administration *(bottom)*. *(From Pepine CJ, el-Tamimi H, Lambert CR: Prinzmetal's angina [variant angina]. Heart Dis Stroke 1:281, 1992. By permission of The American Heart Association.)*

most sensitive. Ergonovine maleate, an ergot alkaloid that stimulates both alpha-adrenergic and serotonergic receptors and therefore exerts a direct constrictive effect on vascular smooth muscle,[693] has been used to induce coronary artery spasm, which results in chest pain and ST segment elevation in patients with Prinzmetal angina. Occasionally, ergonovine may produce a similar response in patients with more typical effort-related anginal symptoms.[690] Coronary arteries that constrict spontaneously appear to be abnormally sensitive to this agent. When administered intravenously in doses ranging from 0.05 to 0.40 mg, ergonovine provides a sensitive and specific test for provoking coronary artery spasm. The majority of patients who have a response to ergonovine do so at a dose of less than 0.2 mg.[690] An inverse correlation is found between the dose of ergonovine required to induce a positive test and the frequency of spontaneous attacks.[694] In low doses and in carefully controlled clinical situations, ergonovine is a relatively safe drug, but prolonged coronary artery spasm precipitated by ergonovine may cause myocardial infarction. Occasionally, conduction disturbances develop (heart block, asystole, or severe tachyarrhythmias).

Because of these hazards, it is recommended that ergonovine be administered only to patients in whom coronary arteriography has demonstrated normal or nearly normal coronary arteries and in gradually increasing doses, beginning with a very low dose. Nitrates and calcium antagonists are usually effective in providing prompt relief from drug-induced spasm, and the intracoronary route is usually the most expeditious in patients already undergoing angiography. To ensure a valid test, nitrates

and calcium antagonists must be withdrawn for 48 hours or more before testing. Women are more sensitive than men to ergonovine.[496] [695]

The ergonovine test should be conducted only in a setting where appropriate resuscitative equipment, drugs, and personnel are readily available, usually in the cardiac catheterization laboratory and with a catheter poised to enter the coronary arteries, so that the angiographic diagnosis of spasm can be made and intracoronary nitroglycerin administered to abolish the spasm. Absolute contraindications to ergonovine testing include pregnancy, severe hypertension, severe left ventricular dysfunction, moderate to severe aortic stenosis, and high-grade left main coronary artery stenosis. Relative contraindications include uncontrolled or unstable angina, uncontrolled ventricular arrhythmias, recent myocardial infarction, and advanced CAD.[496]

The response of the *normal* coronary arterial bed to larger doses (
0.40 mg) of ergonovine is a diffuse reduction in arterial caliber.

HYPERVENTILATION.

This stimulus has also been demonstrated to provoke some episodes of intense angina,[696] ECG ST segment elevations, angiographic evidence of coronary artery spasm, and ventricular arrhythmias. A recent large series documented the relative specificity of the hyperventilation test in patients with vasospastic angina.[697] Patients with positive tests had a statistically significantly greater frequency of high disease activity (five or more attacks per week), severe arrhythmias during attacks, and multivessel spasm.

ACETYLCHOLINE.

Stimulation of acetylcholine receptors produces a uniform endothelium-dependent dilatation of coronary vessels of all sizes that leads to vasoconstriction when endothelial function is impaired.[698] In patients with variant angina, intracoronary injections of acetylcholine have been shown to induce severe coronary spasm and reproduce the clinical syndrome[699] (see Fig. 37-27) . This focal spasm should not be confused with the mild diffuse constriction that acetylcholine induces in patients with abnormal coronary endothelium. Because this method allows induction of spasm separately in the left and right coronary arteries, it is useful in patients with known multivessel disease or spasm. Acetylcholine is infused over a 1-minute period into a coronary artery in incremental doses of 10, 25, 50, and 100 mug, and doses should be separated by 5-minute intervals.[496] [695]

Histamine, dopamine, and serotonin can also induce coronary artery spasm.[700] [701] Like ergonovine and acetylcholine, these agents are capable of causing marked coronary artery spasm in patients with variant angina who have severe underlying arteriosclerotic coronary artery narrowing and in those without such fixed stenoses.

Exercise, the cold pressor test, and induced alkalosis can all cause coronary spasm in patients with variant angina, but none of these tests is as sensitive as ergonovine or acetylcholine.

Management

The mainstay of therapy for vasospastic angina is a calcium channel blocker alone or in combination with long-acting nitrates. Nonetheless, several important differences can be seen between the optimal management of Prinzmetal variant angina and classic (stable and unstable) angina.

1. Patients with both variant and classic angina usually respond well to nitrates; sublingual or intravenous nitroglycerin often abolishes attacks of variant angina promptly, and long-acting nitrates are useful in preventing attacks.[702] However, the mechanism of action of the drugs may differ in the two types of angina. As already discussed (see p. 1287), in chronic (effort-induced) stable angina as well as in unstable angina, one important action of nitrates is to reduce myocardial O_2 need and another is to cause coronary vasodilation. In Prinzmetal angina, nitrates abolish or prevent myocardial ischemia *exclusively* by exerting a direct vasodilating effect on the spastic coronary arteries.
2. In patients with classic angina (stable and unstable), beta blockade is usually beneficial, but the response in patients with Prinzmetal angina to these agents is variable.[703] Some, particularly those with associated fixed lesions, exhibit a reduction in the frequency of exertion-induced angina caused primarily by augmentation of myocardial O_2 requirements. In others, however, nonselective beta-adrenoreceptor blockers may actually be detrimental because blockade of $beta_2$ receptors, which subserve coronary dilation, allows unopposed alpha receptor-mediated coronary vasoconstriction to occur; in these patients, the duration of episodes of vasotonic angina may be prolonged by propranolol.[704]
3. In contrast to the variable effectiveness of beta blockers, calcium antagonists are extremely effective in preventing the coronary artery spasm of variant angina,[705] [706] and they should ordinarily be prescribed in maximally tolerated doses. These drugs, along with long- and short-acting nitrates, are the mainstay of therapy. Because calcium antagonists act through a different mechanism than nitrates, the vasodilatory actions of these two classes of drugs may be additive. All first-generation calcium channel antagonists have similar efficacy in producing relief of symptoms: 94 percent for nifedipine, 40 mg/d; 91 percent for diltiazem, 180 mg/d; and 86 percent for verapamil, 240 mg/d.[650] [705] [706] [707] [708] In rare instances, a patient responds to only one of these three agents, and even less commonly**,** the simultaneous administration of two or even three calcium antagonists is required. Some patients need extremely high doses, although side effects are increased. Slow-release nifedipine has been shown to be highly effective in suppressing not only symptomatic but also asymptomatic myocardial ischemia in patients with variant angina.[707] Second-generation calcium blockers such as the vascular-selective agents felodipine and amlodipine have also been shown to be effective. In addition, once-daily felodipine has been demonstrated to be highly effective in preventing ergonovine-induced myocardial ischemia in patients with variant angina[709] and in patients with spontaneous Prinzmetal angina.[710] In a randomized trial, amlodipine, 5 to 10 mg/d, has also been shown to be effective.[711] Reports have suggested a rebound of symptoms when calcium antagonist therapy is discontinued.[708]
4. *Prazosin*, a selective alpha-adrenoreceptor blocker (see Chap. 29) , has also been found to be of value in patients with Prinzmetal angina.[712] *Nicorandil*, a vasodilator that influences coronary arterial tone by acting through potassium channel activation, appears to be effective for the treatment of vasospastic angina, as suggested by studies in Japan and Europe.[713] *Aspirin*, helpful in unstable angina (see Chap. 36) , may actually *increase* the severity of ischemic episodes in patients with Prinzmetal angina because it inhibits biosynthesis of the naturally occurring coronary vasodilator prostacyclin.[714] *ACE inhibition* with enalapril was shown to be ineffective in comparison with verapamil in patients with vasospastic angina.[715] Other novel but promising approaches to the management of vasospastic angina include troglitazone, an insulin sensitizer,[716] and denopamine, an adrenergic $beta_1$ agonist,[717] and in a small study of patients in whom vasospastic angina was induced by hyperventilation, the infusion of B-type (brain) natriuretic peptide was highly effective.[718]
5. PCI and occasionally CABG may be helpful in patients with variant angina and discrete, proximal fixed obstructive lesions.[719] Calcium antagonists should be continued for at least 6 months following successful revascularization. PCI and coronary artery bypass surgery are *contraindicated* in patients with isolated coronary artery spasm without accompanying fixed obstructive disease.

Prognosis

Many patients with Prinzmetal angina pass through an acute, active phase, with frequent episodes of angina and cardiac events during the first 6 months after diagnosis. Long-term survival at 5 years is excellent (89 to 97 percent).[686] In a large series of 277 patients with a median follow-up of 7.5 years, recurrent angina was common (39 percent), but cardiac death and myocardial infarction were relatively infrequent and occurred in 3.5 and 6.5 percent of patients, respectively.[720] However, recurrent myocardial infarction in the setting of normal coronary arteries and angiography has been described.[674] The extent and severity of the underlying CAD and the activity or the tempo of the syndrome have a major effect on the incidence of late mortality and myocardial infarction. Because occlusive coronary spasm may cause stasis with platelet aggregation and thrombosis, the duration of the episodes of spasm is probably a factor in the development of acute infarction.

Patients with variant angina in whom serious arrhythmias (ventricular tachycardia, ventricular fibrillation, high-degree AV block, or asystole) develop during spontaneous episodes of pain have a higher risk of sudden death.[721] [722]

In most patients who survive an infarction or the initial 3- to 6-month period of frequent episodes, the condition stabilizes and symptoms and cardiac events tend to diminish with time. In patients who experience such remissions, cautious tapering of calcium antagonists may be attempted. In one series, 16 percent of patients had spontaneous remission for 3 months after withdrawal of therapy, 44 percent continued to have symptoms despite treatment with calcium antagonists and nitrates, and the other 40 percent were free of angina but receiving treatment. Remission occurred more frequently in patients without significant coronary artery stenoses and in those who stopped smoking.[723]

For reasons that are not clear, some patients, after a relatively quiescent period of months or even years, experience a recrudescence of vasospastic activity with frequent and severe episodes of ischemia.[724] Fortunately, these patients respond to re-treatment with calcium antagonists and nitrates. Most patients in whom

symptoms recur after a pain-free period demonstrate, on provocative testing, spasm at the same location as previously demonstrated and respond once more to treatment with nitrates and calcium antagonists.

CHEST PAIN WITH NORMAL CORONARY ARTERIOGRAM

The syndrome of angina or angina-like chest pain with a normal coronary arteriogram, often referred to as *syndrome X* (to be distinguished from the metabolic syndrome X characterized by abdominal obesity, hypertriglyceridemia, low HDL cholesterol, insulin resistance, hyperinsulinemia, and hypertension), is an important clinical entity that should be differentiated from classic ischemic heart disease caused by CAD. In this condition, the prognosis is usually excellent,[725] [726] in contrast to the variable outcome in patients with angina caused by coronary atherosclerosis. Patients with chest pain and normal coronary arteriograms may represent as many as 10 to 20 percent of those undergoing coronary arteriography because of clinical suspicion of angina. The cause(s) of the syndrome is unclear. True myocardial ischemia, reflected in the production of lactate by the myocardium during exercise or pacing, is present in some of these patients.[727] The incidence of coronary calcification on double-helical CT scanning is significantly higher than that of normal controls (63 vs. 22 percent), but lower than that in patients with organic heart disease (96 percent).[728]

It is postulated that the syndrome of angina pectoris with normal coronary arteries reflects a number of conditions. Included in syndrome X are patients with microvascular dysfunction or spasm in whom angina may be the result of ischemia.[729] [730] This condition is frequently referred to as *microvascular angina* (Fig. 37-28) . In others, chest discomfort without ischemia may be due to abnormal pain perception or sensitivity. This hypersensitivity may result in an awareness of chest pain in response to stimuli such as arterial stretch or changes in heart rate, rhythm, or contractility. A sympathovagal imbalance with sympathetic

Figure 37-28 Proposed pathogenetic mechanisms of microvascular angina. The syndrome results from a variable combination of two components: an increased sensitivity to painful stimuli associated with coronary microvascular dysfunction (indicated by recurring ST segment depression), both of which have a bell-shaped prevalence in the population. Furthermore, within any individual, either component may vary in time (indicated by the horizontal lines). In patients with markedly enhanced sensitivity to pain, even minimal microvascular dysfunction can cause angina. Conversely, some patients with severe microvascular dysfunction (indicated by recurring ST segment depression) may not come to medical attention if they have normal or low sensitivity to pain. *(From Maseri A: Ischemic Heart Disease: A Rational Basis for Clinical Practice and Clinical Research. New York, Churchill Livingstone, 1995. By permission.)*

predominance in some of these patients has also been postulated. At the time of cardiac catheterization, some patients with syndrome X are unusually sensitive to intracardiac instrumentation, with typical chest pain being consistently produced by direct right atrial stimulation and saline infusion.[731] Other patients appear to have a combination of microvascular dysfunction and abnormal pain sensitivity. Intravascular ultrasound studies have demonstrated the anatomical and physiological heterogeneity of syndrome X, with a spectrum ranging from normal coronary arteries to vessels with intimal thickening and atheromatous plaque.[732] On the other hand, many patients do not have metabolic evidence of ischemia despite abnormal coronary flow reserve after pacing.[733]

MICROVASCULAR DYSFUNCTION (INADEQUATE VASODILATOR RESERVE)(Fig. 37-28) .

Patients with chest pain, angiographically normal coronary arteries, and no evidence of large vessel spasm even after an acetylcholine challenge may demonstrate an abnormally reduced capacity to reduce coronary resistance and increase coronary flow in response to stimuli such as exercise, dipyridamole, and atrial pacing. These patients also have an exaggerated response of small coronary vessels to vasoconstrictor stimuli and an impaired response to intracoronary papavarine.[734] Some evidence indicates that increased endothelin concentrations may be associated with reduced coronary flow responses during atrial pacing.[735] This abnormality appears to affect the smaller resistance vessels that are not visible angiographically, whereas the large proximal conductance vessels are normal.[736] The reduced vasodilator reserve in the microcirculation may be associated with exercise-induced regional wall motion abnormalities, as well as abnormalities in diastolic function.[737] The reduced coronary flow reserve may cause abnormalities in myocardial perfusion that are detectable with PET.[738] It has been reported that these patients also have impaired vasodilator reserve in forearm vessels[739] and airway hyperresponsiveness,[740] which suggests that the smooth muscle of systemic arteries and other organs may be affected in addition to that of the coronary circulation.

A link between coronary microvascular dysfunction and ischemia in response to exercise is an attractive concept that could explain abnormal left ventricular function resulting from exercise in some patients with chest pain and normal coronary arteries.[738] [741] Abnormal endothelial function and increased sympathetic drive or responsiveness have been reported.[742] [743]

EVIDENCE FOR ISCHEMIA.

Despite general acceptance that microvascular and/or endothelial dysfunction (see Fig. 37-28) is present in many patients with syndrome X, whether ischemia is in fact the putative cause of the symptoms in these patients is not clear.[731] [741] The development of left ventricular dysfunction and ECG or scintigraphic abnormalities during exercise in some of these patients supports an ischemic cause. However, transesophageal stress echocardiography with dobutamine has failed to demonstrate regional contraction abnormalities consistent with ischemia.[744] The lack of definitive evidence of ischemia in some patients with syndrome X has focused attention on alternative nonischemic causes of cardiac-related pain, including a decreased threshold for pain perception--the so-called sensitive heart syndrome.[731] [745] It is difficult to distinguish patients with syndrome X in whom chest pain is caused by ischemia from patients with noncardiac pain (see p. 1274). Behavioral or psychiatric disorders may be evident.[746] [747] Esophageal dysmotility and reproduction of pain after the infusion of hydrochloric acid into the esophagus (Bernstein test) or intraesophageal balloon distention have been reported in some of these patients.

Clinical Features

The syndrome of angina or angina-like chest pain with normal epicardial arteries occurs more frequently in women,[748] many of whom are premenopausal, whereas obstructive CAD is found more commonly in men and postmenopausal women. Fewer than half of patients with syndrome X have typical angina pectoris; the majority have a variety of forms of atypical chest pain. Although the features are frequently atypical, the chest pain may nonetheless be severe and disabling. [748] The condition may be benign in regard to survival, but it may have markedly adverse effects on the quality of life, employment, and use of health care resources.[749]

In some patients with minimal or no CAD, an exaggerated preoccupation with personal health is associated with the chest pain, and panic disorder may be responsible in a proportion of such patients. Potts and Bass found that two-thirds of patients with chest pain and normal coronary arteries have predominantly psychiatric disorders.[747] Others have reported that the incidence of obstructive CAD is extremely low in patients with atypical chest pain who are anxious and/or depressed.[750] The association between syndrome X and insulin resistance warrants further study.

PHYSICAL AND LABORATORY EXAMINATION.

Abnormal physical findings reflecting ischemia, such as a precordial bulge, gallop sound, and the murmur of mitral regurgitation, are uncommon in syndrome X. The resting ECG may be normal, but nonspecific ST-T wave abnormalities are often observed, sometimes occurring in association with the chest pain. Approximately 20 percent of patients with chest pain and normal coronary arteriograms have positive exercise tests. However, many patients with this syndrome do not complete the exercise test because of fatigue or mild chest discomfort. Left ventricular function is usually normal

at rest and during stress,[737] unlike the situation in obstructive CAD, in which function often becomes impaired during stress. A small percentage of patients with syndrome X exhibit lactate production and ST segment depression during exercise, a sign of significant ischemia. Some patients have abnormal myocardial perfusion reserve, but no consistent pattern of abnormal myocardial blood flow is seen.

PROGNOSIS.

Important prognostic information on patients with angina and either normal or nearly normal coronary arteriograms has been obtained from the CASS Registry.[725] In patients with an ejection fraction of 50 percent or more, the 7-year survival rate was 96 percent for patients with a normal arteriogram and 92 percent for those whose arteriographic study revealed mild disease (50 percent luminal stenosis). In such patients, an ischemic response to exercise was not associated with increased mortality, although a history of smoking or hypertension was. Thus, long-term survival of patients with anginal chest pain and normal coronary angiograms is excellent,

markedly better than in patients with obstructive CAD and no different from that in an age-matched general population.[731] [741] [751] Nonetheless, the symptoms are persistent, and most patients continue to experience chest pain that leads to repeated cardiac catheterization and hospital admission.[741] [752]

Management

In patients with angina-like chest pain syndrome and normal epicardial coronary arteries, esophageal abnormalities should be considered (see p. 1273). Such patients may show either motility disorders of the esophagus or abnormal reflux. Exercise ECG and/or myocardial perfusion scintigraphy is often helpful in excluding obstructive CAD. When a noninvasive stress test is positive, or even in patients with serious disability and multiple hospital admissions in whom the test is negative, documentation of normal coronary arteries by coronary angiography provides an objective basis for firm reassurance.

In patients with syndrome X in whom ischemia can be demonstrated by noninvasive stress testing, a trial of antiischemic therapy with nitrates and beta blockers is logical, but the response to this therapy is often poor.[731] In contrast to patients with organic CAD, sublingual nitrates are ineffective in improving exercise tolerance in patients with syndrome X, and in some, exercise tolerance may deteriorate further.[753] Calcium antagonists are effective in reducing the frequency and severity of angina and improving exercise tolerance in some patients. When these conditions are present, treatment of esophageal reflux and dysmotility may be effective.

Estrogen has been shown to attenuate normal coronary vasomotor responses to acetylcholine, increase coronary blood flow, and potentiate endothelium-dependent vasodilation in postmenopausal women.[754] Although estrogen would therefore seem to be a logical treatment for postmenopausal women with syndrome X, only short-term estrogen administration has been studied,[755] and long-term clinical effectiveness of estrogen therapy in these patients has not been documented. Imipramine (50 mg) has been reported to be helpful in some.[746]

Oral aminophylline (an adenosine receptor blocker) may have a favorable effect on the exercise-induced chest pain threshold without any effect on exercise-induced ST segment changes.[756]

SILENT MYOCARDIAL ISCHEMIA

The prognostic importance and the mechanisms of silent ischemia have been the subject of considerable interest for almost 30 years.[757] [758] Patients with silent ischemia have been stratified into three categories by Cohn.[759] The first and least common form, type I silent ischemia, occurs in totally asymptomatic patients with obstructive CAD (which may be severe), and these patients *do not experience angina at any time*; some type I patients do not even experience pain in the course of myocardial infarction. Epidemiological studies of sudden death (see Chap. 26) , as well as clinical and postmortem studies of patients with silent myocardial infarction and studies of patients with chronic angina pectoris, suggest that many patients with extensive coronary artery obstruction never experience angina pectoris in any of its recognized forms (stable, unstable, or variant). These patients with type I silent ischemia may be considered to have a *defective anginal warning system*. Type II silent ischemia is the form that occurs in patients with documented previous myocardial infarction.

The third and much more frequent form, designated type III silent ischemia, occurs in patients with the usual forms of chronic stable angina, unstable angina, and Prinzmetal angina. When monitored, patients with this form of silent ischemia exhibit some episodes of ischemia that are associated with chest discomfort and other episodes that are not--i.e., episodes of silent (asymptomatic) ischemia. The "total ischemic burden" in these patients refers to the total period of ischemia, both symptomatic and asymptomatic.

AMBULATORY ELECTROCARDIOGRAPHY.

The extensive use of ambulatory ECG monitoring has led to a greater appreciation of the high frequency of type III "silent" ischemia[760] (Fig. 37-29) . It has become apparent that anginal pain is a poor indicator and underestimates the frequency of significant cardiac ischemia.[761] Exercise-induced hemodynamic changes indicative of myocardial ischemia (increasing left ventricular end-diastolic pressure and decreasing left ventricular ejection fraction) occur in patients with CAD, regardless of the development of ischemic discomfort.[762]

The role of myocardial O_2 demand in the genesis of myocardial ischemia has been evaluated by measuring the heart rate and blood pressure changes preceding silent ischemic events during ambulatory studies. In one series, 92

Figure 37-29 Ambulatory electrocardiograms and coronary angiogram of a severe left anterior descending stenosis in a patient with fatigue (but not angina) during a tennis match. In stage II of a treadmill exercise test (Bruce protocol), 4 mm of ST segment depression was seen in lead V_5 . Ambulatory Holter monitoring of lead V_5 demonstrates ischemic ST segment depression during a number of ordinary activities, e.g., walking, telephoning. During a game of tennis, marked ST segment depression was recorded when the patient was asymptomatic. *(From Nabel EG, Rocco MB, Selwyn AB: Characteristics and significance of ischemia detected by ambulatory electrocardiographic monitoring. Circulation 75[Suppl 5]:74, 1987. By permission of the American Heart Association, Inc.)*

percent of all episodes were silent, and 60 to 70 percent were preceded by significant increases in heart rate or blood pressure. The circadian variations in heart rate and blood pressure also paralleled the increase in silent ischemic events. This and other studies have suggested that increases in myocardial O_2 demand have a significant role in the genesis of silent ischemia but, in other patients, reductions in myocardial O_2 supply may make an important contribution to the initiation of both symptomatic and asymptomatic episodes.[763] The mechanisms underlying the development of ischemia, as detected by ambulatory ECG and exercise testing, may be different, and in patients in the ACIP Study, concordance between the ambulatory ECG and SPECT was only 50 percent. For identification of silent ischemia, the two techniques probably complement each other.[764]

Transient ST segment depression of 0.1 mV or more that lasts longer than 30 seconds is a very rare finding in normal subjects.[765] Patients with known CAD show a strong correlation between such transient ST segment depression and independent measurements of impaired regional myocardial perfusion and ischemia determined by rubidium-82 uptake as measured by PET.[766] In patients with type III silent ischemia, perfusion defects occur in the same myocardial regions during symptomatic and asymptomatic episodes of ST segment depression. Other methods of detecting "silent" ischemia include measurement of the left ventricular ejection fraction with a "nuclear vest" or the presence of regional wall motion abnormalities and perfusion defects on echocardiography or radionuclide scintigraphy.[764]

Type III silent ischemia is extremely common. Analysis of ambulatory ECG recordings among patients with CAD who had both symptomatic and silent myocardial ischemia found that 85 percent of ambulant ischemic episodes occur without chest pain and 66 percent of angina reports were unaccompanied by ST segment depression.[767] Their frequency is such that it has been suggested that overt angina pectoris is merely the "tip of the ischemic iceberg." Among patients with stable CAD enrolled 1 to 6 months after hospitalization for an acute ischemic event, only 15 percent had angina with exercise, yet 28 percent had ST segment depression and 41 percent had reversible myocardial perfusion defects on thallium scintigraphy.[768] Episodes of silent ischemia have been estimated to be present in approximately half of all patients with angina, although a higher prevalence has been reported in diabetics.[760] [769] [770] Episodes of ST segment depression, both symptomatic and asymptomatic, exhibit a circadian rhythm and are more common in the morning. Asymptomatic nocturnal ST segment changes are almost invariably an indicator of two- or three-vessel CAD or left main coronary artery stenosis.

Pharmacological agents that reduce or abolish episodes of symptomatic ischemia, i.e., nitrates, beta blockers, and calcium antagonists, also reduce or abolish episodes of silent ischemia.[771]

MECHANISMS OF SILENT ISCHEMIA.

It is not clear why some patients with unequivocal evidence of ischemia do not experience chest pain whereas others are symptomatic. Maseri has proposed that silent ischemia results from a variable combination of decreased sensitivity to painful stimuli and coronary microvascular dysfunction[1] (Fig. 37-28) . Investigation into the causes of silent ischemia has focused primarily on five areas: (1) The association between diabetes and both silent ischemia and "painless infarctions" has been attributed to an autonomic neuropathy.[757] [770] [772] [773] (2) Patients with silent ischemia have been shown to have a high threshold for other forms of pain, such as that resulting from electrical shock, limb ischemia,[774] or cutaneous application of heat [775] or from balloon inflation in the coronary artery.[776] (3) Hypertensive patients who demonstrated a higher incidence of "silent" ischemia have been shown to have higher pain thresholds and lower reactions to tooth pulp stimulation than normotensive subjects.[776] It has been postulated that these patients produce an excessive quantity of endogenous opioids (and endorphins) that raise the pain threshold, but the existence of such a mechanism is debated.[777] (4) In patients with type III silent ischemia, the asymptomatic episodes may result from a less severe ischemia than the symptomatic episodes. In some of these patients, shorter periods of ischemia on Holter ECG tend to be asymptomatic, whereas longer periods are accompanied by angina.[778] [779] It has been postulated that the pain receptors are not stimulated by the milder episodes of ischemia. (5) A more recent area of investigation suggests

that silent ischemia in some patients may not be due to peripheral nerve dysfunction but instead be the result of a defect in the cerebral cortex.[780] Frontal cortical activation appears necessary to experience cardiac pain, and some evidence indicates that in patients with silent ischemia, afferent pain messages from the heart are subject to abnormal neural processing.[764] [780] [781] The role of psychosocial factors in the perception of pain is controversial.[782]

PROGNOSIS.

Irrespective of the mechanism(s) responsible, ample evidence supports the view that episodes of myocardial ischemia, regardless of whether they are symptomatic or asymptomatic, are of prognostic importance in patients with CAD. As such, myocardial ischemia, as opposed to symptoms alone, has been identified as a valid therapeutic target. In asymptomatic patients, the presence of exercise-induced ST segment depression has been shown to predict a fourfold to fivefold increase in cardiac mortality in comparison with patients without this finding.[783] In a series of patients in the CASS Registry with ST segment depression on treadmill exercise testing, the risk of subsequent myocardial infarction and sudden cardiac death and the relative benefits of surgery versus medical therapy were determined primarily by angiographic variables of CAD severity and not by the presence or absence of ischemia.[512] [784] A greater benefit was noted with CABG than with medical therapy in those with silent ischemia and three-vessel disease.[784] On the other hand, in some subsets of patients, e.g., stable patients with a previous myocardial infarction, the presence of painless exercise-induced ischemia has not been shown to provide additional prognostic information.[785]

It has been well established that the presence of myocardial ischemia on ambulatory ECG, whether silent or symptomatic, is associated with an adverse cardiac outcome, particularly if the episodes are frequent or accelerating.[334] [771] [786] What previously has been less clear is whether the detection of asymptomatic episodes of ischemia on ambulatory ECG adds *independent* prognostic information over and above that provided by the results of the stress test and the frequency and severity of symptoms.[787] [788] In the ACIP Study, among patients treated medically, myocardial ischemia detected by ambulatory ECG and by an abnormal exercise treadmill test were each *independently* associated with adverse cardiac outcomes.[789] Moreover, ischemia detected by ambulatory ECG monitoring did not correlate with the presence and extent of ischemia as quantified by stress SPECT scintigraphy, which suggests that these techniques detect different pathophysiological manifestations of ischemia.[790] Further support for this concept is provided by angiographic evidence from the ACIP Study data base, in which patients with ischemia and ambulatory ECG were more likely to have multivessel CAD, severe proximal stenoses, and a greater frequency of complex lesion morphology, including intracoronary thrombus, ulceration, and eccentric lesions, than were patients without evidence of ischemia on ambulatory monitoring. The presence of severe and complex CAD may partly explain the apparent independent effect of silent ischemia during ambulatory monitoring on prognosis.[791]

Whether the incremental prognostic information provided

by adding an ambulatory ECG to a standard stress test will justify the cost of using this modality as a tool for widespread screening remains to be determined, but it is unlikely. Exercise ECG can identify the majority of patients likely to have significant ischemia during their daily activities and remains the most important screening test for significant CAD. Many patients with type I silent ischemia have been identified because of an asymptomatic positive exercise ECG obtained following myocardial infarction. In such patients with a defective anginal warning system, it is reasonable to assume that asymptomatic ischemia has a significance similar to that of symptomatic ischemia and that their management with respect to coronary angiography and revascularization should be similar.

MANAGEMENT.

Drugs that are effective in preventing episodes of symptomatic ischemia (nitrates, calcium antagonists, and beta blockers) are also effective in reducing or eliminating episodes of silent ischemia[757] [792] (Fig. 37-30) . In the Atenolol Silent Ischemia Study Trial (ASIST), 4 weeks of atenolol therapy decreased the number of ischemic episodes detected on ambulatory ECG (from 3.6 to 1.7; $p<0.001$) and also the average duration (from 30 to 16.4 minutes per 48 hours; $p<0.001$).[334] In another randomized study, long-acting metoprolol taken once daily was as effective as formulations requiring more frequent dosing.[793] In yet another randomized study, metoprolol was shown to be superior to diltiazem in decreasing the mean number of ischemic episodes and the mean duration of ischemia.[794] A combination of a beta blocker and a calcium antagonist is superior to either class of drug alone in suppressing ischemia detected by ambulatory ECG.

Although suppression of ischemia in patients with

Figure 37-30 Atenolol in Silent Ischemia Trial (ASIST). The recently reported ASIST is the first controlled trial to demonstrate modification of cardiac risk through treatment of silent myocardial ischemia (SMI). A total of 306 asymptomatic or minimally symptomatic patients with coronary artery disease, positive exercise tests, and ambulatory electrocardiographic (ECG) episodes of SMI were randomized to receive atenolol or placebo. Ambulatory ECG monitoring was repeated at 4 weeks, and outcome was assessed after 1 year. At 4 weeks, atenolol was associated with a significant reduction in SMI. After 1 year, a significant (56 percent) relative reduction in adverse events (death, resuscitated ventricular tachycardia and fibrillation, nonfatal myocardial infarction, and unstable or worsening angina) was found when patients given atenolol were compared with those given placebo. The presence of ischemia at 4 weeks was the most important independent factor associated with adverse outcomes after 1 year. *(From Bertolet BD, Pepine CJ: Silent myocardial ischemia. In Beller GA, Braunwald E [eds]: Chronic Ischemic Heart Disease. Atlas of Heart Diseases. Vol 5. Philadelphia, Current Medicine, 1995, p 8.9. By permission of W.B. Saunders Co.)*

asymptomatic ischemia is a worthwhile objective, whether treatment should be guided by symptoms or by ischemia as reflected by the ambulatory ECG has not been established. The ACIP Pilot Study showed that the proportion of patients free of ischemia on a 48-hour ambulatory ECG among medically treated patients assigned to an "ischemia-guided" strategy and those assigned to an "angina-guided" strategy was 31 and 36 percent, respectively, at 1 year (p=NS). Among patients treated with coronary revascularization, 57 percent were free of ischemia at 1 year ($p<0.001$). [795] Similar trends were noted in the results of exercise testing.[796]

Coronary revascularization is superior to medical therapy for the relief of both angina and ambulatory ischemia at 12 weeks.[797] Moreover, the early benefits of revascularization on ischemia are associated with improved clinical outcomes. In this pilot study with over 2 years of follow-up, total mortality was 6.6 percent with the angina-guided strategy, 4.4 percent with the ischemia-guided strategy, and 1.1 percent with the revascularization strategy ($p<0.02$). The rate of death or myocardial infarction was 12.1 percent in the angina-guided strategy, 8.8 percent in the ischemia-guided strategy (see Fig. 37-17) , and 4.7 percent in the revascularization strategy, and a strong reduction was also seen in recurrent hospitalizations and the revascularization strategies. These differences were significant, but no differences were noted between the two strategies of medical therapy.[545]

HEART FAILURE IN ISCHEMIC HEART DISEASE

In the current era, the leading cause of heart failure in developed countries is CAD.[798] In the United States, CAD and its complications account for two-thirds to three-fourths of all cases of heart failure. In many patients, the progressive nature of heart failure reflects the progressive nature of the underlying CAD. The term *ischemic cardiomyopathy* is used for the clinical syndrome in which one or more of the above pathophysiological features result in left ventricular dysfunction and heart failure symptoms. This condition is the predominant form of heart failure related to CAD. Additional complications of CAD that may become superimposed on ischemic cardiomyopathy and precipitate heart failure are the development of left ventricular aneurysm and mitral regurgitation caused by papillary muscle dysfunction.

Ischemic Cardiomyopathy

In 1970, Burch and colleagues first used the term *ischemic cardiomyopathy* to describe the condition in which CAD results in severe myocardial dysfunction, with clinical manifestations often indistinguishable from those of primary dilated cardiomyopathy[799] (see Chap. 48) . Symptoms of heart failure caused by ischemic myocardial dysfunction and hibernation, diffuse fibrosis, or multiple infarctions, alone or in combination, may dominate the clinical picture of CAD. In some patients with chronic CAD, angina may be the principal clinical manifestation at one time, but later this symptom diminishes or even disappears as heart failure becomes more prominent. Other patients with ischemic cardiomyopathy have no history of angina or myocardial infarction (type I silent ischemia, see p. 1330), and it is in this subgroup that ischemic cardiomyopathy is most often confused with dilated cardiomyopathy.

It is important to recognize hibernating myocardium in patients with ischemic cardiomyopathy because symptoms resulting from chronic left ventricular dysfunction may be incorrectly thought to result from necrotic and scarred

myocardium rather than from a reversible ischemic process. Hibernating myocardium may be present in patients with known or suspected CAD with a degree of cardiac dysfunction or heart failure not readily accounted for by previous myocardial infarctions (see also p. 1316).

The outlook for patients with ischemic cardiomyopathy treated medically is quite poor, and revascularization or cardiac transplantation may be considered.[800] The prognosis is particularly poor for patients in whom ischemic cardiomyopathy is due to multiple myocardial infarctions, in those with associated ventricular arrhythmias, and in those with extensive amounts of hibernating myocardium. However, this latter group of patients, whose heart failure, even if severe, is due to large segments of reversibly dysfunctional, but viable myocardium, has a significantly better prognosis after revascularization.[564] [568] [569] [570] [571] Revascularization in this group also significantly improves heart failure symptoms.[103] [563] [564] Thus, the key to management of patients with ischemic cardiomyopathy is to assess the extent of residual viable myocardium with a view to coronary revascularization of viable myocardium (see Chap. 13 and p. 50 and 51). Patients with little or no viable myocardium in whom heart failure is secondary to extensive myocardial infarction and/or fibrosis should be managed in a manner similar to those with dilated cardiomyopathy (see Chaps. 21 and 48) . Their prognosis is poor.

Left Ventricular Aneurysm

Left ventricular aneurysm is usually defined as a segment of the ventricular wall that exhibits paradoxical (dyskinetic) systolic expansion. Chronic fibrous aneurysms interfere with ventricular performance principally through loss of contractile tissue. Aneurysms made up largely of a mixture of scar tissue and viable myocardium or of thin scar tissue also impair left ventricular function by a combination of paradoxical expansion and loss of effective contraction. *False aneurysms* (pseudoaneurysms) represent localized myocardial rupture in which the hemorrhage is limited by pericardial adhesions, and they have a mouth that is considerably smaller than the maximal diameter (Fig. 37-31) . True and false aneurysms may coexist, although the combination is extremely rare.[801]

The frequency of ventricular aneurysms depends on the incidence of transmural myocardial infarction and congestive heart failure in the population studied. Left ventricular aneurysms and the need for aneurysmectomy have declined dramatically during the last 5 to 10 years in concert with the expanded use of acute reperfusion therapy in evolving myocardial infarction. More than 80 percent of left ventricular aneurysms are located anterolaterally near the apex. They are often associated with total occlusion of the left anterior descending coronary artery and a poor collateral blood supply.[802] Approximately 5 to 10 percent of aneurysms are located posteriorly. Three-quarters of patients with aneurysms have multivessel CAD.[803]

Left ventricular aneurysms can develop in patients who sustain a blunt chest injury (see Chap. 51) . The condition is attributed to myocardial contusion or to direct vascular damage causing myocardial necrosis; pseudoaneurysms of adjacent vascular structures, including the thoracic aorta, may be present in addition to valvular damage.[804] Death from rupture of a false aneurysm caused by nonpenetrating chest trauma has been described[805] and successfully repaired surgically.[806]

Figure 37-31 Hearts in systole and diastole with true and false anatomical and functional left ventricular aneurysms and healed myocardial infarction. A normal heart in systole and diastole is shown for comparison. A true anatomical left ventricular aneurysm protrudes during both systole and diastole, has a mouth that is as wide or wider than the maximal diameter, has a wall that was formerly the wall of the left ventricle, and is composed of fibrous tissue with or without residual myocardial fibers. A true aneurysm may or may not contain thrombus and almost never ruptures once the wall is healed. A false anatomical left ventricular aneurysm protrudes during both systole and diastole, has a mouth that is considerably smaller than the maximal diameter of the aneurysm and represents a myocardial rupture site, has a wall made up of parietal pericardium, virtually always contains thrombus, and often ruptures. A functional left ventricular aneurysm protrudes during ventricular systole but not during diastole and consists of fibrous tissue with or without myocardial fibers. *(From Cabin HS, Roberts WC: Left ventricular aneurysm, intraaneurysmal thrombus and systemic embolus in coronary heart disease. Chest 77:586, 1980. By permission of The American College of Chest Physicians.)*

Almost 50 percent of patients with moderate or large aneurysms have symptoms of heart failure (with or without associated angina), approximately 33 percent have severe angina alone, and approximately 15 percent have symptomatic ventricular arrhythmias that may be intractable and life threatening.[807] Mural thrombi are found in almost half of patients with chronic left ventricular aneurysms and can be detected by angiography and two-dimensional echocardiography (see Chap. 7) . Systemic embolic events in patients with thrombi and left ventricular aneurysm tend to occur early after myocardial infarction. In the Mayo Clinic series of patients with chronic left ventricular aneurysm (documented at least 1 month after infarction), subsequent systemic emboli were extremely uncommon[808] (0.35 per 100 patient-years in patients not receiving anticoagulants).

DETECTION.

Clues to the presence of aneurysm include persistent ST segment elevations on the resting ECG (in the absence of chest pain)[809] and a characteristic bulge of the silhouette of the left ventricle on a chest roentgenogram. Marked calcification of the left ventricular silhouette may be present[810] (Fig. 37-32) . These findings, when clear-cut, are relatively specific, but they have limited sensitivity. Radionuclide ventriculography and two-dimensional echocardiography can demonstrate ventricular aneurysm more readily; the latter is also helpful in distinguishing between true and false aneurysms based on the demonstration of a narrow neck in relation to cavity size in the latter.[811] Color flow echocardiographic imaging is useful in establishing the diagnosis because flow "in and out" of the aneurysm as well as abnormal flow within the aneurysm can be detected, and subsequent pulsed Doppler imaging can reveal a "to-and-fro" pattern with characteristic respiratory variation in the peak systolic velocity. The use of transesophageal echocardiography and left-heart contrast agents in the assessment of pseudoaneurysms is being evaluated.[812] CT and magnetic resonance imaging are reliable noninvasive techniques for the identification of left ventricular aneurysms (Fig. 37-32 ; see Fig. 10-8) and screening for resectability.[813]

Tomographic three-dimensional echocardiographic calculation of left ventricular volume and systolic function compares favorably with the accuracy of magnetic resonance imaging and cineangiography and has the advantage of being less time consuming and less invasive; also, patient discomfort may be less.[814] However, biplane left ventriculography is still the most widely used method for outlining a true left ventricular aneurysm and assessing septal motion and the extent of residual functioning myocardium. An assessment of the extent of stunned, hibernating but potentially viable, myocardium within the infarct zone is helpful in many patients, particularly those in whom the left ventricular aneurysm is less discrete.

LEFT VENTRICULAR ANEURYSMECTOMY.

True ventricular aneurysms do not rupture, and operative excision is carried out to improve the clinical manifestations, most often heart failure but sometimes also angina, embolization, and life-threatening tachyarrhythmias.[807] [815] Coronary revascularization is frequently performed along with aneurysmectomy, especially in patients in whom angina accompanies heart failure.

A large left ventricular aneurysm in a patient with symptoms of heart failure, particularly if angina pectoris is also present, is an indication for surgery. The operative mortality rate for left ventricular aneurysmectomy is approximately 10 percent (ranging from 0 to 19 percent),[815] [816] with rates of 6 and 7.2 percent reported in more recent series.[816] [817] Among 26 patients undergoing surgery between 1992 and 1994 with the new technique of endoventricular patchplasty, no operative mortality was reported.[817] Risk factors for early death include poor left ventricular function, recent myocardial infarction, the presence of mitral regurgitation, and intractable ventricular arrhythmias.[818] The presence of angina pectoris instead of dyspnea as the dominant preoperative symptom is a determinant of lower operative mortality.[817] Surgery carries a particularly high risk in patients with severe heart failure, a low-output state, and akinesis of the interventricular septum, as assessed echocardiographically.[803] Akinesis or dyskinesia of the posterior

Figure 37-32 Evaluation of an 83-year-old woman for chest discomfort. When she was about 50 years old, this woman had been hospitalized because of acute myocardial infarction of the anteroseptal wall. An electrocardiogram showed an abnormal image characteristic of anteroseptal cardiac aneurysm. A plain chest film *(A* and *B)* showed marked calcification on the left ventricular silhouette. A magnetic resonance image *(C)* of the heart showed thinning of the left ventricular wall. The patient's overall condition improved after treatment with isosorbide mononitrate and diuretics. *(From Nakajima O, Sano I, Akioka H: Marked calcified left ventricular aneurysm. Circulation 95:1974, 1997. By permission of the American Heart Association, Inc.)*

basal segment of the left ventricle and significant right coronary artery stenoses are additional risk factors.[803] Pseudoaneurysms rupture frequently and should therefore be resected on an urgent basis as soon as the diagnosis is established.[819]

Risk factors for late mortality following survival from surgery include incomplete revascularization, impaired systolic function of the basal segments of the ventricle and septum not involved by the aneurysm, the presence of a large aneurysm with a small quantity of residual viable myocardium, and the presence of severe cardiac failure

as the initial feature.[816] [817] [820]

Improvement in left ventricular function has been reported in survivors of resection of left ventricular aneurysms complicated by cardiac failure.[818] [821] By removing the abnormal mechanical burden, left ventricular aneurysmectomy has been associated with late improvement in overall systolic function and improvement in the performance of regional nonischemic myocardium in zones remote from the left ventricular aneurysm,[822] in addition to improvement in measures of ventricular relaxation and cardiovascular neuroregulatory mechanisms.[821] [823] A concomitant improvement in exercise performance and clinical symptoms may also occur, particularly in patients who have undergone complete revascularization. An early series of carefully selected patients documented a 10-year survival rate of 69 percent among patients undergoing left ventricular aneurysmectomy plus coronary revascularization in comparison with 57 percent after aneurysmectomy alone.

New surgical approaches to the repair of left ventricular aneurysms are designed to restore normal left ventricular geometry by using an alternative method of epicardial closure and/or an endocardial patch to divide the area of the aneurysm from the remainder of the ventricular cavity[824] [825] (Fig. 37-33) . Favorable clinical and hemodynamic results following the use of these newer techniques have been reported, with 5-year survival rates ranging from 73 to 87.5 percent[816] [820] and a corresponding improvement in hemodynamics and clinical symptoms. In one series, 88 percent of patients treated with the endoaneurysmorrhaphy technique were in New York Heart Association Class I or II after a mean follow-up of approximately 3.5 years.[826]

Mitral Regurgitation Secondary to Coronary Artery Disease (see also Chap. 46)

Mitral regurgitation is an important cause of heart failure in some patients with CAD. Rupture of a papillary muscle or the head of a papillary muscle usually causes severe acute mitral regurgitation in the course of acute myocardial infarction. The cause of chronic mitral regurgitation in patients with CAD is multifactorial, and the geometrical determinants are complex and include papillary muscle dysfunction from ischemia and fibrosis in conjunction with a wall motion abnormality and changes in ventricular shape in the region of the papillary muscle and/or dilatation of the mitral annulus.[827] [828] Enlargement of the mitral annulus at end systole is asymmetrical, with lengthening primarily involving the posterior annular segments and leading to prolapse of leaflet tissue tethered by the posterior papillary muscle and restriction of leaflet tissue attached to the anterior leaflet.[829] Most patients with chronic CAD and mitral regurgitation have suffered a previous myocardial infarction.

Clinical features that help identify mitral regurgitation secondary to papillary muscle dysfunction as the cause of acute pulmonary edema or the cause of milder symptoms of left-sided failure include a loud systolic murmur and demonstration of a flail mitral valve leaflet on echocardiography. In some patients with severe mitral regurgitation into a small "unprepared" left atrium, the murmur may be unimpressive or inaudible. Doppler echocardiography is helpful in assessing the severity of the regurgitation (see Chap. 7) .

As in mitral regurgitation of other causes, the left atrium is not usually greatly enlarged unless mitral regurgitation has been present for more than 6 months. The ECG is nonspecific, and most patients have angiographic evidence of multivessel CAD.

In patients with posterior papillary muscle dysfunction resulting from acute myocardial infarction, reperfusion therapy with thrombolysis or PCI may be attempted initially because urgent surgery is often accompanied by high mortality. In patients with rupture of a papillary muscle or, more frequently, rupture of one or more heads of a papillary muscle, immediate surgery is required because the natural history after apparent stabilization with medical therapy is labile and unpredictable and sudden unexpected deterioration is frequent.[830]

In patients with severe mitral regurgitation, the indications for surgical correction, usually in association with coronary artery bypass, are fairly clear-cut. Mitral valve repair, as opposed to mitral replacement, is the procedure of choice, but the decision is based on the anatomical characteristics of the structures forming the mitral valve apparatus, the urgency of the need for surgery, and the severity of left ventricular dysfunction.[831] A more complex and frequently

Figure 37-33 Operative techniques used in left ventricular aneurysm repair. The figure depicts resection of the ventricular aneurysm enclosure by one of three methods. The conventional closure is illustrated on the left. The "T" closure and the endocardial patch techniques were developed in an attempt to restore normal left ventricular geometry. *(From Komeda M, David TE, Malik A, et al: Operative risks and long-term results of operation for left ventricular aneurysm. Ann Thorac Surg 53:22, 1992. By permission of The Society of Thoracic Surgeons.)*

encountered problem involves the indications for mitral valve surgery in patients undergoing coronary bypass surgery in whom the severity of mitral regurgitation is moderate. The decision is based partly on the presence or absence of structural abnormalities of the mitral apparatus and the amenability of the valve to repair. Intraoperative transesophageal echocardiography is invaluable in assessing the severity of regurgitation, the reparability of the valve, and the success of the integrity of the repair after discontinuation of cardiopulmonary bypass.[458]

The mortality associated with combined coronary bypass surgery and mitral valve placement in the 1997 Society of Thoracic Surgeons data base was 12.7 percent overall and 8.3 percent for patients undergoing an elective first procedure. For bypass surgery and mitral valve repair, mortality rates were 7.6 percent overall and 4.8 percent for patients undergoing an elective first procedure.[425] Predictors of early mortality include the need for replacement versus repair (in some but not all series) but, in addition, may include other variables such as age, comorbid conditions, the urgency of surgery, and left ventricular function.[831] [832] Late results are strongly influenced by the pathophysiological mechanisms underlying mitral regurgitation and are poorer in patients with regurgitation resulting from annular dilatation or restrictive leaflet motion than in patients with chordal or papillary muscle rupture.[832] [833] It is encouraging that despite the relatively high operative mortality, late survival of hospital survivors is excellent. In patients with very poor left ventricular function and dilatation of the mitral annulus, mitral regurgitation can intensify the severity of left ventricular failure. In such patients, the risk of surgery is high and the benefits less obvious, and a trial of intensive medical therapy, including offload reduction to reduce left ventricular volume and the diameter of the annulus, may be worthwhile.

CARDIAC ARRHYTHMIAS (see also Chap. 25)

In some patients with CAD, cardiac arrhythmias are the dominant clinical manifestation of the disease. Various degrees and forms of ventricular ectopic activity are the most common arrhythmias in patients with CAD, but serious ventricular arrhythmias may be a major component of the clinical findings in other subgroups. Malignant ventricular arrhythmias in CAD may be dynamic, e.g., plaque rupture that causes acute ischemia, which results in polymorphic ventricular tachycardia or ventricular fibrillation.[834] A more frequent manifestation of ventricular arrhythmias in CAD occurs as a consequence of reentrant arrhythmias arising from fixed substrate composed of scar and residual viable myocardium.[835] In this situation, it is presumed that initially stable, sustained monomorphic ventricular tachycardia degenerates into ventricular fibrillation. The former situation is theoretically preventable by coronary revascularization alone, although for patients who have survived an out-of-hospital cardiac arrest, coronary revascularization alone is usually ineffective in preventing occurrences.[559] [836]

Surgical strategies for patients with CAD and ventricular tachycardia, in association with left ventricular aneurysms and/or myocardial scar, were directed primarily at removal of the extensive area of subendocardial scar tissue, with or without electrophysiological mapping.[837] [838] Surgical treatment of ventricular arrhythmias has declined markedly with the advent of the implantable cardioverter-defibrillator and, to a lesser extent, advances in electrophysiological mapping and catheter ablation. Recognition and management of patients with malignant ventricular arrhythmias and/or sudden cardiac death caused by chronic CAD are discussed in detail in Chapter 26 .

NONATHEROMATOUS CORONARY ARTERY DISEASE (see Table 35-1)

Although atherosclerosis is by far the most important cause of CAD, other conditions may also be responsible.[839] [840] The most common causes of nonatheromatous CAD resulting in myocardial ischemia are the syndrome of angina-like pain with normal coronary arteriograms, i.e., so-called syndrome X and Prinzmetal angina, both of which are discussed earlier in this chapter (see pp. 1324 and 1328).

Nonatheromatous CAD may result from other diverse abnormalities, including congenital abnormalities in the origin or distribution of the coronary arteries (see Chaps. 43 and 44) . The most important of these abnormalities are anomalous origin of a coronary artery (usually the left) from the pulmonary artery, origin of both coronary arteries from either the right or the left sinus of Valsalva, and coronary arteriovenous fistula. An anomalous origin of either the left main coronary artery or right coronary artery from the aorta with subsequent coursing between the aorta and pulmonary trunk is a rare and sometimes fatal coronary arterial anomaly.[841]

In an autopsy study of 150 cases of sudden death in persons 35 years or younger, death was attributed to CAD in 48. In 16 of these cases, the disease was not atherosclerosis but attributable to abnormalities in the origin and course of the coronary arteries, including a deep intramyocardial course, ostial obstruction, an abnormal origin of the right or left coronary artery, or spontaneous dissection of a coronary artery. In one patient, effort-induced acute myocardial infarction was noted

in the presence of an intramural coronary arterial trunk.[842]

Myocardial bridging causing systolic compression of the left anterior descending coronary artery is a well-recognized angiographic phenomenon of questionable clinical significance.

Several inherited connective tissue disorders are associated with myocardial ischemia (see Chap. 56) , including the Marfan syndrome (causing aortic and coronary artery dissection), Hurler syndrome (causing coronary obstruction), homocysteinuria (causing coronary artery thrombosis), Ehlers-Danlos syndrome (causing coronary artery dissection), and pseudoxanthoma elasticum (causing accelerated CAD). Kawasaki disease (the mucocutaneous lymph node syndrome) may cause coronary artery aneurysms and ischemic heart disease in children (see Chap. 45) .

Spontaneous coronary dissection is a rare cause of myocardial infarction and sudden cardiac death.[843] Chronic dissection manifested as congestive heart failure has been described. In one series, approximately 75 percent of cases were diagnosed at autopsy, and 75 percent occurred in women, half of which were associated with a postpartum state.[844] Some cases are associated with atherosclerosis. Hypertension has been postulated as a cause of multivessel spontaneous coronary dissection in some patients, and in others, no obvious cause has been identified. In the acute phase, thrombolytic therapy may be dangerous, but early angiography may identify patients who could benefit from stenting or bypass surgery.[845] In survivors of spontaneous coronary artery dissection, the subsequent 3-year mortality was 20 percent, but complete healing as defined angiographically may lead to a favorable outcome without intervention.[846]

Coronary vasculitis resulting from connective tissue diseases or autoimmune forms of vasculitis, including polyarteritis nodosa,[847] giant cell (temporal) arteritis,[848] and scleroderma, [849] is well described (see Chap. 67) . Coronary arteritis is seen at autopsy in about 20 percent of patients with rheumatoid arthritis but is rarely associated with clinical manifestations.[850] The incidence of CAD is increased in women with systemic lupus erythematosus.[851] In patients with systemic lupus erythematosus, CAD has been attributed to a vasculitis, immune complex-mediated endothelial damage, and coronary thrombosis from antiphospholipid antibodies,[851] [852] as well as accelerated atherosclerosis. Giant coronary artery aneurysm associated with systemic lupus erythematosus is an unusual manifestation that has been associated with the development of acute myocardial infarction despite therapy.[852] The antiphospholipid syndrome, which is characterized by arterial and venous thrombosis and is associated with the presence of antiphospholipid antibodies, may be associated with myocardial infarction, angina, and diffuse left ventricular dysfunction.[853]

In rare cases, *Takayasu arteritis* (see Chap. 67) is associated with angina, myocardial infarction, and cardiac failure in patients younger than 40 years.[854] Coronary blood flow may be decreased by involvement of the ostia or proximal segments of the coronary arteries, but disease in distal coronary segments is rare.[855] The average age at the onset of symptoms is 24 years, and the event-free survival rate 10 years after diagnosis is approximately 60 percent.[854] Luetic aortitis may also produce myocardial ischemia by causing coronary ostial obstruction.

The occurrence of CAD and morbid cardiac events in young persons after mediastinal irradiation is highly suggestive of a cause-and-effect relationship.[856] [857] Pathological changes include adventitial scarring and medial hypertrophy with severe intimal atherosclerotic disease.[858] Radiation injury may be latent and may not be manifested clinically for many years after therapy. Contributory factors include higher doses than currently administered and the presence of cardiac risk factors.[859] Among patients without risk factors who receive an intermediate total dose of 30 and 40 Gy, the risk of cardiac death and myocardial infarction is low.[857]

Myocardial ischemia not caused by coronary atherosclerosis can also result from embolism, infective endocarditis (see Chap. 47) , implanted prosthetic cardiac valves (Chap. 46) , calcified aortic valves, mural thrombi, and primary cardiac tumors (Chap. 49) .

An interesting nonatherosclerotic myocardial ischemic syndrome has been described in workers in the nitrate industry, who apparently experience nitrate withdrawal symptoms on weekends. It is presumed to be secondary to coronary spasm in the absence of counterstimulation to the vasoconstriction that they undergo as an adaptation to the vasodilating actions of the high concentrations of nitrates to which they have been exposed.[860]

Cocaine, because of its widespread use, has become a well-documented cause of chest pain, myocardial infarction, and sudden cardiac death.[861] [862] In a population-based study of sudden death among persons 20 to 40 years old in Olmsted County over a 30-year period, a high prevalence of cocaine abuse was observed in the more recent cohort

of young adults who died suddenly.[863] The principal effects of cocaine are mediated by alpha-adrenergic stimulation, which causes an increase in myocardial O_2 demand and a reduction in O_2 supply because of coronary vasoconstriction.[862]

CARDIAC TRANSPLANT-ASSOCIATED CORONARY ARTERIOPATHY (see alsoChap. 20) .

Worldwide, approximately 4500 patients undergo cardiac transplantation annually (2340 in the United States in 1998), and their survival has been extended by improved immunosuppression. Accelerated coronary atherosclerosis has become the principal cause of late death.[864] The link between chronic immune injury to the coronary endothelium of the donor heart and transplant CAD is unclear, but it is believed to be initiated by immunologically mediated damage, followed by intimal smooth muscle proliferation, accumulation of lipids in the vascular wall, and eventually, diffuse luminal narrowing.[865] Other suggested etiological factors include opportunistic infections (cytomegalovirus infection), immunosuppressive therapy, cyclosporine-induced endothelial injury, and dyslipidemia.[866]

By the time that the disease is diagnosed, it is well advanced, but its progression to myocardial infarction, sudden cardiac death, and diffuse left ventricular dysfunction may not be accompanied by chest pain or typical ECG changes. The diagnosis is usually made at coronary angiography, but this visualization technique may underestimate the severity or the extent of the disease.[867] Noninvasive approaches, including dobutamine stress echocardiography and stress thallium imaging, are promising tools that are being investigated.[868]

MANAGEMENT.

Management of cardiac transplant-associated arteriopathy includes retransplantation, PCI in selected patients with focal stenoses (although the incidence of subsequent restenosis is increased), and coronary bypass surgery; however, the latter is confined to a relatively few highly selected patients without distal involvement.[869] A preliminary study suggested that diltiazem may retard the reduction in coronary vessel diameter defined by quantitative angiography, but its clinical impact needs to be determined.[309] In comparison with dietary measures alone, a recent randomized trial demonstrated that the combination of a low-cholesterol diet and simvastatin after heart transplantation led to a significant reduction in cholesterol levels, a significantly higher long-term survival rate, and a lower incidence of accelerated graft vessel disease.[870] Among patients who were not treated with calcium channel blockers, ganciclovir, which is effective in preventing cytomegalovirus illness, appeared to decrease the incidence of CAD in the donor heart in comparison to placebo.

GUIDELINES
MANAGEMENT OF CHRONIC ISCHEMIC HEART DISEASE

Thomas H. Lee

Multiple guidelines are relevant to the care of patients with chronic ischemic heart disease, including the 1999 guidelines developed by an American College of Cardiology/American Heart Association (ACC/AHA) task force.[1] These guidelines will be summarized, as well as the 1993 guidelines for percutaneous transluminal angioplasty[2] (PTCA) and 1999 guidelines for coronary artery bypass graft (CABG) surgery.[3]

According to the usual format of ACC/AHA guidelines, the appropriateness of various tests and procedures in different clinical settings was categorized into the following:

I.
Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.

II.
Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure.

IIa.
Weight of evidence/opinion is in favor of usefulness/efficacy.

IIb.
Usefulness/efficacy is less well established by evidence/opinion.

III.
Conditions for which there is evidence and/or general agreement that the procedure/treatment is no useful/effective and in some cases may be harmful.

Diagnosis

The ACC/AHA guidelines emphasize the importance of using clinical data to make a qualitative estimate of the patient's probability of coronary artery disease. Routine laboratory data that are considered appropriate (Class I) include hemoglobin, fasting glucose, a lipid profile, and resting electrocardiogram (ECG). Chest x-rays are considered appropriate for patients with signs or symptoms of cardiovascular disease but were considered to have uncertain appropriateness for other patients (Table 37-G-1) .

The exercise ECG is an appropriate first-line test for patients with an intermediate probability of coronary artery disease, including patients with complete right bundle branch block or less than 1 mm of ST depression at rest. Other technologies may be appropriate for patients whose ECG has mild ST depression in the setting of digoxin therapy or criteria for left ventricular hypertrophy or patients who had other ECG abnormalities described in Table 37-G-1 . The ACC/AHA guidelines indicate that exercise ECG should be the first-line test for women as well as men.

The ACC/AHA task force was not supportive of echocardiography as a routine test for diagnosis of the cause of acute chest pain unless the patient has a systolic murmur suggesting structural heart disease (Table 37-G-1) . The guidelines did, however, support the use of echocardiography to assess the extent or severity of ischemia when the study could be obtained during or shortly after chest pain.

Imaging during physical or pharmacological stress was considered to be appropriate (Class I) in patients at intermediate risk for coronary disease for whom exercise ECG was unlikely to be useful because of baseline ECG abnormalities. Exercise myocardial perfusion imaging was also considered an appropriate test for risk stratification of patients who had undergone prior revascularization with either PTCA or CABG. Pharmacological stress with adenosine or dipyridamole is appropriate for patients who are unable to exercise. Because of abnormal patterns of myocardial activation, stress echocardiography is *discouraged* as an imaging modality for patients with left bundle branch block.

Coronary angiography was not considered clearly appropriate for the diagnosis of chronic stable angina in most patients, except for those who had survived sudden cardiac death. Several patient subsets were considered possibly appropriate (Class II) for coronary angiography, such as patients whose diagnosis was still uncertain after noninvasive testing or those with an occupational requirement for a definitive diagnosis. Coronary angiography is, however, an important test in risk stratification (see below).

Risk Stratification

The ACC/AHA guidelines emphasize that most patients with stable angina do not need routine echocardiography either for initial baseline studies or for reassessment (Table 37-G-1) . However, the ACC/AHA guidelines support the use of echocardiography or radionuclide angiography in patients with a history or ECG evidence of a prior myocardial infarction or symptoms or signs of congestive heart failure. Assessment of left ventricular function is also endorsed for patients with complex ventricular arrhythmias.

The ACC/AHA guidelines are supportive of exercise ECG as a first-line test for risk stratification or after a significant change in cardiac symptoms. Exceptions are made for patients in whom imaging technologies would provide more accurate information because of a history of CABG or PTCA or ECG abnormalities (see Table 37-G-1) . However, the guidelines do not provide strong support (Class IIb) for routine screening of patients 6 months after revascularization procedures.

Coronary angiography is supported as appropriate for patients with disabling angina despite medical therapy, as well as for those with high-risk exercise test results or signs of congestive heart failure and for survivors of sudden cardiac death. The ACC/AHA guidelines considered coronary angiography inappropriate in patients with Canadian Cardiovascular Society Class I or II angina who respond to medical therapy and have no evidence of ischemia on noninvasive testing (Table 37-G-1) .

Treatment

The ACC/AHA guidelines support the use of aspirin and beta blocker therapy in the absence of contraindications. Calcium antagonists or long-acting nitrates can be administered when beta blockers are contraindicated or ineffective. Short-acting dihydropyridine calcium antagonists are to be avoided.

Multiple efforts are endorsed to reduce the risk of progression of atherosclerosis. Lipid-lowering therapy is considered clearly appropriate (Class I) when low-density lipoprotein (LDL) cholesterol is greater than 130 mg/dl and possibly appropriate (Class IIa) when LDL is between 100 and 129 mg/dl. Also supported by the guidelines are interventions to treat hypertension according to Joint National Conference VI guidelines, cigarette smoking, diabetes, and obesity.

Guidelines for revascularization with CABG or PTCA are similar to those described for unstable angina (Table 37-G-2) . CABG is appropriate for patients with left main coronary artery disease, three-vessel disease, and subsets of patients with two-vessel disease. PTCA is considered appropriate for multivessel disease in patients who

have normal left ventricular function and do not have diabetes. (See below for further information on appropriate indications for these procedures.)

FOLLOW-UP.

The same principles that define the appropriateness of the initial use of tests for patients with chronic stable angina characterize their use during follow-up in patients who have new or worsening cardiovascular symptoms (see Table 37-G-1) . The guidelines are not supportive of annual treadmill exercise tests or other procedures in patients who have had no change in clinical status. For low-risk stable patients, the guidelines suggest that an interval of 3 years or longer between exercise tests may be appropriate.

Percutaneous Transluminal Coronary Angioplasty

The development of guidelines for PTCA is complicated by several trends, including technological innovations (e.g., stents), broadening of the patient population to which this procedure is applied, and lack of data identifying populations in which PTCA confers a survival advantage. As physicians have become more expert in performing this procedure, they have also become more ambitious, and PTCA is now frequently used for patients with acute myocardial infarction and patients with multivessel coronary artery disease. An additional reason for uncertainty over the optimal role for PTCA is that it is an alternative to more than one major strategy--medical therapy or CABG surgery. Hence, trials in which PTCA is directly compared with another strategy (e.g., CABG) do not address the full range of choices for clinicians.

Recent ACC/AHA guidelines for unstable angina[4] and chronic stable angina [1] are beginning to address the question of which patients should preferentially undergo PTCA or CABG. However, for many patients with chronic stable angina, clinical judgment remains the critical mechanism for deciding which procedure should be performed.

TABLE 37--G-1 -- ACC/AHA GUIDELINES FOR MANAGEMENT OF STABLE ANGINA

Issue	Class	Recommendation	Level of Evidence
History and physical examination	I	In patients with chest pain, a detailed symptom history, focused physical examination, and directed risk factor assessment should be performed. With this information, the clinician should estimate the probability of significant CAD (i.e., low, intermediate, high)	B
Initial laboratory tests for diagnosis	I	Hemoglobin	C
		Fasting glucose	C
		Fasting lipid panel, including total cholesterol, HDL cholesterol, triglycerides, and calculated LDL cholesterol	C
ECG, chest x-ray, or electron beam computed tomography in the diagnosis of chronic stable angina	I	Rest ECG in patients without an obvious noncardiac cause of chest pain	B
		Rest ECG during an episode of chest pain	B
		Chest x-ray in patients with signs or symptoms of CHF, valvular heart disease, pericardial disease, or aortic dissection/aneurysm	B
	IIa	Chest x-ray in patients with signs or symptoms of pulmonary disease	B
	IIb	Chest x-ray in other patients	C
		Electron beam computed tomography	B
Diagnosis of obstructive CAD with exercise ECG testing without an imaging modality	I	Patients with an intermediate pretest probability of CAD based on age, gender, and symptoms, including those with complete right bundle branch block or <1 mm of ST depression at rest (exceptions are listed below in Classes II and III)	B
	IIa	Patients with suspected vasospastic angina	C
	IIb	Patients with a high pretest probability of CAD by age, gender, and symptoms	B
		Patients with a low pretest probability of CAD by age, gender, and symptoms	B
		Patients taking digoxin whose ECG has <1 mm of baseline ST segment depression	B
		Patients with ECG criteria for LV hypertrophy and <1 mm of baseline ST segment depression	B
	III	Patients with the following baseline ECG abnormalities:	
		Preexcitation (Wolff-Parkinson-White) syndrome	B
		Electronically paced ventricular rhythm	B
		More than 1 mm of ST depression at rest	B
		Complete left bundle branch block	B
		Patients with an established diagnosis of CAD from prior MI or coronary angiography; however, testing can assess functional capacity and prognosis	B
Echocardiography for diagnosis of cause of chest pain in patients with suspected chronic stable angina pectoris	I	Patients with systolic murmur suggestive of aortic stenosis or hypertrophic cardiomyopathy	C
		Evaluation of extent (severity) of ischemia (e.g., LV segmental wall motion abnormality) when the echocardiogram can be obtained during pain or within 30 min after its abatement	C
	IIb	Patients with a click or murmur to diagnose mitral valve prolapse	C
	III	Patients with a normal ECG, no history of MI, and no signs or symptoms suggestive of heart failure, valvular heart disease, or hypertrophic cardiomyopathy	C

Cardiac stress imaging as the initial test for diagnosis in patients with chronic stable angina who are able to exercise	I	Exercise myocardial perfusion imaging or exercise echocardiography in patients with an intermediate pretest probability of CAD who have one of the following baseline ECG abnormalities:	
		Preexcitation (Wolff-Parkinson-White) syndrome	B
		More than 1 mm of ST depression at rest	B
		Exercise myocardial perfusion imaging or exercise echocardiography in patients with prior revascularization (either PTCA or CABG)	B
		Adenosine or dipyridamole myocardial perfusion imaging in patients with an intermediate pretest probability of CAD and one of the following baseline ECG abnormalities:	
		Electronically paced ventricular rhythm	C
		Left bundle branch block	B
	IIb	Exercise myocardial perfusion imaging and exercise echocardiography in patients with a low or high probability of CAD who have one of the following baseline ECG abnormalities:	
		Preexcitation (Wolff-Parkinson-White) syndrome	B
		More than 1 mm of ST depression	B
		Adenosine or dipyridamole myocardial perfusion imaging in patients with a low or high probability of CAD and one of the following baseline ECG abnormalities:	
		Electronically paced ventricular rhythm	
		Left bundle branch block	C
		Exercise myocardial perfusion imaging or exercise echocardiography in patients with an intermediate probability of CAD who have one of the following:	B
		Digoxin use with <1-mm ST depression on the baseline ECG	B
		LV hypertrophy with <1-mm ST depression on the baseline ECG	B
		Exercise myocardial perfusion imaging, exercise echocardiography, adenosine or dipyridamole myocardial perfusion imaging, or dobutamine echocardiography as the initial stress test in a patient with a normal rest ECG who is not taking digoxin	B
		Exercise or dobutamine echocardiography in patients with left bundle branch block	C
Cardiac stress imaging as the initial test for diagnosis in patients with chronic stable angina who are unable to exercise	I	Adenosine or dipyridamole myocardial perfusion imaging or dobutamine echocardiography in patients with an intermediate pretest probability of CAD	B
		Adenosine or dipyridamole stress myocardial perfusion imaging or dobutamine echocardiography in patients with prior revascularization (either PTCA or CABG)	B
	IIb	Adenosine or dipyridamole stress myocardial perfusion imaging or dobutamine echocardiography in patients with a low or high probability of CAD in the absence of electronically paced ventricular rhythm or left bundle branch block	B
		Adenosine or dipyridamole myocardial perfusion imaging in patients with a low or a high probability of CAD and one of the following baseline ECG abnormalities:	
		Electronically paced ventricular rhythm	C
		Left bundle branch block	B
		Dobutamine echocardiography in patients with left bundle branch block	C
Coronary angiography to establish a diagnosis in patients with suspected angina, including those with known CAD who have a significant change in anginal symptoms	I	Patients with known or possible angina pectoris who have survived sudden cardiac death	B
	IIa	Patients with an uncertain diagnosis after noninvasive testing in whom the benefit of a more certain diagnosis outweighs the risk and cost of coronary angiography	C
		Patients who cannot undergo noninvasive testing because of disability, illness, or morbid obesity	C
		Patients with an occupational requirement for a definitive diagnosis	C
		Patients who by virtue of young age at onset of symptoms, noninvasive imaging, or other clinical parameters are suspected of having a nonatherosclerotic cause of myocardial ischemia (coronary artery anomaly, Kawasaki disease, primary coronary artery dissection, radiation-induced vasculoplasty)	C
		Patients in whom coronary artery spasm is suspected and provocative testing may be necessary	C
		Patients with a high pretest probability of left main or three-vessel CAD	C
	IIb	Patients with recurrent hospitalization for chest pain in whom a definite diagnosis is judged necessary	C
		Patients with an overriding desire for a definitive diagnosis and a greater than low probability of CAD	C
	III	Patients with significant comorbidity in whom the risk of coronary arteriography outweighs the benefit of the procedure	C
		Patients with an overriding personal desire for a definitive diagnosis and a low probability of CAD	C
Measurement of rest LV function by echocardiography or radionuclide angiography in patients with chronic stable angina	I	Echocardiography or radionuclide angiography to assess LV function in patients with a history of prior MI, pathological Q waves, or symptoms or signs suggestive of heart failure	B
		Echocardiography in patients with a systolic murmur suggesting mitral regurgitation to assess its severity and etiology	C
		Echocardiography or radionuclide angiography in patients with complex ventricular arrhythmias to assess LV function	B
	III	Routine periodic reassessment of stable patients for whom no new change in therapy is contemplated	C
		Patients with a normal ECG, no history of MI, and no symptoms or signs suggestive of CHF	B

Exercise testing for risk assessment and prognosis in patients with an intermediate or high probability of CAD	I	Patients undergoing initial evaluation (Exceptions are listed below in Classes IIb and III)	B
		Patients after a significant change in cardiac symptoms	
	IIb	Patients with the following ECG abnormalities:	
		Preexcitation (Wolff-Parkinson-White) syndrome	B
		Electronically paced ventricular rhythm	B
		More than 1 mm of ST depression at rest	B
		Complete left bundle branch block	B
		Patients who have undergone cardiac catheterization to identify ischemia in the distribution of a coronary lesion of borderline severity	C
		Postrevascularization patients who have a significant change in anginal pattern suggestive of ischemia	C
	III	Patients with severe comorbidity likely to limit life expectancy or prevent revascularization	C
Cardiac stress imaging as the initial test for risk stratification of patients with chronic stable angina who are able to exercise	I	Exercise myocardial perfusion imaging or exercise echocardiography to identify the extent, severity, and location of ischemia in patients who do not have left bundle branch block or an electronically paced ventricular rhythm and either have an abnormal rest ECG or are using digoxin	B
		Dipyridamole or adenosine myocardial perfusion imaging in patients with left bundle branch block or electronically paced ventricular rhythm	B
		Exercise myocardial perfusion imaging or exercise echocardiography to assess the functional significance of coronary lesions (if not already known) in planning PTCA	B
	IIb	Exercise or dobutamine echocardiography in patients with left bundle branch block	C
		Exercise, dipyridamole, or adenosine myocardial perfusion imaging or exercise or dobutamine echocardiography as the initial test in patients who have a normal rest ECG and who are not taking digoxin	B
	III	Exercise myocardial perfusion imaging in patients with left bundle branch block	C
		Exercise, dipyridamole, or adenosine myocardial perfusion imaging or exercise or dobutamine echocardiography in patients with severe comorbidity likely to limit life expectation or prevent revascularization	C
Cardiac stress imaging as the initial test for risk stratification of patients with chronic stable angina who are unable to exercise	I	Dipyridamole or adenosine myocardial perfusion imaging or dobutamine echocardiography to identify the extent, severity, and location of ischemia in patients who do not have left bundle branch block or electronically paced ventricular rhythm	B
		Dipyridamole or adenosine myocardial perfusion imaging in patients with left bundle branch block or electronically paced ventricular rhythm	B
		Dipyridamole or adenosine myocardial perfusion imaging or dobutamine echocardiography to assess the functional significance of coronary lesions (if not already known) in planning PTCA	B
	IIb	Dobutamine echocardiography in patients with left bundle branch block	C
	III	Dipyridamole or adenosine myocardial perfusion imaging or dobutamine echocardiography in patients with severe comorbidity likely to limit life expectation or prevent revascularization	C
Coronary angiography for risk stratification in patients with chronic stable angina	I	Patients with disabling (CCS classes III and IV) chronic stable angina despite medical therapy	B
		Patients with high-risk criteria on noninvasive testing regardless of anginal severity	B
		Patients with angina who have survived sudden cardiac death or serious ventricular arrhythmia	B
		Patients with angina and symptoms and signs of CHF	C
		Patients with clinical characteristics that indicate a high likelihood of severe CAD	C
	IIa	Patients with significant LV dysfunction (ejection fraction <45%), CCS class I or II angina, and demonstrable ischemia but less than high-risk criteria on noninvasive testing	C
		Patients with inadequate prognostic information after noninvasive testing	C
	IIb	Patients with CCS class I or II angina, preserved LV function (ejection fraction >45%), and less than high-risk criteria on noninvasive testing	C
		Patients with CCS class III or IV angina, which with medical therapy improves to class I or II	C
		Patients with CCS class I or II angina but intolerance (unacceptable side effects) to adequate medical therapy	C
	III	Patients with CCS class I or II angina who respond to medical therapy and have no evidence of ischemia on noninvasive testing	C
		Patients who prefer to avoid revascularization	C

Pharmacotherapy to prevent MI and death and reduce symptoms	I	Aspirin in the absence of contraindications	A
		Beta blockers as initial therapy in the absence of contraindications in patients with prior MI	A
		Beta blockers as initial therapy in the absence of contraindications in patients without prior MI	B
		Calcium antagonists* or long-acting nitrates as initial therapy when beta blockers are contraindicated	B
		Calcium antagonists* or long-acting nitrates in combination with beta blockers when initial treatment with beta blockers is not successful	B
		Calcium antagonists* and long-acting nitrates as a substitute for beta blockers if initial treatment with beta blockers leads to unacceptable side effects	C
		Sublingual nitroglycerin or nitroglycerin spray for the immediate relief of angina	C
		Lipid-lowering therapy in patients with documented or suspected CAD and LDL cholesterol >130 mg/dl, with a target LDL of <100 mg/dl	A
	IIa	Clopidogrel when aspirin is absolutely contraindicated	B
		Long-acting nondihydropyridine calcium antagonists* instead of beta blockers as initial therapy	B
		Lipid-lowering therapy in patients with documented or suspected CAD and LDL cholesterol of 100-129 mg/dl, with a target LDL of 100 mg/dl	B
	IIb	Low-intensity anticoagulation with warfarin in addition to aspirin	B
	III	Dipyridamole	B
		Chelation therapy	B
Treatment of risk factors	I	Treatment of hypertension according to Joint National Conference VI guidelines	A
		Smoking cessation therapy	B
		Management of diabetes	C
		Exercise training program	B
		Lipid-lowering therapy in patients with documented or suspected CAD and LDL cholesterol >130 mg/dl, with a target LDL of <100 mg/dl	A
		Weight reduction in obese patients with hypertension, hyperlipidemia, or diabetes mellitus	C
	IIa	Lipid-lowering therapy in patients with documented or suspected CAD and LDL cholesterol of 100-129 mg/dl, with a target LDL <100 mg/dl	B
	IIb	Hormone replacement therapy in postmenopausal women in the absence of contraindications	B
		Weight reduction in obese patients in the absence of hypertension, hyperlipidemia, or diabetes mellitus	C
		Folate therapy in patients with elevated homocysteine levels	C
		Vitamin C and E supplementation	B
		Identification and appropriate treatment of clinical depression	C
		Intervention directed at psychosocial stress reduction	C
	III	Chelation therapy	C
		Garlic	C
		Acupuncture	C

Revascularization with PTCA (or other catheter-based techniques) and CABG in patients with stable angina	I	CABG for patients with significant left main coronary disease	A
		CABG for patients with 3-vessel disease. The survival benefit is greater in patients with abnormal LV function (ejection fraction <50%)	A
		CABG for patients with 2-vessel CAD, with significant proximal LAD disease and either abnormal LV function (ejection fraction <50%) or demonstrable ischemia on noninvasive testing	A
		PTCA for patients with 2- or 3-vessel CAD and significant proximal LAD disease who have anatomy suitable for catheter-based therapy, have normal LV function, and do not have treated diabetes	B
		PTCA or CABG for patients with 1- or 2-vessel CAD without significant proximal LAD disease but with a large area of viable myocardium and high-risk criteria on noninvasive testing	B
		CABG for patients with 1- or 2-vessel CAD without significant proximal LAD disease who have survived sudden cardiac death or sustained ventricular tachycardia	C
		In patients with prior PTCA or CABG for recurrent stenosis associated with a large area of viable myocardium or high-risk criteria on noninvasive testing	C
		PTCA or CABG for patients who have not been successfully treated by medical therapy and can undergo revascularization with acceptable risk	B
	IIa	Repeat CABG for patients with multiple saphenous vein graft stenoses, especially with significant stenosis of a graft supplying the LAD. It may be appropriate to use PTCA for focal saphenous vein graft lesions or multiple stenoses in poor candidates for reoperative surgery	C
		Use of PTCA or CABG for patients with 1- or 2-vessel CAD without significant proximal LAD disease but with a moderate area of viable myocardium and demonstrable ischemia on noninvasive testing	B
		Use of PTCA or CABG for patients with 1-vessel CAD and significant proximal LAD disease	B
	IIb	Compared with CABG, PTCA for patients with 2- or 3-vessel CAD and significant proximal LAD disease who have anatomy suitable for catheter-based therapy and who have treated diabetes or abnormal LV function	B
		Use of PTCA for patients with significant left main coronary disease who are not candidates for CABG	C
		PTCA for patients with 1- or 2-vessel CAD without significant proximal LAD disease who have survived sudden cardiac death or sustained ventricular tachycardia	C
	III	Use of PTCA or CABG for patients with 1- or 2-vessel CAD without significant proximal LAD disease who have mild symptoms that are unlikely to be due to myocardial ischemia or who have not received an adequate trial of medical therapy and	C
		Have only a small area of viable myocardium or	
		Have no demonstrable ischemia on noninvasive testing	C
		Use of PTCA or CABG for patients with borderline coronary stenoses (50-60% diameter in locations other than the left main coronary artery) and no demonstrable ischemia on noninvasive testing	
		Use of PTCA or CABG for patients with insignificant coronary stenosis (<50% diameter)	C
		Use of PTCA in patients with significant left main coronary artery disease who are candidates for CABG	B

Echocardiography, treadmill exercise testing, stress imaging studies, and coronary angiography during patient follow-up	I	Chest x-ray for patients with evidence of new or worsening CHF	C
		Assessment of LV ejection fraction and segmental wall motion in patients with new or worsening CHF or evidence of intervening MI by history or ECG	C
		Echocardiography for evidence of new or worsening valvular heart disease	C
		Treadmill exercise test for patients without prior revascularization who have a significant change in clinical status, are able to exercise, and do not have any of the ECG abnormalities listed below	C
		Stress imaging procedures for patients without prior revascularization who have a significant change in clinical status and are unable to exercise or have one of the following ECG abnormalities: Preexcitation (Wolff-Parkinson-White) syndrome Electronically paced ventricular rhythm More than 1 mm of rest ST depression Complete left bundle branch block	C C C C
		Stress imaging procedures for patients who have a significant change in clinical status and required a stress imaging procedure on their initial evaluation because of equivocal or intermediate-risk treadmill results	C
		Stress imaging procedures for patients with prior revascularization who have a significant change in clinical status	C
		Coronary angiography in patients with marked limitation of ordinary activity (CCS class III) despite maximal medical therapy	C
	IIb	Annual treadmill exercise testing in patients who have no change in clinical status, can exercise, have none of the ECG abnormalities listed above, and have an estimated annual mortality rate >1%	C
	III	Echocardiography or radionuclide imaging for assessment of LV ejection fraction and segmental wall motion in patients with a normal ECG, no history of MI, and no evidence of CHF	C
		Repeat treadmill exercise testing in <3 yr in patients who have no change in clinical status and an estimated annual mortality rate <1% on their initial evaluation, as demonstrated by one of the following:	C
		Low-risk Duke treadmill score (without imaging)	C
		Low-risk Duke treadmill score with negative imaging	C
		Normal LV function and a normal coronary angiogram	C
		Normal LV function and insignificant CAD	C
		Stress imaging procedures for patients who have no change in clinical status and a normal rest ECG, are not taking digoxin, are able to exercise, and did not require a stress imaging procedure on their initial evaluation because of equivocal or intermediate-risk treadmill results	C
		Repeat coronary angiography in patients with no change in clinical status, no change on repeat exercise testing or stress imaging, and insignificant CAD on initial evaluation	C

J Am Coll Cardiol 33:2092-2197, 1999. Reprinted with permission from the American College of Cardiology.

*Short-acting dihydropyridine calcium antagonists should be avoided.

An ACC/AHA task force published guidelines for PTCA in 1993[2] (new guidelines are being developed) that defined contraindications to *elective* angioplasty, including relative contraindications to coronary angiography. These guidelines stress that PTCA may be appropriate even in patients with these contraindications who are severely symptomatic and not candidates for CABG. *Absolute contraindications* included

1. Absence of a lesion that causes a 50 percent or greater reduction in coronary diameter
2. Presence of significant left main coronary disease unless this coronary distribution is protected by at least one nonobstructed bypass graft
3. Absence of a formal cardiac surgical program in the institution

Relative contraindications included

1. Conditions associated with an unacceptable risk of serious bleeding or thrombotic occlusion or a recently dilated vessel
2. Diffusely diseased saphenous vein grafts without a focal dilatable lesion
3. Diffusely diseased native coronary arteries with distal vessels suitable for bypass grafting
4. The vessel in question is the sole remaining vessel in the coronary circulation
5. Chronic total occlusions with clinical features suggesting a very low anticipated success rate
6. Borderline stenotic lesion (usually less than 50 percent stenosis)
7. Procedure proposed for a non-infarct-related artery in patients

with multivessel disease who are undergoing direct angioplasty for acute myocardial infarction

The ACC/AHA guidelines also considered anatomical features that increase the risk for abrupt closure (see Chap. 38) to be relative contraindications to PTCA. Because of the risk of such complications, the guidelines recommended that for all elective PTCA procedures, an experienced cardiovascular surgical team be present within the hospital to perform emergency CABG should the need arise. The AHA/ACC task force did not consider formal surgical consultation mandatory before PTCA.

Under some circumstances, the AHA/ACC task force considered PTCA reasonable even if surgical back-up were not available. For patients with a high risk of acute myocardial infarction in whom thrombolytic therapy was contraindicated, emergency PTCA was "acceptable treatment" if the patient could not be transferred expeditiously to a center with surgical back-up. However, the guidelines noted that patients with unstable angina could and should usually be transferred to an institution with a cardiac surgical program before consideration of PTCA.

The experience of the operator is also a critical factor in determining the outcome of PTCA. Therefore, several task forces have provided recommendations for the minimum number of cases during PTCA training and for the minimum annual volume required to maintain competency.[5] [6] [7] The most recent statement from the ACC, published in 1998, concluded that the relationship between individual operator procedural volume and patient outcomes was statistically valid but complex.[7] These guidelines recommended that an institution performing PTCA have an activity level of at least 400 coronary procedures per year and that an institution performing fewer than 200 procedures per year consider discontinuing this service unless it is in a region that is underserved. Institutions offering coronary interventional services should have a physician-director with experience consisting of at least 500 procedures. The ACC statement indicated that individual operators should perform at least 75 procedures per year and that operators who perform 50 to 75 procedures per year should be very cautious in case selection. Ideally, the guidelines said, operators with annual procedural volumes below 75 should work only at institutions with an activity level greater than 600 procedures per year. Recommendations also included a "mentoring" relationship for low-volume operators with a highly experienced operator who has an annual procedural volume greater than 150 procedures per year.

Indications for PTCA

The 1993 AHA/ACC task force developed assessments of the appropriateness of PTCA in various clinical settings according to the same three classes used in other ACC/AHA guidelines.[2] These indications included consideration of the patient's coronary anatomy, symptomatic status, and the clinical syndrome.

SINGLE-VESSEL CORONARY DISEASE.

The ACC/AHA task force included different recommendations for patients with and without symptoms of coronary disease. For patients who were *asymptomatic* or only mildly symptomatic, regardless of whether they had received medical therapy, PTCA was considered appropriate (Class I) in those with a lesion resulting in a 50 percent or greater reduction in the diameter of a coronary artery that supplies a large area of viable myocardium if they also had evidence of myocardial ischemia induced by low levels of exercise (Bruce stage 1, or <4.0 METs, or a heart rate less than 100 beats/min) during noninvasive testing (see Table 37-10) . Other Class I indications for PTCA included prior cardiac arrest or sustained ventricular tachycardia in the absence of acute myocardial infarction and the need to undergo major vascular surgery (such as aortic aneurysm repair, iliofemoral bypass, or carotid artery surgery) if patients had clinical evidence of ischemic heart disease.

In patients with less myocardium in jeopardy, the appropriateness of single-vessel angioplasty was less clear-cut. Indications for PTCA were considered equivocal (Class II) in patients whose stenotic coronary artery supplied a moderate- or large-sized area of viable myocardium if they had objective evidence of ischemia and had coronary anatomy suggesting that PTCA could be performed with a moderate likelihood of success and low risk of complications. PTCA was considered inappropriate (Class III) for patients with only a small area of viable myocardium at risk, no evidence of ischemia, or a moderate to high risk of complications.

For patients who are *symptomatic* from single-vessel coronary disease despite medical therapy, the ACC/AHA guidelines considered PTCA appropriate (Class I) even if only a moderate amount of myocardium was supplied by the stenosed vessel--if they showed evidence of ischemia despite medical therapy, had angina pectoris that was inadequately responsive to medical treatment, or were intolerant of medical therapy. "Inadequately responsive" indicates that the patient and physician agree that angina significantly interferes with the patient's occupation or ability to perform usual activities. All these patients should have at least a moderate likelihood of successful dilation and be at low or moderate risk for morbidity and mortality for PTCA to be considered clearly appropriate.

PTCA was considered to be of equivocal appropriateness (Class II) in patients with an increased risk of complications or failure of the procedure. The ACC/AHA guidelines did not support PTCA's appropriateness in patients with no or only a small area of myocardium at risk in the absence of disabling symptoms or in patients with a high risk of procedural failure or complications.

MULTIVESSEL CORONARY DISEASE.

For *asymptomatic* patients with multivessel disease, the AHA/ACC guidelines indicate that PTCA is reasonable (Class I) if dilation of one major coronary artery could lead to nearly complete revascularization and the chance of success was moderate or high. For PTCA to be considered appropriate in this population, patients should have the same clinical indications as for Class I in asymptomatic patients with single-vessel disease, including evidence of severe ischemia. The indications were less clear (Class II) if the amount of myocardium at risk was only moderate or if there were other coronary stenoses that affected a moderate amount of myocardium. PTCA was considered inappropriate if patients had only a small amount of viable myocardium at risk, had chronic total occlusions, or had a high risk of complications.

For symptomatic patients with multivessel coronary disease, appropriate (Class I) indications for PTCA were similar to those for symptomatic patients with single-vessel disease, except that these indications included patients who had lesions in two or more major arteries affecting at least moderately sized areas of viable myocardium. If these patients had a moderate risk for complications or did not have objective evidence of myocardial ischemia, the appropriateness of PTCA was regarded as uncertain (Class II).

The ACC/AHA task force was also uncertain about the appropriateness of PTCA for patients with multivessel coronary disease and angina that was disabling despite medical therapy if these patients were poor candidates for surgery and were at moderate risk for complications from PTCA. The concern reflected in these guidelines is that PTCA might lead to abrupt closure of a coronary artery, thereby creating a dilemma in which the physicians must decide whether to send a poor surgical candidate for CABG.

Coronary Artery Bypass Graft Surgery

Guidelines for the use of CABG surgery were updated in 1999 by an ACC/AHA task force.[3] When compared with the 1991 guidelines for CABG from the ACC/AHA,[8] this revision reflects greater consideration of the impact of this procedure on relief of symptoms, as well as overall survival. For example, the authors of these guidelines considered CABG beneficial for younger patients without left ventricular dysfunction, even if no improvement in survival could be predicted, because CABG can be performed with low mortality in such patients and because their potential for resuming an active life style is high.

Indications (Table 37-G-2)

The 1999 update of the ACC/AHA guidelines designates an appropriateness class for patient subsets defined by major variables:

1. Symptomatic status
2. Severity of ischemia on noninvasive testing
3. Number of diseased coronary arteries
4. Involvement of the left main coronary artery
5. Involvement of the proximal left anterior descending coronary artery
6. Left ventricular function

In these guidelines, coronary stenosis is defined as a 50 percent or greater reduction in lumen diameter. Certain subsets of coronary anatomy have been found to have better prognoses with surgical than medical therapy and are therefore considered indications for CABG regardless of the patient's symptomatic status and severity of ischemia on noninvasive testing. In the ACC/AHA guidelines, CABG surgery is considered appropriate (Class I) for all patients with any of the following criteria:

1. Significant stenosis (>50 percent) of the left main coronary artery
2. Left main equivalent: significant (>70 percent) stenosis of the proximal left anterior descending coronary artery and proximal left circumflex artery
3. Three-vessel disease, especially if left ventricular function is reduced

TABLE 37--G-2 -- APPROPRIATENESS OF CABG FOR SPECIFIC PATIENT SUBSETS

Clinical Subset	Class I	Class IIa	Class IIb	Class III

Asymptomatic or mild angina	Significant left main coronary artery stenosis Left main equivalent: significant (70%) stenosis of the proximal LAD and proximal left circumflex artery Three-vessel disease	Proximal LAD stenosis with 1- or 2-vessel disease*	One- or 2-vessel disease not involving the proximal LAD	Other
Stable angina	Same as for patients with asymptomatic or mild angina, plus Two-vessel disease with significant proximal LAD stenosis and either an EF <0.50 or demonstrable ischemia on noninvasive testing One- or 2-vessel coronary artery disease without significant proximal LAD stenosis but with a large area of viable myocardium and high-risk criteria on noninvasive testing Disabling angina despite maximal medical therapy	Proximal LAD stenosis with 1-vessel disease* One- or 2-vessel coronary artery disease without significant proximal LAD stenosis but with a moderate area of viable myocardium and demonstrable ischemia on noninvasive testing	None	One- or 2-vessel disease not involving significant proximal LAD stenosis in patients who have mild symptoms that are unlikely to be due to myocardial ischemia or who have not received an adequate trial of medical therapy and Have only a small area of viable myocardium or Have no demonstrable ischemia on noninvasive testing Borderline coronary stenoses (50-60% diameter in locations other than the left main coronary artery) and no demonstrable ischemia on noninvasive testing Insignificant coronary stenosis (<50% diameter reduction)
Unstable angina/non-Q-wave MI	Significant left main coronary artery stenosis Left main equivalent: significant (70%) stenosis of the proximal LAD and proximal left circumflex artery Ongoing ischemia not responsive to maximal nonsurgical therapy	Proximal LAD stenosis with 1- or 2-vessel disease*	One- or 2-vessel disease not involving the proximal LAD	
ST segment elevation (Q wave) MI	None	Ongoing ischemia/infarction not responsive to maximal nonsurgical therapy	Progressive LV pump failure with coronary stenosis compromising viable myocardium outside the initial infarct area Primary reperfusion in the early hours (6 to 12 hr) of an evolving MI with ST segment elevation	Primary reperfusion late (12 hr) in evolving MI with ST segment elevation without ongoing ischemia
Poor LV function	Significant left main coronary artery stenosis Left main equivalent: significant (70%) stenosis of the proximal LAD and proximal left circumflex artery Proximal LAD stenosis with 2- or 3-vessel disease	Poor LV function with significant viable, noncontracting, revascularizable myocardium without any of the aforementioned anatomical patterns		Poor LV function without evidence of intermittent ischemia and without evidence of significant revascularizable, viable myocardium
Life-threatening ventricular arrhythmias	Left main coronary artery stenosis Three-vessel coronary disease	Bypassable 1- or 2-vessel disease causing life-threatening ventricular arrhythmias Proximal LAD disease with 1- or 2-vessel disease		Ventricular tachycardia with scar and no evidence of ischemia
After failed PTCA	Ongoing ischemia or threatened occlusion with significant myocardium at risk Hemodynamic compromise	Foreign body in crucial anatomical position Hemodynamic compromise in patients with impairment of coagulation system and without previous sternotomy	Hemodynamic compromise in patients with impairment of coagulation system and previous sternotomy	Absence of ischemia Inability to revascularize because of target anatomy or no-reflow state
With previous CABG	Disabling angina despite maximal noninvasive therapy	Bypassable distal vessel(s) with a larger area of threatened myocardium by noninvasive studies	Ischemia in the non-LAD distribution with a patent IMA graft to the LAD supplying functioning myocardium, without an aggressive attempt at medical management and/or percutaneous revascularization	

CABG=coronary artery bypass grafting; EF=ejection fraction; IMA=internal mammary artery; LAD=left anterior descending artery; LV=left ventricular; MI=myocardial infarction; PTCA=percutaneous transluminal coronary angioplasty.

From Eagle KA, Guyton RA, Davidoff R, et al: ACC/AHA guidelines for coronary artery bypass graft surgery. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1991 Guidelines for Coronary Artery Bypass Graft Surgery). J Am Coll Cardiol 34:1262-1347, 1999.

*Becomes Class I if extensive ischemia is documented by noninvasive study and/or the left ventricular ejection fraction is less than 50%.

Becomes Class I if there is a large area of viable myocardium and high-risk criteria on noninvasive testing.

Becomes Class I if the arrhythmia is resuscitated sudden cardiac death or sustained ventricular tachycardia.

CABG is considered appropriate in patients with one or more diseased vessels if they have a large area of viable myocardium and high-risk findings on noninvasive testing. The guidelines recommend a lower threshold for surgery in patients with proximal stenoses of the left anterior descending coronary artery than in other patients with one- or two-vessel disease, particularly if they have extensive evidence of ischemia on noninvasive studies or if they have a left ventricular ejection fraction less than 50 percent. The guidelines assume that surgery can be performed with acceptable risk. They also assume that patients' anginal symptoms are typical; if not, objective evidence of ischemia should be obtained.

ASYMPTOMATIC OR MILD ANGINA.

The ACC/AHA task force considered CABG appropriate for patients with no or only mild symptoms even if they had only one- or two-vessel disease as long as they also had evidence of large amounts of myocardium in jeopardy on noninvasive testing. Even in the absence of markedly positive noninvasive tests for ischemia, patients with one- or two-vessel disease were considered to have uncertain (Class II) appropriateness for CABG. These guidelines therefore do not explicitly label as inappropriate any indications for CABG in patients with coronary artery disease. Since these patients are, by definition, free of disabling symptoms, the goal of surgery in this population is to prolong life. Class I subsets represent the groups in which survival benefits are most likely to be realized.

STABLE ANGINA.

For patients with stable mild angina, indications for surgery are based on the likelihood of improving survival and on the probability of relieving life-threatening symptoms. Therefore, the ACC/AHA task force concluded that clearly appropriate indications for CABG in this population should include the same factors as for asymptomatic patients, as well as disabling angina. For patients with chronic stable angina and only moderate amounts of myocardium in jeopardy from ischemia on noninvasive stress testing, CABG was considered to be of uncertain appropriateness (Class IIa).

UNSTABLE ANGINA/NON-Q WAVE MYOCARDIAL INFARCTION.

The indications for CABG in these patients include those for patients with no or stable angina symptoms but reflect uncertainty about the optimal timing of surgery. The guidelines recommend stabilization with aggressive medical therapy if possible before proceeding to CABG.

ST SEGMENT ELEVATION (Q WAVE) MYOCARDIAL INFARCTION.

For patients with ST segment (Q wave) acute myocardial infarction, the ACC/AHA guidelines discourage the use of CABG in favor of thrombolytic therapy or coronary angioplasty. The guidelines recognize that CABG is warranted in certain conditions, such as the presence of left main stenosis, severe three-vessel disease, associated valve disease, and anatomy unsuitable for other forms of therapy. Otherwise, surgery is most likely to be appropriate when patients have not responded to maximal nonsurgical therapy (Class IIa). Recommendations on the optimal timing for repair of the mechanical complications of acute myocardial infarction (e.g., ventricular septal defect) were not included in these guidelines.

IMPAIRED LEFT VENTRICULAR FUNCTION.

CABG is considered an appropriate or potentially appropriate strategy for the management of patients with impaired left ventricular ejection fractions because of evidence that ventricular dysfunction may be due to viable but hibernating myocardium in patients with severe multivessel disease. The guidelines consider surgery to be especially appropriate if the patient has clinical evidence of intermittent ischemia and minimal or no congestive heart failure. In patients with clinical heart failure, the decision to operate should be based on objective evidence of hibernating myocardium.[9] [10]

LIFE-THREATENING VENTRICULAR ARRHYTHMIAS.

CABG can suppress arrhythmia induction in patients with ventricular arrhythmias, particularly when an ischemic etiology for the arrhythmia can be documented. However, because multiple other factors can contribute to the development of life-threatening ventricular arrhythmias, such as reentry pathways in scarred myocardium, concomitant insertion of an implantable cardioverter-defibrillator may be necessary for many patients who are candidates for CABG.

FAILED PTCA.

The decision to perform CABG after failed PTCA must consider a variety of factors, including the mechanism of the failed procedure, the potential to improve the situation surgically, the extent of myocardium in jeopardy, and the patient's ability to tolerate CABG. Surgery is clearly *appropriate* when patients have or are in danger of hemodynamic compromise or when a foreign body such as an undeployed stent must be retrieved. However, CABG is *inappropriate* when patients do not have active ischemia or when CABG is unlikely to lead to revascularization of the myocardium in jeopardy.

AFTER PRIOR CABG.

Reoperation after prior CABG is associated with increased risk and lower rates of relief of symptoms. Therefore, repeat CABG should be reserved for relief of disabling symptoms or clear evidence of life-threatening amounts of myocardium at risk. In patients with functioning internal mammary artery grafts to the left anterior descending artery, the potential loss of this graft with any repeat CABG is a significant disincentive to pursue this strategy.

Recommended Management Strategies

The ACC/AHA guidelines also offer recommendations on the evaluation and management of several specific issues before, during, and after CABG (Table 37-G-3) . Among interventions aimed at reducing neurological damage after CABG is screening for carotid artery stenoses, which are often asymptomatic. Although the guidelines do not

TABLE 37--G-3 -- PROVEN MANAGEMENT STRATEGIES TO REDUCE PERIOPERATIVE AND LATE MORBIDITY AND MORTALITY

Timing	Class Indication	Intervention	Comments
Preoperative			
Carotid screening	I	Carotid duplex ultrasound in a defined population	Carotid endarterectomy if stenosis 80%
Perioperative			
Antimicrobials	I	Prophylactic antimicrobials	
Antifibrinolytics	IIa	Aprotinin in selected groups	Significant reduction in blood transfusion requirements
Antiarrhythmics	I	Beta blockers to prevent postoperative atrial fibrillation	Propafenone or amiodarone are alternatives if beta blockers are contraindicated

Antiinflammatory drugs	IIa	Minimize diffuse inflammatory response to cardiopulmonary bypass	
Postoperative			
Antiplatelets	I	Aspirin to prevent early vein graft attrition	Ticlopidine or clopidogrel are alternatives if aspirin is contraindicated
Lipid-lowering therapy	I	Cholesterol-lowering agent plus low-fat diet if low-density lipoprotein cholesterol >100 mg/dl	3-Hydroxy-3-methylglutaryl/coenzyme A reductase inhibitors preferred if elevated low-density lipoprotein is major aberration
Smoking cessation	I	Smoking cessation education and possibly counseling and pharmacotherapy	

From Gibbons RJ, Chatterjee K, Daley J, et al: ACC/AHA/ACP-ASIM guidelines for the management of patients with chronic stable angina: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients with Chronic Stable Angina). J Am Coll Cardiol 33:2092-2197, 1999. Reprinted with permission from the American College of Cardiology.

explicitly call for all patients to undergo such screening, they note that many centers screen all those 65 years or older. Other patients who should undergo carotid artery ultrasound screening include those with a prior history of cerebrovascular disease.

Aspirin for the first year after CABG is considered the drug of choice for prophylaxis against early saphenous graft closure from thrombus; most patients continue this therapy indefinitely to reduce the risk for myocardial infarction. Patients with LDL cholesterol levels above 100 mg/dl warrant dietary and nondietary interventions to improve their lipid profile. Smoking cessation counseling should also be a routine part of care. The guidelines also indicate that cardiac rehabilitation should be offered to all eligible patients.

ORGANIZATIONAL CONSIDERATIONS.

The ACC/AHA guidelines noted studies suggesting that survival after CABG is worse when performed at institutions or by operators performing a low volume of procedures annually. The guidelines commented that data support close monitoring of institutions or individuals performing fewer than 100 cases annually.

Chapter 38 - Percutaneous Coronary and Valvular Intervention

JEFFREY J. POPMA
RICHARD E. KUNTZ

The use of percutaneous coronary intervention (PCI) in patients with ischemic coronary artery disease (CAD) has expanded dramatically over the past two decades. More than 650,000 patients underwent PCI in 1999 in the United States, far exceeding the number of patients undergoing coronary artery bypass graft surgery (CABG). Continual technological improvements (e.g., stents, atherectomy and thrombectomy devices), refinements in periprocedural adjunctive pharmacology (e.g., glycoprotein IIb-IIIa [GP IIb-IIIa] inhibitors), and a better understanding of early and late outcomes in patients with comorbidities have fostered the expanded use of PCI as definitive therapy for ischemic CAD.

This chapter will review (1) the current methods used for PCI, including conventional balloon angioplasty and new coronary devices; (2) the procedural outcomes and complication rates obtained with contemporary PCI methods; (3) the periprocedural pharmacological strategies to reduce acute complications and restenosis after PCI; and (4) recommendations for coronary revascularization in patients with ischemic CAD, with consideration of the alternatives of medical therapy, PCI, and CABG. A discussion of the current issues in patient selection, technical performance, and outcomes associated with percutaneous mitral and aortic valvuloplasty is also included.

HISTORICAL PERSPECTIVE

Balloon angioplasty, or percutaneous transluminal coronary angioplasty (PTCA), was first performed by Andreas Gruentzig in 1977 with the use of a prototype, fixed-wire balloon catheter.[1] The procedure was initially limited to patients with symptomatic CAD who had focal lesions in proximal coronary vessels and was used as an alternative to CABG.[1] Because of an objective reduction in stenosis severity and consistent improvement in clinical ischemia with this novel method,[2] the number of patients treated with balloon PTCA expanded dramatically over the next decade.[3] Operator experience and equipment design also evolved rapidly, with a transition from poorly steerable, fixed-wire balloon dilatation catheters to highly steerable, over-the-wire, and rapid-exchange balloon dilatation systems. These catheter designs resulted in more flexible, trackable, and lower-profile balloon dilatation systems and allowed the expansion of PCI to a broader spectrum of patients, such as those with multivessel disease, "high-risk" anatomy, reduced left ventricular function, and other serious comorbid medical conditions.[3]

It soon became apparent that two major issues limited the widespread use of balloon PTCA in patients with symptomatic CAD. Abrupt vessel closure resulting from angioplasty-induced dissection and thrombus formation occurred in 6.8 to 8.3 percent of cases,[4] [5] [6] [50A] largely unpredictable in individual patients despite the description of several predisposing factors in a number of series.[7] [8] [9] [10] Although in-laboratory abrupt vessel closure was reversible in most patients, emergency CABG was occasionally (3 to 5 percent of cases) required to relieve ongoing transmural ischemia resulting from catheter-based complications. In some cases, the urgency of surgical revascularization mandated that saphenous vein grafts (SVGs) be used instead of the preferred arterial conduits. The second major limitation of balloon PTCA was the development of restenosis, either clinically manifested by symptom recurrence or identified as recurrent arterial narrowing by routine repeat angiography. The pathology of restenosis has remained poorly understood, and pharmacological agents have not consistently reduced its occurrence.

A number of new coronary devices were developed in the early 1990s to improve upon the early and late procedural outcomes achieved with balloon PTCA. These novel methods were designed to remove (e.g., directional, rotational, or extraction atherectomy), ablate (e.g., excimer laser angioplasty), or scaffold (e.g., stents) atherosclerotic plaque. Randomized clinical trials have shown that some devices (e.g., stents) resulted in better early and late clinical outcome while others (e.g., excimer laser angioplasty) imparted no incremental clinical benefit and were potentially detrimental in comparison to balloon PTCA.

Given these devices' diverse mechanisms of benefit and their niche application in selected patients, it became apparent that a "lesion-specific" approach to coronary angioplasty was required, with the specific type of revascularization tailored to the precise characteristics of the vessel wall pathology. Coronary angioplasty then encompassed the use of both balloons and new devices, and the generic term *percutaneous coronary intervention* was introduced.

BALLOON PTCA

Balloon PTCA expands the coronary lumen by stretching and tearing the atherosclerotic plaque and vessel wall and, to a lesser extent, by redistributing atherosclerotic plaque along its longitudinal axis.[11] [12] There is no evidence that balloon PTCA compresses atherosclerotic plaque.

TECHNICAL ASPECTS.

Balloon PTCA is performed by over-the-wire, rapid-exchange, or fixed-wire balloon dilatation systems. A 1.0 to 1.1:1.0 balloon-to-artery ratio is optimal for balloon size selection; higher ratios are associated with complications, and lower ones predispose to restenosis.[13] Although "stand-alone" balloon PTCA is usually (>80 percent) effective in improving ischemic symptoms, it is limited by substantial early elastic recoil, which results in an average 30 to 35 percent residual stenosis. On occasion, propagation of a coronary dissection and superimposed platelet thrombus formation after balloon PTCA result in early complications, including abrupt vessel closure. An "optimal" angiographic result (<20 percent residual stenosis) is obtained in less than 25 percent of patients after balloon PTCA but is associated with a favorable late clinical outcome. Documentation of an "optimal" anatomical *and* physiological result with balloon PTCA requires the addition of Doppler flow measurements[14]

or determination of transstenosis pressure gradients (e.g., fractional flow reserve[15]) (see Chap. 12) . In a prospective study of 225 patients with an angiographically successful result after balloon PTCA, postprocedural distal coronary flow reserve and percent diameter stenosis were correlated with symptoms and the need for target lesion revascularization (TLR) 1 and 6 months later.[14] Distal coronary flow reserve of 2.5 or higher and residual percent diameter stenosis of 35 or less after balloon PTCA identified lesions with lower rates of 6-month symptom recurrence (23 vs. 47 percent; p=0.005), need for reintervention (16 vs. 34 percent; p=0.024), and restenosis (16 vs. 41 percent; p=0.002) when compared with patients who did not meet these criteria.[14]

Assessment of Outcome.

A number of indices have been used to assess both early and late procedural outcomes. *Anatomical* (or *angiographic*) *success* has been defined as achieving smaller than 50 percent residual diameter stenosis with Thrombolysis in Myocardial Infarction (TIMI) 3 flow (see Chap. 12) after balloon PTCA,[16] with or without a 20 percent or greater improvement in diameter stenosis.[3] Visually determined angiographic success rates may overestimate the results provided by more quantitative

angiographic measurements by 10 to 20 percent, although visual assessment by investigators has been correlated with clinical outcomes in at least one study.[17] *Procedural success* is generally defined as angiographic success without the occurrence of major complications (death, myocardial infarction, or CABG)[16] [18] either during the index hospitalization or within the 30 days of the procedure.[19] Periprocedural vessel closure is defined as *abrupt* (TIMI 0 or 1 flow), *subacute* (abrupt closure occurring after the patient leaves the catheterization laboratory but within 30 days of the procedure), and *threatened* (presence of two or more of the following: angina; ischemic electrocardiographic changes; residual diameter stenosis greater than 50 percent; National Heart, Lung, and Blood Institute [NHLBI] type B or C dissection, with length greater than 8 mm; or NHLBI type D, E, or F dissection or deteriorating angiographic appearance with TIMI flow of 0 to 2). (See Chapter 12 for definitions of TIMI flow grades and NHLBI dissection types.)

Procedure-induced non-Q-wave myocardial infarction, as defined by an elevation in creatine phosphokinase isoenzyme (CPK-MB) of three times normal or higher,[18] [20] [21] occurs in 5 to 10 percent of procedures, [20] [22] but its causal relationship to late mortality is unclear.[22] [23] *Clinical success* is defined as procedural success without the need for urgent repeat PCI or surgical revascularization within the first 30 days of the procedure.[18]

INITIAL CLINICAL RESULTS.

Procedural success rates after balloon PTCA have progressively improved over the past 20 years (Table 38-1) . An 88 percent angiographic success rate was obtained in patients with multivessel CAD enrolled in the 1988-1991 Bypass Angioplasty Revascularization Investigators (BARI) Trial, but major complications were frequent and included death (1.1 percent), Q wave myocardial infarction (2.1 percent), and CABG (6.3 percent).[26] Major complications after balloon PTCA in other registry series include in-hospital death (0.9 to 3.5 percent), Q wave myocardial infarction (1.0 to 1.7 percent), emergency CABG (2.1 to 6.0 percent) and stroke (<0.5 percent).[33] Minor complications after balloon PTCA include acute or subacute vessel closure requiring urgent repeat balloon PTCA, coronary dissection, sidebranch occlusion, ventricular arrhythmias, vascular access complications, renal insufficiency, coronary perforation, and rarely, cardiac tamponade.

The recent availability of "bailout" coronary stents has reduced the emergency CABG rate after balloon PTCA to less than 1 percent.[34] In one series reporting recent procedural outcomes in 34,752 procedures performed in Northern New England Cardiovascular Group hospitals, adjusted clinical success rates increased from 88.2 percent in 1990 to 1993 to 91.9 percent in 1995 to 1997 (p<0.001). [35] With the combination of balloon PTCA and new devices, higher (95 to 99 percent) procedural success rates are now reported, particularly in women.[36]

Early procedural outcome after balloon PTCA has been correlated with a number of clinical, angiographic, and procedural factors identified in the periprocedural period.[7] [8] [24] [33] *Clinical factors* include age, unstable and Canadian Cardiovascular Society (CCS) Class IV angina, congestive heart failure, cardiogenic shock, renal insufficiency, and preprocedural instability requiring intraaortic balloon pump support, among other factors.[33] *Anatomical variables* include multivessel CAD, presence of thrombus, SVG intervention, and American College of Cardiology/American Heart Association (ACC/AHA) type C lesion morphology,[16] [33] including chronic total coronary occlusion. *Procedural factors* also affect procedure outcomes, including a higher final percent diameter stenosis, smaller minimal lumen diameter, and the presence of a residual dissection or transstenotic pressure gradient (see Chap. 12 for definitions of ACC/AHA lesion types). Procedural mortality is associated with balloon PTCA of arteries subtending 50 percent or more of the myocardium, a left ventricular ejection fraction less than 25 percent, a more severe preprocedural percent diameter stenosis, multivessel CAD, and female gender, among other factors.[37] [38] These latter factors indicate a greater risk for cardiovascular collapse should abrupt vessel closure occur.[39]

LATE CLINICAL OUTCOME.

Clinical events after balloon PTCA are attributable to arterial renarrowing at the PTCA site, progression or instability of atherosclerotic disease at remote sites, or both.[40] These processes can be partially distinguished by the time of occurrence of the event--with angiographic and clinical restenosis generally developing within 6 to 9 months after balloon PTCA[41] [42] and death, myocardial infarction, and progression of atherosclerosis occurring with a low, but constant hazard (1 to 2 percent risk per year) indefinitely after the procedure.

Predictors of higher risk of all-cause late mortality include advanced age,[43] reduced left ventricular function or congestive heart failure,[43] presence of diabetes mellitus,[27] [43] female gender,[44] number of diseased vessels, [43] [45] inoperable disease,[43] or severe concomitant disease.[43] In patients undergoing balloon PTCA, a 95 percent 10-year survival rate was reported in those with single-vessel CAD and an 81 percent 10-year survival rate in those with multivessel CAD.[45] Five-year cardiac mortality rates for patients enrolled in the PTCA Registry were 2.8 percent in patients with single-vessel disease, 6.1 percent in patients with two-vessel disease, and 9.9 percent in patients with three-vessel disease.[43] Higher 9-year mortality rates have also been reported in diabetic patients (35.9 vs. 17.9 percent in nondiabetic patients; p<0.01).[46]

The risk of restenosis after balloon PTCA is influenced by *clinical factors*, such as diabetes mellitus, unstable angina, acute myocardial infarction, and prior restenosis, by *anatomical factors*, such as total occlusions, proximal left anterior descending artery lesions, smaller vessel size, long lesions, and lesions involving an SVG, and by *procedural factors*, such as the final minimal lumen diameter or percent diameter stenosis. Exposure to infectious agents may also predispose to the development of restenosis.[47]

INDICATIONS FOR BALLOON PTCA.

A provisional strategy consisting of balloon PTCA with "bailout" (or "provisional") stenting for lesions with abrupt or threatened closure or suboptimal (>40 percent) residual stenosis may be chosen as an alternative to primary stenting in patients with vessel size 2.75 mm or greater and lesion length less than 25 mm, although the advantages of this approach have not been documented in randomized trials. Provisional balloon PTCA may be preferred over primary stenting in small (<2.75 mm) vessels, long (
25 mm) lesions, anastomotic stenoses in SVGs, and others lesions deemed "high risk" for coronary stenting.

CORONARY ATHERECTOMY

Atherectomy devices provide symptomatic relief in patients with CAD by two primary mechanisms: (1) removal or ablation of the atherosclerotic plaque[48] and (2) improvement in vessel wall compliance by plaque fracture and excision.[49] The primary advantage of atherectomy over balloon PTCA is that a larger final minimal lumen diameter can be

achieved with atherectomy.[50] [50A] The loss index, defined as the fractional relationship between acute lumen gain and late lumen loss, is largely unchanged with atherectomy, which suggests that these devices do not lessen the degree of arterial injury and subsequent repair.[50] Atherectomy use reached its peak (30 percent of interventional procedures) between 1992 and 1994 but fell dramatically after the clinical availability of coronary stents. It is estimated that 5 to 20 percent of cases currently involve the use of atherectomy devices, alone or in combination with coronary stenting (Fig. 38-1) .

Directional Coronary Atherectomy

Directional coronary atherectomy (DCA) was first performed in coronary arteries in 1986 with large (7 French), stiff, prototype atherectomy devices. A clinical study of 873 patients treated with DCA was initiated in 1988 and reported a primary success rate (tissue removal,
20 percent reduction in diameter stenosis, and <50 percent residual stenosis after DCA alone) of 85 percent, which increased to 92 percent after adjunct PTCA.[51] Procedural complications included death (0.5 percent), nonfatal Q wave myocardial infarction (0.9 percent), and emergency CABG (4.0 percent). Six-month angiography demonstrated a 42 percent restenosis rate (
50 percent diameter stenosis). The restenosis rate was lower in de novo than restenotic lesions in both native vessels (30 and 46 percent, respectively) and SVGs (31 and 68 percent, respectively).[51]

Approximately 18 to 20 mg of macroscopic tissue is removed with DCA, although plaque excision accounts for only 70 percent of the lumen gain achieved with DCA.[52] [53] The remaining lumen improvement is achieved through mechanical dilatation by the DCA catheter, balloon PTCA, and to a lesser extent, changes in radial compliance of the vessel by excision of deep wall elastic components.[53] Intravascular ultrasound (IVUS) studies show that a substantial amount (43 to 55 percent cross-sectional narrowing) of atherosclerotic plaque remains even after "optimal DCA." [53] [54] [55]

TECHNICAL ASPECTS.

The DCA catheter contains a 9-mm, 120-degree cutting window and a contralateral, low-inflation pressure (15 to 45 psi) balloon that forces atherosclerotic plaque into the cutting window. A cup-shaped rotating (2500 rpm) cutter excises macroscopic amounts of atherosclerotic plaque and stores it in a distal collection chamber until its removal. A 6F DCA catheter is recommended for smaller vessels (<3.0 mm) and a 7F DCA device for larger ones (
3.0 mm). Use of the 5F device is unusual and reserved for subtotal occlusions, calcified vessels, or moderately tortuous vessels; the amount of plaque retrieval with this device is limited.

Large (9.5F to10F) guiding catheters are generally needed for the 5F to 7F DCA catheters. Forceful advancement of the DCA catheter and deep seating of the guiding catheter should be avoided because the stiff guiding catheter may dissect the coronary ostium or proximal portion of the vessel. Tissue removal is achieved by positioning the DCA catheter across the target lesion, inflating the balloon to 10 to 20 psi, and advancing the motor-driven cutter forward slowly. The balloon is deflated after each cut and the device rotated 45 to 90 degrees to reorient it toward the residual plaque. Higher balloon inflation pressures may be used on subsequent cuts to increase the effective working diameter of the device. Adjunct balloon PTCA is often (80 percent) performed to further improve the residual lumen diameter or, less commonly, to treat DCA-induced dissection, although it may have limited incremental benefit on the prevention of restenosis if an "optimal" IVUS-guided DCA result is achieved.[55] An "optimal" DCA result is defined as a final diameter stenosis less than 10 percent, tissue removal, and the avoidance of major clinical complications (death, Q wave myocardial infarction, or emergency CABG).

INITIAL CLINICAL RESULTS.

"Optimal" DCA generally results in low (<20 percent) quantitatively determined residual stenosis and a smooth-appearing lumen without dissection; procedural success rates greater than 95 percent have been reported by experienced centers[29] [53] [56] [57] (Table 38-2) . "Conservative" atherectomy using smaller DCA devices and no adjunct balloon PTCA results in higher (>25 percent) residual stenosis and more complications and has no benefit over balloon PTCA.[58] [59] [60]

Major complications after "optimal" DCA include procedural mortality (<1.0 percent), emergency CABG (
2.0 percent), Q wave myocardial

infarction, (<1.0 percent), and transient or sustained abrupt vessel closure (2.0 to 4.2 percent).[29] [53] [63] The occurrence of dissection resulting from guide catheter trauma,[64] distal nose cone injury, or guidewire trauma has been reduced with improvements in catheter design and greater operator experience. Other complications include perforation (1.0 percent), sidebranch occlusion (3 percent), vasospasm, "no reflow," and distal plaque embolization (2 percent).[65] The frequency of these complications, particularly atheroembolism, may be higher (13.4 percent) in SVGs.[63] No reflow can be treated with intracoronary agents such as verapamil (100 to 200 mug),[65] diltiazem (500 mug),[66] or nitroprusside (100 to 200 mug). Depending on the definition used, coronary aneurysms after successful DCA have been reported in a few cases.

Frequent (11.5 to 19.0 percent) elevations in creatine kinase isoenzymes (CK-MB) have been reported after DCA.[58] [60] Initial series reported an association between CPK-MB elevations and late mortality,[20] [59] although more recent, prospective studies suggest that clinically silent, low-level CPK-MB elevations may not be independently associated with worse outcomes[67] [68] [68A] [68B] ; the causal relationship between periprocedural myocardial necrosis and late mortality may be confounded by the degree of underlying atherosclerosis.[68] The GP IIb/IIIa blocker abciximab reduces the incidence of non-Q-wave myocardial infarction by more than 50 percent in patients undergoing DCA.[69]

LATE CLINICAL OUTCOME.

Arterial remodeling, or vessel constriction, between 1 and 6 months after DCA is the major cause of restenosis after this procedure,[54] although varying amounts of intimal hyperplasia may also occur. Significantly ($p<0.05$) lower angiographic restenosis rates are obtained in patients with discrete, native vessel lesions who undergo "optimal" DCA (31.4 percent) as compared with balloon PTCA (39.8 percent),[29] a finding attributable to the larger final lumen diameter achieved after DCA.[29] [50] "Conservative" atherectomy using smaller DCA devices (without adjunct balloon PTCA) confers no restenosis benefit over balloon PTCA.[58] [60] DCA does not reduce restenosis in de novo lesions located in the body of SVGs[63] and may lead to higher complication rates. Initial concerns that deep adventitial resection results in higher recurrence rates[70] have not been substantiated in larger series.[71]

One small (N=122) randomized trial has suggested that IVUS-guided "optimal" DCA results in lower angiographic restenosis rates than does stenting (15.8 vs. 33.9 percent; $p=0.032$), [61] although it is not known whether DCA is better than stenting when IVUS guidance is not performed. DCA has also been used prior to stent implantation for removal of atherosclerotic plaque, which potentially lessens the degree of late lumen loss and restenosis[62] [72] ; this effect was independent of the final minimal lumen diameter in one case-matched series.[73] The AMIGO Trial, a large randomized trial comparing DCA followed by stent implantation and stent implantation alone, is under way to evaluate the effect of debulking prior to stenting on the prevention of late restenosis.

INDICATIONS.

DCA may be used as an alternative to balloon PTCA to prevent restenosis in patients with de novo lesions in vessels larger than 3.0 mm. DCA may also be used in bifurcation lesions involving a large branch, ostial lesions of the right coronary artery or SVG, and the ostium of the left anterior descending artery, particularly in the case of an acute angle with the origin of the left circumflex. DCA may also be useful for the treatment of in-stent restenosis in larger vessels. Although DCA can be used successfully to rescue failed or suboptimal balloon PTCA, the availability of coronary stents has markedly reduced DCA use in this circumstance. DCA is limited in its ability to remove plaque in the presence of significant (>180 degrees) superficial calcium.[74]

Rotational Atherectomy

The rotational atherectomy (RA) device, or Rotablator (Boston Scientific, Natick, MA), is considered an atherectomy device, although ablation occurs by plaque pulverization rather than by tissue removal. RA relies on differential plaque abrasion in which inelastic tissue (i.e., calcified plaque) is selectively abraded while elastic tissue (i.e., soft plaque) is deflected away from the atherectomy burr.[75] The microparticles generated, 2 to 5 mum in diameter, pass through the coronary microcirculation and are removed by the reticuloendothelial system without interfering with the coronary microcirculation.[75] [76] Lower (140,000 rpm) rotational speeds are associated with less platelet activation and aggregation than are higher (180,000 rpm) speeds.[77] The use of GP IIb-IIIa inhibitors also reduces the degree of platelet aggregation and hypoperfusion associated with RA.[78] Although coronary flow reserve may be impaired after RA,[79] there is generally no long-term impact on

the global left ventricular ejection fraction.

TECHNICAL ASPECTS.

The Rotablator device consists of an olive-shaped, stainless steel burr with diamond chips measuring 20 to 50 mum in diameter embedded in its distal portion.[75] [80] The burr is advanced over a 0.009-inch stainless steel guidewire with a 0.017-inch radiopaque platinum coil at its distal tip. A lubricating 4.3F Teflon sheath encases the drive shaft, and a compressed-air turbine rotates it between 140,000 and 200,000 rpm. Burrs for coronary use are available in diameters ranging from 1.25 to 2.50 mm. Current guiding catheter technology allows the passage of 1.25- to 2.15-mm burrs through an 8F guiding catheter, a 2.25- and 2.38-mm burr through a 9F guiding catheter, and a 2.50-mm burr through a 10F guiding catheter.[75]

A prophylactic temporary pacemaker should be positioned prior to RA of right coronary lesions. Because vasodilator administration is routine during this procedure, all patients should be volume-expanded to avoid hypotension after nitrate or calcium channel antagonist use. Two guidewires are available for RA--a floppy guidewire and an extra-support guidewire. The floppy wire minimizes guidewire bias, thereby preventing deep plaque ablation and tissue injury in regions of angulation or vessel tortuosity, and the extra-support guidewire is useful in lesions that require added wire support for burr advancement. After the burr has been advanced just proximal to the lesion in the reference segment, the "platform" speed is adjusted to 150,000 to 180,000 rpm. Short-duration (15 to 30 seconds) burr advancements are recommended, with rapid decelerations of greater then 5000 rpm avoided.[75] Deceleration below 140,000 rpm can lead to inadvertent stalling, burr entrapment, dissection, or vessel occlusion.[75] Two to four passes are made with each burr, with 30 to 60 seconds between passes to allow coronary perfusion.

A stepped-approach (0.50-mm increments up to 2.0 mm, then 0.25-mm increments thereafter) to RA is generally used in larger (>3.0 mm) vessels or for the treatment of diffuse or heavily calcified lesions. Aggressive RA (burr-to-artery ratios of >0.7) techniques do not provide a restenosis advantage over more conservative (burr-to-artery ratio of >0.7) methods.[81] Adjunctive balloon PTCA is used in most (82 to 88 percent) cases to reduce residual percent diameter stenosis or to treat coronary dissections.[82] [83] [84]

INITIAL CLINICAL RESULTS.

RA registries have reported high (88 to 98.6 percent) procedural success rates in complex lesions[82] [83] [85] [86] (Table 38-3) . In two large multicenter series, major complications were uncommon after RA but included death (0.31 percent), Q wave myocardial infarction (1 to 2.2 percent), and emergency CABG (0.4 to 0.9 percent).[83] [84] A higher (19 percent) incidence of non-Q-wave myocardial infarction after RA was reported in one study of long (>2 cm) lesions.[89] Other complications include transient or sustained dissection (12 percent), sidebranch occlusion (3 percent), distal embolization (3 percent), and abrupt closure (5 percent).[83] "No reflow" occurs significantly more often after RA (7.7 percent) than after balloon PTCA (0.3 percent) and may be improved with the periprocedural use of intracoronary calcium antagonists[66] or pretreatment with GP IIb-IIIa antagonists.[78] Perforations are rare after RA and may be successfully treated with prolonged balloon inflation.[90] Transient bradycardia and atrioventricular block are occasionally seen during RA, particularly during RA of the right coronary artery.

The procedural outcome in complex lesions may be better after RA than after other methods of PCI. In the Excimer, Rotablator, or Balloon Angioplasty for Complex Lesions (ERBAC) Study, patients with complex native coronary lesions were randomly assigned to treatment with RA, excimer laser angioplasty, or balloon PTCA. Procedure success rates were significantly (p=0.016) higher in patients treated with RA (89 percent) than in those treated with balloon PTCA (80 percent) or excimer laser angioplasty (77 percent); major complication rates did not differ among the three groups.[87]

Predictors of major ischemic complications after RA include female gender; lesions with irregularity, lesions 4 mm or longer, or lesions with outflow obstruction; right coronary artery lesions; angulated (
60 degrees) lesions; and lesions involving a bifurcation or 4 mm or longer.[84] Predictors of "no reflow" include a recent history of myocardial infarction and a right coronary lesion.[84] [91] Larger decelerations (>5000 rpm) are also associated with higher complication rates after RA.[75]

LATE CLINICAL OUTCOME.

RA does not appear to reduce restenosis compared with balloon PTCA. Observational studies report high rates of clinical restenosis (38 percent), TLR (36 percent), and angiographic restenosis (31 to 59 percent) (see Table 38-3) . In the ERBAC Study, angiographic restenosis at 6 months was similar in patients treated with RA (57 percent), excimer laser angioplasty (59 percent), or balloon PTCA (47 percent).[87] Although smaller burrs were generally used in this study, no restenosis benefit was found in a randomized study of "aggressive" and "conservative" approaches to RA.[81] Predictors of 1-year clinical events after RA include male gender, high risk for surgery, bifurcation lesions, or lesions that are eccentric, long, or highly stenosed.[83] Two series have shown that adjunct stent placement after RA is associated with larger lumen diameter than attained with balloon

*$p<0.001$.

angioplasty alone.[86] [92] The potential benefit of plaque debulking with RA followed by coronary stenting versus stent placement alone is being evaluated in the randomized SPORT trial.

INDICATIONS.

RA is indicated in lesions not suitable for balloon PTCA because of excess procedural risk, such as ostial and heavily calcified lesions, selected bifurcation lesions, and lesions that are undilatable with balloon PTCA.[93] RA may also be useful for the treatment of in-stent restenosis,[94] with one registry series suggesting a benefit for RA over balloon PTCA in diffuse lesions.[95] Although procedural success rates are high (97 percent) with the use of RA for in-stent restenosis, clinical recurrence is common (35 percent), and high (49 percent) angiographic restenosis rates have been reported.[96] RA should be avoided in the presence of focal or extensive dissection after balloon PTCA, visible thrombus, or extremely eccentric lesions located on the outer surface of a severe bend. The benefit of RA over balloon PTCA in long lesions is not known.

Transluminal Extraction Atherectomy

The transluminal extraction catheter (TEC) (InterVentional Technologies, San Diego, CA) is an over-the-wire, flexible aspiration device that uses a tip-mounted cutting blade and external vacuum to excise and remove thrombus and soft plaque from native vessels and SVGs.[97] The TEC device is less useful for removing laminated thrombus in large SVGs or for the excision of fibrous or fibrocalcific plaque.

TECHNICAL ASPECTS.

The TEC device contains two rotating (750 rpm) stainless steel blades attached to the distal end of the catheter. A hand-held motor drive unit attaches to the proximal end of the cutting catheter, and a vacuum bottle connected to the TEC instrument is used for collection of aspirated atheroma, thrombus, and other debris. A 10F guiding catheter is needed for larger (7.0F and 7.5F) TEC devices, and a 9F guide is used for smaller (5.5F, 6.0F, and 6.5F) ones. A specially designed 300-cm-long, 0.014-inch guidewire with a 2-cm floppy tip terminating in a 0.021-inch ball tip is used to advance the TEC device between two and five times across the lesion. Additional atherectomy or thrombectomy may be performed with larger devices guided by intermittent angiography to assess the residual percent diameter stenosis.

INITIAL CLINICAL RESULTS.

The TEC device has been used for large thrombus-containing lesions and as primary or "rescue" treatment of patients with acute myocardial infarction.[98] Procedural success rates up to 94 percent can be achieved with optimal technique.[98] Complications after TEC use include death (0 to 5.9 percent), emergency CABG (0.7 to 3.9 percent), myocardial infarction (2.0 to 7.8 percent), and a need for transfusion (19 percent).[48] [98] [99] Other angiographic complications include sidebranch occlusion (2.7 percent), abrupt closure (2.7 percent), guide catheter dissection (2.2 percent), perforation (2.2 percent), and distal embolization (0.5 to 12.8 percent).[99] [100] [101] [102] [103]

The TEC or PTCA in Thrombus-Containing Lesions (TOPIT) Trial, a randomized study of 245 patients with unstable or postinfarction angina and thrombus-containing lesions, was performed to assess the value of TEC and balloon PTCA in these "high-risk" patients.[104] The composite rate of in-hospital major adverse cardiac events (death, myocardial infarction, bailout intervention, or emergent CABG) was 4.5 percent in patients treated with TEC and 11.2 percent in patients treated with balloon PTCA ($p=0.06$). A CPK-MB level greater than three times normal occurred significantly ($p=0.03$) less often in the TEC group (4.5 percent) than in the balloon PTCA group (15.4 percent). The TEC instrument has also been used in patients with friable SVG lesions with modest (80 to 90 percent) procedural success.[49] [99] [101] [103] Residual stenoses greater than 50 percent and frequent (33 percent) dissections require that adjunctive balloon angioplasty be used in most (90 percent) cases.[49] [99] Use of the TEC device to treat complex native coronary lesions without thrombus has met with more limited (85 to 95 percent) success.[100] [104]

LATE CLINICAL OUTCOME.

Extraction atherectomy does not reduce restenosis more than balloon PTCA does. Six-month clinical follow-up after TEC use demonstrated that late cardiac death (1.9 to 11 percent), Q wave myocardial infarction (1.3 to 4 percent), and repeat TLR (25.3 to 34.8 percent) were common,[49] [98] [100] probably related to the frequent treatment of friable SVG lesions in these series. Angiographic restenosis (>50 percent follow-up diameter stenosis) occurred in 52 to 69 percent of lesions treated with the TEC device[49] [99] and late vessel total occlusion was found in 11.9 to 29 percent.[49] [100]

INDICATIONS.

TEC atherectomy currently has limited clinical use but may be indicated for the removal of fresh thrombus in SVG and selected native vessel lesions. TEC should not be used for the treatment of dissection caused by other devices, in cases of extreme angulation or calcification, or in vessels less than 2.5 mm in diameter. TEC atherectomy is not useful for routine atherectomy in native vessels or SVG lesions.

ABLATIVE LASER-ASSISTED ANGIOPLASTY

Despite encouraging preclinical studies,[105] laser angioplasty has neither lowered procedural complications nor reduced restenosis in comparison to balloon PTCA.[87] [106] [107] [108] [109] Laser angioplasty is now reserved for a small subset of patients with complex lesion morphology unsuitable for therapy with other devices.

TECHNICAL ASPECTS.

Light amplification by stimulated emission of radiation (LASER) is the process of creating a high-energy, coherent beam of monochromatic light. Different wavelengths (ranging from 300 nm for ultraviolet light to 1,000 to 2,000 nm for infrared light) are produced, depending on the laser medium used. The xenon chloride (XeCl) excimer laser emits light at 308 nm (in the ultraviolet range), whereas the neodymium yttrium-aluminum-garnet (Nd:YAG) laser emits light above 2000 nm (in the infrared light range). Depending on the laser source, tissue ablation results from either vaporization of tissue (photothermal effects), ejection of debris (photoacoustic effect), or direct breakdown of molecules (photochemical dissociation).[110] Ultraviolet lasers result in atherosclerotic plaque absorption, whereas near-infrared lasers result in

thermal energy and photocoagulation (e.g., holmium:YAG). Photoacoustic injury is worsened in the presence of blood and contrast agents.[111]

Two systems are currently available for use in coronary arteries: the XeCl excimer laser coronary angioplasty (ELCA) system and the Ho:YAG laser system. The ELCA system uses a catheter containing a concentric or eccentric array of 61- to 200-mm optical fibers emitting laser light at 308 nm,[110] [112] and the Ho:YAG system has a catheter containing 37 fibers and operates at a wavelength of 2100 nm.[113] A single, slow (0.5 to 1.0 mm/sec) pass of the laser catheter should be performed under fluoroscopic guidance for both systems. The saline flush technique makes certain that all blood and contrast medium are removed from the coronary artery by flushing the guide catheter with 30 ml or more of saline to minimize the degree of photoacoustic injury to the surrounding vessel.[114] [115] After successful laser passage, adjunctive balloon PTCA is needed in most (90 percent) cases to reduce the residual stenosis to below 30 percent.[116] [117] [118]

INITIAL CLINICAL RESULTS.

Clinical success rates with the ELCA system in complex lesion morphologies have ranged from 84 to 94 percent.[87] [106] [107] [119] [120] Three randomized trials have compared procedural outcomes with laser angioplasty and balloon PTCA. The Laser Angioplasty Versus Angioplasty (LAVA) Trial evaluated 215 patients randomly assigned to treatment with "laser-facilitated balloon angioplasty" using the holmium (TAG) laser system or balloon PTCA.[106] No differences were noted in early or late major clinical events between the two groups, although complications occurred significantly (p=0.0004) more often in laser-treated patients (18.0 percent) than in balloon PTCA-treated patients (3.1 percent).[106] The ERBAC Trial randomly assigned 620 patients with type B and C lesions to treatment with ELCA, RA, or balloon PTCA.[87] Procedural outcome and complication rates were similar in patients undergoing ELCA or balloon PTCA.[87] The Amsterdam-Rotterdam (AMRO) Trial randomly assigned 308 patients with lesions 10 mm or longer to treatment with ELCA or balloon PTCA.[108] Procedural success rates were similar in patients treated with ELCA (80 percent) and balloon PTCA (79 percent).[108] The late restenosis rate was 51.6 percent in the laser group and 41.3 percent in the balloon-PTCA group.[108]

ELCA has also been used to treat aorto-ostial and shaft SVG lesions, longer (>15 mm) SVG lesions, lesions located in larger (>3.0 mm) friable SVGs, and lesions undilatable with balloon PTCA.[117] [119] Although laser angioplasty has been frequently used in total occlusions,[121] no restenosis benefit was shown with laser angioplasty over balloon PTCA in one study[107] two large registry series have reported the results of ELCA for the treatment of in-stent restenosis[122] [123] ; a trend toward reduced clinical events was observed in a nonrandomized series.[123] The ongoing Laser Angioplasty Restenosis Study (LARS) compares late angiographic and clinical outcomes in patients treated with ELCA or balloon PTCA for in-stent restenosis.

LATE CLINICAL OUTCOME.

Laser angioplasty does not reduce the occurrence of restenosis, with 47 to 54 percent of patients experiencing symptom recurrence after laser angioplasty.[87] [106] [108] [118] [121] The postprocedural lumen diameter is the most important predictor of restenosis in these series.[118] [120]

INDICATIONS.

Laser angioplasty has a limited role in PCI and is reserved for patients with in-stent restenosis, particularly those in SVGs, aorto-ostial SVG lesions, and potentially,

Figure 38-2 *A,* Thrombosed saphenous vein graft (SVG) to the obtuse marginal branch in a patient with unstable angina. *B,* An Angiojet thrombectomy catheter was used to remove thrombus within the vessel (arrow). *C,* A 4.0-mm Crown stent was deployed in the proximal segment of the SVG. *D,* Final angiographic result without evidence of distal embolization.

lesions located in friable SVGs. Laser angioplasty should not be used in patients with thrombus or in the presence of severe calcification.

CATHETER-BASED THROMBOLYSIS AND MECHANICAL THROMBECTOMY

Coronary thrombus mediates acute coronary syndromes in native coronary arteries and SVGs.[124] The presence of thrombus within the native vessel or SVG imparts a substantial risk for distal embolization, "no reflow," or other embolic complications during PCI.[125] [126] Embolic complications in patients undergoing PCI of a degenerated SVG may also occur as a result of distal fragmentation of atheromatous debris and fibrointima caused by mechanical contact with the SVG.

CATHETER-BASED THROMBOLYTIC USE.

Infusion catheters for intraluminal urokinase administration have been used for the treatment of thrombotic total occlusions in native arteries[127] [128] and SVGs.[129] Recanalization of occluded SVGs was achieved in 69 percent of patients with an average of 3.7 million units of urokinase given by direct catheter-based infusion over a period of 25.4 hours in one study.[129] These favorable results were tempered by a stroke rate of 3 percent and overall mortality rate of 6.5 percent. A randomized study of 469 patients undergoing PCI for unstable angina found that prophylactic use of intracoronary urokinase was associated with a higher (10.2 percent) incidence of abrupt closure (vs. 4.3 percent in placebo-treated patients; p<0.05).[130] This unexpected outcome was possibly caused by plaque hemorrhage and dissection, reduced intimal sealing, or the procoagulant effects of urokinase as a result of platelet activation.

Urokinase may also be delivered directly to the thrombus surface by local drug delivery systems. The Dispatch catheter, an over-the-wire, nondilatation catheter with a 20-mm spiral inflation coil at its tip, has been used to deliver urokinase and has resulted in thrombus dissolution in native coronary and SVG lesions.[131] A hydrogel-coated balloon has been used as a drug delivery system to transfer urokinase locally to the site of thrombotic obstruction.[132] In aggregate, local

Figure 38-3 *A,* Degenerated saphenous vein graft (SVG) to the posterior descending artery with a diffuse stenosis in the proximal segment of the SVG (arrow). *B,* Normal distal perfusion of the SVG with demonstration of secondary and tertiary branches. Positioning of the PercuSurge balloon in the distal portion of the SVG *(C,* arrow) and a 4.0-mm stent in the proximal SVG (*D*) resulted in minimal residual stenosis (*E*) and no evidence of distal embolization (*F*).

thrombolytic therapy has had a limited role in the treatment of patients with unstable angina because of the efficacy of other therapies, such GP IIb-IIIa inhibitors, and the bleeding complications associated with urokinase.

THROMBECTOMY DEVICES.

The Cordis Hydrolyzer removes thrombus by Venturi vacuum suction with the use of an external MedRad power injector. Limited European use of this device has been reported in humans in peripheral vessels,[133] hemodialysis shunts,[134] and coronary artery and SVG lesions.[135] Low-frequency (41.9 kHz) intracoronary ultrasound as in the Acolysis system is used therapeutically for thrombolysis.[136] The ATLAS Trial, a randomized clinical trial evaluating use of the Acolysis catheter and abciximab for the treatment of thrombus-containing SVG lesions, is under way.

RHEOLYTIC THROMBECTOMY.

The Angiojet (Possis Medical, Inc., Minneapolis, MN) is a 5F catheter with a stainless steel tip connected to a high-pressure flexible cylinder, or hypotube. Saline is injected into the hypotube at the distal tip, where three high-speed saline jets are directed toward the proximal end of the catheter lumen. Venturi suction is created at the catheter tip, and surrounding blood, thrombus, and saline are entrained into the tip opening. The jets fracture the thrombus into small particles and propel the fragments proximally through the catheter lumen, where they are removed from the body. Repeated passes of the Angiojet may be performed until angiography shows no further evidence of improvement in lumen diameter or thrombus burden (Fig. 38-2) .

Angiographic thrombus was reduced by 86 percent with the Angiojet in a multicenter registry of 90 patients with acute ischemic syndromes and evidence of intraluminal thrombus.[137] The Angiojet was successfully delivered in all cases, and the overall procedural success rate was 87 percent. Two (2.2 percent) procedure-related deaths occurred within 30 days of the procedure. Other complications included a reduced final TIMI flow grade of less than 3 (4.4 percent), persistent abrupt closure (3.3

percent), and coronary perforation (1.1 percent). The TLR rate was 15.6 percent and the overall target vessel failure rate was 27.5 percent at 1 year. The VEGAS-2 trial randomly assigned 349 patients with angiographic thrombus to treatment with the Angiojet or prolonged intraluminal urokinase consisting of a 250,000-unit bolus over a 30-minute period, followed by urokinase at 20,000 to 240,000 units/hr for 6 to 30 hours.[138] No significant differences were observed in the primary endpoint, target vessel failure, which is defined by at least one of the following: (1) occurrence of a major clinical event, i.e., death, myocardial infarction, or revascularization; (2) failure to achieve less than 50 percent diameter stenosis; (3) presence of final TIMI flow of less than 3; or (4) failure to achieve greater than 20 percent improvement in stenosis severity.[138] The procedure success rate was higher and the complication rate was lower in Angiojet-treated patients.[138]

The Angiojet is currently indicated in patients with moderate to large thrombus-containing native vessels or SVGs prior to definitive therapy with balloon PTCA and stents. The Angiojet is useful for the treatment of recent thrombus, particularly in the setting of acute myocardial infarction or failed thrombolytic therapy. The Angiojet should not be used in small (
2.0 mm) vessels because of the risk of perforation.

DISTAL EMBOLIC PROTECTION DEVICES.

Several devices have been developed to prevent (or trap) macroparticulate embolic material from passing into the distal microcirculation during PCI. The PercuSurge Guardwire is a compliant balloon mounted on a hypotube that can function as a 0.014-inch steerable guidewire for catheter transport.[139] Once positioned across the lesion, the balloon is inflated to block the flow of blood in the vessel and PCI is performed over the Guardwire. Liberated debris is trapped by the inflated Guardwire balloon, and an aspiration catheter is used to remove blood and suspended debris. The Guardwire balloon is then deflated and distal flow to the vessel is restored. The aspirated material contains thrombus and macroparticulate atheromatous debris.[139] This device and others are now undergoing clinical evaluation in patients at risk for distal embolization during PCI (Fig. 38-3) .

CORONARY STENTS

Coronary stents have fundamentally changed the practice of interventional cardiology by reducing early complications and improving late clinical outcomes in a broad array of patients. Charles Dotter introduced the concept of a temporary endoluminal splint to scaffold an occluded peripheral vessel nearly 40 years ago,[140] but the first human coronary implantation was not performed until 1986, when Puel and colleagues[141] and, subsequently, Sigwart and associates[142] deployed self-expanding stents to prevent abrupt closure and reduce restenosis after balloon PTCA. Over the next decade an explosive growth in the use of coronary stents took place as a result of both an expanding number of randomized trials demonstrating benefit in specific lesion subsets and clinicians' empirical satisfaction with the early and late benefits of stents (Fig. 38-4) .

Although it is estimated that 50 to 80 percent of PCI procedures now involve the use of at least one stent,[143] the majority of patients receiving a stent do not meet the criteria for currently approved indications. In a series of 700 patients, less than 20 percent would have been candidates for the initial randomized trials demonstrating the benefit of stents.[144] Expanded "off-label" coronary stent use has identified patients at "high-risk" for recurrent symptoms after stenting,[144] such as those with smaller (<2.75 mm) vessels and diffuse (lesions >25 mm) disease. One study has suggested that patients undergoing "off-label" stent use have a risk of angiographic restenosis that is nearly three times higher than observed in patients undergoing stent placement for approved indications.[144] Randomized trials with balloon PTCA in these subsets are ongoing. The results of randomized trials comparing coronary stenting and balloon PTCA are reviewed (Table 38-4) .

Indications

DE NOVO OR RESTENOTIC NATIVE VESSEL LESIONS.

At least five randomized trials have shown that coronary stent use in larger (>3.0 mm), de novo native coronary vessels is associated with an improved outcome when compared with balloon PTCA (Fig. 38-5) . In the first two of these studies, the Stent Restenosis Study (STRESS) and the Belgium Netherlands Stent (BENESTENT) Trial, Palmaz-Schatz stent placement resulted in a 26 to 31 percent reduction in angiographic restenosis and a 27 to 31 percent lowering of 1-year clinical events when compared with balloon PTCA.[30] [145] A third study, the Stent Versus Angioplasty Restenosis Trial (START), demonstrated similar findings that were maintained up to 4 years after the procedure.[149]

The benefit of stent use over balloon PTCA in restenotic lesions was shown in the Restenosis Stent (REST) Study, a randomized trial of 383 patients with restenosis after balloon PTCA who were randomly assigned to Palmaz-Schatz stent placement or repeat balloon PTCA.[146] Angiographic restenosis (>50 percent follow-up diameter stenosis) was lower (18 percent) in stent-treated patients (vs. 32 percent in balloon PTCA-treated patients; p=0.03); TLR also occurred less often (10 percent) in stent-treated patients (vs. 27 percent in balloon PTCA-treated patients; p=0.001).

ABRUPT OR THREATENED CLOSURE AFTER BALLOON PTCA.

Patients in whom periprocedural coronary occlusion develops during balloon PTCA have substantially higher morbidity and mortality than do those in whom this complication does not develop,[4] including death (4 percent),

Data from Stent Restenosis Study (STRESS),[30] Belgium Netherlands Stent (BENESTENT) Trial I[145] and II,[31] Restenosis Stent Study (REST),[146] Saphenous Vein Graft De Novo Trial (SAVED),[147] and Stenting in Chronic Coronary Occlusion (SICCO) Trial.[148]

Figure 38-5 A focal, de novo stenosis is identified in a patient treated with tissue-type plasminogen activator for acute myocardial infarction *(A*, magnified in *B)*. Direct advancement of a 3.0-mm Guidant Duet across the lesion and inflation to 16 atm *(C)* resulted in an excellent angiographic result *(D*, magnified in *E)*.

Figure 38-6 *A,* Emergency coronary arteriography in a patient with an acute myocardial infarction demonstrates a total occlusion in the midportion of the left anterior descending coronary artery (LAD). *B,* A "nipple" found on a magnified view (arrow) allowed an entry point for the coronary guidewire to pass into the distal segment of the LAD. Reperfusion is reestablished *(C),* and a 3.5-mm stent deployed at the site of occlusion *(D)* resulted in 0% residual stenosis and TIMI 3 flow into the distal part of the vessel *(E)*.

myocardial infarction (20 percent), or the need for urgent CABG (7 percent).[4] Self-expanding[141] [142] and balloon-expandable coiled[150] and slotted tube[151] stents were first used to scaffold coronary dissections in patients with balloon PTCA-induced complications. The Trial of Angioplasty and Stents in Canada (TASC II), a randomized evaluation of 43 patients with abrupt closure assigned to primary Palmaz-Schatz stent placement or prolonged autoperfusion balloon PTCA with "bailout" stent placement, showed a higher clinical success rate in stent-treated patients (90 vs. 42 percent).[152] Subsequent attempts to compared prolonged balloon inflation with primary stent placement for abrupt closure were unable to recruit patients[153] given the dramatic effect that stents had on the correction of major coronary dissections and avoidance of emergency CABG. Stents are currently indicated for the treatment of abrupt and threatened closure after balloon or new device PCI.

SAPHENOUS VEIN GRAFTS.

Although balloon PTCA of SVG lesions is associated with high (88 percent) procedural success rates,[154] clinical recurrence because of restenosis or progression of disease at other SVG sites is common.[154] Restenosis rates are highest in ostial lesions (58 percent) and in the body of the SVG (52 percent).[154] The Saphenous Vein Graft De Novo (SAVED) Trial randomly assigned 220 patients with de novo SVG lesions to treatment with Palmaz-Schatz stent placement or balloon PTCA alone.[147] Stenting was associated with higher procedural success rates (92 vs. 69 percent in balloon-treated patients; $p<0.001$) at the expense of more bleeding events (17 vs. 5 percent in balloon PTCA-treated patients; $p<0.01$) attributable to the aggressive anticoagulation regimen used in this study. Although restenosis was not significantly lower in stent-treated patients (37 percent) than in balloon PTCA-treated patients (46 percent), freedom from significant cardiac events was better in the stent group (73 vs. 58 percent in balloon PTCA-treated patients; $p=0.03$). [147] Stents are the preferred therapy in patients with ostial or body SVG lesions. The risk of "no reflow" or distal embolization is higher in patients with severe SVG friability and in those with SVG thrombus.

TOTAL CORONARY OCCLUSIONS.

Balloon PTCA of chronic coronary occlusions is associated with reduced (47 to 69 percent) procedural success[155] [156] [157] and frequent (45 to 55 percent) recurrence,[158] [159] [160] [161] often (19 percent) as total coronary occlusion. Procedural success rates with total occlusion have steadily increased over the past several years, partly as a result of the introduction of hydrophilic guidewires[162] for crossing the occluded segments, but late (6 to 9 months) recurrence rates remain high (Fig. 38-6) .

After beneficial results were shown in pilot studies,[163] [164] three randomized trials confirmed the benefit of stent placement over balloon PTCA alone in patients with chronic occlusions.[148] [165] [166] In the Stenting in Chronic Coronary Occlusion (SICCO) Study, 119 patients with successful balloon PTCA of a chronic coronary occlusion were assigned to no further intervention or to Palmaz-Schatz stent placement.[148] Angiographic restenosis occurred less often in stent-treated patients (32 percent) than in patients receiving no further therapy (74 percent) ($p<0.001$). TLR was also needed less often in stent-treated patients (22 percent) than in balloon PTCA-treated patients (42 percent) ($p=0.025$). [148] This benefit was sustained at late follow-up.[167] In the Gruppo Italiano per lo Studio sullo Stent nelle Occlusioni Coronariche (GISSOC) trial, 110 patients with total occlusions successfully treated by balloon PTCA were assigned to Palmaz-Schatz stent implantation or to no further

Figure 38-7 Acute posterior wall myocardial infarction caused by an acute left circumflex coronary artery in the right anterior oblique *(A,* arrow) and left anterior oblique *(B,* arrow) projection. A 3.0-mm balloon was used to recanalized the vessel *(C),* and placement of two 3.5-mm S670 stents resulted in an excellent final angiographic result *(D)*.

therapy. Angiographic restenosis occurred less often in stent-treated patients (32 vs. 68 percent in patients without stent placement; $p<0.001$). Stent-treated patients also had lower rates of reocclusion (8 vs. 34 percent; $p=0.003$) and TLR (5.3 vs. 22 percent; $p=0.038$).[165] A third study showed similar benefit with the Wiktor stent.[161]

ACUTE MYOCARDIAL INFARCTION.

When compared with thrombolytic therapy, primary balloon PTCA improves TIMI 3 flow rates and reduces the frequency of mortality, reinfarction, and stroke[168] [169] [170] [171] [172] [173] [174] (Fig. 38-7) . Primary balloon PTCA is limited in some cases by recurrent in-hospital ischemia or reinfarction (10 to 15 percent), restenosis (37 to 49 percent), or late reocclusion (9 to 14 percent).[175] Failed primary balloon PTCA is associated with high (31 percent) in-hospital mortality rates and occurs more often in patients in cardiogenic shock and those with multivessel CAD.[176]

Stent placement may be useful in patients with acute myocardial infarction, either as primary therapy or as a "bailout" for the treatment of coronary dissection or residual stenosis after balloon PTCA. In a pilot multicenter study of 312 patients treated with primary PCI for acute myocardial infarction, stent placement was attempted in all eligible patients, provided that the infarct-related artery was between 3.0 and 4.0 mm, the lesion required only one or two stents, and no large

thrombus, major sidebranch jeopardy, or excessive proximal tortuosity or calcification in the infarct-related artery occurred after PTCA.[177] Stenting was performed in 77 percent of patients and was successful in 98 percent, with TIMI 3 flow in 96 percent. Patients treated with stents had low rates of in-hospital death (0.8 percent), reinfarction (1.7 percent), recurrent ischemia (3.8 percent), and predischarge TLR for recurrent ischemia (1.3 percent).[177]

Smaller randomized trials comparing primary stenting and balloon PTCA in patients with acute myocardial infarction have shown a benefit for primary stent placement.[178] [179] [180] [181] [182] The Primary Angioplasty in Myocardial Infarction (PAMI) stent trial randomly assigned 900 patients with acute myocardial infarction to treatment with primary balloon PTCA or placement of the Palmaz-Schatz heparin-coated stent.[183] After 6 months, fewer patients in the stent group had angina (11.3 vs. 16.9 percent in the balloon group; p=0.02) or needed TLR (7.7 vs. 17.0 percent in the balloon group; p<0.001). Angiographic restenosis also occurred less often in stent-treated patients (20.3 vs. 33.5 percent in balloon-treated patients; p<0.001). [183]

Based on these results, primary PTCA (and primary or "provisional" stent placement) is indicated as an alternative to thrombolytic therapy in patients with acute myocardial infarction who are seen within 12 hours of symptom onset (or
12 hours with persistent symptoms), provided that the door-to-balloon time is less than 90 minutes, the hospital performs more than 200 PCI procedures per year, and the operator meets the ACC/AHA proficiency standards of more than 75 cases per year.[184] Primary PTCA is also indicated in patients in cardiogenic shock, provided that revascularization can be performed within 18 hours of the onset of cardiogenic shock, and in patients who have a contraindication to thrombolytic therapy.[184]

OTHER LESION SUBSETS.

It is less clear whether primary stent placement is preferred over balloon PTCA with "bailout" stenting in other lesion subsets.[184A] Although a subset analysis of STRESS suggested an advantage of stenting over balloon PTCA in smaller (<3.0 mm) vessels,[185] other studies have shown a worse outcome when stents are used in this setting.[143] It is not known whether primary stenting (vs. balloon PCA with "bailout" stenting) is preferred in bifurcation lesions, diffuse disease, ostial lesions, or unprotected or protected (Fig. 38-8) left main lesions in patients with patent grafts to one or more left coronary territories.[143] Larger trials in the subsets are ongoing.

Complications

THROMBOSIS.

The early use of coronary stents was limited by high (3.5 to 8.6 percent) subacute thrombosis rates[30] [145] [151] [186] [187] [188] despite aggressive antithrombotic therapy with aspirin (
325 mg daily), dipyridamole (225 mg daily), periprocedural dextran 40, and intravenous heparin followed by oral warfarin. Clinical events associated with subacute thrombosis were profound, virtually always resulting in an untoward outcome (e.g., death, myocardial infarction, or emergency revascularization). Patients at "high-risk" for subacute thrombosis included those with unstable angina, residual proximal or distal dissection, angiographic thrombus or a filling defect, in-laboratory transient or sustained abrupt closure, multiple (more than three) stent implants, smaller (<3.0 mm) vessels, total occlusions, complex (type "C") morphology, left anterior descending or left circumflex lesion location, failed balloon PTCA, or recent (<1 week) myocardial infarction. Anatomical factors after stent deployment (e.g., underdilation of the stent, proximal and distal dissections, poor inflow or outflow obstruction, <3-mm vessel diameter) appeared to play more of a role than did suboptimal anticoagulation regimens in the development of subacute thrombosis in the early stent experience.[189] [190] [191] Lower frequencies of subacute stent thrombosis have been achieved with optimal stent deployment.[190]

Prompt vessel recanalization is paramount for the management of subacute thrombosis after stent placement. Although repeat balloon dilatation and, less commonly, CABG are the most prompt and effective methods of establishing reperfusion, intravenous thrombolysis should be used when a catheterization facility is not readily available.[192] Although recanalization can often be achieved after subacute thrombosis within 2 hours of symptom onset, myocardial infarction may still occur.[192]

BLEEDING.

Hemorrhagic complications were a major limitation associated with the use of coronary stents,[30] [145] [193] [194] particularly when aggressive anticoagulation regimens that included warfarin (Coumadin) were used. The introduction of reduced anticoagulation regimens has had a profound impact on the reduction of bleeding complications after stent placement. Brachial[195] and radial[196] [197] access sites, percutaneous vascular closure devices, and collagen implants have also reduced bleeding complications with modest success.[198] The safety and efficacy of collagen implants for sealing the femoral puncture site after stent implantation have also been evaluated.[198]

OTHER COMPLICATIONS.

Other problems include sidebranch occlusion (6 to 14 percent),[199] particularly in bifurcation lesions involving the origin of the sidebranch.[200] The clinical importance of the sidebranch occlusion relates to the size of the sidebranch and extent of myocardium that the sidebranch supplies. Open-cell and coiled stent designs may provide better access to sidebranches than afforded by

Figure 38-8 Complex stenosis involving the distal segment of the left main and proximal segment of the left anterior descending coronary arteries *(A,* arrow). After predilation, placement of a 3.0×18 mm NIR stent across the stenosis *(B)* resulted in the final angiographic result *(C)*.

the closed-cell, tubular slotted stent designs. Stent dislodgment from the delivery catheter is an uncommon occurrence with second- and third-generation stents with enhanced retention designs, but it may occur more often when stents are "hand-crimped" onto a balloon catheter. Stent embolization within the coronary artery is generally benign.[201] Stent margin dissections can occur during stent deployment or during postdeployment stent dilatation, particularly when stent dilatation strategies are directed at maximizing the internal stent diameter. The availability of shorter (15 mm), noncompliant balloons allows more precise stent dilatation when using high (16 atm) pressure, thereby reducing the frequency of edge dissections. Coronary perforation is also an uncommon occurrence after stent deployment, but it may occur during poststent deployment dilatation with an oversized balloon inflated to high pressure. No evidence indicates that higher balloon inflation pressures predispose to higher rates of stent restenosis.

RESTENOSIS.

"Very late" (>1 year) restenosis is a rare occurrence after coronary stenting in native coronary arteries. Three-year angiographic and clinical follow-up was obtained in 143 patients (147 lesions) who underwent Palmaz-Schatz stent placement in native coronaries.[202] After 14 months, TLR was necessary in only 2.1 percent of patients, whereas balloon PTCA of a new lesion was required in 7.7 percent of patients. Follow-up coronary angiography showed no further decrease in minimal lumen diameter between 6 months and 1 year (1.95 mm in both groups), as well as a significant (p<0.001) improvement in minimal lumen diameter between 6 months (1.94 mm) and 3 years (2.09 mm).[202] Similar very late improvements in lumen diameter have been reported in two other series,[203] [204] and sustained improvement in the very late (3 to 9 year) clinical outcomes of patients treated with stents has also been reported.[205] [206]

Designs

A number of balloon-expandable and self-expanding stents have become available for clinical use over the past several years (Tables 38-5 and 38-6) . Each of these stents varies with respect to its metallic composition, strut design, stent length, delivery and deployment system, and arterial surface coverage, among other factors. One classification system suggested for stent design includes mesh stents, tubular stents, coil stents, ring stents, multidesign stents, and custom-designed stents.[207] Given the proliferation of new stent designs, it is likely that the classification system for stent design will also remain in continuous evolution. A number of stent-versus-stent trials have been used to evaluate the clinical equivalency of these stent designs. Although no stent has proved superior to the Palmaz-Schatz design for the prevention of restenosis in these series, substantial differences in clinical outcome may be found with the various stent designs as their use is expanded beyond the scope of randomized clinical study.[208]

PALMAZ-SCHATZ STENT.

The Palmaz-Schatz PS-153 stent (Cordis Corp., Warren, NJ) is a 15-mm, articulated slotted tube composed of 316L stainless steel that is available on a 5F delivery sheath in the United States or as a freestanding stent that is "crimped" onto a conventional balloon outside the United States. The Palmaz-Schatz stent was the first to show superiority over balloon PTCA for the prevention of restenosis[30] [145] [147] and has also been used for the treatment of major dissections and acute and threatened closure.[151] [209] Its slotted tube design imparted high radial compressive strength and yielded symmetrical expansion after deployment. The Palmaz-Schatz stent is no longer used clinically because it is relatively inflexible, is available in only a single 15-mm length, has a 1-mm articulation defect, which is a potential site for restenosis because of protrusion through the articulation site, and lends tenuous access to large sidebranches, among other factors. Because of deformation of the PS-153 at larger expansion diameters, other slotted tube stents, e.g., the P-104, P-154, and PS-204 biliary stents, were used "off-label" for the treatment of large (>4.0 to 5.0 mm) native coronaries and SVGs.[210] Newer stent designs with larger expansion diameters have obviated the need for these stents in current practice.

THE GIANTURCO-ROUBIN STENT.

The Gianturco-Roubin (GR) stent was the first stent approved for the treatment of abrupt vessel closure after balloon PTCA.[211] The GR stent is composed of a single 0.006-inch 316L stainless steel wire coiled into a series of interdigitating loops in a "clamshell" design; its 25-mm length provided adequate coverage for lesions up to 20 mm long. The major limitations of the first-generation GR stent were its relative inflexibility, requirement for larger (8F to 9F guides) guiding catheters for 3.5- and 4.0-mm stents, and an inability to precisely localize the position of the stent after deployment. The second-generation GR-II stent, available in 20- and 40-mm lengths, has gold radiopaque markers at both ends of the stent to allow easy visualization of the proximal and distal stent margins. A flat wire design and a central articulation spine prevent stent axial shortening on expansion. The GR-II stent is approved for the treatment of abrupt and threatened closure after balloon PTCA. It has limited use because of high restenosis rates associated with the clinical use of this stent.[212]

THE WIKTOR CORONARY STENT.

The Medtronic Wiktor stent is composed of a 0.005-inch tantalum wire arranged in a sinusoidal helical wave. Its radiopacity, preserved access to sidebranches, and flexibility led to its clinical evaluation and subsequent Food and Drug Administration approval for the treatment of abrupt and threatened closure after balloon PTCA.[213] The major disadvantages of the Wiktor stent are its potential for longitudinal elongation and lack of radial scaffolding in ostial lesions. Unraveling of the stent wire may also occur during withdrawal of the balloon catheter, from guide catheter trauma,[214] or after high-pressure balloon dilatation.

THE MULTILINK AND DUET STENTS.

The Multilink stent (Guidant Corp., Santa Clara, CA) is a 15-mm balloon-expandable, stainless steel stent designed with multiple rings connected by multiple links. The Multilink stent provides unique longitudinal flexibility, high radial compressive strength, minimal (<5 percent) longitudinal shortening after deployment, and lack of an articulation defect. A low (16.0 percent) restenosis rate was reported in the ASCENT Trial.[215] The DUET stent, a more flexible, radiopaque, next-generation balloon-expandable stent, is approved for the prevention of restenosis in larger (>2.75 mm) native vessels and for the management of abrupt or threatened closure. Strut thickness has been increased from 0.0022 to 0.0055 inches, and to improve stent flexibility, the shape of the ring has been rounded at its apex and the number of articulations between repeating units has been decreased from three articulations per unit to alternating three and two articulations per unit.[207] Edge dissections have been noted after clinical use of the DUET stent and are due to proximal and distal balloon margins up to 1.8 mm beyond the axial stent length and asymmetrical stent expansion as a result of stent compression from "dogboning" of the balloon if the balloon is inflated too rapidly. The TriStar stent with its very short (0.4 mm) balloon margin and a novel centering technology has reduced the frequency of these findings in early clinical experience; this stent was approved for clinical use in the United States in December 1999.

AVE MODULAR STENTS.

The Microstent II (Medtronic-Arterial Vascular Engineering, Santa Rosa, CA) is a balloon-expandable stent with 3-mm ring segments arranged in a zigzag design with eight axial struts connected by four crowns. Its major advantages are its marked flexibility in tortuous vessel and through previously deployed stents and its radiopacity for precise positioning in ostial locations or in bifurcation lesions. The Microstent II[216] has been progressively replaced with subsequent generations of the stent, the GFX and GFX-2 and, more recently, the S670 on the discrete balloon. These stents have shortened the repeating subunit from 3 to 2 mm for the GFX and GFX-2 stents and 1.5 mm for the S670 stent; these changes were accompanied by an increase in the number of crowns and laser junction points per unit. The S670 and S660 (for vessels <2.75 mm) are broadly functional stents that are distinguished by their ability to position the stent in distal lesions with proximal tortuosity and through previously stented regions.

THE NIR STENT.

The NIR stent (Boston Scientific, Natick, MA) is a balloon-expandable stent composed of 316L stainless steel that is etched from a metal sheet, folded, and welded into its slotted tube design.[207] The NIR stent has seven or nine closed cells around its circumference[207] that impart a unique "transformable geometry" resulting in longitudinal flexibility during stent advancement and radial strength after stent deployment. The NIR stent provides symmetrical arterial scaffolding, and the smooth initial angiographic lumen contour is associated with infrequent late clinical events.[217] An equivalency study comparing the NIR stent with the PS-153 stent demonstrated comparable early and late clinical outcomes, with subsequent clinical approval in the United States.[218] Potential drawbacks of the NIR stent are its radiolucency, closed-cell design that limits access to large sidebranches, and lack of a high-pressure deployment balloon. Each of these issues has been addressed with subsequent NIR stent generations, including the NIR-ON-SOX high-pressure deployment system and the NIR Royal gold-plated stent, which enhances visualization.

THE CROSSFLEX-LC STENT.

The first-generation Cordis CrossFlex stent was a 15-mm balloon-expandable stent composed of a 0.005-inch tantalum wire arranged in a single, sinusoidal helical coil. Its major advantage was that it was flexible and radiopaque.[219] The current generation of the CrossFlex-LC is laser-cut from a 316L stainless steel hypotube configured into a dual-spine "S" wave design, now available in a broad range of diameters and stent lengths. Improved

vessel scaffolding and access to large sidebranches are the major clinical advantages of the CrossFlex-LC over previous iterations of this stent.[220] It can be applied in a broad range of lesion morphologies. The SLAM Trial will compare the results of the CrossFlex-LC and balloon PTCA for the treatment of long lesions.

RADIUS STENT.

The Radius stent is a self-expanding, multiple-zigzag, nitinol stent that has a flexible restraining sheath allowing access to distal lesions, regions of calcification, and vessels distal to previously deployed stents.[207] Proper sizing is essential because the stent will not expand beyond its parent diameter.[207] Once deployed, Radius stents that are slightly larger than the vessel diameter will continue to expand after adjunct balloon PTCA.[221] A limitation of the Radius stent is that it requires precise positioning to avoid distal stent deployment. The Radius stent was approved for use in the United States in native coronary and SVG lesions based on results of the Stent Comparative Restenosis (SCORES) Trial, which demonstrated equivalency to the PS-153 stent in late clinical outcome.[222]

THE MAGIC WALLSTENT.

The Magic Wallstent is a self-expanding, wire mesh stent composed of a cobalt-based alloy with a platinum core. The Magic Wallstent is notable for its longitudinal flexibility, but precise localization can be somewhat difficult because of its somewhat unpredictable shortening (up to 20 percent) after deployment. Its major clinical uses are large (>4.0 mm) native vessels, particularly the right coronary artery, and SVGs. Sidebranch access is limited with the use of this stent, and it cannot be expanded beyond its nominal unconstrained diameter.

Stent-Versus-Stent Equivalency Studies

The Palmaz-Schatz PS-153 stent has been the traditional "gold standard" for regulatory-based stent comparisons (Table 38-7) . A series of randomized stent-versus-stent equivalency studies were performed to ensure the safety and efficacy of late outcomes associated with newer stent designs.[216] [224] Although these studies were designed to compare freedom from late target vessel failure, i.e., procedure success and freedom from TLR, death, or large myocardial infarction, it is now apparent that selection of stents by interventionists for clinical use is based on a number of secondary factors, including the profile, flexibility, and ease of use of the stent.

Stent equivalency trials have included patients with focal or restenotic native vessel lesions approachable with one or two coronary stents (lesion length <25 mm). In general, lesions were selected for treatment if they were suitable for Palmaz-Schatz stenting, and lesions with angulation greater than 45 degrees, proximal tortuosity,

calcification, and thrombus were generally not included. It is likely

Figure 38-9 Two cases of in-stent restenosis. *A,* Diffuse in-stent restenosis in the proximal segment of the left anterior descending artery. A magnified view demonstrates diffuse tissue growth within the axial length of the stent (arrows). *B,* Another case of in-stent restenosis involving the left anterior descending artery (arrow). A focal region of renarrowing (large arrows) is seen in the proximal portion *(C)* and margin *(D)* of the stent (small arrows).

Figure 38-10 *A,* Restenosis after coronary stent placement in the midportion of the left circumflex coronary artery. *B,* After rotational atherectomy and balloon angioplasty with a 3.5-mm balloon, an excellent angiographic result is obtained. This patient was enrolled in the randomized Stent and Radiation Therapy (START) Trial, which used catheter-based brachytherapy with strontium-90. *C,* The catheter is positioned (large arrows) and the radiation source train is advanced to the midportion of the circumflex artery (small arrows) to cover the margins of the injured segment by 5 to 10 mm.

that a performance difference may have been shown with the second- and third-generation stents had more complex lesion subsets been included in the studies.

These stent trials have identified a number of multivariable predictors of angiographic restenosis, including patient age, history of diabetes, left anterior descending artery lesion location, small postprocedural minimal lumen diameters, and longer lesion and total stent length. Multivariable predictors of target vessel revascularization (or failure) after stent placement include male gender, presence of thrombus, smaller postprocedural minimal lumen or reference vessel diameters, proximal left anterior descending artery location, longer lesion and total stent length, total number of stents, type C lesions, mandated follow-up angiography, restenotic lesions, or lesion calcification.

In-Stent Restenosis

The mechanism of restenosis after stent placement in virtually all cases is neointimal proliferation within the axial stent length.[225] Recurrence of symptoms may occur in 10 to 20 percent of patients within 12 months after stent implantation; after 6 to 12 months, it appears that contraction of intimal tissue results in slightly larger lumen dimensions over time.[226] Although some patients with multivessel CAD or multiple stent restenoses are best served by referral CABG, the majority of patients with in-stent restenosis can be safety and effectively treated with repeat PCI.[227] The mechanism of benefit of balloon angioplasty relates to both expansion of the stent and extrusion of the tissue through the stent struts and axially along its length.[228] Early tissue recoil may account for loss of 2.0 mm^2 in nearly 30 percent of patients within 40 minutes of the procedure.[229] Recurrence rates after balloon PTCA for stent restenosis ranged from 11 to 17 percent in two large series,[230] [231] although higher (up to 80 percent) recurrence rates have been reported depending on vessel size, pattern of restenosis (e.g., intrastent, stent margin, or remote disease), and the time to presentation[231A] (Fig. 38-9) .

Atheroablation by DCA, RA, or ELCA has been used in patients at "high risk" of recurrence after PCI for in-stent restenosis,[227] but an advantage over conventional balloon PTCA alone has not been demonstrated in a prospective, randomized study. A consecutive registry series of 60 patients with "diffuse" native vessel in-stent restenosis compared early and late outcomes in patients treated with either conventional balloon PTCA or debulking by RA or DCA followed by balloon PTCA.[232] The procedural success rate was 100 percent in both groups, and despite longer lesion lengths in the debulking group (18.4 vs. 13.5 mm in the PTCA-only group; p=0.09), treatment with atherectomy resulted in a lower frequency of postprocedure stenoses (18 vs. 26 percent in the PTCA-only group; p=0.01). One-year repeat TLR was required in 28 percent of patients in the debulking group and 46 percent in the balloon PTCA group (p=0.18). Pending the results of additional randomized studies, it appears that debulking is most useful in patients with diffuse (>15 mm) in-stent restenosis.

Three studies have shown the value of gamma irradiation with iridium-192 in preventing angiographic and clinical recurrence in patients undergoing treatment for in-stent restenosis. In the Scripps Radiation to Inhibit Proliferation after Stent Implantation (SCRIPPS) Trial, 55 patients were randomly assigned to the iridium-192 group or placebo group after treatment of stent restenosis. Angiographic restenosis occurred in 17 percent of the iridium-treated patients and 54 percent of the placebo-treated patients (p=0.01) as a result of a reduction in late lumen loss in the iridium-192 group (0.38 vs. 1.03 mm in placebo-treated patients; p=0.03). [233] These effects have been sustained for up to 3 years after the procedure.[233A] Two other larger studies have shown similar benefits.[234] [235] Studies evaluating results of the use of beta radiation for the treatment of in-stent restenosis are ongoing (Fig. 38-10) .

ANTICOAGULATION DURING PERCUTANEOUS CORONARY INTERVENTIONS (See also Chap. 62)

The safety of PCI has been substantially improved over recent years with the routine use of conventional (e.g., aspirin, ticlopidine, clopidogrel) and novel (e.g., GP IIb-IIIa inhibitors) platelet inhibitors and conventional (e.g., unfractionated

heparin, low-molecular-weight heparin [LMWH]) thrombin inhibitors.[236] [237] [238] The safety and efficacy of second-generation direct thrombin inhibitors (e.g., hirudin, bivalirudin [Hirulog], argatroban) have also been evaluated in the setting of PCI, but their clinical use is currently limited to the setting of heparin-induced thrombocytopenia syndromes.

Antiplatelet Therapy

ASPIRIN.

This agent reduces the frequency of ischemic complications after PCI by 64 to 77 percent.[236] [239] Although the minimum effective aspirin dosage is not known, doses ranging between 80 and 325 mg are generally given 2 or more hours before PCI. The use of dipyridamole provides no incremental value over aspirin alone, so dipyridamole is not currently recommended.[240] Aspirin-intolerant patients may be treated with thienopyridine blockers of platelet adenosine diphosphate (ADP) receptors, such as ticlopidine (250 mg twice daily)[239] or clopidogrel (300-mg loading dose followed by 75 mg daily), but these agents should be given earlier than 24 hours prior to elective PCI to achieve maximum platelet inhibition.[241]

TICLOPIDINE.

In patients undergoing stent implantation, ticlopidine, as an adjunct to aspirin, reduces the frequency of 30-day clinical events, including the occurrence of subacute thrombosis.[242] [243] In a clinical trial of 517 patients at "high risk" for stent thrombosis after Palmaz-Schatz stenting, those treated with aspirin plus ticlopidine experienced a 75 percent reduction in early complications in comparison to those who received aspirin plus intravenous heparin plus phenprocoumon.[242] Patients receiving antiplatelet therapy also had an 82 percent lower risk of myocardial infarction and a 78 percent lower need for repeat balloon PTCA than did patients receiving anticoagulation therapy.[242] Bleeding complications were also lower in patients treated with antiplatelet therapy.[242] The Stent Anti-thrombotic Regimen Study (STARS) evaluated the effect of aspirin alone, aspirin plus ticlopidine, and aspirin plus warfarin on the occurrence of 30-day ischemic endpoints in 1653 "low-risk" patients undergoing successful Palmaz-Schatz stent placement.[243] Clinical events, including subacute thrombosis, were reduced by 85 percent in patients treated with aspirin plus ticlopidine.[243]

Ticlopidine has a number of significant side effects in comparison to aspirin, including gastrointestinal distress (20 percent), cutaneous rashes (4.8 to 15 percent), and liver function test abnormalities. Severe, but generally reversible neutropenia and aplastic anemia occur in 1 percent or less of patients. Rare episodes of fatal thrombotic thrombocytopenic purpura have also been reported with ticlopidine.[244] A shorter (10 to 14 days) duration of ticlopidine therapy may reduce the risk of these side effects.[245] [246]

CLOPIDOGREL.

This newer thienopyridine inhibitor of ADP-mediated platelet aggregation has also been used in patients undergoing stent placement.[247] [248] The CLASSICS trial showed no difference in clinical efficacy between clopidogrel and ticlopidine, with fewer side effects in patients treated with clopidogrel.[249] Based on randomized studies and single center registries that did not show a difference in outcome with these two agents,[250] [250A] clopidogrel may be used as an alternative to ticlopidine in

patients undergoing stent implantation.

GLYCOPROTEIN IIb-IIIa INHIBITORS.

Aspirin is only a partial inhibitor of platelet function, and early ischemic events develop in 3.0 to 12.8 percent of aspirin-treated patients undergoing PCI.[5] [6] [9] Thrombin and collagen are potent platelet agonists that can cause ADP and serotonin release and activate GP IIb-IIIa fibrinogen receptors on the platelet surface.[251] Functionally active GP IIb-IIIa activation serves as the "final common pathway" of platelet aggregation by binding fibrinogen and other adhesive proteins that bridge adjacent platelets.[252] A number of intravenous and oral inhibitors of the GP IIb-IIIa receptor have been developed for clinical use.

ABCIXIMAB

The safety and efficacy of abciximab was first evaluated in the Evaluation of 7E3 for the Prevention of Ischemic *C*omplications (EPIC) Trial, a clinical study of 2099 patients at "high risk" for complications after PCI[19] (Table 38-8) . "High-risk" criteria included patients with acute myocardial infarction, refractory unstable angina, and "high-risk" clinical and angiographic features. All patients received aspirin 325 mg and a non-weight-adjusted, 10,000- to 12,000-IU heparin bolus prior to PCI and were then randomly assigned to treatment with placebo, a bolus of abciximab 0.25 mg/kg, or the same bolus of abciximab followed by a 12-hour abciximab infusion at 10 mug/min. Bolus and infusion abciximab was associated with a 35 percent reduction in frequency of the composite clinical endpoint, defined as death, nonfatal myocardial infarction, repeat revascularization, or procedural failure (8.3 vs. 12.8 percent in placebo-treated patients; p=0.008). [19] This benefit was greatest in patients with unstable clinical syndromes (acute myocardial infarction and refractory unstable angina).[259] [259A] Pretreatment with abciximab in a randomized trial of 429 patients with acute myocardial infarction was associated with a significant (p=0.03) reduction in the incidence of death, reinfarction, or urgent target vessel revascularization at 30 days in patients treated with abciximab (4.9 percent) versus placebo (10.3 percent). No difference in 6-month restenosis was noted between the two groups.[260]

The Evaluation of PTCA to Improve Long-Term Outcome by Abciximab GP IIb-IIIa Blockade (EPILOG) Trial randomly assigned 2792 "low-risk" patients who were treated with aspirin to standard-dose, weight-adjusted (100 units/kg) heparin and placebo; standard-dose, weight-adjusted heparin and abciximab; or low-dose, weight-adjusted (70 units/kg) heparin. The 30-day composite event rate was significantly (p<0.001) lower in patients treated with abciximab and low-dose (5.2 percent) or standard-dose (5.4 percent) heparin than in patients treated with standard-dose heparin and placebo (11.7 percent).[253] While one study suggested a beneficial effect with abciximab in patients undergoing SVG angioplasty,[261] a larger study failed to demonstrate a convincing reduction in these patients at high risk for macroembolization.[262] "Bailout" abciximab is often given during or just after PCI for the presence of residual dissection, thrombus, or suboptimal results,[263] although its value has not been demonstrated in prospective studies.

The EPISTENT trial randomly assigned 2399 patients with ischemic CAD to stenting plus placebo, stenting plus abciximab, or balloon PTCA plus abciximab.[254] The primary 30-day endpoint, a combination of death, myocardial infarction, or need for urgent revascularization, occurred in 10.8 percent of patients in the stent-plus-placebo group, 5.3 percent of patients in the stent-plus-abciximab group (hazard ratio 0.48; p<0.001), and 6.9 percent of patients in the balloon-plus-abciximab group (hazard ratio 0.63; p=0.007). [254] The occurrence of death and large (CPK-MB more than five times normal) myocardial infarction occurred in 7.8 percent of the placebo group versus 3.0 percent of the stent-plus-abciximab group (p<0.001) and 4.7 percent of the balloon PTCA-plus-abciximab group (p=0.01). [254] No significant differences in bleeding complications were noted among the groups.[254] The need for late revascularization was not significantly (p=0.22) lower in patients receiving stenting plus abciximab (8.7 percent) than in patients receiving stenting plus placebo (10.6 percent).[255] However, a significant (p=0.02) reduction was seen in revascularization in diabetic patients assigned to stenting plus abciximab (8.1 percent) when compared with patients receiving stenting plus placebo (16.6 percent).[255] A pooled analysis also suggests that abciximab may reduce mortality in diabetic patients.[263A]

EPTIFIBATIDE

The effect of eptifibatide (Integrelin) on 30-day clinical events was evaluated in 4010 patients undergoing PCI. The patients were assigned to placebo, an eptifibatide bolus of 135 mug/kg followed by a low-dose eptifibatide infusion at 0.5 mug/kg/min for 20 to 24 hours, or the same eptifibatide bolus and a higher-dose infusion at 0.75 mug/kg/min for 20 to 24 hours.[256] The primary endpoint was a 30-day composite occurrence of death, myocardial infarction, unplanned CABG or repeat PCI, or coronary stenting for abrupt closure. Such events occurred in 11.4 percent of patients in the placebo group versus 9.2 percent in the 135/0.5 eptifibatide group (p=0.063) and 9.9 percent in the eptifibatide 135/0.75 group (p=0.22). [256] In a treatment-received analysis, the eptifibatide 135/0.5 regimen produced a significant reduction in the composite endpoint (9.1 vs. 11.6 percent in placebo-treated patients; p=0.035), but the eptifibatide 135/0.75 regimen produced a less substantial reduction (10.0 vs. 11.6 percent in placebo-treated patients; p=0.18). Eptifibatide treatment did not increase rates of major bleeding or transfusion. It is now recognized that the eptifibatide infusion dosage in the Integrelin to Minimise Platelet Aggregation and Coronary Thrombosis-II (IMPACT-II) Trial was insufficient to provide adequate platelet inhibition. The ongoing randomized ESPRIT Trial will compare a 180-mug/kg double bolus of eptifibatide

Data from Evaluation of 7E3 for the Prevention of Ischemic Complications (EPIC) Trial,[19] Evaluation of PTCA to Improve Long-Term Outcome by Abciximab Glycoprotein IIb-IIIa Blockade (EPILOG) Trial,[253] EPISTENT,[254] [255] Integrelin to Minimise Platelet Aggregation and Coronary Thrombosis-II (IMPACT-II),[256] and Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis (RESTORE).[257] [258]

followed by a 2.0-mug/kg/min infusion with placebo in lower-risk patients undergoing stent implantation.

TIROFIBAN

The effect of tirofiban, a nonpeptidyl tyrosine derivative, on outcomes after PCI was evaluated in the Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis (RESTORE) Trial, a randomized, double-blind, placebo-controlled study involving 2139 patients undergoing PCI who were seen within 72 hours of an acute coronary syndrome.[257] All patients received aspirin and heparin and were randomly assigned to a tirofiban bolus (10 mug/kg over a 3-minute period) plus infusion (0.15 mug/kg/min) or to a placebo bolus plus infusion for 36 hours after PCI. The primary 30-day composite endpoint was 16 percent lower with tirofiban treatment (p=0.160), although a 38 percent relative reduction in the composite end point was noted at 48 hours (p=0.005) and a 27 percent relative reduction at 7 days (p=0.022). [257] When only urgent or emergency balloon PTCA or CABG were included in the composite endpoint, the 30-day event rates were 10.5 percent for the placebo group and 8.0 percent for the tirofiban group, a relative reduction of 24 percent (p=0.052). Major bleeding tended to be higher in tirofiban-treated patients (5.3 vs. 3.7 percent in the placebo-treated patients; p=0.096), although no difference in bleeding events could be found when using the TIMI criteria[264] for major bleeding.[257] A prospective trial, the TARGET study, will compare clinical outcome in over 4000 patients undergoing PCI treated with either abciximab or tirofiban.

As a class of agents, the GP IIb-IIIa inhibitors (i.e., abciximab, eptifibatide, and tirofiban) have demonstrated benefit in improving clinical outcomes within the first 30 days after PCI. The primary effect of these agents has been on the reduction of ischemic complications, including non-Q-wave myocardial infarction and recurrent ischemia. No consistent evidence indicates that GP IIb-IIIa inhibitors reduce the frequency of restenosis. These agents should be considered for use in all patients undergoing PCI, particularly in those with unstable angina, primary balloon PTCA, or stent placement for acute myocardial infarction, and in other patients at higher risk for ischemic complications after PCI.

Antithrombin Therapy

UNFRACTIONATED HEPARIN (see also Chap. 62) .

Unfractionated heparin is the most common thrombin inhibitor used during PCI, although other antithrombin III-dependent agents (e.g., LMWH) and antithrombin III-independent agents (e.g., hirudin, bivalirudin, and argatroban) have also been tried. Intravenous heparin is used during PCI to prevent arterial thrombus formation at the site of vessel wall injury and on coronary guidewires and other catheter equipment used for coronary dilatation.[265] Patients with acute coronary syndromes may also benefit from prolonged (>24 hours) heparin therapy alone before PCI[266] or in combination with GP IIb-IIIa inhibitors.[267] [268] [269]

Activated partial thromboplastin times have been used to monitor the intensity of anticoagulation *before* and *after* PCI, but these methods have been less useful for monitoring anticoagulation *during* PCI inasmuch as large amounts of heparin are required to prevent thrombus formation during arterial manipulations.[270] "Near-patient" activated clotting time (ACT) monitoring has facilitated heparin dose titration during PCI,[271] although ACT responses have shown marked variability in patients who received a non-weight-adjusted heparin bolus. These differences have been attributed to patient-to-patient differences in heparin sensitivity and clearance, body weight, nitroglycerin use, and coexisting conditions that predispose to heparin resistance (e.g., heparin antibodies, oral contraceptive use, endocarditis, disseminated intravascular coagulation, and placement of an intraaortic balloon pump). Patients with unstable angina and those with complex coronary lesions (irregular borders, overhanging edges, or filling defects) also have higher heparin dosing requirements.[272]

At least two studies have retrospectively related the ACT value to clinical outcome after PCI.[237] [238] Patients who had complications after PCI in one study had lower mean baseline ACT (HemoTec) values after the initial heparin bolus and at the end of the procedure than did those without complications,[238] although this finding may be confounded because heparin resistance may be a marker of high-risk anatomy.[273] In another study, patients with abrupt closure had a lower mean ACT (Hemochron) at the time of first balloon inflation than did those without this complication (352 vs. 388 seconds; p<0.002). [237] An inverse relationship was shown between in-laboratory ACT values and the probability of abrupt closure (p=0.018). [237] Higher ACT levels [274] and other markers of excess anticoagulation[193] are also independent predictors of bleeding complications after PCI.

More recent studies have also evaluated the safety of lower-dose heparin during PCI. Low-dose bolus heparin at 5000 IU, followed by early (<12 hours) postprocedural sheath removal, in 1375 consecutive patients was associated with infrequent fatal complications (0.3 percent), emergency CABG (1.7 percent), myocardial infarction (3.3 percent), or repeat angioplasty within 48 hours (0.7 percent).[275] In a randomized study of 400 patients assigned to fixed-dose heparin at 15,000 IU or weight-adjusted heparin at 100 IU/kg, clinical outcomes were similar in the two groups (95 percent success rates).[276] Use of the weight-adjusted heparin did result in earlier sheath removal and more rapid transfer to a step-down unit.[276] Lower anticoagulation levels are also needed to avoid bleeding complications during the concomitant administration of agents such as GP IIb-IIIa inhibitors.[253]

The effect of subcutaneous heparin on the reduction in bleeding complications was evaluated in 151 patients treated either with an intravenous heparin infusion at 1000 units/hr for 12 to 18 hours after angioplasty or with subcutaneous heparin at 12,5000 units every 12 hours for three doses and early sheath removal.[277] The rate of ischemic complications was similar in both groups, but the risk of bleeding was significantly lower in the group managed with early (<12 hours) sheath removal and treated with subcutaneous heparin.[277]

Weight-adjusted heparin dosing regimens of 70 to 100 IU/kg or sex-adjusted bolus heparin consisting of 7000 units for women and 8000 units for men is now used in an attempt to avoid "overshooting" the ACT.[278] It is generally recommended that sufficient unfractionated heparin be administered during PCI to achieve an ACT between 250 and 300 seconds with the HemoTec monitor and between 300 and 350 seconds when using the Hemochron monitor.[271] When heparin is not adjusted by weight, the ACT should be monitored frequently and additional, smaller heparin boluses of 2000 to 5000 IU given until the target ACT is achieved. Routine use of intravenous heparin after PCI is no longer indicated because of several randomized studies showing no benefit in reducing ischemic complications and higher access site bleeding complication rates.[279] [280] Early sheath removal is strongly encouraged when the ACT falls to less than 150 to 180 seconds.

LOW-MOLECULAR-WEIGHT HEPARIN (see also Chap. 62) .

An increasing number of patients with unstable angina are treated with LMWH prior to PCI.[281] Because of the difficulty monitoring anticoagulation levels with LMWH during PCI, conventional dosages of unfractionated heparin are also recommended. In this setting, conventional monitoring methods, such as the ACT, may underestimate the true degree of periprocedural anticoagulation. A pilot randomized trial of 60 patients undergoing PCI and treated with unfractionated heparin or enoxaparin (1 mg/kg intravenously) showed no difference in safety between the two anticoagulants.[282] Routine use of LMWH as the sole anticoagulant during PCI cannot be recommended at this time pending the results of large, multicenter trials evaluating the use of LMWH during PCI.

DIRECT THROMBIN INHIBITORS

A number of direct thrombin inhibitors have been evaluated during PCI. In the Hirudin in a European Trial Versus Heparin in the Prevention of Restenosis after PTCA (HELVETICA) Study,[283] 1141 patients with unstable angina scheduled for PCI were treated with aspirin and randomized to receive a heparin bolus of 10,000 units plus infusion at 15 units/kg/hr for 24 hours; a hirudin bolus of 40 mg plus intravenous infusion at 0.2 mg/kg/hr for 24 hours; or a hirudin bolus of 40 mg, intravenous infusion at 0.2 mg/kg/hr for 24 hours, and subcutaneous infusion of 40 mg twice daily for an additional 3 days. Hirudin use was associated with a 39 percent reduction in early cardiac events (p=0.023), although clinical outcomes were similar 7 months later in the three groups. A recombinant hirudin (lepirudin) bolus of 0.4 mg/kg and infusion at 0.15 mg/kg/hr is approved for use in the United States in patients with heparin-induced thrombocytopenia.

Bivalirudin (Hirulog or AngioMax) was compared with unfractionated heparin in the Hirulog Angioplasty Study, a randomized trial of 4098 patients with postinfarction or unstable angina undergoing coronary angioplasty and then assigned to receive a heparin bolus at 175 units/kg and a 15-unit/kg/hr infusion for 18 to 24 hours or to receive a bivalirudin bolus of 1.0 mg/kg and a 2.5-mg/kg/hr infusion for 4 hours, followed by 0.2 mg/kg/hr for 14 to 20 hours.[284] Although bivalirudin did not reduce the likelihood of in-hospital death, Q wave or non-Q-wave myocardial infarction, or emergency CABG, bivalirudin therapy reduced the likelihood of bleeding complications (odds ratio of 0.4; p<0.001). [284] In the prospectively stratified cohort of 704 patients with post-myocardial infarction angina, bivalirudin resulted in lower rates of major ischemic complications (9.1 vs. 14.2 percent in heparin-treated patients; p=0.04) and lower rates of bleeding (3.0 vs. 11.1 percent in heparin-treated patients; p<0.001).

PHARMACOLOGICAL APPROACHES TO RESTENOSIS

IVUS studies have provided unique insight into the dynamic changes that occur within the vessel wall after PCI and suggest that arterial remodeling[285] and, to a lesser extent, intimal thickening account for most of the lumen renarrowing that occurs after balloon PTCA or coronary atherectomy.[12] [285] [286] In contrast, restenosis after stent implantation is due to intimal thickening within the axial length of the stent and its border in virtually all cases.[225] Conventional pharmacological strategies have not consistently reduced the frequency of angiographic or clinical restenosis indices after PCI (Table 38-9) despite a large number of agents having been tried.[287]

PLATELET INHIBITORS.

Randomized studies evaluating the effect of aspirin on restenosis have produced conflicting results, potentially attributable to the varied dosage and duration of aspirin therapy.[236] [288] [289] [290] The majority of these studies have shown little, if any sustained effect of aspirin on restenosis prevention, although long-term aspirin at dosages greater than 100 mg daily is recommended after PCI for secondary prevention of cardiac events.[278] Platelet thromboxane A_2 and serotonin receptor antagonists, such as

sulotroban, ketanserin, and prostacyclin, have also been tried without success.[291] [292] [293] [294] [295]

Platelet aggregation during PCI may occur as a result of GP IIb-IIIa activation by a number of agonists, which renders the inhibition of a single agonist problematic for the prevention of restenosis. "Final common pathway" GP IIb-IIIa platelet receptor inhibitors provide potent (>80 percent) blockade of platelet aggregation during PCI, irrespective of the platelet agonist. The EPIC study reported a 23 percent reduction in cumulative 6-month clinical events (p=0.001),[296] but these events were primarily related to the prevention of early (<30 day) periprocedural events.[19] Other studies did not show a consistent reduction in clinical or angiographic restenosis with GP IIb-IIIa inhibitors.[258] A subgroup analysis of diabetic patients undergoing stent implantation in EPISTENT demonstrated a reduction in clinical restenosis at 12 months from 22.4 percent in those receiving placebo to 13.7 percent in those receiving abciximab.[297] These findings in diabetic patients require confirmation in future prospective trials.

ANTITHROMBINS.

Neither intravenous[279] or subcutaneous[298] unfractionated heparin nor LMWH, including enoxaparin, reviparin, nadroparin, and fraxiparin,[299] [300] [301] prevents restenosis after PCI. Antithrombin III-independent thrombin inhibitors such as bivalirudin,[302] hirudin, [283] and long-term warfarin[303] also have had little effect on the prevention of restenosis. It is not known whether local delivery of LMWH will result in a reduction in restenosis after stent placement, although studies evaluating this method of delivery are ongoing.

VASODILATORS.

Although calcium channel antagonists may reduce the occurrence of coronary vasospasm early after PCI, diltiazem and verapamil do not prevent restenosis after PCI.[304] Treatment with the nitric oxide donors linsidomine and molsidomine was associated with a modest improvement in the long-term angiographic result after PCI but had no effect on clinical outcome.[305] The improved angiographic result related mostly to a better immediate procedural result because late lumen loss did not differ significantly between groups.[305]

ANTIPROLIFERATIVE AGENTS.

Agents thought to interfere with smooth muscle cell migration and proliferation, such as cilazapril[306] [307] and fosinopril,[308] do not reduce the frequency of restenosis after balloon PTCA, although their effect after stent placement is less well studied.[309] Angiopeptin, a nonspecific growth factor inhibitor, has had inconsistent effects on restenosis, related in part to the short half-life and varied administration among studies.[310] [311] Preliminary studies using trapidil, an agent that may antagonize platelet-derived growth factor, have been favorable,[312] but larger studies are needed.

ANTIINFLAMMATORY AGENTS AND ANTIOXIDANTS.

Probucol, an anti-antioxidant agent, has been shown to reduce restenosis after balloon angioplasty,[313] [314] primarily as a result of its effect on the prevention of arterial remodeling.[314] In one study, 317 patients undergoing PCI were randomly assigned to either twice-daily placebo; probucol 500 mg; multivitamins consisting of 30,000 IU of beta-carotene, 500 mg of vitamin C, and 700 IU of vitamin E; or both probucol and multivitamins for 4 weeks before and 6 months after PCI. Restenosis rates were 20.7 percent in the probucol group, 28.9 percent in the combined-treatment group, 40.3 percent in the multivitamin group, and 38.9 percent in the placebo group (p=0.003 for probucol vs. no probucol).[314] Probucol, not marketed in the United States, lowers high-density lipoprotein levels. Tranilast, an antiallergic drug used widely in Japan, has been shown to reduce restenosis after successful DCA from 26 percent in patients not treated with tranilast to 11 percent in patients treated with tranilast (p=0.03). [315] A large-scale trial evaluating the effect of tranilast on the prevention of restenosis is ongoing. Other antiinflammatory agents such as dexamethasone[316]

and colchicines[317] have had limited effect on the prevention of restenosis.

LIPID-LOWERING AGENTS.

Several lipid-lowering agents, such as lovastatin, [318] [319] pravastatin,[320] and fluvastatin,[321] have been evaluated as treatment to prevent restenosis after PTCA. While these agents have had limited clinical success in preventing restenosis, lipid reduction therapy is indicated after PCI for the progression of atherosclerosis at remote sites.[322] [323] At least one pilot study has shown that low-density lipoprotein (LDL) apheresis may also reduce restenosis after PCI.[324]

While meta-analysis of several smaller studies suggests a benefit of fish oil on the prevention of restenosis,[325] little evidence supports the routine use of omega-3 fatty acid supplements for preventing restenosis after PTCA[326] [327] [328] [329] despite initially encouraging pilot studies. [330] [331] [332]

WHY DRUGS HAVE NOT BEEN EFFECTIVE.

The limited success in identifying a single pharmacological agent to prevent restenosis after PCI may be related to several factors. Most importantly, our understanding of the pathogenesis of restenosis after PCI has changed dramatically over the past 5 years. Arterial remodeling and contraction of the arterial wall have emerged as important contributors to restenosis after balloon PTCA,[12] [285] although the factors leading to these dynamic changes are not known. Animal models have been poorly predictive of agents that prevent restenosis in clinical studies, possibly because of differences in the pathogenesis of restenosis in different models (i.e., lipid-rich narrowings in hypercholesterolemic rabbits vs. intimal hyperplasia in arteries injured by overexpanded balloons [rats] or stents [pig]). Also, drug dosages higher than the dosage clinically tolerable in humans have been used in the experimental models,[333] [306] and the ineffectiveness of some agents may relate to inadequate drug levels. Given the differences in the pathogenesis of balloon PTCA and stent restenosis, it is possible that agents found ineffective for the prevention of restenosis after balloon PTCA may have value in preventing stent restenosis.

RADIATION THERAPY TO RETARD RESTENOSIS.

Emerging data suggest that intracoronary radiotherapy can reduce the intimal hyperplasia in animal models of restenosis.[334] [335] [336] [337] Early pilot trials have suggested that both gamma[338] and beta[339] sources prevent restenosis after PCI in native coronary lesions.[340] [341] [342] A number of studies are currently ongoing to assess the effect of radiation on the prevention of de novo and restenotic coronary lesions.

INDICATIONS FOR PERCUTANEOUS CORONARY INTERVENTIONS

The major value of coronary revascularization, whether performed by surgical or percutaneous methods, is the relief of symptoms and signs of ischemic CAD caused by obstructive epicardial disease. While two studies have suggested that PCI may reduce mortality and subsequent myocardial infarction risk when compared with medical therapy,[343] these events are better treated with systemic therapies aimed at reducing the extent of atherosclerosis, such as lipid-lowering therapy.[344] In contrast, CABG prolongs life in certain anatomical subsets, such as patients with left main disease, three-vessel CAD, or left anterior descending artery disease with involvement of one or two additional vessels, irrespective of left ventricular function.[345] The risks and benefits of coronary revascularization must be carefully reviewed with the patient and family members, if appropriate, before these procedures are performed. Guidelines for the performance of PCI and CABG have been published by the ACC/AHA.[18] [345]

ASYMPTOMATIC PATIENTS OR THOSE WITH MILD ANGINA.

Patients who are asymptomatic or have only mild symptoms are generally best treated with medical therapy, unless one or more significant lesions subtend a large area of viable myocardium confirmed by objective noninvasive testing, the patient prefers to maintain an aggressive life style or has a high-risk occupation, and the procedure can be performed with a high chance of success and low likelihood of complications.[18] Coronary revascularization should not be performed in patients with no or mild symptoms if only a small area of myocardium is at risk, if no objective evidence of ischemia can be found, or if the likelihood of success is low or the chance of complications is high.[18]

PATIENTS WITH MODERATE TO SEVERE ANGINA (see Chap. 37) .

Patients with CCS Class II to IV angina, particularly those who are refractory to medical therapy, are suitable candidates for coronary revascularization, provided that the lesion subtends a moderate to large area of viable myocardium as determined by noninvasive testing.[18] Patients with recurrent symptoms while receiving medical therapy are candidates for revascularization even if they have a higher risk for an adverse outcome with revascularization.[18] Patients with Class II to IV symptoms should not undergo revascularization without noninvasive evidence of myocardial ischemia or a trial of medical therapy, particularly if only a small region of myocardium is at risk, the likelihood of success is low, or the chance of complications is high.

PATIENTS WITH UNSTABLE ANGINA OR NON-Q-WAVE MYOCARDIAL INFARCTION (see Chap. 36) .

Cardiac catheterization and coronary revascularization in selected patients with unstable angina or non-Q-wave myocardial infarction may improve the prognosis, although it is less clear whether *routine* angiography and revascularization are indicated in all patients with acute coronary syndromes. The TIMI IIIB trial found no difference in 1-year death or myocardial infarction in patients undergoing routine angiography and those undergoing angiography and revascularization only for recurrent ischemia, although patients treated with an aggressive approach experienced less angina and were rehospitalized less often than those treated with a conservative approach.[346] Patients assigned to early catheterization and revascularization in the Veterans Affairs Non-Q-Wave Infarction Strategies in Hospital (VANQWISH) Trial experienced no reduction in the rate of death or the composite of death and myocardial infarction 1 year later when compared with patients assigned to cardiac catheterization and revascularization only for recurrent ischemia, although the mortality rate was high (>10 percent) in patients undergoing CABG in the aggressive limb.[347] In contrast to these studies, the Fragmin and Fast Revascularization During Instability in Coronary Artery Disease (FRISC II) Study demonstrated a 22 percent reduction (p=0.031) in death or myocardial infarction at 6 months in patients assigned to routine catheterization and revascularization (9.4 percent) versus those assigned to a conservative approach (12.1 percent).[343]

Pending the results of additional trials such as the TACTICS (TIMI-18) Study, early catheterization and coronary revascularization are indicated in patients with acute coronary syndromes at "intermediate" or "high" risk of subsequent death or myocardial infarction.[348] High-risk features include prolonged ongoing (>20 minutes) chest pain, pulmonary edema or worsening mitral regurgitation, dynamic ST segment depression of 1 mm or greater, or hypotension. [348] Intermediate-risk features include angina at rest (>20 minutes) that is relieved with rest or sublingual nitroglycerin, angina associated with dynamic electrocardiographic changes, recent-onset angina with a high likelihood of CAD, pathological Q waves or ST segment depression less than 1 mm in multiple leads, or age older than 65 years. [348] Coronary revascularization is not indicated in patients with unstable angina who do not demonstrate high-risk criteria upon exercise testing after stabilization with

---

medical therapy, patients who do not have objective signs of coronary ischemia, or those in whom revascularization will not improve the quality of life.[348]

PATIENTS WITH ACUTE MYOCARDIAL INFARCTION TREATED WITH THROMBOLYTIC THERAPY (see Chap. 35) .

Cardiac catheterization and selective coronary revascularization in patients who have received thrombolytic therapy are indicated in those with recurrent ischemia, in patients with cardiogenic shock or those in whom it later develops, or in those in whom signs of reperfusion fail to develop after thrombolytic administration.[16] Routine coronary revascularization is not indicated within hours to days in patients who are asymptomatic and have no evidence of substantial residual myocardium at risk. Patients in whom recurrent ischemia develops spontaneously or after exercise provocation are candidates for revascularization. In the Danish Trial in Acute Myocardial Infarction (DANAMI) Study, 503 patients with inducible myocardial ischemia after thrombolytic treatment of acute myocardial infarction were assigned to an invasive strategy of coronary revascularization between 2 and 10 weeks after the acute myocardial infarction or to a conservative strategy of revascularization 2 months later.[349] At a 2.4-year follow-up (median), mortality was similar in both groups, although patients treated with the invasive strategy had a lower incidence of acute myocardial infarction (5.6 vs. 10.5 percent; p=0.0038) and a lower incidence of admission for unstable angina (17.9 vs. 29.5 percent; p<0.00001) than did conservatively treated patients.[349]

OPTIONS FOR MEDICAL THERAPY OR CORONARY REVASCULARIZATION (see also Chap. 37)

In patients with symptomatic CAD, the clinician must decide whether medical therapy or referral for coronary revascularization by PCI or CABG will provide the best prognosis for the individual patient. A number of factors will ultimately affect the decision to undertake one strategy over another, including (1) the patient's general vigor, comorbid conditions, initial symptoms, and personal preferences; (2) the coronary anatomy, number of lesions, and their location and morphology, including the presence of total occlusions; (3) left ventricular function; and (4) whether CABG has already been performed.

PCI VERSUS MEDICAL THERAPY (See Chap. 37)

At least four randomized studies have compared the outcomes of patients assigned to medical therapy or PCI for the treatment of ischemic CAD. In the Veterans Administration Angioplasty Compared to Medicine (ACME) trial, 212 patients with single-vessel coronary disease and stable angina were randomly assigned to medical therapy or balloon PTCA.[350] Although rates of death and myocardial infarction were similar in the two groups, superior symptom control and a better exercise duration were found in patients treated with balloon PTCA.[350] These effects were less pronounced in patients with two-vessel CAD.[351] More recently, the Atorvastatin Versus Revascularization Therapy (AVERT) Trial compared the effect of aggressive lipid lowering with atorvastatin 80 mg daily and coronary angioplasty in 341 patients with asymptomatic or mildly symptomatic (Class I or II) CAD.[352] At an 18-month follow-up, 13 percent of medically treated patients experienced an ischemic event as compared with 21 percent of patients treated with PCI (p=0.048). Although patients in both groups experienced improvement in their angina, more improvement was found at follow-up in patients treated with PCI.[352]

In the second Randomized Intervention Treatment of Angina (RITA-2) Trial, 1018 patients with single-vessel and/or multivessel disease and grade 2 or higher angina were randomly assigned to medical therapy or PCI.[353] Death or definite myocardial infarction occurred significantly (p=0.02) more often in PCI-treated patients (6.3 percent) than in medically treated patients (3.3 percent), primarily attributable to the occurrence of periprocedural myocardial infarction. More angina improvement and better exercise durations were achieved in the PCI group.[353] These benefits of PTCA were greatest in patients with more severe baseline angina.[353] The authors concluded that in patients with CAD considered suitable for either PCI or medical care, early PCI was associated with greater symptomatic improvement, especially in patients with more severe angina, although these benefits should be weighed against the small excess hazard for periprocedural myocardial infarction.[353]

In the Asymptomatic Cardiac Ischemia Pilot (ACIP) Study, 558 patients with asymptomatic ischemia by stress testing and ambulatory ischemia monitoring were randomly assigned to angina-guided therapy (n=183), angina plus ischemia-guided therapy (n=183), or revascularization using PCI or CABG.[348] The incidence of death or myocardial infarction at 2 years was significantly lower (p<0.01) in patients treated with revascularization (4.7 percent) than in patients assigned to angina-guided (12.1 percent) or ischemia-guided (8.8 percent) therapy.

These studies suggest that patients with mild Class I or II angina have a favorable prognosis, whether treated with medical therapy or PCI, although angina relief is greater in patients treated with PCI. A pilot randomized trial suggested that the prognosis is improved with revascularization (PCI or CABG) in patients with Holter monitor-documented ischemia,[354] but these findings will require confirmation in larger studies. Patients with moderate to severe angina, particularly those who have failed medical therapy, should be considered candidates for PCI.

PCI VERSUS CABG (See Chap. 37)

At least nine randomized trials have evaluated the relative value of PCI and CABG in patients with multivessel CAD.[345] [355] [356] [357] [358] [359] [360] [361] [362] While these trials were designed to address a critical issue for clinicians managing patients with multivessel CAD, they have had certain unavoidable design limitations, including relatively small sample sizes (127 to 1792 patients), inclusion of both patients with single-vessel and multivessel CAD, low screened-to-recruitment ratios (limiting the generalizability of the study), and limited (1 to 5 years) follow-up. The relatively low, late-term mortality rates (0 to 13.7 percent) and small sample sizes in these studies make it difficult to exclude the *possibility* of a difference between these two strategies (type II error). Not withstanding these limitations, a number of important conclusions can be drawn from these trials.

In the largest randomized trial, BARI, 1792 patients with multivessel CAD were assigned to initial treatment with PCI or CABG. In-hospital Q wave myocardial infarction was significantly (p<0.05) higher in patients assigned to CABG (4.6 percent) than PCI (2.1 percent), although 6.3 percent of PCI-treated patients required emergency CABG for procedure-induced complications. No significant differences were found in long-term survival or freedom from myocardial infarction at 5.4 years' follow-up, although PCI patients had more repeat hospitalization and required more repeat procedures than did CABG patients. One subset was identified in BARI that benefited from CABG over PCI. Diabetic patients assigned to PCI had a significantly (p=0.003) worse survival rate (65.5 percent) than did diabetic patients assigned to CABG (80.6 percent), primarily because of a reduced cardiac mortality rate (20.6 percent in PCI patients vs. 5.8 percent in CABG patients; p=0.003).[26] [27] [28] [263A] Placement of at least one internal mammary graft was the primary factor contributing to the improved prognosis with CABG in diabetic patients.

A weighted analysis of patients enrolled in the nine randomized trials comparing CABG and PCI for the treatment of single-vessel and multivessel CAD demonstrated similar in-hospital major clinical events, including death (1.3 percent in CABG patients and 1.0 percent in PCI patients) and Q wave myocardial infarction (4.1 percent in CABG patients and 2.3 percent in PCI patients).[345] Late major clinical events were also similar in the two groups and included death (6.5 percent in CABG patients and 7.7 percent in PCI patients) and Q wave myocardial infarction (11.3 percent in CABG patients and 11.0 percent in PCI patients). CABG patients had less frequent recurrence of angina (10.4 percent in CABG patients and 15.5 percent in PCI patients) and fewer repeat revascularization procedures (7.3 percent in CABG patients and 42.3 percent in PCI patients).[345] It should be noted that these trials were completed before the widespread use of stents, GP IIb-IIIa inhibitors, and postprocedural lipid-lowering therapies.

The ultimate choice of the method of revascularization should be made after a frank discussion with the patient about the options of revascularization. In a patient with diffuse involvement of three coronary vessels, particularly in the setting of complex anatomy, including total occlusions, CABG may provide a more definitive long-term benefit, especially if one or more arterial conduits are used. In contrast, in a patient with focal lesions involving two or three large epicardial vessels, multivessel coronary stent placement may be the preferred approach since it is associated with a lower risk of Q wave myocardial infarction and a shorter hospital stay than CABG is. Diabetic patients with diffuse two- or three-vessel CAD are best served with CABG. These recommendations in diabetic patients are supported by preliminary results from the ARTS Trial, a randomized trial of multivessel stenting or CABG in patients with multivessel disease.[363] In all patients with multivessel CAD who are undergoing CABG or PCI, aggressive

risk factor modification is warranted, with a target LDL cholesterol of less than 100 mg/dl.[344]

TRAINING STANDARDS AND PROFICIENCY IN INTERVENTIONAL CARDIOLOGY

Standards for core curriculum development and procedural proficiency for interventional cardiology training programs have been established by the ACC[364] ; these criteria, coupled with standards for the maintenance of technical competency,[364] [365] [366] are now prerequisites for the Certification Examination for Added Qualification in Interventional Cardiology, established by the American Board of Internal Medicine.[367] Proficiency requirements for interventional training have become more rigorous over time, with the minimum case volume for interventional training increasing from 125 to 250 cases as the primary operator[366] [368] ; maintenance of proficiency now requires more than 75 cases per year as the primary operator, unless special circumstances are identified.[366] Operator- and hospital-specific procedural outcomes after PCI are also collected by governmental and managed care organizations.

The focus on minimum volume criteria is based on studies that relate procedural outcome after PCI to both hospital and individual operator volumes[369] [370] [371] [372] [373] (Tables 38-10 and 38-11) . PCI complication rates are higher when the hospital procedural volume is less than 200 to 400 cases per year or individual operator volume is less than 75 to 100 coronary interventions per year.[369] [370] [371] [372] The ACC has recommended that hospitals perform more than 200 to 400 cases per year and individual operators perform more than 75 cases per year.[18] [366] It has been suggested that many interventional cardiologists do not meet these minimal procedural requirements.[373]

Individual institutions need to establish valid methods for peer review, including documentation of procedural success and failure rates of individual operators, minimum volume performance for the hospital and individual operators, quality of the laboratory facility, and training of the support staff. Establishment of an outcomes data base is strongly encouraged for all institutions.[384]

PERCUTANEOUS VALVULOPLASTY (see also Chap. 46)

Percutaneous valve dilatation has been used as an alternative to definitive surgical repair or replacement in selected patients with symptomatic valvular heart disease. After a decade of experience with these techniques, it is clear that mitral valvuloplasty is a safe and effective alternative to surgical repair in selected patients with mitral stenosis[385] whereas aortic valvuloplasty provides only short-term palliation and should be reserved for inoperable patients

TABLE 38-10 -- RELATIONSHIP BETWEEN HOSPITAL PROCEDURAL VOLUME AND OUTCOME AFTER CORONARY INTERVENTION

STUDY	TIME PERIOD	DATA SOURCE	NUMBER OF PATIENTS	NUMBER OF OPERATORS	CONCLUSIONS	COMMENTS
Hartz et al.[374]	1989-91	Wisconsin Medicare	2091	16	No relationship between volume and outcome	Very low number of cases and hospitals examined
Ritchie et al.[375]	1989	California State	24,883	110	Increased CABG (not death) with <200 cases/yr; finding is valid for both acute MI and non-MI patients	
Jollis et al.[373]	1987-90	MEDPAR	217,836	1194	Death and CABG inversely related to low volume (risk increases with Medicare patient volume [<100-200 total/yr for death, <200-300/yr for CABG])	
Kimmel et al.[372]	1992-93	SCAI Registry	19,594	48	Fewer major complications for labs with >400 cases/yr	Able to risk-adjust more completely than in other studies
GUSTO IIb[168]	NA	GUSTO	565	59	No difference between 200 and 625 cases/yr vs. >625 cases/yr for acute MI patients	All operators >50 cases per year
O'Neill et al.[376]	NA	PAMI-II	1100	34	No difference between <500, 501-1000, and >1,000 cases/yr for acute MI	
Jollis et al.[373]	1992	Medicare	97,498	984	Incremental decrease in death + CABG as hospital Medicare volume increased from <100, 100-200, and >200 cases/yr	
Tiefenbrunn et al.[377]	NA	Second NRMI	4939	NA	Increased acute MI mortality for hospitals with <25 acute MI cases/yr	
Hannan et al.[370]	1991-94	New York State	62,670	31	Death alone and same-stay CABG increased with caseloads <600/yr	Risk adjusted
Zahn et al.[378]	1992-95	German Hospital Constortium	4625	NA	For patients with acute MI, increased mortality in hospital with <40 acute MI PTCA/yr	No risk adjustment

* Medicare patients usually account for 35 to 50 percent of the total interventional caseload.

with degenerative calcific aortic stenosis.[385] [386] The indications and contraindications for mitral and aortic valvuloplasty are reviewed in detail elsewhere (see Chap. 46) . This chapter focuses on the technical issues, patient selection, and outcomes associated with mitral and aortic valvuloplasty.

Mitral Valvuloplasty (See also Chap. 46)

Percutaneous mitral valvuloplasty (PMV) was first performed in 1984 as an alternative to surgical mitral valve commissurotomy,[387] and later reports confirmed the immediate and long-term benefits of this procedure.[388] [389] [390] Although the majority of PMV procedures are performed in developing countries,[389] [391] where rheumatic fever and valvular heart disease continue to be endemic, a few specialized centers in Western countries have developed technical expertise in PMV, and their single[392] and multicenter[393] reports have provided valuable insight into the outcomes associated with PMV.

TECHNICAL ISSUES

A variety of technical approaches may be used for PMV.[385] A transvenous, or anterograde, method is most commonly performed, with a transseptal puncture used to gain access to the left atrium. A wire (or balloon) is then passed across the mitral valve into the left ventricle. Less often, a retrograde, transarterial approach is used to avoid the creation of a large atrial septal defect. Two retrograde methods have been described. In the first, a 0.038-inch exchange wire passed from the right atrium to the left atrium via a transseptal puncture is advanced through the left ventricle into the descending aorta, where it is retrieved with a snare.[394] The mitral valve dilatation balloon is then advanced retrogradely through the descending and ascending aorta into the left ventricle and across the mitral valve.[394] This method has had limited application because it is time consuming, requires advanced technical expertise, and mandates the use of large arterial sheaths. The second retrograde technique involves the use of a specially designed catheter to gain access to the left atrium from the left ventricle while avoiding transseptal puncture.[395] [396] [397] Experience with this method is limited except for a few specialized centers.

Two types of balloon approaches are used for PMV.[398] With the double-balloon method, a transseptal puncture is performed and a balloon catheter is advanced across the mitral valve into the left ventricle.[385] Two long exchange wires are then positioned in the left ventricle, and the interatrial septum is dilated with a 6- to 8-mm peripheral dilatation balloon. A combination of two mitral valvuloplasty balloons (trefoil balloon or conventional balloon) are advanced across the mitral valve and inflated.[385] The second technique uses the Inoue balloon,[399] [400] which is a self-positioning, pressure-distensible balloon that allows progressive diameter dilatation by increasing the inflation pressure[385] (Fig. 38-11) . A stepwise dilatation technique is performed to minimize the risk of mitral valve rupture and mitral regurgitation. Selection of balloon size is generally based on patient height, body surface area, and diameter of the mitral annulus.

Figure 38-11 Mitral valvoloplasty. After transseptal puncture, a Mullins sheath is advanced into the left atrium, as demonstrated by contrast injection *(A)*. An Inoue guidewire is coiled in the left atrium and a Inoue dilator is advanced across the intraatrial septum *(B)*. Advancement of the Inoue balloon dilatation catheter into the left ventricle *(C)* and inflation *(D)* resulted in a successful procedure. (Courtesy of Andrew Eisenhauer, M.D.).

Comparative studies of these two techniques have shown similar clinical success rates,[391] [401] but shorter procedure times and higher disposable costs with the Inoue technique.[391] [401] The Inoue balloon has also been used in patients with severe mitral valve calcification[402] and subvalvular fibrosis[403] with reported success.

HEMODYNAMIC ASSESSMENT

Serial hemodynamic measurements, alone or in combination with echocardiography, may be used to evaluate the result achieved with PMV.[385] An immediate improvement in left atrial mean pressure (and reduction of the transmittal gradient) should be seen, with a gradual decrease in pulmonary artery pressure and an increase in cardiac output.[385] Criteria for termination of the procedure include (1) a mitral valve area larger than 1 cm^2 per square meter of body surface area, (2) complete opening of at least one commissure, or (3) the appearance or an increment in mitral regurgitation.[385] Transesophageal echocardiography may also be performed during the procedure[404] [405] [406] [407] and, in particular, may guide the transseptal puncture in patients with obscure cardiac landmarks or skeletal deformity.[408]

PROCEDURE OUTCOME.

Procedure success has been related to institutional volume (>25 cases per year), baseline mitral valve area (>0.5 cm^2), and the age of the patient (<70 years).[393] Procedural mortality associated with mitral valvuloplasty ranges from 0 to 3 percent in most series and is primarily related to the development of left ventricular perforation[409] resulting from the transseptal technique or advancement of the guidewire or balloon catheter into the left ventricle[410] or to general patient comorbidity.[411] Cerebral or coronary emboli occur in 0.5 to 5.0 percent of patients and are related to dislodgment of thromboembolic material from the left atrium or air within the dilatation apparatus.[412] Severe mitral regurgitation resulting from rupture of the chordae tendineae or papillary muscle rupture may also occur. Atrial septal defects are commonly (80 percent) seen after PMV, but the magnitude of the left-to-right shunt is generally insignificant.[405] The atrial septal defect also closes in the majority (90 to 100 percent) of cases within 3 months after PMV.[405] [413] Emergency surgery may be required in a minority of cases after PMV. When PMV is required for mitral regurgitation, left ventricular

TABLE 38-12 -- ECHOCARDIOGRAPHIC ANATOMICAL CLASSIFICATION OF THE MITRAL VALVE IN RELATION TO SUITABILITY FOR PERCUTANEOUS VALVULOPLASTY

POINTS	ECHOCARDIOGRAPHIC VARIABLE
	Leaflet Mobility
1	Highly mobile valve with restriction of only the leaflet tips
2	Midportion and base of leaflets have reduced mobility
3	Valve leaflets move forward in diastole mainly at the base
4	No or minimal forward movement of the leaflets in diastole
	Valvular Thickening
1	Leaflets near normal (4-5 mm)
2	Midleaflet thickening, marked thickening at the margins
3	Thickening extends through the entire leaflets (5-8 mm)
4	Marked thickening of all leaflet tissue (>8-10 mm)
	Subvalvular Thickening
1	Minimal thickening of chordal structures just below the valve
2	Thickening of the chordae extending up to one-third of chordal length
3	Thickening extending to the distal third of the chordae
4	Extensive thickening and shortening of all chordae extending down to the papillary muscles
	Valvular Calcification
1	A single area of increased echo brightness
2	Scattered areas of brightness confined to leaflet margins
3	Brightness extending into the midportion of the leaflets
4	Extensive brightness through most of the leaflet tissue

Adapted from Wilkins G, Gillam L, Weyman A, et al: Percutaneous balloon dilatation of the mitral valve: An analysis of echocardiographic variables related to outcome and the mechanism of dilatation. Br Heart J 60:299-308, 1988.

rupture, or the development of a left-to-right shunt or as a result of a failed procedure, the mortality rate rises substantially.[414]

LATE OUTCOME.

Transthoracic echocardiography may be useful to assess the prognosis after PMV by semiquantitatively scoring leaflet mobility, valvular and subvalvular thickening,

and valvular calcification[415] [416] (Table 38-12) . In one series of 136 patients undergoing successful PMV, the estimated 5-year mortality rate was 24 percent; the 5-year event rate (i.e., mitral valve replacement, repeat valvuloplasty, or death from cardiac causes) was 49 percent.[392] Multivariable predictors of late events after PMV were a high mitral valve echocardiographic score, an elevated left ventricular end-diastolic pressure, and a worse New York Heart Association (NYHA) functional class (p=0.04).[392] Patients with fewer than two risk factors for early restenosis (echocardiographic score >8, left ventricular end-diastolic pressure >10 mm Hg, or NYHA functional Class IV) had a predicted 5-year event-free survival rate of 60 to 84 percent, whereas patients with two or three risk factors had a predicted 5-year event-free survival rate of only 13 to 41 percent.[392]

Aortic Valvuloplasty (See also Chap. 46)

The most frequent cause of acquired valvular heart disease in Western countries is degenerative calcific aortic stenosis.[385] Percutaneous aortic valvuloplasty (PAV) fractures the calcified aortic leaflets, thereby increasing their flexibility, but its overall effect is modest and hemodynamic improvements are transient (days to weeks).[385] The long-term clinical benefit associated with PAV for calcific aortic stenosis is limited.[417] [418] [419] [420] [421]

PAV is generally reserved for adult patients with severe calcific aortic stenosis who have severe comorbidities that preclude aortic valve replacement,[422] [423] [424] such as in patients with cardiogenic shock or other significant comorbid conditions, in patients as a "bridge" to definitive surgical correction,[425] [426] [427] [428] or in patients with severe left ventricular dysfunction (i.e., "low flow, low gradient") in whom the hemodynamic response to aortic valve replacement cannot be determined.[429] [430] In the absence of these indications, definitive aortic valve replacement rather than PAV should be performed, even in elderly patients.[431] PAV in patients with congenital aortic stenosis is discussed in Chapters 43 and 44 .

TECHNICAL ISSUES

The femoral approach is most frequently used for PAV.[385] After crossing the aortic valve with a guidewire, an extra-stiff 0.038-inch wire is inserted into the apex of the left ventricle to stabilize the balloon during inflation. In patients with severe peripheral vascular disease, a brachial approach or anterograde approach using a transseptal puncture can be used to pass a long wire through the left ventricle, across the aortic valve, and into the descending aorta.[385] The interatrium septum is then dilated with a peripheral balloon, and the PAV balloon is then advanced across the aortic valve.

PAV balloons ranging in diameter between 15 and 25 mm and in length between 3 and 5 cm have variable shapes, including a conventional, bifoil, trifoil, and double-sized configuration, with the proximal portion measuring 20 to 23 mm and the distal portion 15 to 18 mm.[385] The size of the balloon should not exceed 1.2 to 1.3 times the diameter of the aortic ring.[385]

HEMODYNAMIC ASSESSMENT

The transaortic valve gradient should be reduced immediately after the procedure, although little change may be noted in cardiac output.[385] After successful dilatation, 25 to 47 percent of patients will obtain a final valve area larger than 1 cm^2 , while 22 to 39 percent of patients achieve a valve area less than 0.7 cm^2 . [385]

PROCEDURAL SUCCESS AND COMPLICATION RATES.

The clinical success rate for patients undergoing PAV ranges from 68 to 75 percent.[420] [432] [433] [434] Hospital mortality after PAV varies from 3.5 to 13.5 percent, and 20 to 25 percent of patients experience at least one complication during their hospitalization.[385] [433] [435] [436] Complications include a need for vascular access repair, embolic cerebrovascular events, aortic regurgitation, and with the use of oversized balloons, rupture of the aortic ring[434] [437] (Fig. 38-12) . Predictors of procedural mortality include the patient's age,[438] NYHA Class,[438] concomitant coronary artery disease, [438] congestive heart failure,[438] lower initial left ventricular systolic pressure,[435] [438] smaller final aortic valve area,[435] lower baseline cardiac output,[434] [435] [438] and the development of procedural complications. [385] [435] Predictors of patient morbidity are depressed left ventricular function, low cardiac output, diffuse coronary disease, and final valve area smaller than 0.7 cm^2 .[385] [432] [439] [440]

The major limitation of PAV is the early recurrence of symptoms in most patients. The estimated incidence of late restenosis is 36 to 80 percent in the first year.[441] [442] [443] [444] Determinants of late outcomes after PAV were studied in 205 patients undergoing this procedure.[445] The event-free survival rate, defined as survival without recurrent symptoms, repeated valvuloplasty, or aortic valve replacement, was 18 percent over the 24-month follow-up (range, 1 to 47 months). [445] Significant predictors of event-free survival included the left ventricular ejection fraction, left ventricular and aortic systolic pressure before PAV, and percent reduction in the aortic valve pressure gradient; the pulmonary capillary wedge pressure was inversely associated with event-free survival.[445] Although the predicted event-free survival rate for the entire patient group was 50 percent at 1 year and 25 percent at 2 years, the probability of event-free survival at 1 year varied between 23 and 65 percent when patients were stratified according to three independent predictors: aortic systolic pressure, pulmonary capillary wedge pressure, and percent reduction in the peak aortic valve gradient.[445] The best long-term results after valvuloplasty were observed among patients who would also have been expected to have excellent long-term results after aortic valve replacement.[445] Repeat PAV for symptom recurrence has also been reported.[446]

Figure 38-12 Aortic valvuloplasty. A 16-mm aortic valvuloplasty balloon is inflated across the aortic valve *(A)* and exchanged for a 24-mm balloon *(B)* because of a persistent gradient. To further improve the aortic gradient, two 16-mm valvuloplasty balloons are advanced across the aortic valve *(C)*. Because of the relative oversizing of the balloons to the aortic ring, aortic regurgitation results *(D)*.

Chapter 39 - Comprehensive Rehabilitation of Patients with Coronary Artery Disease

GERALD F. FLETCHER
KEITH R. OKEN
ROBERT E. SAFFORD

Coronary artery disease (CAD) is the most important public health problem in developed societies. Although the cardiovascular mortality rate for the United States has declined in recent decades, CAD remains the single leading cause of death. Each year, more than 1 million persons in the United States have a myocardial infarction.[1] The economic costs of CAD in the United States are increasing, with estimates of at least $50 billion annually[2] (see Chaps. 1 and 2) .

Long-term analysis of case fatality rates for acute myocardial infarction in the community suggests that at least some of the reduction in cardiovascular disease mortality in recent decades can be attributed to the benefits of primary and secondary prevention strategies[3] (see Chap. 32) . The American Heart Association has stated that "compelling scientific evidence, including data from recent studies in patients with CAD, demonstrates that comprehensive risk factor interventions extend overall survival, improve the quality of life, decrease the need for interventional procedures such as angioplasty and bypass grafting, and reduce the incidence of subsequent myocardial infarction."[4] [4A] Both genders benefit.[4B]

Comprehensive cardiac rehabilitation and secondary prevention of atherosclerotic cardiovascular disease are complex tasks because of the marked heterogeneity of patients and the numerous factors influencing prognosis and symptoms. Although management by a cardiovascular specialist does confer a survival advantage in patients after myocardial infarction when compared with patients treated by generalists,[5] even cardiologists underuse recommended therapies. Risk factor interventions shown to be effective in clinical trials often do not prove equally effective in community practice, perhaps in part as a result of a paucity of resources, especially nonphysician personnel to facilitate appropriate follow-up of patients. Case management systems with nurses trained to initiate interventions in smoking cessation, exercise training, and pharmacological therapy for hyperlipidemia have proved to be considerably more effective than usual medical care for modification of coronary risk factors after myocardial infarction.[6]

In this chapter, we present the background, science, and implementation of comprehensive rehabilitation in patients with CAD. Principles of secondary prevention are discussed in Chapter 32 and are summarized in Table 39-1 . The approach to cardiac rehabilitation and secondary prevention is shown in Table 39-2 .

REHABILITATION PROGRAMS

Inpatient Programs

Hospitalization for cardiovascular illnesses or operations now tends to be brief. Consequently, comprehensive, multifaceted inpatient cardiac rehabilitation programs are presently impractical. After initial treatment of an acute coronary syndrome (or following coronary artery bypass surgery) is completed and the patient stabilized, having the patient sit in an armchair should be encouraged, even in the intensive care unit, to minimize the loss of postural reflexes and the onset of orthostatic hypotension resulting from bed rest.[7] Limited range-of-motion exercises are usually safe at this point, except in very unstable patients, and are advisable to minimize deconditioning.[8] Once the patient is moved from the intensive care unit, walking, at first with assistance, should be encouraged as long as the patient is not severely symptomatic. The period of hospitalization is the optimal time to begin long-term pharmacological therapies to improve the patient's risk factor profile, minimize symptoms, and improve long-term event-free survival. Since acute myocardial infarction may result in a transient decline in total and high-density lipoprotein cholesterol,[9] [10] it is important to base initiation of pharmacological therapy for hyperlipidemia on lipid data from prehospital records or from blood drawn at the time of admission.[9]

EDUCATION.

It is vital to begin intensive efforts to educate the patient and family regarding the nature of the patient's illness, prognosis, symptoms, medications, and important life style changes. Only one-third of patients maintain risk factor modification long-term.[4] Physicians and paramedical personnel must attempt to influence the patient at a time when concern about heart disease is at its highest. Multimedia approaches are useful adjuncts to verbal and written presentations. Educational efforts must address the need for reinforcement, variations in patient learning styles, and impediments to learning, including anxiety, pain, and sleep deprivation. Dietary guidelines, smoking cessation intervention, and instructions about walking, driving, and resumption of sexual activity[10A] are needed to minimize confusion and anxiety and to foster resumption of a normal life style.

Patients should be taught the proper response to certain symptoms should they arise after discharge, including how

TABLE 39-1 -- GUIDE TO COMPREHENSIVE RISK REDUCTION FOR PATIENTS WITH CORONARY AND OTHER VASCULAR DISEASE

RISK INTERVENTION	RECOMMENDATIONS
Smoking Goal: Complete cessation	Strongly encourage patient and family to stop smoking. Provide counseling, nicotine replacement, and formal cessation programs as appropriate
Blood pressure control Goal: 140/90 mm Hg	Initiate life style modification--weight control, physical activity, alcohol moderation, and moderate sodium restriction--in all patients with blood pressure >140 mm Hg systolic or 90 mm Hg diastolic Add blood pressure medication, individualized to other patient requirements and characteristics (i.e., age, race, need for drugs with specific benefits) if blood pressure is not <140 mm Hg systolic or 90 mm Hg diastolic in 3 mo or if *initial* blood pressure is >160 mm Hg systolic or >100 mm Hg diastolic
Lipid management	Start AHA step II diet in all patients: 30% fat, <7% saturated fat, and <200 mg/d cholesterol and promote physical activity
Primary goal LDL <100 mg/dl	Assess fasting lipid profile. In post-MI patients, lipid profile may take 4-6 wk to stabilize. Add drug therapy according to the following guide

	LDL <100 md/dl	LDL 100-130 mg/dl	LDL >130 mg/dl	HDL <35 mg/dl
Secondary goals HDL >35 mg/dl TG <200 mg/dl	No drug therapy	Consider adding drug therapy to diet, as follows:	Add drug therapy to diet, as follows:	Emphasize weight management and physical activity. Advise smoking cessation If needed to achieve LDL goals, consider niacin, statin, fibrates

Suggested Drug Therapy

TG <200 mg/dl	*TG 200-400 mg/dl*	*TG >400 mg/dl*
Statin Resin Niacin	Statin Niacin	Consider combined drug therapy (niacin, fibrates, statin)

If LDL goal not achieved, consider combination drug therapy

Weight management	Start intensive diet and appropriate physical intervention, as outlined above, in patients with BMI >25 kg/m^2 for weight Emphasize need for weight loss especially in patients with hypertension or elevated TG or glucose levels
Antiplatelet agents/anticoagulants	Start aspirin 80-325 mg/d if not contraindicated Manage warfarin to international normalized ratio of 2-3.5 in post-MI patients not able to take aspirin
ACE inhibitors post-MI	Start early post-MI in stable high-risk patients (anterior MI, previous MI, Killip class II [S_3 gallop, rales, radiographic heart failure]) Continued indefinitely for all with LV dysfunction (ejection fraction 40%) or symptoms of failure Use as needed to manage blood pressure or symptoms in all other patients
Beta blockers	Start in high-risk post-MI patients (arrhythmia, LV dysfunction, inducible ischemia) at 5-28 d. Continue 6 mo minimum. Observe usual contraindications Use as needed to manage angina, rhythm, or blood pressure in all other patients
Estrogens	Consider estrogen replacement in all postmenopausal women Individualize recommendation consistent with other health risks

ACE=angiotensin-converting enzyme; AHA=American Heart Association; BMI=body mass index; HDL=high-density lipoprotein; LDL=low-density lipoprotein; LV=left ventricular; MI=myocardial infarction; TG=triglycerides.

Modified from Consensus Panel Statement: Preventing heart attack and death in patients with coronary disease. Circulation 92:2-4, 1995.

to access local first-responder systems. Unfortunately, patients with CAD frequently do not seek help at the onset of acute myocardial infarction for multiple reasons. Some patients do not recognize the symptoms of acute myocardial infarction, particularly when they are not severe or consist of chest pressure, dyspnea, or nausea.[11] Other patients simply deny the symptoms in the hope that they will resolve.[12] [13]

TABLE 39-2 -- TRENDS IN CARDIAC REHABILITATION AND SECONDARY PREVENTION

Aggressive risk factor modification
Primary prevention in families of those with atherosclerotic vascular disease
Home telephone--electrocardiographically monitored cardiac rehabilitation exercise
Home individualized nonmonitored cardiac rehabilitation exercise
Behavior modification and compliance intervention
A greater role in managed and capitated care

Still others are too embarrassed to seek medical care if the symptoms do not seem typically cardiac for fear of wasting a physician's time because of a "false alarm." Patients who are alone, particularly when they are away from home, may respond more rapidly than if surrounded by the comforts of home and family members.[14] Consequently, education of the family is helpful in minimizing delays. Understanding the emotions of patients as they cope with acute myocardial infarction is important.[15] One should not expect that large amounts of information will be assimilated by most patients during their brief hospitalization. Continued reinforcement of these points at follow-up visits is essential and can be done quite effectively in an outpatient cardiac rehabilitation and secondary prevention setting. Broad areas, including end-of-life care, can be discussed.[15A]

Outpatient Programs

Outpatient exercise activity can be accomplished by using different formats, including supervised, nonsupervised, home (group and individual), monitored, and nonmonitored settings.

Figure 39-1 Format of a typical aerobic exercise training session illustrating the warm-up, stimulus, and cool-down phases along with a representative heart rate response. The target heart rate zone for training corresponds to 70 to 85 percent of the peak heart rate achieved during symptom-limited exercise testing. *(From Franklin BA, McCullough PA, Timmis GC: Exercise. In Hennekens CH [ed]: Clinical Trials in Cardiovascular Disease. Philadelphia, WB Saunders, 1999, pp 278-295.)*

SUPERVISED PROGRAMS.

An exercise test and supervision are essential for this type of program.[16] The cardiovascular manifestations that require precautions can vary but usually include ventricular tachycardia, other symptomatic or hemodynamically significant arrhythmias (see Chap. 25) , chest discomfort consistent with angina pectoris, exercise-induced ST depression of 2 mm or greater, or a decrease in systolic blood pressure of 20 mm Hg or greater from baseline.

Exercise testing is performed in the usual fashion (see Chap. 6) , with the heart rate at which ischemia or arrhythmia is manifested used to determine the training intensity (Fig. 39-1) . If the patient continues the exercise test to a high level of effort, a heart rate of 50 to 60 percent of maximum can be used if it falls at least 10 beats/min below the level at which symptoms, ST depression, or arrhythmia occurs. Otherwise, the recommended peak training heart rate is 10 beats/min less than that associated with symptoms, ST depression, or arrhythmia. It is desirable that these patients have medically supervised cardiac rehabilitation and reevaluation to "restratify" them 6 to 12 weeks later. Exercise testing should be repeated at least yearly. These supervised programs are usually conducted in a group hospital or center-based setting and include electrocardiographic (ECG) monitoring until a subject is restratified to low risk.

NONSUPERVISED PROGRAMS.

Exercise intensity in these programs should approximate 50 to 80 percent of maximum oxygen consumption (O_{2max}), as determined by an exercise test or the estimated metabolic equivalent (MET).[16] If a test is not done initially, a target of 20 beats/min above the resting heart rate is adequate until testing is performed.

The exercise training heart rate should be designated as 50 to 75 percent of the heart rate reserve ([maximal heart rate-resting heart rate]×50 to 75 percent) plus the resting heart rate. Activities can be prescribed according to the work intensity at which the training heart rate is achieved after 5 to 10 minutes at the same workload (steady state). This intensity may be expressed as watts on an ergometer, speed on a treadmill, or METs. If a patient cannot assess intensity, heart rate counting (manually or with a cardiotachometer) is especially useful. Heart rate counters are widely available and generally accurate for low- to moderate-intensity exercise. However, erroneous readings may occur in patients with irregular rhythms. Group programs may be followed by home programs of various types. Patients can be given an exercise prescription form (Fig. 39-2 , Table 39-3) .

Figure 39-2 Exercise prescription form. *(From Franklin BA, McCullough PA, Timmis GC: Exercise. In Hennekens CH [ed]: Clinical Trials in Cardiovascular Disease. Philadelphia, WB Saunders, 1999, pp 278-295.)*

TABLE 39-3 -- FUNDAMENTALS IN DEVELOPING AN EXERCISE PRESCRIPTION

Obtain the maximum exercise heart rate--preferably with exercise testing
Designate a target heart rate at a level 60-80% of the maximum heart rate
Begin at a low level (60-70%) and progress over 4-6 wk to the 80% level
Exercise activity should be done for 30-60 min, 4-6 times weekly, preferably on most days
Exercise sessions should incorporate aerobic activity, such as walking, jogging, cycling, or water aerobics, with appropriate warm-up and cool-down
Resistance activities such as light weights should be used on a less frequent basis--2-3 times weekly

Home Programs

Strategies for cardiac rehabilitation have changed over recent years. Currently, less emphasis is being placed on office or hospital visits for ECG monitoring and supervised group programs. Many patients are unable to participate in such programs because of travel considerations, expense, or inconvenience. Consequently, more are being managed individually through home programs. These programs involve aggressive coronary risk modification with specific emphasis on smoking cessation, lipid control, blood pressure control, and physical activity.

MONITORED PROGRAMS.

Home telephone ECG-monitored programs have been evaluated in several studies. Such monitoring is done by means of a telephone ECG transmitter, in concert with voice transmission, through a standard telephone system. These voice and ECG signals are transmitted, locally or long distance, to a central monitoring station with nurse supervision for interpretation. During these sessions, voice communication may be useful for sharing information, obtaining exercise advice, or discussing safety concerns. The ECG signal is used to document the heart rate and rhythm. A recent study comparing home-monitored exercise with standard hospital-based programs found home programs to be safe and effective in providing rehabilitative exercise.[17] [17A]

UNMONITORED PROGRAMS.

Home exercise programs without telephone monitoring are also used by cardiologists and primary care physicians for patients who have been evaluated with an exercise test. Such individual programs should, however, include periodic face-to-face physician counseling. Patients assigned to these programs are predominantly those at low risk as defined by the American Heart Association[16] and show no evidence of left ventricular dysfunction, high-grade arrhythmias, unstable angina pectoris, or other compromising medical problems. An initial exercise test is important for these patients, and some physicians periodically repeat the test to ensure the safety and efficacy of the program, as well as to confirm that the level of exercise training is appropriate.

Exercise Physiology

The circulatory response to exercise involves a complex series of adjustments resulting in a large increase in cardiac output proportional to the increased metabolic demands. These changes ensure that the metabolic needs of exercising muscles are met, that hyperthermia does not occur, and that blood flow to essential organs is protected.

HEART RATE RESPONSE TO EXERCISE.

At the transition from rest to strenuous exercise, the heart rate increases rapidly to values of 160 to 180 beats/min. During short periods of maximal exercise, rates as high as 240 beats/min have been recorded. The initial rapid increase is thought to be the result of central command influences or a brisk reflex from muscle mechanoreceptors. The almost instantaneous acceleration in heart rate is due more to vagal withdrawal than an increase in sympathetic tone. Later increases stem from reflex activation of pulmonary stretch receptors, which trigger increased sympathetic tone and additional parasympathetic withdrawal. Increased circulating catecholamines from the adrenal glands play a role as well. It has been shown that during exercise the increase in heart rate accounts for a greater percentage of the increase in cardiac output than does the increase in stroke volume. For instance, stroke volume normally reaches its maximum when cardiac output has increased by only half its maximum. Any further increase in cardiac output occurs by increasing the heart rate alone (Fig. 39-3) .

STROKE VOLUME CHANGES WITH EXERCISE.

Two physiological mechanisms influence stroke volume. The first involves enhanced cardiac filling secondary to increased venous return, followed by a more forceful contraction (increased preload, Frank-Starling mechanism). The second mechanism involves normal ventricular filling, but with a more forceful contraction secondary to neurohormonal influences that leads to more complete emptying (increased inotropy).

Greater ventricular filling during diastole, or preload, is enhanced by a slower heart rate, increased venous return, and application of the Frank-Starling principle (see Chap. 14) . Cardiac output and stroke volume are highest in the supine position. In this position, stroke volume is nearly maximal at rest and increases only slightly during exercise. In the upright position at rest, the diminished venous return to the heart results in smaller stroke volume and cardiac output. During upright exercise, however, stroke volume can approach the maximum stroke volume observed in the recumbent position, usually without an increase in ventricular diastolic dimensions.[18] This effect is achieved in part by increased venous tone and skeletal muscle compression.

DISTRIBUTION OF CARDIAC OUTPUT DURING EXERCISE.

During exertion, parasympathetic activity is withdrawn and sympathetic activity is maximal. This shift in activity results in increased release of norepinephrine from sympathetic postganglionic nerve endings. Plasma epinephrine levels are also increased. As a result, the majority of the vascular beds of the body are constricted, except those in the exercising muscles and the coronary and cerebral circulations. Blood flow to the skin increases during light and moderate exercise to facilitate body cooling. Further increases in workload cause a progressive decrease in skin flow as the rising cutaneous sympathetic vascular tone overcomes the thermoregulatory vasodilatory response.[19] The kidneys

Figure 39-3 Graphic display of the relationship of heart rate and stroke volume increase. Of note, stroke volume reaches its maximum when oxygen uptake has increased by only half maximum.

and splanchnic tissue extract 10 to 25 percent of the oxygen delivered. Consequently, considerable reductions in blood flow to these tissues can be tolerated through increased extraction of oxygen from the available blood supply.[20] At rest, the heart extracts about 75 percent of the oxygen in the coronary blood flow. Because of this limited reserve, the increased myocardial oxygen demands during exercise are met mainly by a fourfold increase in coronary blood flow. Cerebral blood flow also increases during exercise by approximately 25 to 30 percent.[21] During maximal exercise, however, cerebral flow may also decrease in association with hyperventilation and respiratory alkalosis.

On cessation of exercise, an abrupt decrease in heart rate and cardiac output occurs secondary to removal of sympathetic drive and reactivation of vagal activity. In contrast, systemic vascular resistance remains lower for some time because of persistent vasodilation in muscles. As a result, arterial pressure falls, often below preexercise levels, for periods of up to 12 hours into recovery.[22] Blood pressure is then stabilized at normal levels by baroreceptor reflexes.

CARDIOVASCULAR RESPONSE TO DIFFERENT TYPES OF EXERCISE.

Different types of exercise impose various loads on the cardiovascular system. Isotonic (dynamic) exercise is defined as muscular contraction of large muscle groups that results in movement and primarily places a volume load on the heart. *Isometric* (static) exercise is defined as a constant muscular contraction of smaller muscle groups without movement and results in more pressure than volume load on the heart. Significant increases in both cardiac output and oxygen consumption and a fall in systemic vascular resistance characterize the acute load posed by isotonic exercise. In contrast, isometric exercise acutely increases systemic vascular resistance and blood pressure while producing only minimal changes in cardiac output and oxygen consumption.[23] *Resistance* exercise is a combination of isometric and isotonic exercise that produces muscular contraction with movement, as in free weight lifting. Most activities (such as sports or employment-related activities) usually combine all three types of exercise.

CHRONIC ADAPTATIONS TO EXERCISE.

Physical conditioning or exercise training affects the cardiovascular and skeletal muscle systems in a variety of ways to improve work performance. The response of the cardiovascular system to regular exercise is an increase in its capacity to deliver oxygen to the active muscle. Physical training also improves the ability of the muscles to use oxygen. Conditioning induced by repetitive periods of dynamic exercise may increase maximum oxygen consumption twofold to threefold. About half of this increase is due to increased cardiac output, and about half is induced by peripheral adaptations that improve oxygen extraction.[24]

RISKS OF EXERCISE TRAINING.

Exercise has both risks and benefits, and the challenge to the physician is to provide guidelines that minimize risks and maximize benefits. Many factors affect the risk associated with exercise. Three of the most important are age, presence of heart disease, and intensity of exercise. Sudden cardiac death is rare in apparently healthy individuals (see Chap. 26) . In individuals younger than 35 years, sudden cardiac death is usually attributed to hypertrophic cardiomyopathy or congenital heart disease, whereas CAD is a more likely cause for those older than 35 (see Chap. 59) . Selected studies reporting risk of sudden cardiac arrest during exercise training indicate that in the general population, the risk of sudden cardiac death during vigorous exercise is very low.[16] Since these studies were not randomized controlled trials, the contribution of all potential variables to sudden cardiac arrest or death cannot be determined. However, it is generally believed that the benefits of exercise exceed the risks, and individuals should be encouraged to exercise prudently.

Efficacy of Cardiac Rehabilitation

Several studies have evaluated the cardioprotective effect of exercise training in the setting of cardiac rehabilitation programs for survivors of myocardial infarction (see Chap. 35) . A review of these trials revealed that cardiovascular rehabilitation programs lead to improved functional capacity and cardiovascular efficiency, as well as an enhanced sense of well-being.[25] The evidence, however, fell short of indicating that exercise conditioning programs can independently reduce fatal or nonfatal coronary events. Anginal thresholds remain unchanged (Fig. 39-4) .

Although more than 4700 patients have been studied in randomized trials of cardiac rehabilitation, most of the individual trials enrolled small numbers of patients and did not have sufficient power to distinguish significant differences between groups.[26] The largest study performed in the United States was the National Exercise and Heart Disease Project, which randomized 651 men who survived myocardial infarction to exercise training or to a control group.[27] The favorable trends seen in both overall mortality and cardiovascular mortality after 3 years in the exercise group failed to reach statistical significance. Recent analysis of the data, however, has revealed that increases in maximum physical work capacity on exercise testing in the study (1-MET increase at each stage) were associated with a reduction in all-cause mortality of 8 to 14 percent for up to 19 years.[28]

Two meta-analyses have examined the effect of cardiovascular rehabilitation. The first combined the results of 10 randomized clinical trials involving over 4300 patients.[29] The rehabilitation programs began 8 weeks to 3 years after myocardial infarction. The duration of the programs ranged from 6 weeks to 4 years. Cardiac rehabilitation resulted in a beneficial effect on mortality but not on nonfatal recurrent myocardial infarction. All-cause mortality was decreased by 24 percent and cardiovascular mortality by 25 percent for patients in the rehabilitation program. The reason for the lack of benefit on recurrent nonfatal myocardial infarction is unclear. The second meta-analysis reported a 20 percent decrease in both overall mortality and cardiovascular mortality.[26] The results were apparent as early as 1 year after randomization and persisted for at least 3 years after infarction. Trials that used a multifactorial approach to risk factor modification showed a greater reduction in mortality than did those that used only exercise training, which suggests that not all of the benefit could be attributed to exercise alone (Fig. 39-5) .

Exercise training is the mainstay of cardiac rehabilitation

Figure 39-4 Effect of physical conditioning on the product of heart rate (HR)×systolic blood pressure (SBP) and on myocardial O_2 consumption (M_{O_2}) at submaximal and peak exercise. Peak body O_2 uptake and workload are augmented by exercise. Myocardial O_2 requirements are reduced at a given workload of O_2 uptake, but angina occurs at the same HR×SBP product. *(From Franklin BA, McCullough PA, Timmis GC: Exercise. In Hennekens CH [ed]: Clinical Trials in Cardiovascular Disease. Philadelphia, WB Saunders, 1999, pp 278-295.)*

Figure 39-5 Chart of effects of pooling from randomized trials of cardiac rehabilitation on the estimate of mortality 3 years after randomization. Short vertical lines indicate point estimates; horizontal lines depict 95 percent confidence intervals. "Exercise Plus" usually refers to the life style and dietary modifications in both the exercise and control groups. *(From O'Connor GT, Buring JE, Yusuf S, et al: An overview of randomized trials of rehabilitation with exercise after myocardial infarction. Circulation 80:234, 1989. By permission of the American Heart Association, Inc.)*

and can be used with impressive benefits for many cardiac patients.[29A] [29E] Recent studies using coronary arteriography have shown regression or lack of progression of coronary lesions in patients who performed high-intensity exercise and were also ingesting a low-fat diet.[30] [31] These changes were maintained during a follow-up period of 6 years. High-intensity exercise training has been shown to result in a higher left ventricular ejection fraction in men with CAD than has low-intensity exercise.[32] Other studies report that exercise training programs either have no harmful effects or have significant beneficial effects on ventricular function and/or "remodeling" in subjects with CAD.[33] [34] [35]

Cardiac rehabilitation must be carried out simultaneously with an aggressive program to reduce risk factors (secondary prevention), including antiplatelet and antithrombotic therapy, beta blockade, angiotensin-converting enzyme (ACE) inhibition, and statin therapy. Secondary prevention is described in Chapter 32 .

Secondary Prevention

ASPIRIN (See Chap. 62) .

Ensuring that patients seen in the cardiac rehabilitation and secondary prevention center are receiving optimal antiplatelet/anticoagulant therapy is very important. Aspirin in a dose of 81 to 325 mg daily should be used chronically in all patients with CAD who are not intolerant of or allergic to it and who do not have other definite indications for warfarin anticoagulation.[36] An initial dose of 325 mg should be used in acute settings. For those who are unable to take aspirin and do not require warfarin, clopidogrel 75 mg daily is recommended and may be substituted for or added to aspirin in patients with peripheral arterial disease.[37]

BETA BLOCKADE.

Beta-adrenergic blocking agents are a "cornerstone" of pharmacological therapy for CAD (see Chap. 37) and should be used within rehabilitation programs whenever possible. Although multiple clinical trials have documented the benefits of beta blockers initiated as a secondary prevention measure during hospitalization for acute

myocardial infarction, continued long-term beta blockade remains underused.[38]

Following myocardial infarction, survival of patients who receive beta blockers is greatly improved in comparison to those who do not receive them, predominantly because of fewer sudden deaths. Greater benefit is seen in those with poor left ventricular function.[38] In one study of beta-blocker therapy following acute myocardial infarction, 6 lives were saved per 100 nondiabetic patients treated with beta blockers as opposed to 13 lives saved per 100 diabetics.[39] Because a reduction in heart rate is important, beta blockers with intrinsic sympathomimetic effects should not be used in patients with CAD.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS.

ACE inhibitors are a mainstay in the treatment of patients following myocardial infarction. Heart failure develops in half of all patients seen with acute myocardial infarction.[40] More than 120,000 patients in major clinical trials have been randomized to receive either an ACE inhibitor or placebo in addition to optimal conventional therapy for acute myocardial infarction (see Chap. 35) . As a consequence of these studies, ACE inhibitors have been shown to reduce mortality and morbidity during and following myocardial infarction.[41] [42] [43]

Most of the benefits associated with early ACE inhibitor use occur during the first week after myocardial infarction, when mortality is the highest.[43] The absolute benefit in mortality reduction is greatest in high-risk groups, such as patients with tachycardia or anterior wall myocardial infarction.[43] In the Trandolapril Cardiac Evaluation (TRACE) Study, trandolapril saved 87 lives per 1000 people treated over a 3-year period. Patients with hypertension and diabetes mellitus benefited the most.[44] Five lives per 1000 are saved in the first week alone if ACE inhibitor therapy is started within the first 36 hours after acute myocardial infarction.[43] Acute, short-term ACE inhibitor therapy was not found to be harmful in any subgroup in a meta-analysis of 100,000 patients with acute myocardial infarction, but hypotension and renal dysfunction were more common side effects in patients older than 75 years.[43] Current recommendations are that ACE inhibitors be continued indefinitely in patients with clinical heart failure or impaired left ventricular systolic dysfunction, but their use may be discontinued after 6 weeks if neither is present.[45] These recommendations should be implemented routinely in the secondary prevention phase of patient care.

ACE inhibitors attenuate the progressive left ventricular dilatation after large, especially anterior myocardial infarction[46] (Fig. 39-6) (see Chap. 35) . ACE inhibitors have also been shown to reduce the likelihood of clinical heart failure in patients with asymptomatic left ventricular dysfunction.[47] Large prospective clinical trials are evaluating the potential efficacy of ACE inhibitors in reducing ischemic events

Figure 39-6 Attenuation of left ventricular enlargement by captopril therapy after anterior wall myocardial infarction (MI). *(Modified from Quigg R, Salyer J, Mohanty PK, Simpson P: Impaired exercise capacity late after cardiac transplantation: Influence of chronotropic incompetence, hypertension, and calcium channel blockers. Am Heart J 136:465-473, 1998.)*

and mortality in patients with CAD and preserved left ventricular systolic function (Prevention of Events with Angiotensin-Converting Enzyme Inhibition[48] [PEACE]) and in patients at high risk for CAD[49] (Heart Outcomes Prevention Evaluation [HOPE]). In the HOPE Study, nearly 10,000 patients, most older than 65 years, were randomized to the ACE inhibitor ramipril or to placebo (see Chap. 37) . The trial was terminated by the Data and Safety Monitoring Board after 4.5 years because of the clinically important benefit of ramipril therapy.[50] The results of the HOPE Trial suggest that ACE inhibitors can be continued indefinitely in post-myocardial infarction patients with normal left ventricular function.

By blocking the production of angiotensin II and the degradation of bradykinin, ACE inhibitors cause vasodilatation, increased production of nitric oxide, decreased aldosterone secretion (lessening salt and water retention), decreased sympathetic tone, improved endothelial function, reduced left ventricular mass, antiplatelet effects, and reduced blood pressure.[51] [52] [53] [54] ACE inhibitors also have an antiischemic effect, with a 25 percent reduction in the risk of subsequent myocardial infarction. Patients in the Survival and Ventricular Enlargement[55] (SAVE) and Studies of Left Ventricular Dysfunction[47] (SOLVD) trials had a reduced need for coronary revascularization and fewer admissions for unstable angina while receiving ACE inhibitor therapy.[47] [51] [55]

ACE inhibitors have important clinical benefits, are easy to use, and are safe, but they are underused.[56] [57] Angiotensin II receptor blockers, which are now more widely used, may be administered to patients in whom ACE inhibitors cause coughing. Both these classes of drugs have similar effects and must be appropriately used in cardiac rehabilitation and secondary prevention programs.

STATIN THERAPY (see Chaps. 31 to 33).

A wealth of clinical data strongly support the use of cholesterol reduction therapy for secondary prevention in patients with established CAD. This conclusion results from a large number of well-controlled clinical trials, the most convincing of which used the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statin drugs. The relationship between on-treatment low-density lipoprotein (LDL) cholesterol and the relative risk of coronary heart disease is probably curvilinear, with diminishing returns as LDL cholesterol is reduced.[58] [59] In general, it is recommended that LDL cholesterol be reduced to less than 100 mg/dl.[60] Some have proposed that even a lower goal would be better, a hypothesis that has not yet been tested in clinical trials but will be addressed by the Treat to New Targets (TNT) Study.

Statin therapy is remarkably safe and may exert beneficial effects by several mechanisms other than reduction of LDL cholesterol, including stimulation of endothelial nitric oxide production,[61] as well as antiinflammatory[62] and antithrombotic properties.[63] [64] The survival curves of patients with cardiovascular disease who are taking statins in general diverge quickly (at 6 to 12 months) from those of patients randomized to placebo in major trials. It is believed that plaque stabilization by reducing LDL core size, inflammation, and thrombosis leads to decreased rates of plaque rupture and fissuring, thereby accounting for a decrease in cardiovascular events and improved survival.[65]

Lipid treatment strategies are progressively being refined. Published studies indicate that nurse-managed facilities can give as good, if not better results than physician-managed facilities.[6] Lipid-lowering therapy is one of the most effective areas of cardiac therapeutics (see Chaps. 33 and 37) . When combined with a proper diet and exercise, meaningful improvement in lipids is feasible in most patients, who should not be denied these benefits because they are the cornerstone of modern secondary prevention of CAD.

DIETARY SUPPLEMENTS AND ALTERNATIVE THERAPIES.

Nonprescription medications are used widely throughout the United States. In one series of patients undergoing periodic general health examinations, 61 percent were taking dietary supplements. Only half of them reported using these substances on questionnaires completed just before the examination.[66] Because of extensive attention to this subject in the lay press, it is possible that an even higher percentage of patients entering cardiac rehabilitation and secondary prevention might be using dietary supplements. Although plausible biological mechanisms for the beneficial effects of many of these supplements have been proposed, data supporting their use in clinical practice are limited to cohort and retrospective observational studies. Few significant data have been derived from controlled clinical trials.

SMOKING CESSATION.

Cigarette smoking increases platelet aggregation, serum fibrinogen, and oxidation of LDL cholesterol. Cessation also reduces high-density lipoprotein cholesterol and induces coronary artery spasm, with consequently decreased coronary and collateral flow reserve as a result of endothelial dysfunction.[67]

The dose-dependent effect of smoking is clearly defined. A 20-year follow-up study of British male physicians found that those who smoked 25 or more cigarettes per day had 2.3 times the relative risk of mortality from coronary heart disease as nonsmokers do.[68]

Patients who continue to smoke after a myocardial infarction have twice the risk of death from recurrent myocardial infarction than those who stop.[69] Many studies, including the Atherosclerosis Risk in Community Study, have shown a substantial increase in the risk of progression of atherosclerosis that is greatest in those who actively smoke, intermediate in those who formerly smoked, and lowest in those who never smoked.[70] Cigarette smoking was believed to be the single most substantial risk factor for progression of disease and a particularly potent factor in patients who had other risk factors such as hypertension or diabetes mellitus. The influence of smoking on disease progression holds for both native vessels[71] and coronary artery bypass grafts.[72]

The cardiovascular benefits of smoking cessation are striking.[73] [74] The risk of myocardial infarction declines quickly after smoking cessation. By 1 year, the risk has declined by approximately one-third from peak values, and by 3 to 4 years after cessation, the risk is equivalent to that of patients who have never smoked. The total

cardiovascular mortality rate, however, takes about 10 years to decline to the level of nonsmokers.

Addiction to nicotine is difficult to break. Most patients who are able to terminate the habit have made five or more attempts before they are ultimately successful.[75] Measures such as nicotine replacement, bupropion, and continuous reinforcement by medical professionals are helpful and safe.[75] [76] Patients who smoke more than 20 cigarettes per day, who smoke within 30 minutes of awakening in the morning, or who have significant withdrawal symptoms and relapse within a week of cessation on initial attempts or those who have a current or a past history of a significant psychiatric disorder are generally considered the most difficult to treat.[75]

Unfortunately, success rates at 1 year range from only approximately 6 percent with physician counseling as the sole intervention to 20 to 40 percent with pharmacological interventions. Nonetheless, organized smoking cessation programs appear to be cost-effective and can be implemented

in concert with secondary prevention programs. One program that reported a 22 percent smoking cessation rate at 1 year costs approximately $400 per patient (clinic visits plus drug costs). It was estimated that the cost of a net year of life gained (YLG) by the program was $6128, which compares favorably with the cost of pneumococcal vaccine in the elderly ($1500/YLG), treatment of mild to moderate hypertension ($11,300 to $24,400/YLG), heart transplantation ($16,200/YLG), and breast cancer screening ($26,800/YLG).[77]

Fear of weight gain, particularly in women, can be an impediment to smoking cessation. However, exercise improves aerobic capacity and delays weight gain after smoking cessation and can thus be a helpful part of smoking cessation programs.[78] Since a high percentage of patients coming to a cardiac rehabilitation and secondary prevention clinic for advice and follow-up are smokers, it is natural that such clinics would incorporate smoking cessation as a major focus. Evidence-based clinical guidelines from the Agency for Health Care Policy and Research and other professional organizations now define treatment strategies for physicians and health care delivery systems.[79] Because of the importance of the problem, further refinement and proliferation of such guidelines are likely to occur.[80] Smoking cessation is therefore one of the most important components of secondary prevention of CAD and should be aggressively implemented in every patient. Nicotine chewing gum, skin patches, nasal sprays and inhalers, drugs such as mecamylamine and clonidine, serotonergic treatments such as buspirone, antidepressants such as bupropion, and cigarette substitutes are techniques that can be tried. [81]

Heart Failure

Although convincing data indicating that cardiac rehabilitation prolongs life in heart failure patients do not exist, it is clear that rehabilitation is safe and helpful in improving quality of life and exercise tolerance in both medically treated patients and those who have undergone cardiac transplantation.[82] [83] Leg fatigue and exercise intolerance are common symptoms in patients with heart failure (Fig. 39-7) . Decreased cardiac reserve as a result of left ventricular systolic dysfunction is important as a cause of exercise intolerance, but the left ventricular ejection fraction and pulmonary capillary wedge pressure actually correlate quite poorly with exercise limitation.[84] [85] Abnormalities of skeletal muscle, including reductions in the number of type I muscle fibers, concentration of aerobic enzymes, and capillary density, as well as changes in contractile muscle proteins, are present in heart failure patients.[86] However, oxygen extraction (utilization) is not impaired.

Rehabilitation exercise programs for heart failure patients typically use aerobic exercises that increase cardiac output, such as treadmill walking and cycling,[87] but these exercises may also increase filling pressure.[88] One study suggested that cardiac rehabilitation was helpful only in patients who had a normal cardiac output response to exercise.[89] In another study, 68 clinically stable patients already receiving maximum medical therapy and awaiting heart transplantation were prescribed a walking program for 6 months. Walking 20 to 30 minutes at moderate intensity for a distance of up to 2 miles, four times a week, led to improved peak exercise tolerance in 38 of the 68 patients. Thirty-one of the 38 responders were subsequently removed from the heart transplant waiting list.[90] A recent randomized Italian study of predominantly men with ischemic cardiomyopathy showed a decreased rate of hospital readmission for heart failure in patients randomized to moderate exercise training (5/50) versus no exercise (14/49) during 14 months of follow-up.[91] Fewer deaths were observed in the exercise group (9/50) than in the nonexercise group (20/49).[92]

An aerobic exercise program in patients who are able to

Figure 39-7 Peripheral abnormalities leading to physical deconditioning are responsible for some of the exercise intolerance symptoms in chronic heart failure; by reducing physical deconditioning, exercise training is able to partially reverse peripheral and autonomic abnormalities and thus slow or block the vicious cycle. *(Modified from Piepoli MF, Flather M, Coats AJ: Overview of studies of exercise training in chronic heart failure: The need for a prospective randomized multicentre European trial. Eur Heart J 19:830-841, 1998.)*

tolerate it is an important adjunct to pharmacological therapy for congestive heart failure. Large randomized trials are needed to further define mechanisms of benefit, selection of patients most likely to benefit, optimal modes of training, risks, and costs.[92]

Cardiac Transplantation (see Chap. 20)

Cardiac transplantation is well established as an effective treatment in selected patients with end-stage heart disease. Cardiac rehabilitation following cardiac transplantation is recommended for its salutary effects on functional capacity.[93] [94] [95]

In the only currently available randomized trial, 27 cardiac transplant recipients were assigned to participate in a 6-month structured cardiac rehabilitation program or to undergo unstructured therapy at home.[95] Despite spending more time on the transplant waiting list and being more likely to undergo urgent transplantation, the group randomized to structured cardiac rehabilitation manifested greater increases in peak oxygen consumption and workload, as well as a greater reduction in the ventilatory equivalent for carbon dioxide.[95] The structured rehabilitation cohort demonstrated greater exercise capacity at 1 year despite inferior performance 1 month after transplantation. Although exercise training yields significant improvement at 1 year,[95] [96] [97] peak oxygen consumption fails to improve further over the ensuing 4 to 5 years,[98] [99] primarily because of limited improvement in chronotropic response beyond the first year.[98] [100]

The impaired chronotropic response of the denervated cardiac allograft is manifested by a high resting heart rate, reduced heart rate reserve, and diminished maximum heart rate during exercise. The allograft is dependent on elevated levels of circulating catecholamines for increases in stroke work and heart rate during exercise.[101] Although biochemical [102] and physiological[103] evidence of reinnervation following human cardiac transplantation is mounting, such reinnervation is usually clinically insignificant.[100] [104]

PERIPHERAL ABNORMALITIES IN OXYGEN TRANSPORT.

In addition to chronotropic incompetence and diastolic dysfunction, peripheral abnormalities in oxygen transport/utilization have been reported.[99] [105] These abnormalities may be the result of pretransplantation deconditioning (see Fig. 39-7) or posttransplantation corticosteroid use. Studies in patients with severe heart failure awaiting heart transplantation have demonstrated abnormalities in skeletal muscle morphology and bioenergetics, including reductions in type I fibers, capillary density, and oxidative enzyme activity.[86] Similar findings are seen in patients following transplantation and may contribute to the impaired exercise performance.[106] A longitudinal study of 12 transplant recipients during the first postoperative year suggested improvement in (but not complete normalization of) myocyte fiber cross-sectional area and skeletal muscle enzyme activity commensurate with gains in peak oxygen consumption.[106] Capillary density and fiber-type distribution did not change during follow-up despite 3 months of structured physical rehabilitation.[106] These observations have prompted recommendations for resistance weight training as part of posttransplantation rehabilitation.[93] [94] [107]

In the immediate postoperative phase, rehabilitation is limited to passive and active range of motion.[108] Following extubation, rehabilitation continues with mobilization, progressive ambulation, and incentive spirometry to aid pulmonary toilet. Predischarge exercise testing of patients free of acute allograft rejection or surgical complications has been suggested as a guide for outpatient exercise prescription.[94]

EXERCISE PRESCRIPTIONS IN TRANSPLANT RECIPIENTS.

The abnormal exercise physiology of cardiac transplant recipients mandates modification of standard exercise prescriptions. Target heart rates are problematic because of the chronotropic incompetence and diminished heart rate reserve of the denervated allograft. Many authorities recommend the use of Borg[109] ratings of

perceived exertion.[93] [94] [108] However, individuals vary considerably in the percentage of maximum heart rate or peak oxygen consumption that they achieve at commonly prescribed levels of perceived exertion.[110] Such variability limits the safety and efficacy of this approach in some patients.[110] Some suggest that exercise training be predicated on fixed-distance/fixed-speed prescriptions fine-tuned by perceived exertion ratings.[110]

The general principles of cardiac rehabilitation, including frequency, intensity, duration, and progression of training, apply to the heart transplantation population. Longer duration of exercise may be appropriate to allow for the delayed response to circulating catecholamines by the denervated allograft. Warm-up and cool-down periods with appropriate stretching before and after exercise are important. At least 20 minutes of sustained exercise at the prescribed intensity is desirable.

Initiation of supervised rehabilitation will vary according to the preoperative status of the recipient and the postoperative course. Generally, training can start 2 to 6 weeks after surgery[111] and should continue for at least 6 to 8 weeks.[94] Although significant improvement in exercise capacity and strength has been demonstrated with prolonged, home-based training in motivated patients, many programs start with supervised sessions 3 days per week. One study recently demonstrated the benefits of adding supervised aerobic and resistive exercise training to progressive, home-based therapy.[95] Resistive arm training should be deferred for 6 weeks to allow adequate healing of the sternotomy.[111] It should be incorporated thereafter to increase strength and functionality and to improve the skeletal muscle abnormalities of chronic heart failure and mitigate the deleterious muscular effects of immunosuppressive agents. It may also combat the osteoporosis common to this population.

Ideally, initial exercise sessions should be guided by graded exercise test results with a rating of perceived exertion that matches the ventilatory threshold,[97] or 60 to 70 percent of peak oxygen consumption. If rating of perceived exertion alone is used, an initial target of 11 to 13 is appropriate for those debilitated by chronic heart failure or postoperative recovery.[94] The exercise prescription should be advanced as the ventilatory and lactate thresholds, peak oxygen consumption, and maximum heart rate predictably improve with training and postoperative convalescence.[96] [97] [112]

Cardiovascular Rehabilitation in Obese Patients

Weight loss is a key component of cardiovascular rehabilitation in an obese patient.[112A] Exercise training is an important contributor to weight loss, although the effect of exercise is quite variable. It is not clear how much exercise is required to prevent weight gain or weight regain, although it has been suggested that the levels may be much higher than the currently recommended doses of physical activity.[113] Most controlled exercise training studies show only modest weight loss (approximately 2 to 3 kg) in the exercise group. However, when caloric restriction is added to the exercise program, the average weight loss is 8.5 kg, most of which is body fat, while diet alone results in less weight loss (5.1 kg). Over the same study period, those undergoing neither diet nor exercise programming increase weight by an average of 1.7 kg.[114] [115]

These data strongly support a role for both exercise and diet in weight loss programs. Body composition and fat distribution are linked to cardiovascular mortality[114] and are improved by exercise. Physically active men and women have a more favorable waist-to-hip ratio (i.e., less central obesity) than do sedentary individuals.[116] In general, exercise for the obese should be low-impact exercise, such as brisk walking or cycle ergometry, and be performed with greater duration and frequency and less intensity.

One study (unpublished) in obese patients with CAD in a cardiac rehabilitation program compared one group receiving extreme calorie restriction and moderate-intensity exercise with another receiving moderate caloric restriction and high-intensity exercise. The intervention results revealed that the extreme caloric restriction-moderate-intensity exercise group lost significantly more weight over the 6-month study period.

Cardiovascular Rehabilitation in Elderly Patients (see Chap. 57)

A critical factor in an elderly (
70 years) person's ability to function independently is mobility, the ability to move without assistance.[117] [118] [119] [120] [121] [122] [123] [123A] The overall focus for cardiac rehabilitation and exercise training in the elderly should be to enhance health-related conditioning while simultaneously assisting in the reduction of risk factors for various chronic diseases and improving the overall quality of life. Considerable evidence exists that physical activity, both endurance and resistance-type exercise, can provide for functional independence and overall well-being in older adults.[123B]

Exercise prescription guidelines as described previously are generally appropriate for older participants. As with younger persons, the combination of endurance and resistance

exercise is best for achieving health and conditioning goals.[124] [125] [126] [127] [128] The exercise capacity of the elderly, both before and after exercise training, is usually lower than that observed in younger persons[117] [129] (Table 39-4) . Thus, it is important to recommend activities that require low-level energy expenditure (40 to 50 percent of
O_{2max}), particularly during the first few weeks of the program. High-intensity exercise training must be recommended with caution in this age group because of the potential for musculoskeletal injury. Those whose exercise duration is limited (
15 minutes per session) because of physical or psychosocial limitations should also attempt to exercise more frequently. Conversely, lengthening the duration of activity to as much as 45 to 60 minutes per session is valuable for increasing caloric expenditure despite lower-intensity exercise.

Cardiovascular Rehabilitation in Patients with Peripheral Vascular Disease (see Chap. 41)

Patients with symptomatic peripheral vascular disease commonly have many traditional risk factors for atherosclerosis and often have severe coexistent CAD that may be symptomatic or clinically silent.[130] Frequently, occult CAD is found in these patients by screening pharmacological stress tests or angiography because exercise is often limited by claudication before the onset of cardiac symptoms. This limited exercise capacity may decrease the diagnostic accuracy of exercise stress testing. CAD is usually the life-limiting illness in these patients.[131] Consequently, aggressive risk factor modification is needed not only to slow the pace of peripheral vascular disease but also to reduce cardiovascular events and the rate of progression of coexisting CAD. Measures to protect the feet and prompt treatment of foot ulcers appear to reduce the risk of amputation.[132]

The initial therapeutic intervention for most patients with intermittent claudication is a walking program. Thirty to 45 minutes of walking performed 4 or more days weekly was reported to increase walking distance by 200 percent or more.[133] However, therapeutic trials in patients with claudication have commonly treated only a small number of patients, are often not randomized, and are difficult to interpret because of a large placebo effect and publication bias.[134] [135] [136] [137] A recent meta-analysis of such studies, including only 112 patients, concluded that the increase in pain-free walking distance at the end of an exercise program was 140 meters with a concomitant increase in total walking distance of 180 meters.[134] Thus, although exercise programs are safe and improve physical conditioning, weight control, and hypertension, the magnitude of the treatment effect is not well defined.

Small studies comparing supervised versus home-based training of claudication patients suggest an advantage in favor of the supervised setting.[134] [137] [138] Since the data are so limited at this point, prescription of expensive supervised programs is controversial and cannot yet be recommended on a routine basis.[134] However, in patients who are already enrolled in cardiac rehabilitation programs, where benefit is more readily demonstrable and better documented, treatment of peripheral vascular disease with an exercise program can be an additional benefit.

Peripheral vascular disease usually coexists with CAD. Cardiac rehabilitation programs are beneficial to patients

TABLE 39-4 -- AGE-ASSOCIATED CHANGES IN THE PHYSIOLOGICAL RESPONSE TO AEROBIC EXERCISE

Reduced aerobic capacity--a decline in maximum oxygen consumption of 8-10% per yr in nontrained populations
Reduced maximum heart rate of 1 beat/min/yr
More rapid increase in systolic blood pressure with exercise
Attenuated elevation in left ventricular ejection fraction

with peripheral vascular disease, and walking improves claudication, but the mode of exercise may need to be altered (treadmill, cycle, or swimming) to limit the likelihood that claudication will prevent a training effect. Secondary preventive measures (smoking cessation, lipid-lowering therapy) are just as important as they are in patients undergoing rehabilitation for CAD alone.

Cardiovascular Rehabilitation in Patients with End-Stage Renal Disease (see Chap. 72)

Cardiovascular disease is the leading cause of morbidity and mortality in patients with end-stage renal disease (ESRD).[139] Although many patients with ESRD are candidates, cardiac rehabilitation is underused in this high-risk cohort.

In one multicenter study of chronic hemodialysis patients, 76 percent manifested ventricular arrhythmias and 69 percent demonstrated supraventricular arrhythmias on 48-hour ambulatory monitoring.[140] Thirty-nine percent manifested multiple episodes of complex ventricular ectopy. The frequency of ventricular arrhythmias increased significantly in the second hour of dialysis and lasted up to 5 hours after dialysis. These findings suggest that close ECG monitoring and avoidance of the early postdialysis period would be prudent in scheduling exercise training sessions.

Several alterations in physiology have an impact on the rehabilitation process. Autonomic insufficiency is common in ESRD and mandates monitoring of supine and standing vital signs and caution with positional changes. Problematic contributing factors include underlying systemic disease (e.g., diabetes mellitus, amyloidosis), antihypertensive medications, aluminum toxicity, and uremia.[141] [142]

Many factors contribute to an imbalance in myocardial oxygen supply and demand in patients with ESRD.[143] Hypertension, increased intravascular volume, diastolic left ventricular dysfunction, valvular heart disease, and left ventricular systolic dysfunction can all contribute to elevated left ventricular end-diastolic pressure and reduced coronary perfusion pressure. Tachycardia-induced shortening of diastolic perfusion time, reduced coronary perfusion pressure, anemia, and dialysis-induced shifts in the hemoglobin oxygen dissociation curve conspire to reduce myocardial oxygen supply. These factors contribute to a propensity for ischemia, including ischemia during exercise training. Coupled with the higher prevalence of silent ischemia in patients with ESRD, these features make supervised, monitored exercise programs prudent for this population.

Many patients with ESRD have reduced exercise capacity[144] as a result of age, malnutrition, comorbidity, deconditioning, immobility, and advanced cardiovascular disease. Fortunately, exercising to target heart rates 50 to 70 percent of those achieved on screening maximum exercise tests achieve improvements in exercise capacity and symptomatology that are similar to those attained with traditional targets of 70 to 85 percent.[93]

Several small studies of dialysis patients free of obvious CAD suggest that intradialysis exercise programs improve quality of life, blood pressure, and some measures of metabolic health.[145] [146] [147] The safety of such programs in patients with recent acute coronary events has not been established and cannot be assumed. Limited data suggest potential hemodynamic compromise with exercise in later stages of hemodialysis sessions.[148]

The benefits of exercise training in ESRD patients after major cardiac events should be similar to those derived by others with ESRD and the cardiac rehabilitation population at large. However, profound limitations in exercise capacity may limit the effectiveness of cardiac rehabilitation for some, thus mandating careful selection of rehabilitation candidates and appropriate medical supervision.

PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE AND CORONARY ARTERY DISEASE

General principles of cardiac rehabilitation are applicable to patients with chronic obstructive pulmonary disease who have suffered a major cardiac event. Those who manifest resting or exercise-induced hypoxia (oxygen saturation less than 88 percent) should receive continuous supplemental oxygen during training sessions. High-risk individuals should be monitored closely in supervised programs and are not candidates for home-based programs.[149] These patients demonstrate less improvement in peak
O_2 than those participating in cardiac rehabilitation.

Cardiovascular Rehabilitation in Patients with Diabetes Mellitus (see Chap. 63)

Ninety percent of all diabetics manifest insulin resistance as a primary metabolic derangement.[150] These type II diabetics manifest a high prevalence of hypertension, dyslipidemia, abdominal obesity, and endothelial dysfunction, all remedial by weight loss and exercise. Thus cardiac rehabilitation is particularly beneficial in this high-risk population.

In addition to standard pharmacological intervention,

comprehensive cardiac rehabilitation is an important intervention for diabetics after major coronary events. Because of the far-ranging benefits of weight loss and exercise on the atherogenic physiology of insulin resistance, this population is particularly well suited for exercise training, behavioral counseling, and risk factor modification. Their increased risk of cardiovascular events suggests that supervised programs may be more appropriate following acute coronary events. Several unique features of this population warrant consideration during exercise training.

The adrenergic response to exercise can exacerbate hyperglycemia in suboptimally treated diabetics. Conversely, patients treated with insulin or sulfonylurea medications can experience hypoglycemia during or after exercise.[151] Monitoring blood sugar before and after exercise is an important tool during exercise training. Results should be used to tailor therapy, educate and reassure patients, and ensure safety during training sessions.[152] If preexercise glucose levels are less than 100 mg/dl, oral glucose should be administered before exercising. Fruit, a starch, or 4 to 5 gm of oral glucose tablets is recommended.[151] Emergency equipment, including glucose tablets or gels and glucagon injection kits, should be readily available to treat hypoglycemic episodes. Recurrent episodes of hypoglycemia should lead to downward adjustment of preexercise sulfonylurea or insulin doses or prompt ingestion of carbohydrate before exercise. Evening exercise sessions can occasionally induce early morning hypoglycemia and necessitate bedtime snacks or a change in the timing of exercise sessions.

To avoid excessive hyperglycemia, exercise should be avoided in the setting of poor glycemic control. If preexercise finger-stick glucose levels exceed 300 mg/dl (or if lesser degrees of hyperglycemia are present in the setting of ketonuria), exercise should be postponed until glycemic control has improved.[151]

DIABETIC NEUROPATHY.

Somatic neuropathy puts patients at risk for cutaneous and orthopedic injury during exercise. As many as 22 percent of diabetics with somatic neuropathy and cutaneous foot ulcers have radiographic evidence of foot fractures, often asymptomatic.[153] Screening for sensory deficits, cutaneous lesions, ingrown toenails, or foot deformities is an important part of intake evaluation for exercise rehabilitation programs. Patients with sensory deficits should be coached in regular foot examination before and after exercise. Proper athletic footwear, with orthotics when appropriate, is essential to minimize the risk of injury. Patients with severe neuropathy, including those with Charcot joints, should pursue non-weight-bearing exercises such as swimming, bicycling, rowing, and arm or chair calisthenics.[154]

Exercise training in patients with autonomic neuropathy should be conducted to minimize the adverse consequences of orthostatic hypotension, silent ischemia, and arrhythmia. Patients should be adequately hydrated before exercise. They should avoid exercising after meals or during the morning when orthostatic hypotension is more likely. They should adjust doses or the timing of antihypertensive medications to minimize orthostatic hypotension during or after exercise and avoid vasodilation caused by environmental heat or ethanol ingestion during training sessions. They should use compressive stockings when appropriate and exercise in a supervised setting with ECG monitoring and resuscitative equipment in the early stages after an acute coronary event.[151]

Targets for exercise should be predicated on perceived exertion rather than the heart rate in patients with autonomic neuropathy because of decreased maximum heart rates and resting tachycardia. Moderate levels of perceived exertion should be sought over 2 to 4 weeks of gradual training.[154]

Patients with nonproliferative retinopathy can engage in most forms of exercise with minimal risk of progressive disease. However, most authorities suggest limiting diabetics with severe nonproliferative retinopathy in a similar fashion to those with proliferative disease.[155] [156]

Psychological Factors in Cardiovascular Rehabilitation (see Chap. 70)

RISK FACTORS.

The concept that mental stress contributes to CAD pathogenesis or events seems logical. Blood pressure and serum lipids increase with mental stress. Factors

promoting thrombosis, decreased endothelial-dependent vasodilation, and paradoxical coronary artery constriction during mental stress have also been identified.[157] [158] However, the type A personality concept and its relationship to CAD remain controversial.[159]

Several studies have indicated that depression often precedes acute myocardial infarction. More commonly, depression begins during hospitalization for the infarction and is first noticed by the patient, family members, and/or caregivers upon the patient's return home.[160] Patients with major depression have a fivefold increase in mortality in the first 6 months following myocardial infarction, and even those with mild depression exhibit increased risk.[161] [162]

PREVENTIVE MEASURES.

Cardiac rehabilitation programs improve anxiety and depression in the short term, but proof of long-term benefit is lacking.[163] One 4-month, randomized trial of aerobic exercise, stress management, or standard medical therapy showed a statistically significant 74 percent reduction in cardiac events in the stress management group. Although the patients randomized to the exercise limb improved their aerobic conditioning and lost weight, their risk of cardiac events was not statistically different from that of the standard medical therapy group.[164] However, a meta-analysis of 23 randomized controlled trials concluded that the addition of psychological treatment to standard cardiac rehabilitation programs reduces mortality and morbidity the first 2 years after treatment.[165]

Practical approaches include vigorous measures to encourage and enable patients to return to work[166] because return to work often provides reassurance, helps focus attention away from health problems, and may address the concern that low-income patients have higher mortality after myocardial infarction.[167] Experienced clinicians frequently recount having seen widows or widowers who themselves die shortly after returning home from hospitalization for acute myocardial infarction within months of the death of their spouse. Attempts should also be made to have patients avoid social isolation inasmuch as those living alone after myocardial infarction seem to have higher mortality than those who do not live alone.[168]

Clearly, the cardiac rehabilitation and secondary prevention clinic is most appropriate to address the psychological needs of cardiac patients. These issues need to be dealt with openly and with great sensitivity on the part of all concerned. As the psychological contributions to CAD are better refined, more explicit guidelines will be feasible.

Compliance with Rehabilitation Programs

A recent review of studies regarding physical activity interventions and compliance in health care settings included 12 studies in apparently healthy subjects and 24 randomized studies in patients with cardiovascular disease.[169] Only about half of the programs were successful in increasing physical activity or cardiorespiratory training in their subjects. Characteristics of successful interventions included long-term sustained intervention and multiple contacts, supervised exercise (such as in a cardiac rehabilitation program), provision of exercise equipment, and behavioral approaches. Importantly, the behavioral component fostered subject selection of an enjoyable activity, as well as setting realistic goals, identifying barriers, problem solving, self-monitoring, providing feedback and positive reinforcement, and enhancing social support.[170] Continuing intervention and behavioral approaches have been shown to increase activity levels in CAD patients for as long as 4 to 5 years.[171] [172]

One approach to promote an increase in physical activity

is for exercise to begin slowly and then gradually progress to the recommended exercise prescription, with assessment of success and reinforcement provided regularly. Patients can begin at a more moderate intensity, shorter duration, and lower frequency than the ultimate goal. Not only are gradual increases in activity safer for sedentary people and for patients with CAD, but short-term successes may also increase the patient's self efficacy in being physically active.[173] The health care provider can use this positive outcome for feedback and reinforcement. Such an approach requires repeated follow-up visits. The most effective interventions--those with multiple components and a continued maintenance intervention--can be delivered via a model in which physicians provide advice and other members of the health care team provide more in-depth behavioral counseling and follow-up.[174]

For successful implementation of physical activity counseling in a health care setting, a coordinated, multilevel intervention should encompass strategies directed toward the practice environment, patients, and providers.[175] Systematic delivery of a counseling program might be enhanced through the use of encounter forms[176] and case management systems.[177] In addition, achieving greater implementation of physical activity interventions in health care settings will require improved education and training of health professionals and attention to health care policy and reimbursement issues. The cardiac rehabilitation setting is an excellent milieu in which to use the aforementioned modalities to implement physical activity and improve compliance in a motivated population.

Cost-Effectiveness of Cardiac Rehabilitation (see Chap. 2)

A comprehensive economic analysis of cardiac rehabilitation and secondary prevention includes not only the direct costs of the cardiac rehabilitation intervention but also indirect costs and cost savings attributed to treatment benefits. In addition to the expense of the cardiac rehabilitation program and exercise tests, diminished work time while attending the program, transportation, rehospitalization, costs of medical disability, and the medical and pension costs of enhanced longevity must be considered.[178] A number of studies have addressed these issues, but unfortunately, no single study is comprehensive, randomized, and controlled. Furthermore, studies performed in one area or region or in one country are not necessarily relevant in another area or country because of variations in health plans, differences in incentives to return to work, and wide diversity in management "styles" and the availability of revascularization procedures.

One method shown to be effective 3 weeks after myocardial infarction is the performance of an "occupational work evaluation." This intervention consists of an exercise test and advice about exercise with specific recommendations for early return to work in patients stratified by the exercise test to a low-risk category.[179] When compared with a usual care control group, patients randomized to the intervention had an earlier return to work with an average increase in individual earnings of $2100 over a 6-month period. They also realized a decrease of $500 per patient in total medical costs during follow-up.

Several investigations from Sweden and the United States have evaluated the effect of cardiac rehabilitation participation on subsequent rehospitalization and cost. In an American study, the authors investigated the effect of cardiac rehabilitation on subsequent rehospitalization cost in 580 patients over a mean follow-up period of 21 months.[180] In the rehabilitation group, per capita charges for cardiac rehospitalizations were $739 lower than in control patients. The cost difference was explained by both fewer hospitalizations and lower cost per hospitalization in the cardiac rehabilitation intervention group. Of note, admissions for evaluation of chest pain decreased by 42 percent.

The results of three controlled trials from Sweden further support decreased health care cost after cardiac rehabilitation.[181] [182] [183] In an initial study of 147 coronary bypass patients, hospital readmissions over a 1-year period were reduced by 62 percent in the comprehensive cardiac rehabilitation group.[183] Another controlled trial of 190 patients 65 years of age or older after myocardial infarction defined the effects of a nurse-managed education program lasting 4 months and low-intensity exercise training of 8 weeks' duration.[182] This program resulted in lower rates of rehospitalization (32 vs. 47 percent) over a 1-year period and significantly fewer visits to the emergency department.

The most detailed economic evaluation to date compared comprehensive cardiac rehabilitation (exercise and risk factor modification) with usual care in 305 nonselected myocardial infarction patients over a 5-year period.[181] In addition to a lower rate of total cardiac events (39 vs. 53 percent), the average total duration of in-hospital care was reduced from 16.1 to 10.7 days in the intervention group. The authors concluded that the actual cost of rehabilitation was balanced over the 5-year period by the decrease in hospital readmissions for cardiovascular disease. They also noted that cardiac rehabilitation patients had a higher 5-year return-to-work rate (43 vs. 38 percent). Increased work productivity (i.e., less disability and sick leave) resulted in $12,250 savings per patient to the Swedish disability system.

Finally, a randomized trial of an 8-week cardiac rehabilitation intervention that focused on anxious or depressed patients after myocardial infarction noted a cost-effectiveness of $9200 per quality-adjusted life year,[184] similar to the cost-effectiveness of well-established medical interventions such as coronary bypass surgery for left main coronary disease and beta-adrenergic blockers after myocardial infarction. It is more cost-effective than other accepted practices such as ACE inhibitors for the treatment of hypertension and lovastatin for hypercholesterolemia.[185] Therefore, limited data support the cost-effectiveness of cardiac rehabilitation in the care of patients after a coronary event.

Chapter 40 - Diseases of the Aorta

ERIC M. ISSELBACHER

THE NORMAL AORTA

FUNCTION

Appropriately called "the greatest artery" by the ancients, the aorta is admirably suited for its task. In an average lifetime, this thin but large and remarkably tough vessel must absorb the impact of 2.3 to 3 billion heartbeats while carrying roughly 200 million liters of blood through the body. Arteries can be categorized as either *conductance* or *resistance* vessels. Conductance vessels are conduits for blood, and the aorta is the ultimate conductance vessel.

The aorta is composed of three layers: the thin inner layer, or *intima;* a thick middle layer, or *media;* and a rather thin outer layer, the *adventitia.* The strength of the aorta lies in the media, which is composed of laminated but intertwining sheets of elastic tissue arranged in a spiral manner that affords maximum tensile strength. Indeed, as thin as it is, experimentally the aortic wall can withstand the pressure of thousands of millimeters of mercury without bursting. In contrast to the peripheral arteries, the aortic media contains multiple layers of elastic laminae (see Chap. 30) . It is this tremendous accretion of elastic tissue that gives the aorta not only tensile strength but also distensibility and elasticity, which serve a vital circulatory role. The aortic intima is a thin, delicate layer that is lined by endothelium and easily traumatized. The adventitia contains mainly collagen and carries the important vasa vasorum, which nourish the outer half of the aortic wall, including much of the media.

During ventricular systole, the aorta is distended by the force of the blood ejected into it by the left ventricle, and in this manner, part of the kinetic energy generated by the contracting left ventricle is converted into potential energy stored in the aortic wall. Then, during diastole, this potential energy is transformed back into kinetic energy as the aortic walls recoil and propel the blood in the aortic lumen distally into the arterial bed. Thus, the aorta plays an essential role in maintaining forward circulation of the blood in diastole after it is delivered into the aorta by the left ventricle during systole. The pulse wave itself, with its milking effect, is transmitted along the aorta to the periphery at a speed of about 5 meter/sec. This speed is much faster than the velocity of the intraluminal blood itself, which travels at only 40 to 50 cm/sec.

The systolic pressure developing within the aorta is a function of the volume of blood ejected into the aorta, the compliance or distensibility of the aorta, and resistance to blood flow. This resistance is determined primarily by the tone of the peripheral muscular arteries and arterioles and, to a slight extent, by the inertia of the column of blood in the aorta when systole commences.

In addition to its conductance and pumping functions, the aorta also plays a role in indirectly controlling systemic vascular resistance and heart rate. Pressure-responsive receptors, analogous to those in the carotid sinus, lie in the ascending aorta and aortic arch and send afferent signals to the vasomotor center in the brain stem by way of the vagus nerves. An increase in intraaortic pressure causes reflex bradycardia and a reduction in systemic vascular resistance, whereas a decrease in intraaortic pressure increases the heart rate and vascular resistance.

ANATOMICAL CONSIDERATIONS

The aorta is divided anatomically into thoracic and abdominal components. The thoracic aorta is further divided into the *ascending, arch,* and *descending* segments, while the abdominal aorta consists of *suprarenal* and *infrarenal* segments.

The *ascending aorta* is some 5 cm long and has two distinct segments. The lower segment is the *aortic root*, which begins at the level of the aortic valve and extends to the sinotubular junction. This portion of the ascending aorta is the widest and measures about 3.3 cm. The bases of the aortic leaflets are supported by the aortic root, from which the three sinuses of Valsalva bulge outward to allow for full excursion of the aortic valve leaflets during systole. In addition, the two coronary arteries arise from these sinuses of Valsalva. The upper tubular segment of the ascending aorta rises to join the aortic arch. Normally, the ascending aorta sits just to the right of midline, with its proximal portion lying within the pericardial cavity.

The *arch of the aorta* gives rise to all the brachiocephalic arteries. From the ascending aorta it courses slightly leftward in front of the trachea and then proceeds posteriorly to the left of the trachea and esophagus. The pulmonary artery bifurcation and right pulmonary artery lie inferior to the arch, as does the left lung.

The *descending thoracic aorta* begins in the posterior mediastinum to the left of the vertebral column and gradually courses in front of the vertebral column as it descends, where it occupies a position immediately behind the esophagus. Distally, it passes through the diaphragm, usually at the level of the 12th thoracic vertebra.

The point at which the aortic arch joins the descending aorta is called the *aortic isthmus.* The aorta is especially vulnerable to trauma at this site because it is here that the relatively mobile portion of the aorta--the ascending aorta and arch--becomes relatively fixed to the thoracic cage by the pleural reflections, the paired intercostal arteries, and the left subclavian artery. This point is also where coarctations of the aorta are located.

The abdominal aorta continues from the thoracic aorta, gives rise to the mesenteric and renal arteries, and ends at its bifurcation at the level of the fourth lumbar vertebra.

AGING OF THE AORTA

As discussed above, the elastic properties of the aorta are crucial to its normal function. However, the elasticity and distensibility of the aorta decline with age. Such changes occur even in normal healthy adults, and for unknown reasons, these changes occur earlier and are more progressive in men than women.[1] The loss of elasticity and aortic compliance probably accounts for the increase in pulse pressure commonly seen in the elderly. This progressive loss of aortic elasticity with aging is accelerated among those with hypertension when compared with age-matched normotensive controls.[2] Similarly, those with hypercholesterolemia[3] or coronary artery disease show a greater loss of elasticity than do controls.[4] Conversely, among healthy athletes, aortic elasticity is higher than in their age-matched controls.[4]

Histologically, the aging aortic wall exhibits fragmentation of elastin with a concomitant increase in collagen that results in an increased collagen-to-elastin ratio, which contributes to the loss of aortic distensibility observed physiologically.[5] Recent experimental animal data suggest that impairment of vasa vasorum flow to the aortic

wall results in stiffening of the aorta with similar histological changes and may therefore be one cause of the degenerative changes seen with age.[6]

In animal models, loss of aortic distensibility directly affects the mechanical performance of the left ventricle, with increases noted in left ventricular systolic pressure and wall tension and in end-diastolic pressure and volume.[7] Furthermore, reduced aortic compliance causes a 20 to 40 percent increase in myocardial oxygen consumption to maintain a given stroke volume.[8] It is therefore likely that over time, the changes in aortic compliance seen with age may cause clinically important alternations in cardiac function.[7]

EXAMINATION OF THE AORTA

Unless the aorta is abnormally enlarged, the only location in which it can be palpated is the abdomen. The ease with which it can be felt depends largely on body habitus and

pulse pressure: It is readily felt in thin individuals. It may be quite sensitive to palpation. Auscultation is usually unrevealing in aortic diseases, except for occasional bruits at sites of narrowing of the aorta or its arterial branches. Diseases of the aortic root and proximal ascending aorta sometimes involve the aortic valve, with resultant aortic regurgitation that may be detectable on auscultation. Regurgitant murmurs secondary to root dilatation rather than primary valvular disease are often loudest along the right sternal border.

Chest radiography and fluoroscopy are valuable and simple procedures for assessing the aorta. Normally, the ascending aorta is not visible on the direct anteroposterior chest roentgenogram. The aorta is seen as a "knob" in the superior mediastinum just to the left of the vertebral column. The lateral border of the descending thoracic aorta can often be found to the left of the spine. On the lateral chest roentgenogram, the aortic root and proximal ascending aorta are visible as an indistinct shadow in the middle of the mediastinum arising from the base of the heart. The ascending aorta and arch are best demonstrated in a left anterior oblique projection--a view that should always be included when disease of the thoracic aorta is suspected.

A number of imaging modalities are available for diagnostic examination of the aorta, including aortography, computed tomography (CT), magnetic resonance imaging (MRI), and both transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE). The respective utility of these imaging modalities is discussed below in the context of specific aortic diseases.

AORTIC ANEURYSMS

The term *aortic aneurysm* refers to a pathological dilatation of the normal aortic lumen involving one or several segments. Although perhaps no definition is universally accepted, an aortic aneurysm is best described as a permanent localized dilatation of the aorta having a diameter at least 1.5 times that of the expected normal diameter of that given aortic segment.[9] Aneurysms are usually described in terms of their location, size, morphology, and etiology. The morphology of an aortic aneurysm is typically either *fusiform,* which is the more common shape, or *saccular.* A fusiform aneurysm is fairly uniform in shape, with symmetrical dilatation that involves the full circumference of the aortic wall. The dilatation seen in saccular aneurysms, on the other hand, is more localized and appears as an outpouching of only a portion of the aortic wall. In addition, the aorta may have a *pseudoaneurysm* or *false aneurysm,* which is not actually an aneurysm at all, but rather a well-defined collection of blood and connective tissue outside the vessel wall. This defect may be a consequence of a contained rupture of the aortic wall.

The presence of an aortic aneurysm may be a marker of more diffuse aortic disease. Overall, up to 13 percent of all patients in whom an aortic aneurysm is diagnosed are found to have multiple aneurysms,[10] with up to 25 to 28 percent of those with thoracic aortic aneurysms having concomitant abdominal aortic aneurysms.[11] [12] For this reason, Crawford and Cohen have recommended that a patient in whom an aortic aneurysm is discovered should undergo examination of the entire aorta for the possible presence of other aneurysms.[10]

Abdominal Aortic Aneurysms

Abdominal aortic aneurysms are much more common than thoracic aortic aneurysms. Age is an important risk factor inasmuch as the incidence rises rapidly after 55 years of age in men and 70 years of age in women,[13] and abdominal aortic aneurysms occur four to five times more frequently in men than women. The incidence of abdominal aneurysms has increased threefold in recent decades, from 8.7 per 100,000 person-years in 1951 to 36.5 to 60 per 100,000 person-years in 1971 to 1980.[14] Because the incidence of abdominal aneurysms of all sizes has increased, it is believed that these data at least in part reflect a true increase in disease incidence. Other factors that may have contributed to the marked rise in the incidence of such aneurysms include the increasing mean age of the population, a greater awareness of the association of aneurysmal disease with other prevalent cardiovascular conditions, and improvements in diagnostic evaluation. The prevalence of abdominal aortic aneurysms in the population 50 years of age and older is at least 3 percent.[15]

ETIOLOGY AND PATHOGENESIS

Although it is now evident that abdominal aortic aneurysms arise as a consequence of multiple interacting factors, classically, atherosclerosis has been considered the common underlying etiology. (See also Chap. 30.) The infrarenal abdominal aorta is most affected by the atherosclerotic process and is similarly the most common site of abdominal aneurysm formation; only a fraction of abdominal aortic aneurysms are suprarenal, with these tending to arise only as an extension of a thoracic (thoracoabdominal) aneurysm. The atherosclerotic process less often involves the thoracic aorta.

Atherosclerotic disease of the aorta may produce either stenotic obstruction, a process that tends to be confined to the infrarenal abdominal aorta, or aneurysmal dilatation; why one process should predominate over the other in any given individual, however, is unknown.[15] Although the mechanism by which atherosclerosis results in aortic aneurysms is obscure, a recent hypothesis may account for the disease's predilection for the infrarenal abdominal aorta over other segments.[16] The media of the infrarenal aorta in humans has no vasa vasorum, and as a consequence, at least the inner media must receive oxygen and nutrients by diffusion from the aortic lumen. Atherosclerotic disease causes thickening of the intima and may thereby compromise the diffusion of such oxygen and nutrients to the medial layer. Exacerbated by increases in aortic wall stress from hypertension, this tissue hypoxia may injure the media and thus initiate a process of degeneration of the media and its elastic elements.[16] The damage produces a weakening of the aortic wall that over time allows the formation of fusiform or, less commonly, saccular dilatation of the aorta. As the aorta then widens, tension in the vessel wall rises in accordance with Laplace's law, which states that tension is proportional to the product of pressure and radius. Further widening results in even greater wall tension, which in turn leads to acceleration of aneurysm enlargement. A vicious circle is thus established in which the dilatation is often rapidly progressive.

Although atherosclerosis certainly contributes to the pathogenesis of abdominal aortic aneurysms, genetic and cellular factors play important roles as well. A genetic predisposition to the development of abdominal aortic aneurysms has been repeatedly suggested by studies of familial incidence, with up to 28 percent of patients who have an abdominal aortic aneurysm having a first-degree relative similarly affected.[17] A report analyzing 313 pedigrees has confirmed the importance of familial factors in the pathogenesis of abdominal aortic aneurysms and supports the hypothesis that abdominal aortic aneurysm might be a predominantly genetic disease.[18] At present, however, few single gene mutations are known to cause aneurysm formation (e.g., Marfan syndrome and Ehlers-Danlos syndrome type IV).[18A] (See also Chap. 56.) It appears likely that the genetic factors involved may be polygenic.

An area of expanding investigation is the role of cellular mechanisms in the pathogenesis of aortic aneurysms. Destruction of the media and its elastic tissue is the striking histological feature of aortic aneurysms when compared with the normal aorta. Experimental evidence indicates excessive activity of proteolytic enzymes in the aortas of affected patients, which may lead to deterioration of structural matrix proteins such as elastin and collagen in the aortic media and thereby promote or perpetuate the formation of aneurysms.[19] Studies have shown that aneurysmal aortas contain elastolytic activity with an active elastase not present in the normal aorta[20] and that other active proteolytic enzymes are present as well. An active inflammatory process may also contribute, given that an abnormal presence of macrophages[21] and elevated levels of cytokines[22] have been demonstrated in aneurysmal aortic tissue.

As a result of flow disturbance through the aneurysmal aortic segment, blood may stagnate along the walls and thus allow the formation of mural thrombus. Such thrombus, as well as atherosclerotic debris, may embolize distally and compromise the circulation of tributary arteries. However, the major risk posed by abdominal aortic aneurysms is that of aneurysm rupture. When rupture does occur, 80 percent rupture into the left retroperitoneum, which may

contain the rupture, whereas most of the remainder rupture into the peritoneal cavity and cause uncontrolled hemorrhage and rapid circulatory collapse.[23] Rarely, an

aneurysm may rupture into the inferior vena cava, iliac vein, or renal vein.

Clinical Manifestations

The majority of abdominal aortic aneurysms are asymptomatic and discovered incidentally on routine physical examination or on an abdominal roentgenogram[14] or ultrasound scan ordered for other indications. Younger patients (50 years old or less), however, are several times more likely to be symptomatic at the time of diagnosis.[24] Among these patients, pain is the most frequent complaint[14] and is usually located in the hypogastrium or lower part of the back. The pain is usually steady, has a gnawing quality, and may last for hours to days at a time. In contrast to musculoskeletal back pain, aneurysm pain is not affected by movement, although patients may be more comfortable in certain positions, such as with the legs drawn up.

RUPTURED ANEURYSM.

Expansion and impending rupture are heralded by the development of new or worsening pain, often of sudden onset. This pain is characteristically constant, severe, and located in the back or lower part of the abdomen, sometimes with radiation into the groin, buttocks, or legs. Actual rupture is associated with abrupt onset of back pain along with abdominal pain and tenderness. Most patients have a palpable, pulsatile abdominal mass, and many are hypotensive when initially seen. However, this familiar triad of abdominal/back pain, a pulsatile abdominal mass, and hypotension--recognized as pathognomonic of a ruptured abdominal aortic aneurysm--is seen in as few as one-third of cases.[25] Moreover, a ruptured aneurysm may mimic other acute abdominal conditions, such as renal colic, diverticulitis, or a gastrointestinal hemorrhage, and may therefore be initially misdiagnosed in as many as 30 percent of cases.[2]

Patients who suffer rupture of an abdominal aortic aneurysm are critically ill. Hemorrhagic shock may ensue rapidly and is manifested by hypotension, vasoconstriction, mottled skin, diaphoresis, mental obtundation, and oliguria and, terminally, by arrhythmias and cardiac arrest. Retroperitoneal hemorrhage may be signaled by hematomas in the flanks and groin. Rupture into the abdominal cavity may result in abdominal distention, whereas rupture into the duodenum is manifested as massive gastrointestinal hemorrhage.

PHYSICAL EXAMINATION.

Many aneurysms can be detected on physical examination,[26A] although even large aneurysms may be difficult or impossible to detect in obese individuals.[27] When palpable, a pulsatile mass extending variably from the xiphoid process to the umbilicus may be appreciated. Because of difficulty distinguishing the abdominal aorta from surrounding structures by palpation, the size of an aneurysm tends to be overestimated on physical examination. Moreover, it may be difficult to differentiate a tortuous, ectatic aorta from true aneurysmal dilatation. Aneurysms are often sensitive to palpation and may be quite tender if rapidly expanding or about to rupture. While tender aneurysms should be examined cautiously, no risk is known to be associated with palpation of the abdominal aorta.[27]

Associated occlusive arterial disease is sometimes present in the femoral pulses and distal pulses in the legs and feet. Bruits arising from associated narrowed arteries may be heard over the aneurysm. Occasionally, an arteriovenous fistula may be formed by spontaneous rupture into the inferior vena cava, iliac vein, or renal vein and cause a syndrome of hemodynamic collapse and acute high-output cardiac failure.

DIAGNOSIS AND SIZING.

Several diagnostic imaging modalities are currently used for detecting, sizing, and serially monitoring abdominal aortic aneurysms, as well as for precisely defining the aortic anatomy preoperatively. Abdominal ultrasonography is perhaps the most practical way to screen for abdominal aortic aneurysms. It can visualize an aneurysm in the transverse and longitudinal planes, has a sensitivity of nearly 100 percent,[28] and can accurately define aneurysm size to within ±0.3 cm.[29] [30] Its major advantages are that it is inexpensive and noninvasive and does not require the use of a contrast agent. However, ultrasound is limited by its inability to visualize the cephalic or pelvic extent of disease or define the associated mesenteric and renal arterial anatomy. Therefore, it is insufficient for planning operative repair.

Computed tomography is an extremely accurate method for both diagnosing aortic aneurysms (Fig. 40-1) and sizing them to within ±0.2 cm.[31] CT has an advantage over ultrasonography in that it can better define the shape and extent of the aneurysm as well as the local anatomical relationships of the visceral and renal vessels. Its disadvantages are that the procedure is more expensive and less widely available than ultrasonography, and it also requires the use of ionizing radiation and intravenous contrast. Although CT may therefore be less practical than ultrasonography as a screening tool, its high accuracy in sizing aneurysms makes it an excellent modality for serially monitoring changes in aneurysm size.[30] It is important to note that CT measurements of aneurysm size tend to be larger than ultrasound measurements by an average of 0.27 cm.[32] Conventional CT scanning is limited in the preoperative evaluation of abdominal aortic aneurysms because it does not provide information regarding renal or mesenteric arterial occlusive disease. However, newer techniques such as spiral (helical) CT with three-dimensional display of the aorta and its branches[33] provide more comprehensive preoperative evaluation of the anatomy of an abdominal aortic aneurysm.

Aortography has long been the standard imaging modality for the preoperative definition of abdominal aortic aneurysm anatomy. Although it is well recognized that aortography may underestimate aneurysm size in the presence of nonopacified mural thrombus lining the aneurysm walls, it nevertheless remains an excellent technique for defining the suprarenal extent of the aneurysm and any associated iliofemoral disease. It is also excellent for defining renal and mesenteric arterial anatomy. The need for routine preoperative aortography is open to debate,[34] and in fact, many surgeons now use it only selectively.[35] Its disadvantages are that it is expensive, it is an invasive procedure with inherent risks, and it requires the use of intraarterial contrast and ionizing radiation.

Most recently, *magnetic resonance (MR) angiography* has been promoted as an alternative to aortography for the preoperative evaluation of aortic aneurysms.[34] Whereas flowing blood appears as a signal void on conventional spin-echo MRI, with the use of MR angiography blood has a bright appearance and vessels can be displayed in a projective fashion similar to what is seen with traditional angiography. Moreover, because tomographic images are reconstructed to create a three-dimensional image, the aorta may be visualized from a series of projections to facilitate appreciation of anatomical relationships. MR angiography is extremely accurate in determining aneurysm size, and it correctly defines the proximal extent of disease and iliofemoral involvement in greater than 80 percent of cases.[34] The exact role of MR angiography in the evaluation of abdominal aortic aneurysms continues to be investigated.[34] [36]

An important, but unresolved, issue regarding the detection of abdominal aortic aneurysms is the potential place, if any, of screening asymptomatic patients for the presence of aneurysms. At present, no controlled trials of aneurysm screening have provided outcomes data that might be used in guiding any such recommendations. A recent study based on the existing literature suggests that screening men 60 to 80 years of age by physical examination is cost-effective,

Figure 40-1 *A,* Axial contrast-enhanced CT scan showing a 6.6-cm abdominal aortic aneurysm (A) lined with mural thrombus (T). Blistering of the aneurysm (B) is indicative of a weakened aortic wall and suggests impending rupture. *B,* Three-dimensional shaded-surface display of the same CT scan. This anteroposterior projection demonstrates that the aneurysm (A) is infrarenal and displays its anatomical relationship to surrounding structures, including the renal arteries (R) proximally and the aortic bifurcation distally. *(Courtesy of John A. Kaufman, M.D., Division of Vascular Radiology, Massachusetts General Hospital, Boston.)*

although of small benefit, whereas screening the same population with ultrasonography is at the upper limit of cost-effectiveness and of modest benefit.[37] Repeated screening was found to be not cost-effective. Many authors currently recommend the use of screening ultrasonography only for those at high risk, in particular those with a family history of abdominal aortic aneurysm[17] or those older than 60 years with a history of smoking or hypertension.

NATURAL HISTORY.

The paramount concern in managing abdominal aortic aneurysms is their tendency to rupture. Mortality from rupture is quite high: Sixty percent of patients die before receiving medical attention[38] and the operative mortality for those reaching the hospital is approximately 50 percent,[29] for an overall mortality from rupture of 80 percent. In 1950, before the introduction of modern surgical repair, Estes first assessed survival rates for those with abdominal aortic aneurysms[39] and found survival at 3 and 5 years to be 49 percent and 19 percent, respectively, far lower than for age-matched controls, with two-thirds of deaths caused by aneurysm rupture. However, after the introduction of modern surgical repair, it was found that survival among abdominal aortic aneurysm patients undergoing operative repair was significantly higher than among those managed nonoperatively. Surgical repair thus remains the therapy of choice for aneurysms considered to be at risk of rupture.

Darling and colleagues convincingly demonstrated that the risk of rupture increases with aneurysm size.[40] Present estimates suggest that aneurysms smaller than 4.0 cm have a 0 to 2 percent risk of rupture,[41] [42] whereas those larger than 5.0 cm have a 22 percent risk of rupture within 2 years.[42] Because 80 percent of abdominal aortic aneurysms expand over time--with as many as 15 to 20 percent expanding rapidly (>0.5 cm/yr)--the risk of rupture may concomitantly increase with time.

Accordingly, the ability to predict rates of aortic aneurysm expansion would be useful in estimating the risk of future rupture. Although the mean rate of abdominal aortic aneurysm expansion appears to be approximately 0.4 cm/yr,[29] the rates of expansion within a population are extremely variable, and expansion rates even vary within one individual over time. Baseline aneurysm size is perhaps the best predictor of aneurysm expansion rate,[29] with larger aneurysms expanding more rapidly than small ones--probably as a consequence of Laplace's law. A rapid rate of expansion apparently also predicts aneurysm rupture, especially abdominal aneurysms 5.0 cm or greater in diameter.[43] Many surgeons therefore consider both large size and rapid expansion to be indications for repair.

Management

SURGICAL TREATMENT.

Debate on the optimal timing of surgical repair in asymptomatic abdominal aortic aneurysms is ongoing. The decision to operate must weigh the natural history of the aneurysm and life expectancy of the patient against the anticipated morbidity and mortality of the proposed surgical procedure. Operative mortality is 4 to 6 percent overall for elective aneurysm repair and as low as 2 percent in low-risk patients. However, operative mortality rises to 19 percent for urgent aortic repair and reaches 50 percent for repair of a ruptured aneurysm.[29] [44] As of this writing, aneurysm size remains the primary indicator for repair of asymptomatic aneurysms, although no clear consensus yet exists regarding the minimum aneurysm diameter that necessitates surgery. Whereas all vascular surgeons would operate for an abdominal aortic aneurysm larger than 6.0 cm in diameter and most for aneurysms larger than 5.0 cm in patients who are reasonable surgical risks, few would operate for an asymptomatic aneurysm smaller than 4.0 cm. The benefit of surgery for asymptomatic aneurysms 4.0 to 5.0 cm in size, however, has not yet been defined. The recommendation of the Society for Vascular Surgery and the International Society for Cardiovascular Surgery is for elective repair of abdominal aortic aneurysms 4.0 cm or larger in diameter,[29] although many other surgeons still consider 5.0 cm or larger to be the indication for surgery.[44A] Prospective controlled multicenter trials currently under way in the United States, Canada, and the United Kingdom should help address the optimal timing of surgery based on aneurysm size.[45] [46]

Surgical repair of abdominal aortic aneurysms consists of opening of the aneurysm and insertion of a synthetic prosthesis, usually fabricated of Dacron or expanded polytetrafluoroethylene (Gore-Tex). Sometimes, a simple tube graft is all that is necessary, although frequently the operation must be carried distally into one or both of the iliac arteries to excise the aneurysm completely. In the case of large aneurysms, much of the aneurysm wall may be left in situ ("intrasaccular approach of Creech"), thereby reducing the need for extensive dissection and thus decreasing aortic cross-clamping time.

A promising new interventional option for the treatment of abdominal aortic aneurysms is the use of percutaneously implanted, expanding endovascular stent-grafts (see Figs. 42-5 and 42-6) . The device consists of a collapsible prosthetic tube graft that is inserted remotely (e.g., via the femoral artery), advanced transluminally across the aneurysm under fluoroscopic guidance, and then secured at both its proximal and distal ends with an expandable stent attachment system. For aortic aneurysm repair, the stent-graft serves to bridge the region of the aneurysm, thereby excluding it from the circulation while allowing aortic blood flow to continue distally through the prosthetic stent-graft lumen. In some cases, stent-grafts are bifurcated, with two arms on the distal end designed to extend into the common iliac arteries when these vessels are aneurysmal as well. The rate of successful stent-graft implantation in several recent series ranged from 78 to 94 percent,[47] [48] [49] [50] with some outcome variability resulting from differing definitions of procedural success. Despite these promising results, only 30 to 60 percent of patients with abdominal aortic aneurysms have aneurysm anatomy suitable for possible endovascular repair. Moreover, the long-term outcomes of endovascular repair versus conventional surgical repair are not yet known. One of the major technical difficulties associated with the stent-graft technique that has yet to be overcome is the frequent occurrence of *endoleaks,* which are seen angiographically as persistent contrast flow into the aneurysm sac because of failure to completely exclude the aneurysm from the aortic circulation. Such endoleaks, if left untreated, may leave the patient at continued risk for aneurysm expansion or rupture.[51] Therefore, the use of stent-grafts for endovascular repair of abdominal aortic aneurysms is at present limited to a subset of patients, typically older patients or those at high operative risk.[51A]

Assessing Operative Risk (See also Chap. 61) .

Because patients with abdominal aortic aneurysms, by definition, have vascular disease, their high likelihood of concomitant coronary, renal, and cerebrovascular arterial disease significantly increases the risk of major vascular surgery. Indeed, Hertzer found that half of all perioperative deaths from aneurysm repair are due to myocardial infarction.[52] In addition, routine coronary arteriography in those undergoing aneurysm repair revealed severe correctable coronary artery disease in 31 percent of all patients, including an 18 percent incidence in patients without prior clinical manifestations of coronary disease.[53] Moreover, among those with angiographically significant coronary artery disease, multivessel disease was seen in the majority.[53]

Studies by Boucher and colleagues[54] and Eagle and associates [55] have suggested that dipyridamole-thallium cardiac scanning is an effective means of identifying patients at highest risk for perioperative ischemic events (see also Chaps. 9 and 13) . Patients with reversible thallium defects in multiple segments of myocardium are at highest risk,[56] and it is in this subgroup that coronary angiography is likely to be most helpful. The safety of dipyridamole-thallium studies in such patients has been well established. Although exercise thallium scintigraphy is also a useful screening method, many patients with vascular disease fail to achieve an adequate heart rate because of limited exercise capacity. Other techniques shown to be effective for preoperative evaluation of myocardial ischemia include dobutamine stress echocardiography and electrocardiographic exercise testing in patients with a normal baseline electrocardiogram and adequate exercise tolerance.

Selective preoperative evaluation to identify the presence and severity of coronary artery disease in patients with clinical markers of coronary artery disease has been widely advocated,[57] and some further suggest screening those with strong cardiac risk factors despite the absence of clinical evidence of coronary artery disease.[58] Although patients found to have significant correctable coronary artery disease are presumed to benefit from preoperative coronary revascularization with selective coronary artery bypass surgery or angioplasty, at present this conclusion remains unproved.[58] Data available from nonrandomized studies of patients with significant coronary artery disease undergoing vascular surgery do demonstrate lower mortality for those who have undergone coronary bypass surgery.[59] Furthermore,

---

a recent randomized study has demonstrated that the long-term outcome of patients with combined peripheral vascular disease and high-risk coronary artery disease is improved by coronary artery revascularization in those with three-vessel coronary disease.[60] As is the case for coronary artery bypass surgery, no data are yet available to confirm that preoperative coronary angioplasty for significant coronary stenoses decreases the risk from major vascular surgery.

In addition to such preoperative screening and potential coronary revascularization, operative risk secondary to cardiac ischemic events may be further reduced through the use of perioperative invasive hemodynamic monitoring and careful perioperative surveillance for evidence of ischemia. Furthermore, myocardial ischemia and perhaps myocardial infarction may be prevented by using beta-adrenergic blockers perioperatively.[61]

Late Survival.

A review by Kiell and Ernst of late survival following abdominal aortic aneurysm repair among almost 2500 patients revealed 1-, 5-, and 10-year survival rates of 93, 63, and 40 percent, respectively.[25] The long-term survival of patients with concomitant coronary artery disease has been found to be approximately 10 percent lower than that for those without overt coronary disease.[62]

MEDICAL MANAGEMENT.

Risk factor modification is fundamental in the medical management of abdominal aortic aneurysms. Hypercholesterolemia and hypertension should be carefully controlled. Most patients with abdominal aortic aneurysms are cigarette smokers, and smoking must be discontinued. Beta blockers have long been considered an important therapy for reducing the risk of aneurysm expansion and rupture, and both animal and human studies support such a role. Brophy and coworkers demonstrated that propranolol delays the development of aneurysms in a mouse model prone to spontaneous aortic aneurysms. [63] Interestingly, it appears that the drug's efficacy in this model may have been independent of reductions in blood pressure or diminution of the force of left ventricular ejection (dP/dt) and, instead, may have been the result of changes in connective tissue metabolism and the structure of the aortic wall. In humans, a recent study has shown that the mean rate of abdominal aortic aneurysm expansion was slower in patients treated with beta blockers than in those not treated with beta blockers, with the effect most marked in large aneurysms.[43]

Should one elect to observe an abdominal aortic aneurysm 4.0 cm in size or larger, careful routine follow-up is indicated to detect either rapid expansion (0.5 cm/yr) or an increase in size to 5.0 cm or larger, either of which is an indication for surgery.[64] CT scanning every 6 months, perhaps as frequently as every 3 months for those at higher risk, has been advocated as an effective method of follow-up in such patients.[29] CT scanning is preferable to ultrasound for monitoring aneurysm growth because CT measurements of aneurysm size are more accurate.

Thoracic Aortic Aneurysms

Thoracic aortic aneurysms are much less common than aneurysms of the abdominal aorta, and their incidence did not increase over the same 30-year period that saw a marked increase in the incidence of abdominal aortic aneurysms[12] (as noted above). Thoracic aneurysms are classified by the portion of aorta involved, i.e., the ascending, arch, or descending thoracic aorta. This anatomical distinction is important because the etiology, natural history, and treatment of thoracic aneurysms differ for each of these segments. Aneurysms of the descending aorta occur most commonly, followed by aneurysms of the ascending aorta, whereas arch aneurysms occur much less often.[11] In addition, descending thoracic aneurysms may extend distally to involve the abdominal aorta and create what is known as a *thoracoabdominal aortic aneurysm*. Sometimes, the entire aorta may be ectatic, with localized aneurysms seen at sites in both the thoracic and abdominal aorta.

ETIOLOGY AND PATHOGENESIS.

Aneurysms of the ascending thoracic aorta most often result from the process of *cystic medial degeneration* (or *cystic medial necrosis*). Histologically, cystic medial degeneration has the appearance of smooth muscle cell necrosis and elastic fiber degeneration, with the presence in the media of cystic spaces filled with mucoid material. Although these changes occur most frequently in the ascending aorta, in some cases the entire aorta may be similarly affected. The histological changes lead to weakening of the aortic wall, which in turn results in the formation of a fusiform aneurysm. Such aneurysms often involve the aortic root and may consequently result in aortic regurgitation. The term *annuloaortic ectasia* is often used to describe this condition (see below).

Cystic medial degeneration is found in virtually all cases of the Marfan syndrome[65] and may be associated with other connective tissue disorders as well, such as the Ehlers-Danlos syndrome. The Marfan syndrome (see Chap. 56) is an autosomal dominant heritable disorder of connective tissue that has been discovered to be due to mutations in one of the genes for fibrillin, a structural protein that helps direct and orient elastin in the developing aorta.[66] These mutations result in a decrease in the amount of elastin in the aortic wall,[67] together with a loss of elastin's normally highly organized structure. As a consequence, from an early age a marfanoid aorta exhibits markedly abnormal elastic properties and increased systemic pulse wave velocities, and over time the aorta exhibits progressively increasing degrees of stiffness and dilatation.[68]

In patients without the Marfan syndrome, however, it is not possible to recognize the histological diagnosis of cystic medial degeneration prospectively (i.e., without surgery or necropsy).[69] This fact has significantly limited our understanding of medial degeneration and its natural history, and it remains unclear to what extent this syndrome may represent an independent disease process versus a manifestation of another disease state. It has long been suspected that some patients who have annuloaortic ectasia and proven cystic medial degeneration without the classic phenotypic manifestations of the Marfan syndrome may, in fact, have a variation, or *forme fruste,* of the Marfan syndrome,[70] although this theory remains unproved. On the contrary, many patients with ascending thoracic aortic aneurysms appear to have nothing more than idiopathic cystic medial degeneration.

ATHEROSCLEROSIS.

Atherosclerotic aneurysms infrequently occur in the ascending aorta and, when they do, tend to be associated with diffuse aortic atherosclerosis. Aneurysms in the aortic arch are often contiguous with aneurysms of the ascending or descending aorta. They may be due to atherosclerotic disease, cystic medial degeneration, syphilis, or other infections. The predominant etiology of aneurysms of the descending thoracic aorta is atherosclerosis.[71] These aneurysms tend to originate just distal to the origin of the left subclavian artery and may be either fusiform or saccular.[72] The pathogenesis of such atherosclerotic aneurysms in the thoracic aorta may be similar to that of abdominal aneurysms but has not been extensively examined.

SYPHILIS.

Syphilis was once a common cause of ascending thoracic aortic aneurysm, but today it has become a rarity in most major medical centers[12] [73] as a result of aggressive antibiotic treatment of the disease in its early stages. The latent period from initial spirochetal infection to aortic complications may range from 5 to 40 years but is most commonly 10 to 25 years. During the secondary phase of the disease, spirochetes directly infect the aortic media, most commonly involving the ascending aorta. The muscular and elastic medial elements are destroyed by the infection and inflammatory response and are replaced by fibrous tissue that frequently calcifies. Weakening of the aortic wall from medial destruction results in progressive aneurysmal dilatation. In addition, the infection may spread into the aortic root, and the subsequent root dilatation may result in aortic regurgitation.

INFECTIOUS AORTITIS.

This rare cause of aortic aneurysm may result from a primary infection of the aortic wall causing aortic dilatation with the formation of fusiform or saccular aneurysms. More commonly, infected or *mycotic* aneurysms may arise secondarily from an infection occurring in a preexisting aneurysm of another etiology. When an infected aneurysm involves the ascending aorta, it is often the consequence of direct spread from aortic valve bacterial endocarditis.

Several other causes of thoracic aortic aneurysms are discussed in detail elsewhere in this or other chapters, including giant cell arteritis (see Chap. 67) , aortic trauma (see Chap. 5) , and aortic dissection (p. 1431). Note that the clinical features, natural history, and treatment of thoracic aneurysms discussed below apply specifically to *nondissecting thoracic aortic aneurysms*.

Figure 40-2 MRI in the coronal projection of a large thoracic aortic aneurysm in an elderly woman with a complaint of dyspnea and cough. In this view the markedly dilated aortic arch (A) is compressing the trachea (T) and causing rightward tracheal deviation. The aneurysm is also compressing the left main stem bronchus (B). In addition, all four cardiac chambers are dilated, consistent with the patient's known idiopathic dilated cardiomyopathy.

Clinical Manifestations

Forty percent of patients with thoracic aortic aneurysms are asymptomatic at the time of diagnosis,[11] with such aneurysms typically discovered as incidental findings on a routine physical examination or chest roentgenogram. When patients do experience symptoms, the symptoms tend to reflect either a vascular consequence of the aneurysm or a local mass effect. Vascular consequences include aortic regurgitation from dilatation of the aortic root, often associated with secondary congestive heart failure; sinus of Valsalva aneurysms that may rupture into the right side of the heart and cause a continuous murmur and congestive heart failure; and thromboembolism causing stroke, lower extremity ischemia, renal infarction, or mesenteric ischemia.

A local mass effect from an ascending or arch aneurysm may cause superior vena cava syndrome as a result of obstruction of venous return via compression of the superior vena cava or innominate veins. Aneurysms of the arch or descending aorta may compress the trachea (Fig. 40-2) or main stem bronchus and produce tracheal deviation, wheezing, cough, dyspnea (with symptoms that may be positional), hemoptysis, or recurrent pneumonitis. Compression of the esophagus may produce dysphagia, and compression of the recurrent laryngeal nerve may cause hoarseness. Chest pain and back pain occur in 37 and 21 percent, respectively, of nondissecting aneurysms[11] and result from direct compression of other intrathoracic structures or the chest wall or from erosion into adjacent bone. Typically, such pain is steady, deep, boring, and at times extremely severe.

As with abdominal aortic aneurysms, the most worrisome consequence of thoracic aneurysms is leakage or rupture. Rupture is accompanied by the dramatic onset of excruciating pain, usually in the region where less severe pain had previously existed. Rupture occurs most commonly into the left intrapleural space or the intrapericardial space and is manifested as hypotension. The third most common site of rupture is from the descending thoracic aorta into the adjacent esophagus (an aortoesophageal fistula), which causes life-threatening hematemesis.[74] Acute aneurysm expansion, which may herald rupture, can cause similar pain. Thoracic aneurysms may also be accompanied by aortic dissection, as discussed in detail later in this chapter.

DIAGNOSIS AND SIZING.

Many thoracic aneurysms are readily visible on chest roentgenograms (Fig. 40-3) and are characterized by widening of the mediastinal silhouette, enlargement of the aortic knob, or displacement of the trachea from the midline. Unfortunately, smaller aneurysms, especially saccular ones, may not be evident on the chest roentgenogram; therefore, this technique cannot exclude the diagnosis of aortic aneurysm.

Aortography is still the preferred modality for the preoperative evaluation of thoracic aortic aneurysms and for precise definition of the anatomy of the aneurysm and great vessels (Fig. 40-4) . As for abdominal aortic aneurysms, contrast-enhanced CT scanning is very accurate in detecting and sizing thoracic aortic aneurysms[75] and is useful as a method to monitor aneurysm size (see Fig. 10-49) . MRI is also useful in defining thoracic aortic anatomy and detecting aneurysms[76] (see Fig. 40-2) and is of particular utility in patients with preexisting aortic disease. MR angiography may prove especially useful in defining the anatomy of aortic branch vessels.

TTE (Figs. 7-113 and 7-114) is not very accurate for diagnosing thoracic aneurysms and is particularly limited in its ability to examine the descending thoracic aorta. TEE, a far more accurate method for assessing the thoracic aorta, has become widely used for detection of aortic dissection. There has been less experience with TEE, however, in the evaluation of nondissecting thoracic aneurysms. (The advantages and disadvantage of each imaging modality are discussed in greater detail on p. 1437.)

NATURAL HISTORY.

Defining the natural history of thoracic aortic aneurysms is complex given the numerous contributing factors. The cause of an aneurysm may affect both its rate of growth and propensity for rupture. The presence or absence of aneurysm symptoms is another important predictor inasmuch as symptomatic patients have a much poorer prognosis than do those without symptoms,[71] in large part because the onset of new symptoms is frequently a harbinger of rupture or death. Moreover, the high prevalence

Figure 40-3 Chest roentgenogram of a patient with a very large aneurysm of the ascending thoracic aorta. Evident are both marked widening of the mediastinum and an abnormal aortic contour.

Figure 40-4 Lateral aortogram in a man with annuloaortic ectasia and aneurysmal dilation of the ascending thoracic aorta. The bulbous, pear-shaped aortic root can easily be seen. The left ventricle is partially opacified because of aortic regurgitation.

of additional cardiovascular disease in these patients may have a dramatic impact on mortality; in fact, next to aneurysm rupture, the most common causes of death in this population are other cardiovascular diseases.[72] [77]

Several small studies of the natural history of thoracic aortic aneurysms have been reported, but the data are far more limited than those available regarding abdominal aortic aneurysms. In the largest modern series, the 1-, 3-, and 5-year survival rates for patients with thoracic aortic aneurysms not undergoing surgical repair were approximately 65, 36, and 20 percent, respectively.[12] [77] [78] Aneurysm rupture occurs in 32 to 68 percent of patients not treated surgically, with rupture accounting for 32 to 47 percent of all patient deaths.[71] [77] [78] Fewer than half of patients with rupture may arrive at the hospital alive[73] ; mortality at 6 hours is 54 percent and at 24 hours reaches 76 percent.[73] No apparent association has been made between thoracic aneurysm location and the risk of death from rupture.[77]

Because size is an important predictor of the risk of aneurysm rupture, several studies have examined the rate of expansion of thoracic aortic aneurysms. As with abdominal aneurysms, initial size is the only independent predictor of the rate of thoracic aneurysm growth,[75] although some data also suggest that descending thoracic aneurysms may expand more slowly than others.[79] Dapunt and colleagues monitored 67 patients with thoracic aortic aneurysms by serial CT scanning and found a mean rate of expansion of 0.43 cm/yr.[80] The only independent predictor of rapid expansion (>0.5 cm/yr) was an initial aortic diameter larger than 5.0 cm. Aneurysms that were 5.0 cm or smaller showed mean growth rates of 0.17 cm/yr, whereas those larger than 5.0 cm grew by 0.79 cm/yr. Unfortunately, even when controlling for initial aneurysm size, substantial variation was still seen in individual aneurysm growth rates, thus making such mean growth rates of little value in predicting aneurysm growth for a given patient. More helpful, however, was the finding that growth rates among small aneurysms were more consistent, with only 1 of 25 aneurysms 4.0 cm or smaller at baseline showing rapid growth. Two additional findings in this series were that no aneurysm smaller than 5.0 cm ruptured during the follow-up period and that the only predictor of survival was initial aneurysm size.

Management

SURGICAL TREATMENT.

The optimal timing of surgical repair of thoracic aortic aneurysms remains uncertain for several reasons. First, as noted above, the data available on the natural history of thoracic aneurysms are limited, especially with respect to the outcomes of surgical intervention. Second, with the high incidence of coexisting cardiovascular disease in this population, many patients die of other cardiovascular diseases before their aneurysms ever rupture. Finally, significant risks are associated with thoracic aortic surgery, particularly in the arch and descending aorta, which in many cases may outweigh the potential benefits of aortic repair.

We currently recommend surgery when aneurysms of the ascending thoracic aorta reach 5.5 to 6.0 cm and those of the descending thoracic aorta reach 6.0 cm or larger, or often 7.0 cm or larger in patients at high operative risk. Indications for surgery in patients with smaller aneurysms include a rapid rate of expansion, associated significant aortic regurgitation, or the presence of aneurysm-related symptoms. In patients with the Marfan syndrome, given their higher risk of dissection and rupture, we recommend repair of thoracic aneurysms when they reach only 5.5 cm in size.[81] Surgery should be considered even sooner in Marfan syndrome patients at especially high risk, such as those with rapid and progressive aortic dilatation, those with a family history of the Marfan syndrome plus aortic dissection, or women planning pregnancy.[82] Of course, the aggressiveness with which surgical repair is undertaken in any case should be appropriately influenced by the general condition of the individual patient.

Thoracic aortic aneurysms are generally resected and replaced with a prosthetic sleeve of appropriate size. Cardiopulmonary bypass is necessary for the removal of ascending aortic aneurysms, and partial bypass to support the circulation distal to the aneurysm while the aortic site being repaired is cross-clamped is often advisable when resecting descending thoracic aortic aneurysms.[83] The use of such adjuncts is less important, however, than the nature and extent of the aneurysm in determining the incidence of postoperative complications.[84]

The use of a composite graft consisting of a Dacron tube with a prosthetic aortic valve sewn into one end (the Bentall procedure) is generally the method of choice in treating ascending thoracic aneurysms involving the root and associated with significant aortic regurgitation.[85] The valve and graft are sewn directly into the aortic annulus and the coronary arteries, then reimplanted into the Dacron aortic graft (Fig. 40-5) . The operative risk for mortality is about 5 percent.[85] For patients with structurally normal aortic valve leaflets whose aortic regurgitation is secondary to dilatation of the root, David and colleagues have successfully repaired the native valve by either reimplanting it in a Dacron graft or reconstructing the aortic root. In a series of 45 patients, 41 had mild or no aortic regurgitation after this method of aortic valve repair and were stable postoperatively at a mean of 18 months.[86]

Aneurysms of the aortic arch may be successfully excised surgically, but the procedure may be particularly challenging. The brachiocephalic vessels must be removed from the aortic arch before its resection. Then, after interposition of the prosthetic tube graft, the island of native aortic tissue containing the brachiocephalic vessels is reimplanted into the graft and normal cerebral perfusion restored. However, the risk of stroke is significantly increased because of variable periods of cerebral ischemia. The incidence of stroke in recent series is 3 to 7 percent.[87] [88] The

cardiopulmonary bypass. *Bottom,* The composite graft is shown, with a low-profile, tilting disc aortic prosthesis attached to its inferior end. (1) The aneurysm is resected with the native aortic valve. (2) The coronary ostia have been excised and mobilized with a button of aortic wall. (3) The composite graft has been secured in place with Teflon felt reinforcement for the suture line. The coronary artery ostia are then reimplanted directly into the graft.

standard method for carrying out this operation today is with the use of profound hypothermic circulatory arrest, as reported by Griepp and coworkers in 1975.[89] Some have attempted to add selective cerebral perfusion during aneurysmectomy, but cannulation techniques are difficult. In fact, the incidence of stroke may actually be as high or higher with this method, possibly because of cannulation-induced cerebral emboli.[88] [90] A more recent adjunct for cerebral protection during hypothermic arrest is the use of retrograde cerebral perfusion via a superior vena cava cannula.[87] Not only does this technique provide nutrients and oxygen to the brain,[91] but it may also serve to flush out both air and particulate matter from the cerebral and carotid arteries that would otherwise embolize. The results of retrograde cerebral perfusion have been quite encouraging, with trends toward lower stroke rates.[92] [93]

More than half of patients undergoing surgical repair of a thoracic aortic aneurysm in Crawford and colleagues' series had multiple aortic segments involved, and almost three-quarters of those with descending thoracic aneurysms had multiple involvement.[94] Such widespread aneurysmal dilatation of the aorta presents a particular challenge to the surgeon and often precludes surgery. However, Crawford and associates have demonstrated that it is possible to successfully replace virtually the entire diseased thoracic and abdominal aorta.[94] A method known as the "elephant trunk" technique, carried out in sequential stages of aortic replacement, has been shown to facilitate such extensive surgical procedures and reduce the associated risks.[92] [95]

Elective surgical repair of ascending and descending thoracic aortic aneurysms is associated with a 90 to 95 percent early survival rate in most centers.[96] [97] Major complications are technical, especially hemorrhage from tearing of the diseased aorta. A catastrophic complication of resection of descending thoracic aortic aneurysms is postoperative paraplegia secondary to interruption of the blood supply to the spinal cord. The incidence of paraplegia ranges from 0 to 17 percent,[83] [84] although most series show an incidence of about 5 to 6 percent.[84] [98] [98A] A number of methods have been proposed to reduce the likelihood of paraplegia, although none has proved to be consistently safe and effective. One of the more promising techniques involves regional hypothermic protection of the spinal cord with epidural cooling during surgical repair of the aorta, which has reduced the frequency of spinal cord complications to 3 percent in one large series by Cambria and colleagues.[99] Other important techniques that may also reduce the risk of spinal cord injury include the reimplantation of patent critical intercostal arteries,[99] cerebrospinal fluid drainage,[100] the use of intraoperative somatosensory evoked potential monitoring,[101] and maintenance of distal aortic perfusion during surgery with the use of atriofemoral bypass.[99] Controlled trials might better clarify the efficacy of such techniques.

An alternative approach to the surgical management of descending thoracic aneurysms is the use of a transluminally placed endovascular stent-graft (see Fig. 42-7). This technique has the advantage of being far less invasive than surgery with potentially fewer postoperative complications and lower morbidity. Dake and coworkers recently reported the results of a large series in which "first-generation" endovascular stent-grafts were implanted in 103 patients with thoracic aortic aneurysms, only 62 (60 percent) of whom were judged to be reasonable candidates for traditional surgical aortic repair.[102] Complete thrombosis of the aortic aneurysm was achieved in 83 percent of patients, but rates of early stroke and paraplegia were 3 and 7 percent, respectively. The authors suggest that with newer and more refined devices together with more precise stent-graft deployment, the overall success rates should rise and complication rates fall. Although still experimental at present, such a device may in the future have an important role in the management of patients who are at risk for aortic rupture but are otherwise poor surgical candidates. Unfortunately, the curvilinear nature of the ascending aorta and arch makes application of similar techniques to aneurysms of these proximal aortic segments far more problematic.

Complications of associated atherosclerosis, such as myocardial infarction, cerebrovascular accidents, and renal failure, often become manifested under the massive physiological stress of aortic surgery. The most frequent causes of early postoperative death are myocardial infarction, congestive heart failure, stroke, renal failure, hemorrhage, respiratory failure, and sepsis. Advanced age, emergency surgery,

prolonged aortic cross-clamp time, extent of the aneurysm, diabetes, prior aortic surgery, aneurysm symptoms, and intraoperative hypotension are the most important factors determining perioperative morbidity and mortality. Many patients with atherosclerotic aneurysms are heavy smokers, and pulmonary complications following surgery are common. The left lung may be severely traumatized by compression during resection of large aneurysms of the descending thoracic aorta, a complication that may seriously jeopardize the patient's survival, particularly in the setting of underlying pulmonary disease.

Late deaths are usually associated with cardiac complications, aneurysm rupture, respiratory failure, or stroke.[96] Aneurysm rupture may be due to aneurysm formation at the graft margins or the appearance of new aneurysms at other aortic sites.[11]

MEDICAL MANAGEMENT.

The long-term impact of medical therapy on aneurysm growth and survival in patients with typical atherosclerotic thoracic aneurysms has not been examined. However, in a recent report, Shores and colleagues examined the efficacy of beta blockers in adult patients with the Marfan syndrome.[103] They randomized 70 patients to treatment with propranolol versus no beta blocker therapy and monitored them over a 10-year period. The treated group showed a significantly slower rate of aortic dilatation, fewer adverse clinical endpoints (death, aortic dissection, aortic regurgitation, aortic root >6 cm), and significantly lower mortality from the 4-year point onward.[103] Although this study examined only the effect of beta blockade in the Marfan syndrome, it follows logically that medical therapy to reduce dP/dt and control blood pressure is essential to the treatment of thoracic aortic aneurysms, both for those with smaller aneurysms being monitored serially and for patients having undergone aortic aneurysm repair.

Annuloaortic Ectasia

The term *annuloaortic ectasia* was first used by Ellis and colleagues in 1961 to describe a clinicopathological condition seen in a subset of patients with thoracic aortic aneurysms in whom idiopathic dilatation of the proximal aorta and the aortic annulus leads to pure aortic regurgitation.[104] The entity has subsequently been recognized with increasing frequency and makes up about 5 to 10 percent of the population undergoing aortic valve replacement for pure aortic regurgitation. Annuloaortic ectasia is more common in men than women, typically occurring in the fourth, fifth, and sixth decades with progressively more severe aortic regurgitation. Sudden onset of symptoms followed by rapid progression is occasionally seen.

The common pathological feature shared by patients with annuloaortic ectasia is that of cystic medial degeneration of the afflicted aortic wall leading to progressive dilatation. With widening of the aortic root, the valve annulus dilates and the aortic leaflets are pulled apart, thereby resulting in aortic regurgitation despite the fact that the aortic valve leaflets themselves are structurally normal. The weakened aortic walls are also prone to dissection.

Clinically, little distinguishes aortic regurgitation in patients with annuloaortic ectasia from that due to other causes. On physical examination, the diastolic murmur tends to be of greater intensity to the right of the sternum in cases of annuloaortic ectasia and to the left of the sternum in cases of primary aortic regurgitation. Lemon and White found that two features--acute or subacute development of symptoms and the presence of associated chest pain--were more common in patients with annuloaortic ectasia than primary aortic regurgitation.[105]

The chest roentgenogram usually shows a grossly dilated aortic root and ascending aorta with left ventricular enlargement proportional to the degree of aortic regurgitation. Aortographically, annuloaortic ectasia has one of three typical appearances. Most common is a pear-shaped enlargement of the ascending aorta (see Fig. 40-4) . Also seen are diffuse symmetrical dilatation and dilatation limited to the aortic root.[105]

Surgical correction is usually undertaken for relief of aortic regurgitation when it is severe and responsible for symptoms of left ventricular failure or when the left ventricle or ascending aorta is increasing in size. In such cases, the aortic valve together with the proximal ascending aorta is usually replaced with a composite prosthetic graft (see Chap. 46) .

AORTIC DISSECTION

Acute aortic dissection is an uncommon but potentially catastrophic illness that occurs with an incidence of at least 2000 cases per year in the United States. Early mortality is as high as 1 percent per hour if untreated,[106] but survival may be significantly improved by the timely institution of appropriate medical and/or surgical therapy. Prompt clinical recognition and definitive diagnostic testing are therefore essential in the management of patients with aortic dissection.

Aortic dissection is believed to begin with the formation of a tear in the aortic intima that directly exposes an underlying diseased medial layer to the driving force (or pulse pressure) of intraluminal blood (Fig. 40-6 *A*). This blood penetrates the diseased medial layer and cleaves the media longitudinally, thereby dissecting the aortic wall. Driven by persistent intraluminal pressure, the dissection process extends a variable length along the aortic wall, typically antegrade (driven by the forward force

of aortic blood flow) but sometimes retrograde from the site of the intimal tear. The blood-filled space between the dissected layers of the aortic wall becomes the *false lumen.* Shear forces may lead to further tears in the *intimal flap* (the inner portion of the dissected aortic wall) and produce exit sites or additional entry sites for blood flow into the false lumen. Distention of the false lumen with blood may cause the intimal flap to bow into the *true lumen* and thereby narrow its caliber and distort its shape.

It has also been suggested that aortic dissection may begin instead with rupture of the vasa vasorum within the aortic media, i.e., with the development of an intramural hematoma (Fig. 40-6 *B*). Local hemorrhage then secondarily ruptures through the intima layer and creates the intimal tear and aortic dissection. Since in autopsy series as many as 13 percent of aortic dissections do not have an identifiable intimal tear,[107] at least in a minority of cases independent medial hemorrhage does appear to be the primary cause of dissection. On the other hand, one might argue that the lack of an intimal tear in these patients indicates they do not, in fact, have classic aortic dissection, but rather have intramural hematoma of the aorta, a closely related condition (see below).

CLASSIFICATION.

Most classification schemes for aortic dissection are based on the fact that the vast majority of aortic dissections originate in one of two locations: (1) the ascending aorta, within several centimeters of the aortic valve, and (2) the descending aorta, just distal to the origin of the left subclavian artery at the site of the ligamentum arteriosum. Sixty-five percent of intimal tears occur in the ascending aorta, 20 percent in the descending aorta, 10 percent in the aortic arch, and 5 percent in the abdominal aorta.[90]

Three major classification systems are used to define the location and extent of aortic involvement, as defined in Table 40-1 and depicted in Figure 40-7 : (1) DeBakey types I, II, and III[108] ; (2) Stanford types A and B[109] ; and (3) the anatomical categories "proximal" and "distal." All three

Figure 40-6 Proposed mechanism of initiation of aortic dissection.

schemes share the same basic principle of distinguishing aortic dissections with and without ascending aortic involvement for prognostic and therapeutic reasons; in general, surgery is indicated for dissections involving the ascending aorta, whereas medical management is reserved for dissections without ascending aortic involvement. Accordingly, because both DeBakey types I and II involve the ascending aorta, they are grouped together for simplicity in the Stanford (type A) and anatomical (proximal) classification systems. Aortic dissections confined to the abdominal aorta, although quite uncommon, are best categorized as type B or distal dissections. Proximal or type A dissections occur in about two-thirds of cases, with distal dissections composing the remaining third.

In addition to its location, aortic dissection is also classified according to its duration, defined as the length of time from symptom onset to medical evaluation. The mortality from dissection and its risk of progression decrease progressively

TABLE 40-1 -- COMMONLY USED CLASSIFICATION SYSTEMS TO DESCRIBE AORTIC DISSECTION

TYPE	SITE OF ORIGIN AND EXTENT OF AORTIC INVOLVEMENT
DeBakey	
Type I	Originates in the ascending aorta, propagates at least to the aortic arch and often beyond it distally
Type II	Originates in and is confined to the ascending aorta
Type III	Originates in the descending aorta and extends distally down the aorta or, rarely, retrograde into the aortic arch and ascending aorta
Stanford	
Type A	All dissections involving the ascending aorta, regardless of the site of origin
Type B	All dissections not involving the ascending aorta
Descriptive	
Proximal	Includes DeBakey types I and II or Stanford type A
Distal	Includes DeBakey type III or Stanford type B

over time, which makes therapeutic strategies for longstanding aortic dissections quite different from those seen acutely. A dissection present less than 2 weeks is defined as "acute," whereas those present 2 weeks or more are defined as "chronic" because the mortality curve for untreated aortic dissections begins to level off at 75 to 80 percent at this time.[106] At diagnosis, about two-thirds of aortic dissections are acute while the remaining third are chronic.[110]

ETIOLOGY AND PATHOGENESIS.

Medial degeneration, as evidenced by deterioration of medial collagen and elastin, is considered to be the chief predisposing factor in most nontraumatic cases of aortic dissection.[69] [87] Therefore, any disease process or other condition that undermines the integrity of the elastic or muscular components of the media

Figure 40-7 Commonly used classification systems for aortic dissection. (Refer to Table 40-1 for definitions.)

predisposes the aorta to dissection. Cystic medial degeneration is an intrinsic feature of several hereditary defects of connective tissue, most notably the Marfan and EhlersDanlos (see Chap. 56) syndromes. In addition to their propensity for thoracic aortic aneurysms, patients with the Marfan syndrome are indeed at high risk for aortic dissection--especially proximal dissection--at a relatively young age. In fact, the Marfan syndrome accounts for 5 to 9 percent of all aortic dissections.[110] [111] [112] (See also Chap. 56.)

In the absence of the Marfan syndrome, histologically classic cystic medial degeneration is identified in only a minority of cases of aortic dissection.[110] [111] Nevertheless, the degree of medial degeneration found in most other cases of aortic dissection still tends to be qualitatively and quantitatively much greater than that expected as part of the aging process. Although the cause of such medial degeneration remains unclear, advanced age and hypertension appear to be two of the most important factors.

The peak incidence of aortic dissection is in the sixth and seventh decades of life, with men affected twice as often as women.[112] A coexisting history of hypertension is found in 72 to 80 percent of cases of aortic dissection.[112] A bicuspid aortic valve is a well-established risk factor for proximal aortic dissection and has historically been found in 7 to 14 percent of all aortic dissections.[110] [111] Interestingly, the risk of aortic dissection appears to be independent of the severity of the bicuspid valve stenosis.[111] Certain other congenital cardiovascular abnormalities predispose the aorta to dissection, including coarctation of the aorta.[111] Aortic dissection has also been reported to occur in association with the Noonan and Turner syndromes.[110] [113] Rarely, aortic dissection complicates arteritis involving the aorta (see Chap. 67) , particularly giant cell arteritis.[114] A number of reports describe aortic dissection in association with cocaine abuse among younger men,[115] [116] but no direct causal relationship has yet been established.

An unexplained relationship exists between pregnancy and aortic dissection (see Chap. 65) . About half of all aortic dissections in women younger than 40 years occur during pregnancy, typically in the third trimester[117] and also occasionally in the early postpartum period.[118] The increases in blood volume, cardiac output, and blood pressure seen in late pregnancy may contribute to the risk, although this explanation cannot account for postpartum occurrence. Women with the Marfan syndrome and a dilated aortic root are at particular risk for acute aortic dissection during pregnancy,[119] and in some cases, diagnosis of the Marfan syndrome is first made when such women are evaluated for peripartum aortic dissection.

Direct trauma to the aorta may also cause aortic dissection. Blunt trauma tends to cause localized tears, hematomas, or frank aortic transection (see Chap. 51) and only rarely causes classic aortic dissection.[120] Iatrogenic trauma, on the other hand, is associated with true aortic dissection. Both intraarterial catheterization[121] and the insertion of intraaortic balloon pumps[122] may induce aortic dissection, probably from direct trauma to the aortic intima. Cardiac surgery is associated with a very small risk of acute aortic dissection. The majority of these dissections are discovered intraoperatively and repaired at that time, although 20 percent are detected only after a delay.[123] In addition, aortic dissection sometimes occurs late (months to years) after cardiac surgery; in fact, as many as 18 percent of those with acute aortic dissection have a history of prior cardiac surgery.[112] Of cardiac surgical patients, those undergoing aortic valve replacement are at highest risk for aortic dissection as a late complication.[124] [125] von Kodolitsch and colleagues have found that patients with a dilated ascending aorta together with aortic regurgitation or a thinned aortic wall at the time of aortic valve replacement are most likely to have such a late aortic dissection.[126]

Clinical Manifestations

SYMPTOMS.

Much of the data presented regarding the clinical manifestations of aortic dissection are from the earlier clinical series of Slater and DeSanctis[127] and Spittel and colleagues, [110] as well as from a recent series from the International Registry of Aortic Dissection (IRAD), which studied 464 consecutive patients with acute aortic dissection from 12 international referral centers.[112] By far the most common initial symptom of acute aortic dissection is severe pain, which is found in up to 96 percent of cases,[110] [127] [112] whereas the large majority of those without pain are found to have chronic dissections.[110] The pain is typically severe and of sudden onset[112] and is as severe at its inception as it ever becomes, in contrast to the pain of myocardial infarction, which usually has a crescendo-like onset. In fact, the pain may be all but unbearable in some instances and force the patient to writhe in agony, fall to the ground, or pace restlessly in an attempt to gain relief. Several features of the pain should arouse suspicion of aortic dissection. The quality of the pain as described by the patient is often morbidly appropriate to the actual event, with adjectives such as "tearing," "ripping," "sharp," and "stabbing" frequently used.[112] Another important characteristic of the pain of aortic dissection is its tendency to migrate from its point of origin to other sites, generally following the path of the dissection as it extends through the aorta. However, such migratory pain is described in as few as 17 percent of cases.[112]

The location of pain may be quite helpful in suggesting the location of the aortic dissection because localized symptoms tend to reflect involvement of the underlying aorta. In the series of Spittell and associates, when the location of chest pain was anterior only (or if the most severe pain was anterior), more than 90 percent of patients had involvement of the ascending aorta.[110] Conversely, when the chest pain was interscapular only (or when the most severe pain was interscapular), more than 90 percent of patients had involvement of the descending thoracic aorta (i.e., DeBakey type I or III). The presence of any pain in the neck, throat, jaw, or face strongly predicted involvement of the ascending aorta, whereas pain anywhere in the back, abdomen, or lower extremities strongly predicted involvement of the descending aorta. In rare cases the presenting pain is only pleuritic in nature, due to acute pericarditis that results from hemorrhage into the pericardial space froom the dissected ascending aorta. In such cases the underlying diagnosis may be overlooked if one does not search for other symptoms or signs that might suggest the presence of aortic dissection.

Less common symptoms at initial evaluation, occurring with or without associated chest pain, include congestive heart failure (7 percent), syncope (9 percent), cerebrovascular accident (5 percent),[112] ischemic peripheral neuropathy, paraplegia, and cardiac arrest or sudden death. The presence of acute congestive heart failure in this setting is almost invariably due to severe aortic regurgitation induced by a proximal aortic dissection (discussed below). The occurrence of syncope without focal neurological signs, found in 4 to 5 percent of aortic dissections,[110] [127] may be an ominous sign suggesting a surgical emergency. It is associated most often with rupture of a proximal aortic dissection into the pericardial cavity with resultant cardiac tamponade and, less often, associated with rupture of the descending thoracic aorta into the intrapleural space.[110] On occasion, a patient presents with acute chest pain, and the initial imaging study reveals hemopericardium yet fails to demonstrate an aortic dissection. In such a scenario, unless another diagnosis--such as tumor metastatic to the pericardium--is evident, one must still suspect the presence of acute aortic dissection (or contained aortic rupture). Ideally, such a patient would be taken presumptively to the operating room or, at the very least, immediately undergo additional

imaging with other modalities to confirm the diagnosis.[127A]

PHYSICAL FINDINGS.

Although extremely variable, findings on physical examination generally reflect the location of aortic dissection and the extent of associated cardiovascular involvement. In some cases, physical findings alone may be sufficient to suggest the diagnosis, whereas in other cases, such pertinent physical findings may be subtle or absent, even in the presence of extensive aortic dissection. Hypertension is seen in 70 percent of those with distal aortic dissection but in only 36 percent with proximal dissection.[112] Hypotension, on the other hand, occurs much more commonly among those with proximal than with distal aortic dissection (25 and 4 percent, respectively).[112] [127] True hypotension is usually the result of cardiac tamponade, acute severe aortic regurgitation, intrapleural rupture, or intraperitoneal rupture. Dissection involving the brachiocephalic vessels may result in "pseudohypotension," an inaccurate measurement of blood pressure caused by compromise or occlusion of the brachial arteries.

The physical findings most typically associated with aortic dissection--pulse deficits, the murmur of aortic regurgitation, and neurological manifestations--are more characteristic of proximal than distal dissection. Reduced or absent pulses in patients with acute chest pain strongly suggest the presence of aortic dissection. Such pulse abnormalities are present in about 50 percent of proximal aortic dissections and occur throughout the arterial tree, but they are seen in only 15 percent of distal dissections, where they usually involve the femoral or left subclavian artery. Impaired pulses--and similarly, visceral ischemia--result from extension of the dissection flap into a branch artery with compression of the true lumen by the false channel, which diminishes blood flow in the aortic true lumen because of narrowing or obliteration by the distended false lumen (occurring most commonly in the descending or abdominal aorta); impaired pulses may also result from proximal obstruction of flow caused by a mobile portion of the intimal flap overlying the branch vessel's orifice. Whichever the cause, the pulse deficits in aortic dissection may be transient, secondary to decompression of the false lumen by distal reentry into the true lumen or secondary to movement of the intimal flap away from the occluded orifice.

Aortic regurgitation is an important feature of proximal aortic dissection, with the murmur of aortic regurgitation detected in 32 percent of cases.[112] When aortic regurgitation is present in patients with distal dissection, it generally antedates the dissection and may be the result of preexisting dilatation of the aortic root from the underlying aortic pathology, such as cystic medial degeneration. The murmur of aortic regurgitation may wax and wane, the intensity varying directly with the height of the arterial blood pressure. Depending on the severity of the regurgitation, other peripheral signs of aortic incompetence may be present, such as collapsing pulses and a wide pulse pressure. However, in some cases, congestive heart failure secondary to severe acute aortic regurgitation may occur with little or no murmur and no peripheral signs of aortic runoff.

The acute aortic regurgitation associated with proximal aortic dissection, which occurs in one-half to two-thirds of cases,[128] may result from any of several mechanisms as depicted in Figure 40-8 . First, the dissection may dilate the aortic root, thereby widening the sinotubular junction from which the aortic leaflets hang so that the leaflets are unable to coapt properly in diastole (incomplete closure). Second, the dissection may extend into the aortic root and detach one or more aortic leaflets from their commissural attachments at the sinotubular junction, thereby resulting in diastolic leaflet prolapse. Not infrequently, both incomplete closure and leaflet prolapse are present at the same time. Finally, in the setting of an extensive or circumferential intimal tear the unsupported intimal flap may prolapse into the left ventricular outflow tract,[129] occasionally appearing as frank intimal intussusception,[130] and produce severe aortic regurgitation.

Neurological manifestations occur in as many as 6 to 19 percent of all aortic dissections[110] [127] [131] but are more common with proximal dissection. Cerebrovascular accidents may occur in 3 to 6 percent when the innominate or left common carotid arteries are directly involved.[131] Less frequently, patients may have altered consciousness or even coma. When spinal artery perfusion is compromised (more common in distal dissection[110]), ischemic spinal cord damage may produce paraparesis or paraplegia.

In a small minority, about 1 to 2 percent of cases,[110] [132] a proximal dissection flap may involve the ostium of a coronary artery and cause acute myocardial infarction. The dissection more often affects the right coronary artery than the left, which explains why these myocardial infarctions tend to be inferior in location.[110] Unfortunately, when secondary myocardial infarction does occur, its symptoms may complicate the clinical picture by obscuring symptoms of the primary aortic dissection. Most worrisome is the possibility that in the setting of electrocardiographic evidence of myocardial infarction, the underlying aortic dissection may go unrecognized. Moreover, the consequences of such a misdiagnosis in the era of thrombolytic therapy can be catastrophic. In a review of the literature, Kamp and colleagues described an early mortality of 71 percent (many from cardiac tamponade) among 21 cases of aortic dissection treated

Figure 40-8 Mechanisms of aortic regurgitation in proximal aortic dissection. *A,* Normal aortic valve anatomy, with the leaflets suspended (dotted lines) from the sinotubular junction. *B,* A type A dissection dilates the ascending aorta, which in turn widens the sinotubular junction from which the aortic leaflets hang so that the leaflets are unable to coapt properly in diastole (incomplete closure). Aortic regurgitation (arrow) results. *C,* A type A dissection extends into the aortic root and detaches an aortic leaflet from its commissural attachment to the sinotubular junction. Diastolic leaflet prolapse results. *D,* In the setting of an extensive or circumferential intimal tear, the unsupported intimal flap may prolapse across the aortic valve and into the left ventricular outflow tract and prevent normal leaflet coaptation.

with thrombolysis.[133] It thus remains essential that when evaluating patients with acute myocardial infarction--particularly inferior infarctions--one carefully consider the possibility of an underlying aortic dissection before thrombolytic or anticoagulant therapy is instituted. Although some physicians feel reassured that performing a chest roentgenogram before the institution of thrombolysis is adequate to exclude the diagnosis of dissection, a blinded study of roentgenogram interpretation in this setting suggests that chest radiography is not sufficient.[134]

Extension of aortic dissection into the abdominal aorta may cause other vascular complications. Compromise of one or both renal arteries occurs in about 5 to 8 percent[131] [135] and may lead to renal ischemia or frank infarction and, eventually, severe hypertension and acute renal failure. Mesenteric ischemia and infarction are also occasional complications of abdominal dissection seen in 3 to 5 percent of cases.[131] [135] In addition, aortic dissection may extend into the iliac arteries and cause diminished femoral pulses (12 percent[131]) and acute lower extremity ischemia. If in such cases the associated chest pain is minimal or absent, the pulse deficit and ischemic peripheral neuropathy may be mistaken for a peripheral embolic event.

Additional clinical manifestations of aortic dissection include the presence of pleural effusions, seen more commonly on the left side. The effusion typically arises secondary to an inflammatory reaction around the involved aorta, but in some cases it may result from hemothorax caused by a transient rupture or leak from a descending dissection. Several rarely encountered clinical manifestations of aortic dissection include hoarseness, upper airway obstruction, rupture into the tracheobronchial tree with hemoptysis, dysphagia, hematemesis from rupture into the esophagus, superior vena cava syndrome, pulsating neck masses, Horner syndrome, and unexplained fever. Other rare findings associated with the presence of a continuous murmur include rupture of the aortic dissection into the right atrium, into the right ventricle, or into the left atrium with secondary congestive heart failure.

A variety of conditions may mimic aortic dissection, including myocardial infarction or ischemia, acute aortic regurgitation without dissection, nondissecting thoracic or abdominal aortic aneurysms, pericarditis, musculoskeletal pain, or mediastinal tumors. Diagnostic confusion may be particularly likely when a patient with chest pain coincidentally has another clinical symptom, physical finding, or chest roentgenographic finding typically associated with aortic dissection.[136]

LABORATORY FINDINGS.

Chest roentgenography is included in the discussion of clinical manifestations of aortic dissection rather than the discussion of diagnostic techniques because an abnormal incidental finding on a routine chest roentgenogram may first raise clinical suspicion of aortic dissection. Moreover, although chest roentgenography may help support a diagnosis of suspected aortic dissection, the findings are nonspecific and rarely diagnostic. The results of chest roentgenography therefore add to the other available clinical data used in deciding whether suspicion of aortic dissection warrants proceeding to a more definitive diagnostic study.

The most common abnormality seen on chest radiography in aortic dissection is widening of the aortic silhouette, which appears in 81 to 90 percent of cases.[110] [127] Less often, nonspecific widening of the superior mediastinum is seen. If calcification of the aortic knob is present, separation of the intimal calcification from the outer aortic soft tissue border by more than 1.0 cm--the "calcium sign"--is suggestive, although not diagnostic, of aortic dissection. Comparison of the current chest roentgenogram with a previous study may reveal acute changes in the aortic or mediastinal silhouettes that would otherwise have gone unrecognized (Fig. 40-9) . Pleural effusions are common, typically

Figure 40-9 Chest roentgenogram of a patient with aortic dissection. *A,* The patient's baseline study 3 years before admission shows a normal-appearing aorta. *B,* The chest roentgenogram on admission is remarkable for the interval enlargement of the aortic knob (arrow). The patient was found to have proximal aortic dissection. *(From Isselbacher EM, Cigarroa JE, Eagle KA: Aortic dissection. In Creager M [ed]: Vascular Disease. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 7. Philadelphia, Current Medicine, 1996.)*

occur on the left side, and are more often associated with dissection involving the descending aorta. Although the majority of patients with aortic dissection have one or more of these roentgenographic abnormalities, the remainder, up to 12 percent,[110] [137] have chest roentgenograms that appear unremarkable. Therefore, a normal chest roentgenogram can never exclude the presence of aortic dissection.

Electrocardiographic findings in aortic dissection are nonspecific. One-third of electrocardiograms show changes consistent with left ventricular hypertrophy, while another third are normal. Nevertheless, obtaining an electrocardiogram is diagnostically important for two reasons: (1) in aortic dissection, nonspecific chest pain and the absence of ischemic ST segment and T wave changes on electrocardiogram may argue against the diagnosis of myocardial ischemia and thereby prompt consideration of other chest pain syndromes, including aortic dissection, and (2) in patients with proximal dissection, the electrocardiogram may reveal acute myocardial infarction when the dissection flap has involved a coronary artery.

A promising new biochemical method has recently been introduced that uses serial immunoassays of monoclonal antibodies to smooth muscle myosin heavy chains to detect the presence of acute aortic dissection. In a small prospective study of 27 patients with aortic dissection, the sensitivity and specificity of the assay within the first 12 hours of acute dissection were 90 and 97 percent, respectively.[138] Importantly, the method could also accurately differentiate myocardial infarction from aortic dissection.

Because of the variable extent of aortic, branch vessel, and cardiac involvement occurring with aortic dissection, the signs and symptoms associated with the condition occur sporadically. Consequently, the presence or absence of aortic dissection cannot be diagnosed accurately in most cases on the basis of symptoms and clinical findings alone. In the series of Spittell and associates, of all aortic dissections (without a known diagnosis), the initial clinical diagnosis was aortic dissection in only 62 percent,[110] and the other 38 percent were initially thought to have myocardial ischemia, congestive heart failure, nondissecting aneurysms of the thoracic or abdominal aorta, symptomatic aortic stenosis, pulmonary embolism, and so forth. Among this 38 percent in whom aortic dissection went undiagnosed at initial evaluation, nearly two-thirds had their aortic dissection detected incidentally while undergoing a diagnostic procedure for other clinical questions, and in nearly one-third the aortic dissection remained undiagnosed until necropsy.[110] Given the clinical challenge that detection of aortic dissection presents, physicians should remain vigilant for any risk factors, symptoms, and signs consistent with aortic dissection if a timely diagnosis is to be made.

Diagnostic Techniques

Once the diagnosis of aortic dissection is suspected on clinical grounds, it is essential to confirm the diagnosis both promptly and accurately.[139] The diagnostic modalities currently

Figure 40-10 Thoracic aortogram in the anteroposterior view demonstrating the presence of proximal aortic dissection. *A,* The well-opacified true lumen (T) and the poorly opacified false lumen (F) are separated by an intimal flap (I) that is visible within the ascending aorta as a thin radiolucent line. In addition, the proximal portions of both coronary arteries are well visualized. *B,* In a subsequent aortographic exposure, the false lumen has filled in late and the intimal flap is now clearly visible as it courses distally down the descending aorta. *(A reprinted, by permission, from Cigarroa JE, Isselbacher EM, DeSanctis RW, Eagle KA: Diagnostic imaging in the evaluation of suspected aortic dissection: Old standards and new directions. N Engl J Med 328:35, 1993. B from Isselbacher EM, Cigarroa JE, Eagle KA: Aortic dissection. In Creager M [ed]: Vascular Disease. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 7. Philadelphia, Current Medicine, 1996.)*

available for this purpose include aortography, contrast-enhanced CT, MRI, and TTE or TEE. Each modality has certain advantages and disadvantages with respect to diagnostic accuracy, speed, convenience, risk, and cost, but none is appropriate in all situations.

When comparing the four imaging modalities, one must begin by considering what diagnostic information is needed.[140] First and foremost, the study must confirm or refute the diagnosis of aortic dissection. Second, it must determine whether the dissection involves the ascending aorta (i.e., proximal or type A) or is confined to the descending aorta or arch (i.e., distal or type B). Third, if possible, it should identify a number of the anatomical features of the dissection, including its extent, the sites of entry and reentry, the presence of thrombus in the false lumen, branch vessel involvement by the dissection, the presence and severity of aortic regurgitation, the presence or absence of pericardial effusion, and any coronary artery involvement by the intimal flap. Unfortunately, no single imaging modality provides all of this anatomical detail. The choice of diagnostic modalities should therefore be guided by the clinical scenario and by targeting information that will best assist patient management.

AORTOGRAPHY.

Retrograde aortography was the first accurate diagnostic technique for evaluating suspected aortic dissection. The diagnosis of aortic dissection is based on direct angiographic signs, including visualization of two lumina or an intimal flap (considered diagnostic), as in Figure 40-10 , or on indirect signs (considered suggestive), such as deformity of the aortic lumen, thickening of the aortic walls, branch vessel abnormalities, and aortic regurgitation.[141] Earnest and colleagues showed that the false lumen was visualized in 87 percent, the intimal flap in 70 percent, and the site of intimal tear in 56 percent of dissections.[142]

Aortography had long been considered the diagnostic standard for the evaluation of aortic dissection because for several decades it was the only accurate method of diagnosing aortic dissection antemortem, although its true sensitivity could not be defined. However, the more recent introduction of alternative diagnostic modalities has shown that aortography is not as sensitive as previously thought. A prospective study by Erbel and colleagues found that for the diagnosis of aortic dissection, the sensitivity and specificity of aortography were 88 and 94 percent, respectively.[143] Furthermore, a series by Bansal and associates found that the sensitivity of aortography was only 77 percent when the definition of aortic dissection included intramural hematoma with noncommunicating dissection.[144] False-negative aortograms occur because of thrombosis of the false lumen, equal and simultaneous opacification of both the true and false lumina,[145] or the presence of an intramural hematoma.

Figure 40-11 Aortogram in the left oblique view demonstrating proximal aortic dissection and its associated cardiovascular complications. *A,* The aortic root is dilated. The true lumen (T) and false lumen (F) are separated by the intimal flap (I), which is faintly visible as a radiolucent line following the contour of the pigtail catheter. The abundance of contrast in the left ventricle (LV) is indicative of significant aortic regurgitation (see Fig. 40-8) . *B,* The true lumen is better opacified than the false lumen, and two planes of the intimal flap can now be distinguished (arrows). The branch vessels are opacified, along with marked narrowing of the right carotid artery (CA), which suggests that its lumen is compromised by the dissection. *(A reprinted, by permission, from Cigarroa JE, Isselbacher EM, DeSanctis RW, Eagle KA: Diagnostic imaging in the evaluation of suspected aortic dissection: Old standards and new directions. N Engl J Med 328:35, 1993. B from Isselbacher EM, Cigarroa JE, Eagle KA: Aortic dissection. In Creager M [ed]: Vascular Disease. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 7. Philadelphia, Current Medicine, 1996.)*

Figure 40-12 Digital subtraction angiogram of the abdominal aorta to assess the status of renal perfusion in a patient with distal thoracic aortic dissection. This study confirmed the presence of an intimal flap extending down into the left common iliac artery. The celiac axis, superior mesenteric artery, and right renal artery are widely patent and fill from the true lumen. The left renal artery fills from the false lumen, with the intimal flap involving the ostium of the artery and impairing distal flow. As a consequence, minimal contrast is excreted by the left kidney in comparison to the right.

Important advantages of aortography include its ability to delineate the extent of the aortic dissection, including branch vessel involvement (Figs. 40-11 and 40-12). It is also useful in detecting some of the major complications of aortic dissection, such as the presence of aortic regurgitation (see Fig. 40-11), and often useful in revealing patency of the coronary arteries (see Fig. 40-10). In addition to the limited sensitivity of aortography, other disadvantages are the inherent risks of the invasive procedure, the risks associated with the use of contrast material, and the time needed to complete the study, both in assembling an angiography team and the long duration of the procedure. Finally, aortography requires that potentially unstable patients travel to the angiography suite.

COMPUTED TOMOGRAPHY.

In contrast-enhanced CT scanning, aortic dissection is diagnosed by the presence of two distinct aortic lumina, either visibly separated by an intimal flap (Fig. 40-13) or distinguished by a differential rate of contrast opacification. In two large prospective series of patients with suspected aortic dissection, Erbel and colleagues found conventional contrast-enhanced CT scanning to have a sensitivity of 83 percent with a specificity of 100 percent,[143] while Nienaber and coworkers found a sensitivity of 94 percent with a specificity of 87 percent.[146] Spiral (helical) CT scanning, which was introduced more recently and permits three-dimensional display of the aorta and its branches (Fig. 40-14) , has improved the accuracy of CT in diagnosing aortic dissection, as well as in defining anatomical features.[147] Indeed, two small series have found that spiral CT scanning has both a sensitivity and specificity for acute aortic dissection of 96 to 100 percent.[148] [149] (See also Figs. 10-48 and 10-49 .)

CT scanning has the advantage that unlike aortography, it is noninvasive. However, it does require the use of an intravenous contrast agent. Most hospitals are equipped with a readily accessible CT scanner available on an emergency basis. CT is also helpful in identifying the presence of thrombus in the false lumen and in detecting pericardial effusion. A disadvantage of CT scanning is that the site of intimal tear is rarely identified. CT scanning also cannot reliably detect the presence of aortic regurgitation.

MAGNETIC RESONANCE IMAGING.

The use of MRI has particular appeal for diagnosing aortic dissection in that it is entirely noninvasive and does not require the use of intravenous contrast material or ionizing radiation. Furthermore, MRI produces high-quality images in the transverse, sagittal, and coronal planes, as well as in a left anterior oblique view that displays the entire thoracic aorta in one plane (see Figs. 10-28 , 10-29 , and 10-30). The availability of these multiple views facilitates the diagnosis of aortic dissection and determination of its extent and in many cases reveals the presence of branch vessel involvement. MRI is ideal for the evaluation of patients with preexisting aortic disease, such as those with thoracic aortic aneurysms or prior aortic graft repair, because it provides sufficient

Figure 40-13 Contrast-enhanced CT scan of the chest at the level of the left ventricle showing an intimal flap separating the contrast-filled true (T) and false (F) lumina of an aortic dissection of the descending thoracic aorta.

Figure 40-14 Reformatted left anterior oblique view of a contrast-enhanced CT angiogram of the thoracic aorta (same patient as in Fig. 40-13) showing aortic dissection of the descending thoracic aorta. The intimal flap originates beyond the left subclavian artery and extends distally well into the abdominal aorta. The true lumen (T) and false lumen (F) are easily distinguished and separated by the dark intimal flap (I).

anatomical detail to distinguish aortic dissection from other aortic pathology.[135]

In the series by Nienaber and colleagues, MRI was used to evaluate 105 patients with suspected aortic dissection and found to have both a sensitivity and specificity of 98 percent,[146] consistent with previous findings.[150] [151] MRI had a sensitivity of 88 percent for identifying the site of intimal tear, 98 percent for the presence of thrombus, and 100 percent for the presence of pericardial effusion. Furthermore, use of the cine-MRI technique in a subset of these patients showed 85 percent sensitivity for detecting aortic regurgitation.

The remarkably high accuracy of MRI has made it the current gold standard for diagnosing the presence or absence of aortic dissection. Still, MRI does have a number of disadvantages. It is contraindicated in patients with pacemakers, certain types of vascular clips, and certain older types of metallic prosthetic heart valves.[152] MRI provides only limited images of branch vessels and does not consistently identify the presence of aortic regurgitation. MR scanners are not available in many hospitals and, when present, may not be readily available on an emergency basis. Many patients with aortic dissection are hemodynamically unstable, often intubated or receiving intravenous antihypertensive medications with arterial pressure monitoring, but MR scanners limit the presence of many monitoring and support devices in

the imaging suite and also limit patient accessibility during the lengthy study. Understandably, concern for the safety of unstable patients has led many physicians to conclude that the use of MRI is relatively contraindicated for unstable patients. Notably, despite such concerns, in the studies of Nienaber and colleagues, no complications occurred among their patients with unstable aortic dissection during the performance of MRI.[146] [150]

ECHOCARDIOGRAPHY.

Echocardiography is well suited for the evaluation of patients with suspected aortic dissection because it is readily available in most hospitals, it is noninvasive and quick to perform, and the full examination can be completed at the bedside. The echocardiographic finding considered diagnostic of an aortic dissection is the presence of an undulating intimal flap within the aortic lumen that separates the true and false channels. Reverberations and other artifacts can cause linear echodensities within the aortic lumen that mimic aortic dissection; to definitively distinguish an intimal flap from such artifacts, the flap should be identified in more than one view, it should have motion independent of that of the aortic walls or other cardiac structures, and a differential in color Doppler flow patterns should be noted between the two lumina. In cases in which the false lumen is thrombosed, displacement of intimal calcification[143] or thickening of the aortic wall may suggest aortic dissection.

Transthoracic Echocardiography.

TTE has a sensitivity of 59 to 85 percent and specificity of 63 to 96 percent for the diagnosis of aortic dissection.[140] Such poor sensitivity significantly limits the general utility of this technique. Furthermore, image quality is often adversely affected by obesity, emphysema, mechanical ventilation, or small intercostal spaces.

Transesophageal Echocardiography.

The proximity of the esophagus to the aorta enables TEE to overcome many of the limitations of transthoracic imaging and permits the use of higher frequency ultrasonography, which provides better anatomical detail (Fig. 40-15) . The examination is generally performed at the bedside with the patient under sedation or light general anesthesia and typically requires 10 to 15 minutes to complete. The procedure is relatively noninvasive and requires no intravenous contrast or ionizing radiation. Relative contraindications include known esophageal disease (strictures, tumors, and varices), and the required esophageal intubation may not be tolerated in up to 3 percent of patients.[153] The incidence of important side effects (such as hypertension, bradycardia, bronchospasm, or rarely, esophageal perforation) is much less than 1 percent.[153] One important disadvantage of TEE is its limited ability to visualize the distal ascending aorta and proximal arch because of interposition of the air-filled trachea and main stem bronchus.[154]

The results of large prospective studies by Erbel and colleagues[143] and Nienaber and associates[146] demonstrated that the sensitivity of TEE

Figure 40-15 Cross-sectional transesophageal echocardiogram of the descending thoracic aorta demonstrating aortic dissection. The aorta is dilated. Evident is an intimal flap (I) dividing the true lumen (T) anteriorly and the false lumen (F) posteriorly. The true lumen fills during systole and is therefore seen bowing slightly into the false lumen in this systolic image.

Figure 40-16 Cross-sectional transesophageal echocardiogram of a descending aortic dissection demonstrating a site of intimal tear. Blood flow (in orange) is evident in the true lumen (T) during systole, while a narrow jet of high-velocity blood (in blue) crosses into the false lumen (F) through a tear in the intimal flap (I).

Figure 40-17 Transesophageal echocardiogram of the proximal ascending aorta in long-axis view in a patient with proximal aortic dissection. \i\A,\r\ The left atrium (LA) is closest to the transducer. The aortic valve (AV) is seen on the left in this view, with the ascending aorta extending to the right. Within the proximal aorta is an intimal flap (I) that originates just at the level of the sinotubular junction above the right sinus of Valsalva. The true lumen (T) and the false lumen (F) are separated by the intimal flap. \i\B,\r\ The addition of color flow Doppler in the same view confirms the presence of two distinct lumina. The true lumen (T) fills completely with brisk blood flow (bright blue color), while at the same time minimal retrograde flow (dark orange) is seen in the false lumen (F)

for aortic dissection is 98 to 99 percent. The sensitivity for detecting an intimal tear was 73 percent (Fig. 40-16) , and for detecting the presence of thrombus in the false lumen, the sensitivity was 68 percent.[146] Furthermore, TEE detected both aortic regurgitation and pericardial effusion in 100 percent.[146] The specificity of TEE for the diagnosis of aortic dissection was less well defined in these series. Although Erbel and colleagues found the specificity to be as high as 97 percent,[143] Nienaber and coworkers found it to be 77 percent.[146] However, in the latter study the early inexperience of those performing the examinations and the use of monoplane transducers may have contributed to the incidence of false-positives. More recent studies using biplane or multiplane TEE have consistently demonstrated a specificity of 94 to 95 percent.[149] [155]

Several methods have been suggested to reduce the possibility of a false-positive diagnosis by TEE,[140] including the use of multiplane ultrasound transducers to confirm the presence of the intimal flap in multiple planes, the confirmation of two lumina by the demonstration of differential color flow patterns (Fig. 40-17) , and the use of M-mode echocardiography to distinguish artifacts.[156] We have proposed that if, in addition to an intimal flap, confirmatory evidence of at least one other echocardiographic feature of aortic dissection is identified, the aortic dissection may be called "definite."[140] If an intimal flap alone is seen (i.e., one that is not considered an artifact) with no other supporting evidence, the diagnosis of dissection should not be considered definitive, and examination with another imaging modality should be performed to exclude the possibility of a false-positive. If this conservative approach were applied to echocardiographic interpretation in the study by Nienaber and colleagues,[146] the specificity of "definite" aortic dissection would have been 100 percent.[140]

In addition to its high sensitivity for detecting aortic dissection, TEE may provide other important information useful to the surgeon. Some surgeons wish to know preoperatively whether the intimal flap involves the ostia of the coronary arteries, but this determination has traditionally required the performance of coronary angiography.[157] Ballal and colleagues performed TEE on 34 patients with aortic dissection, 7 of whom had coronary artery involvement confirmed at surgery.[158] In 6 of these 7 patients, TEE identified the intimal flap extending into the coronary ostia. However, TEE delineates only the very proximal portions of the coronary arteries, so when assessment of coronary atherosclerosis is necessary, coronary angiography is still required (see below).

Among patients with suspected aortic dissection, the diagnosis is excluded in 42 to 68 percent,[150] [159] which yields a group of patients with a chest pain syndrome of unknown etiology. Chan found that among patients determined to not have dissection, TEE detected other aortic abnormalities in 73 percent and evidence of acute myocardial infarction or ischemia in 23 percent.[160] More recently, Armstrong and associates identified such alternative cardiovascular diagnoses by TEE in 66 percent of those found to not have aortic dissection.[137]

INTRAVASCULAR ULTRASONOGRAPHY.

One of the more recent developments in the echocardiographic evaluation of aortic dissection has been the use of intravascular ultrasound to define the detailed anatomy of the involved aorta and determine the extent of dissection. The intravascular ultrasound catheter is inserted through an introducer in the femoral artery and positioned within the aortic lumen under fluoroscopic guidance. The aorta is then imaged in a transverse plane through its short axis, which allows visualization of the two lumina and intimal flap.

The most extensive assessment of this technique to date was reported by Yamada and coauthors, who studied 15 patients with previously known chronic aortic dissection and compared the findings of intravascular ultrasound with those of other established imaging modalities.[161] Intravascular ultrasound accurately detected the intimal flap in all segments of the aorta, although it was poor at detecting the sites of intimal tear in the thoracic aorta, probably because of vessel curvature. However, intravascular ultrasound was quite useful in evaluation of the abdominal aorta: It demonstrated the origins of the renal arteries and the distal extent of dissection in all cases and identified the site of intimal tear of the abdominal aorta in 78 percent of cases. Accurate assessment of the abdominal aorta with this technique may have particular relevance given the inability of TEE to image this portion of the aorta. It may also have advantages over TEE in fully imaging the aortic arch.[162] Furthermore, intravascular ultrasound may play an important role in the positioning and deployment of endovascular stenting devices[163] (see below). Nevertheless, the potential future role of intravascular ultrasound in both the evaluation and management of patients with aortic dissection requires further study.

Selecting an Imaging Modality

Each of the four imaging modalities has particular advantages and disadvantages. In selecting among them, one must consider the accuracy as well as the safety and availability of each test. Given its unsurpassed sensitivity and specificity, MRI is considered by most to be the present gold standard for evaluating aortic dissection.

The four modalities differ in their ability to detect complications associated with dissection, so the specific diagnostic information sought by the treating physician and/or surgeon should have a bearing on the procedure chosen. A summary of the diagnostic performance of each of the four imaging modalities is presented in Table 40-2 .

Both the accessibility of imaging studies and the time required to complete them are key considerations given the high early mortality associated with unoperated proximal aortic dissection. Aortography can only rarely be performed on an emergency basis because it requires assembly of an angiography team at night and is subject to the risks associated with an invasive procedure and use of a contrast agent. MRI, although optimal in its accuracy, is also generally unavailable on an emergency basis and poses the risk of limited patient monitoring and accessibility during the lengthy procedure. CT scanning is more readily available in most emergency departments and is quickly completed. TEE is also readily available in most larger centers and can be completed quickly at the bedside, which makes it ideal for evaluating unstable patients. A practical assessment of the four imaging modalities is summarized in Table 40-3 (Table Not Available) .

In a setting in which all these imaging modalities are available, we believe that TEE should be considered first in the evaluation of suspected aortic dissection in light of its accuracy, safety, speed, and convenience. In many institutions, TEE has indeed become the procedure of

choice, [137] [155] [164] with surgeons taking patients to the operating room on the basis of echocardiographic findings alone.[165] [166] In institutions where TEE is not readily available, CT scanning is instead the recommended imaging modality for the evaluation of suspected aortic dissection. However, if the diagnosis of aortic dissection is confirmed by CT, after patient transfer to a tertiary care center an additional diagnostic study may be required to more completely define the aortic anatomy before surgery. However, in such instances, the patient may be taken directly to the operating room, where TEE can then be performed to confirm the diagnosis and better define the dissection anatomy without unduly delaying surgery.[165]

Although MRI is less practical than other modalities for the assessment of suspected acute aortic dissection, it is nonetheless well suited for stable or chronic dissections. Given its extraordinary accuracy and high-quality detailed images, we recommend the use of MRI for monitoring patients with aortic dissection, whether treated medically or surgically, as a means of identifying subsequent aneurysm formation, extension of the dissection, or other complications.

Despite its relative disadvantages, aortography still plays an important role when clear definition of the anatomy of the branch vessels is essential for management. Performance of aortography should also be considered when a definitive diagnosis is not made by one or more of the other imaging modalities.

In the final analysis, each institution must determine its own best diagnostic approach to the evaluation of suspected aortic dissection and base it on available human and material resources and the speed with which such resources can be mobilized. It must be emphasized that regardless of which of the four imaging modalities are available at a given institution, the level of skill and experience of those who carry out each diagnostic procedure must, with good reason, also be be considerations in deciding the study of choice.

The Role of Coronary Angiography

The importance of assessing the status of coronary artery patency before surgical repair of acute aortic dissection continues to be controversial. Some surgeons believe that obtaining this information before surgery is essential, whereas others are content to assess the coronaries intraoperatively. Two types of coronary artery involvement must be considered in the setting of aortic dissection. The first is acute proximal coronary narrowing or occlusion as a result of the dissection itself, often caused by occlusion of the coronary ostia by the intimal flap. The second is the possible presence of chronic atherosclerotic coronary artery disease, which although generally independent of the dissection process, may complicate its surgical management.

In some cases, coronary involvement by the intimal flap is self-evident if the electrocardiogram shows evidence of acute myocardial ischemia or infarction. However, should this acute process not be clinically evident, TEE can effectively define the patency of the proximal coronaries in a majority of cases.[158] Aortography may also reveal such coronary artery involvement. More comprehensive evaluation requires the performance of coronary angiography; however, this study may be risky in patients with aortic dissection and often prolongs the time to aortic repair by several hours. Moreover, catheterization of the coronary arteries is sometimes unsuccessful in patients with proximal dissection and a dilated root, in which case the added procedural delay gains no potential benefit. In addition, such proximal coronary obstructions can usually be readily identified at the time of surgery.

Chronic coronary artery disease is seen in about one-quarter of patients with aortic dissection. Identifying the presence of this underlying coronary disease is beyond the capability of any of the four imaging modalities discussed above. Furthermore, accurately defining such atherosclerotic disease intraoperatively is challenging, although Rizzo and coworkers have suggested probing of the proximal coronaries, epicardial palpation, and angioscopy as possible means to identify coronary stenoses.[165]

The impact of unrecognized coronary artery disease on outcome is not certain. In a 10-year review examining 54 patients undergoing urgent aortic repair, Kern and colleagues found that only 1 of 27 patients with a proximal dissection had a perioperative myocardial infarction; this patient had a prior history of coronary artery disease.[157] In addition, Rizzo and associates observed that of those in whom unrecognized coronary artery disease was discovered at autopsy, none died of coronary ischemia but several died of aortic rupture.[165] Lastly, Penn and colleagues studied 122 consecutive patients undergoing emergency aortic repair and found no difference in in-hospital mortality between those who had preoperative angiography and those who did not.[166A] Accordingly, we and others[157] recommend avoiding preoperative coronary angiography unless a specific indication exists, such as a known history of coronary artery disease, prior coronary artery bypass grafting,[167] or the presence of ischemic electrocardiographic changes. Conversely, Creswell and coauthors reported good outcomes when performing combined aortic repair and coronary artery bypass grafting in patients with underlying coronary artery disease and therefore argue that all stable patients with acute proximal dissection should undergo preoperative coronary angiography.[168] While the debate continues unresolved, the trend in the literature has been a retreat from the routine performance of coronary angiography in acute aortic dissection.

Management

Therapy for aortic dissection is directed at halting progression of the dissecting hematoma because lethal complications

arise not from the intimal tear itself but rather from the subsequent course taken by the dissecting aorta, e.g., vascular compromise or aortic rupture. [137] Without treatment, aortic dissection has a high mortality. In a collective review of long-term survival in untreated aortic dissection, more than 25 percent of all patients died within the first 24 hours after the onset of dissection, more than 50 percent died within the first week, more than 75 percent died within 1 month, and more than 90 percent died within 1 year.[169]

The first surgical approach to aortic dissection was a fenestration procedure in which the dissected aorta was incised and a distal communication created between the true and false channels, thereby decompressing the false lumen. This procedure is, in fact, still used by some surgeons in selected cases of dissection involving the descending aorta to relieve limb, renal, or mesenteric ischemia.[170] Definitive surgical therapy was pioneered by DeBakey and colleagues in the early 1950s.[171] Its purpose is to excise the intimal tear, obliterate the false channel by oversewing the aortic edges, reconstitute the aorta directly or with the interposition of a synthetic graft, and in the case of proximal dissection, restore aortic valve competence either by resuspension of the displaced aortic leaflets or by prosthetic aortic valve replacement.

Aggressive medical treatment of aortic dissection was first advocated by Wheat and colleagues.[172] They established reduction of systolic blood pressure and diminution of the force of left ventricular ejection (dP/dt) as the two primary goals of pharmacological therapy. This force is thought to be a major stress acting on the aortic wall that contributes to both the genesis and subsequent propagation of aortic dissection. Originally introduced for patients too ill to withstand surgery, medical therapy is now the initial treatment for virtually all patients with aortic dissection before definitive diagnosis and furthermore serves as the primary long-term therapy in a subset of patients, particularly those with distal dissections.

Immediate Medical Management

All patients in whom acute aortic dissection is strongly suspected should immediately be placed in an acute care setting for hemodynamic stabilization and monitoring of blood pressure, cardiac rhythm, and urine output. Two large-bore intravenous catheters should be inserted for intravenous medications and fluid resuscitation if necessary. An arterial line should be placed, preferably in the right arm so that it remains functional during surgery when the aorta is cross-clamped. However, in cases in which the blood pressure is significantly greater on the left than on the right, the arterial line should be placed on the left. In those with a lower likelihood of dissection who are hemodynamically stable, a automatic blood pressure cuff should suffice.

A central venous or pulmonary arterial line to monitor central venous or pulmonary artery wedge pressure and cardiac output should be considered in patients with hypotension or congestive heart failure. Femoral lines and blood gas studies should be avoided if possible to conserve these sites for bypass cannulation during potential aortic repair. If a femoral line must be placed urgently, the opposite groin site should be protected from needle puncture.

BLOOD PRESSURE REDUCTION.

Initial therapeutic goals include the elimination of pain and reduction of systolic blood pressure to 100 to 120 mm Hg (mean of 60 to 75 mm Hg) or the lowest level commensurate with adequate vital organ (cardiac, cerebral, renal) perfusion. Simultaneously, arterial dP/dt, which reflects the force of left ventricular ejection, should be reduced through the use of beta-blocking agents, regardless of whether pain or systolic hypertension is present. The use of long-acting medications should be avoided in patients who are surgical candidates because they may complicate intraoperative arterial pressure management. Pain, which may itself exacerbate hypertension and tachycardia, should be promptly treated with intravenous morphine sulfate.

For the acute reduction of arterial pressure, the potent vasodilator sodium nitroprusside is very effective. It is initially infused at 20 mug/min with the dosage titrated upward, as high as 800 mug/min, according to the blood pressure response. When used alone, however, sodium nitroprusside can actually cause an increase in dP/dt, which in turn may potentially contribute to propagation of the dissection. Therefore, when this drug is used concomitantly achieving adequate beta blockade is essential.

To reduce dP/dt acutely, an intravenous beta blocker should be administered in incremental doses until evidence of satisfactory beta blockade is noted, usually indicated by a heart rate of 60 to 80 beats/min in the acute setting. Because propranolol was the first generally available beta blocker, it has been used most widely in treating aortic dissection. However, it is believed that other noncardioselective beta blockers are equally effective. Propranolol should be administered in intravenous doses of 1 mg every 3 to 5 minutes until the desired effect is achieved, although the maximum initial dose should not exceed 0.15 mg/kg (or approximately 10 mg). To maintain adequate beta blockade, as evidenced by the heart rate, additional propranolol should be given intravenously every 4 to 6 hours, usually in doses somewhat lower than the total initial dose, i.e., 2 to 6 mg.

Labetalol, which acts as both an alpha- and beta-adrenergic receptor blocker, may be especially useful in the setting of aortic dissection because it effectively lowers both dP/dt and arterial pressure. The initial dose of labetalol is 20 mg, administered intravenously over a 2-minute period, followed by additional doses of 40 to 80 mg every 10 to 15 minutes (up to a maximum total dose of 300 mg) until the heart rate and blood pressure have been controlled. Maintenance dosing may then be achieved with a continuous intravenous infusion starting at 2 mg/min and titrating up to 5 to 10 mg/min.

The ultra-short-acting beta blocker esmolol may be particularly useful in patients with labile arterial pressure, especially if surgery is planned, because use of this drug can be abruptly discontinued if necessary. It is administered as a 500 mcg/kg intravenous bolus followed by continuous infusion at 50 mcg/kg/min and titrated up to 200 mcg/kg/min. Esmolol may also be useful as a means to test beta blocker safety and tolerance in patients with a history of obstructive pulmonary disease who may be at uncertain risk for bronchospasm from beta blockade. In such patients, a cardioselective beta blocker, such as atenolol or metoprolol, may be considered.

When contraindications exist to the use of beta blockers--including sinus bradycardia, second- or third-degree atrioventricular block, congestive heart failure, or bronchospasm--other agents to reduce arterial pressure and dP/dt should be considered. Calcium channel antagonists, which are effective in managing hypertensive crisis, are used on occasion in the treatment of aortic dissection. The combined vasodilator and negative inotropic effects of both diltiazem and verapamil make these agents well suited for the treatment of aortic dissection. Moreover, both these agents may be administered intravenously. Nifedipine has the advantage that it can be given immediately by the sublingual route while other medications are being prepared. A key limitation of nifedipine, however, is that it has little negative chronotropic or inotropic effect.

Refractory hypertension may result when a dissection flap compromises one or both of the renal arteries, thereby causing the release of large amounts of renin. In this situation,

the most efficacious antihypertensive may be the intravenous angiotensin-converting enzyme (ACE) inhibitor enalaprilat, which is administered initially in doses of 0.625 mg every 4 to 6 hours and the dose then titrated upward.

In the event that a patient with suspected aortic dissection has significant hypotension, rapid volume expansion should be considered given the possible presence of cardiac tamponade or aortic rupture. Before initiating aggressive treatment of such hypotension, however, the possibility of pseudohypotension, which occurs when arterial pressure is being measured in an extremity whose circulation is selectively compromised by the dissection, should be carefully excluded. If vasopressors are absolutely required for refractory hypotension, norepinephrine (Levophed) or phenylephrine (Neo-Synephrine) is preferred. Dopamine should be reserved for improving renal perfusion and used only at very low doses, given that it may raise dP/dt.

Once appropriate medical therapy has been initiated and the patient sufficiently stabilized, a definitive diagnostic study should be promptly undertaken. If a patient remains unstable, TEE is preferred because it can be performed at the bedside in the emergency department or intensive care unit, thereby allowing both monitoring and therapeutic intervention to continue uninterrupted. When a patient with a strongly suspected dissection becomes extremely unstable, aortic rupture or cardiac tamponade is likely and the patient should go directly to the operating room rather than delaying surgery for diagnostic imaging. In such situations, intraoperative TEE can be used both to confirm the diagnosis and to guide surgical repair.

MANAGEMENT OF CARDIAC TAMPONADE.

Cardiac tamponade frequently complicates acute proximal aortic dissection and is one of the most common mechanisms of death in these patients. It is often the cause of hypotension when patients have aortic dissection, and pericardiocentesis is commonly performed in this setting in an effort to stabilize patients while they await definitive surgical repair. However, in a retrospective series we found that pericardiocentesis may be harmful rather than beneficial in this setting because it may precipitate hemodynamic collapse and death rather than stabilize the patient as intended.[173] Seven patients in this series were relatively stable initially (six hypotensive, one normotensive). Three of four who underwent successful pericardiocentesis died suddenly between 5 and 40 minutes after the procedure secondary to acute electromechanical dissociation. In contrast, none of the three patients without pericardiocentesis died before surgery. It may be that in such patients the increase in intraaortic pressure that follows pericardiocentesis causes a closed communication between the false lumen and pericardial space to reopen, thereby leading to recurrent hemorrhage and lethal cardiac tamponade.

Therefore, when a patient with acute aortic dissection complicated by cardiac tamponade is relatively stable, the risks of pericardiocentesis probably outweigh the benefits and *every effort should be made to proceed as urgently as possible to the operating room for direct surgical repair of the aorta with intraoperative drainage of the hemopericardium*. However, when patients have electromechanical dissociation or marked hypotension, an attempt to resuscitate the patient with pericardiocentesis is warranted. A prudent strategy in such cases might be to aspirate only enough pericardial fluid to raise blood pressure to the lowest acceptable level.[173]

Definitive Therapy

Despite minor variations from center to center, a reasonable consensus regarding definitive therapy for aortic dissection has evolved over the past several decades. It is universally agreed that surgical therapy is superior to medical therapy for acute proximal dissection.[174] [175] With even limited progression of a proximal dissection, patients may suffer the potentially devastating consequences of aortic rupture or cardiac tamponade, acute aortic regurgitation, or neurological compromise. Thus, by controlling this risk, immediate surgical repair promises a better outcome. Occasional patients with proximal dissection who refuse surgery or for whom surgery is contraindicated (e.g., by age or prior debilitating illness) may potentially be treated successfully with medical therapy with a 30-day survival rate of up to 42 percent.[112]

Patients suffering acute distal aortic dissection, on the other hand, are generally at lower risk of early death from complications of the dissection than are those with proximal dissection.[128] Furthermore, because patients with distal dissection tend to be older and have a relatively increased prevalence of advanced atherosclerosis or cardiopulmonary disease, their surgical risk is often considerably higher. A large retrospective series involving patients from both Duke and Stanford universities has, by multivariate analysis, shown that medical therapy provides an outcome equivalent to that of surgical therapy in patients with uncomplicated distal dissection.[176] As a consequence, medical therapy for such patients is currently favored by most groups. An important exception is that when distal dissection is complicated by rupture, expansion, saccular aneurysm formation, vital organ or limb ischemia, or continued pain, the results of medical therapy are poor and surgery is therefore recommended.[170] [175]

Patients with chronic aortic dissection have, through self-selection, survived the early period of highest mortality, and whether treated medically or surgically, their subsequent hospital survival rate is approximately 90 percent. [177] Accordingly, medical therapy is recommended for the management of all stable patients with chronic proximal and distal dissection, again unless complicated by rupture, aneurysm formation, aortic regurgitation, arterial occlusion, or extension or recurrence of dissection.

SURGICAL MANAGEMENT.

Generally advocated indications for definitive surgical therapy are summarized in Table 40-4 . Surgical candidacy should be determined whenever possible at the start of the patient's evaluation because this option guides the selection of diagnostic studies. Surgical risk for all patients is increased by age, comorbid disease (especially pulmonary emphysema), aneurysm leakage, cardiac tamponade, shock, or vital organ compromise as a result of such conditions as myocardial infarction, cerebrovascular accident, and in particular, preexisting renal failure.

Preoperative mortality in patients with acute dissection ranges from 3 percent when surgery is expedited to as high as 20 percent when the preoperative evaluation is more prolonged.[165] These data reinforce the need for prompt diagnosis

TABLE 40-4 -- INDICATIONS FOR DEFINITIVE SURGICAL AND MEDICAL THERAPY IN AORTIC DISSECTION

SURGICAL
Treatment of choice for acute proximal dissection
Treatment for acute distal dissection complicated by the following:
Progression with vital organ compromise
Rupture or impending rupture (e.g., saccular aneurysm formation)
Retrograde extension into the ascending aorta
Dissection in the Marfan syndrome
MEDICAL
Treatment of choice for uncomplicated distal dissection
Treatment for stable, isolated arch dissection
Treatment of choice for stable chronic dissection (uncomplicated dissection presenting 2 weeks or later after onset)

and repair to prevent even minimal progression of the dissection, which might lead to further complications.[88]

The usual objectives of definitive surgical therapy include resection of the most severely damaged segment of aorta, excision of the intimal tear when possible, and obliteration of entry into the false lumen by suturing the edges of the dissected aorta both proximally and distally. After resecting the diseased segment containing the intimal tear, typically a segment of the ascending aorta in proximal dissections or the proximal descending aorta in distal dissections, aortic continuity is then reestablished by interposing a prosthetic sleeve graft between the two ends of the aorta (Fig. 40-18) .

Importantly, Miller and colleagues have found that the immediate and long-term survival of patients treated surgically was not significantly affected by failure to excise the intimal tear.[174] [178] Some patients with proximal dissection have an intimal tear located in the aortic arch. Because surgical repair of the arch may increase the morbidity and mortality associated with the procedure and because resection of the tear may not necessarily improve mortality,[178A] many authors have elected to not repair the arch if the sole purpose of surgery is resection of the intimal tear.[178] However, with improvements in surgical technique during the last decade, several groups now suggest that even these challenging lesions can be resected with favorable results.[179] [180]

When aortic regurgitation complicates aortic dissection, simple decompression of the false lumen is sometimes all that is required to allow resuspension of the aortic leaflets and restoration of valvular competence. More often, however, preservation of the aortic valve requires approximation of the two layers of dissected aortic wall and resuspension of the commissures with pledgeted sutures. In this setting, the use of intraoperative TEE may be particularly helpful to the surgeon in guiding aortic valve repair.[181] This resuspension technique has had favorable results with a fairly low incidence of recurrent aortic regurgitation in long-term follow-up.[118] [182] Preserving the aortic valve in this fashion may avoid the complications associated with prosthetic valve replacement, especially the requirement for oral anticoagulation, which may pose an added risk in patients prone to future aortic rupture.

Prosthetic aortic valve replacement is sometimes necessary, however, either because attempts at valve repair are unsuccessful or in the setting of preexisting valvular disease or the Marfan syndrome.[182] Many surgeons are aggressive about replacing the aortic valve if it appears that even moderate aortic regurgitation will remain after the leaflets are resuspended and choose to avoid the risk of having to replace the aortic valve at some later date in a second operation through a diseased aorta. When the proximal aorta is fragile or badly torn, most use the Bentall procedure in which a composite prosthetic graft--a prosthetic aortic valve sewn onto the end of a Dacron tube graft--facilitates replacement of both the ascending aorta and aortic valve together (see Fig. 40-5). The coronary arteries are then reimplanted as buttons

of aortic tissue into the graft wall. The operative procedure in aortic dissection is technically demanding. The wall of the diseased aorta is often friable, and the repair must be performed with meticulous care. The use of Teflon felt to buttress the wall and prevent sutures from tearing through the fragile aorta is essential (see Fig. 40-18) . Determining the sources of vital organ perfusion distal to the surgical site by diagnostic imaging studies may be of critical importance. For example, if one or both renal arteries are supplied by the false lumen and are not going to be directly corrected surgically, the surgeon may leave communication between the true and false channels distal to the site of aortic repair so that renal perfusion is not jeopardized.

COMPLICATIONS.

Bleeding, infection, pulmonary failure, and renal insufficiency constitute the most common early complications of surgical therapy. Spinal cord ischemia with paraplegia caused by inadvertent interruption of the blood supply from the anterior spinal or intercostal arteries is an uncommon but dreaded consequence of descending thoracic aortic repair. Late complications include progressive aortic regurgitation if the aortic valve has not been replaced, localized aneurysm formation, and recurrent dissection at the original site or at a secondary site.[178] With modern operative techniques, 30-day surgical survival rates for proximal and distal dissections are 74 and 69 percent, respectively. [112]

NEWER SURGICAL TECHNIQUES.

As a modification of more standard operative techniques, several investigators have unified the layers of the dissected aortic wall by using either a fibrin sealant[183] or gelatin-resorcine-formaldehyde glue.[184] After resection of the diseased aortic segment, this glue is used in place of pledgeted sutures to seal the false lumen of the aortic stumps, before implantation of the Dacron prosthesis. The glue not only hardens and reinforces the fragile dissected

Figure 40-18 Several steps in the surgical repair of proximal *(A, B,* and *C)* and distal *(D, E,* and *F)* aortic dissection. *A* and *D* show the dissections and intimal tears. *B,* The aorta has been transected, and the ends of the aorta have been oversewn to obliterate the false lumen and buttressed with Teflon felt to prevent the sutures from tearing through the fragile tissue. *C,* The aortic ends are brought together in such a way that the Teflon is again used to reinforce the suture line between the two ends of the aorta and between the aorta and a sleeve graft, if such a graft is necessary for reconstitution of the aorta. *E,* Resection of a distal dissection, with a Teflon graft interposed in *F*. *(D, E, and F reprinted, by permission, from Austen WG, DeSanctis RW: Surgical treatment of dissecting aneurysm of the thoracic aorta. N Engl J Med 272:1314, 1965.)*

aortic tissue but may also simplify the operation, facilitate resuspension of the aortic valve, and potentially reduce the incidence of late aortic root aneurysm formation.[183] Another group has used such glue in carrying out direct surgical repair of the aorta without an interposing graft by first suturing the intimal tear, then applying the glue in the false lumen to unify the layers of the dissected aorta, and finally reattaching the free aortic ends. Although early reports show favorable morbidity and mortality with the use of these new techniques,[184] direct comparison with standard operative techniques is needed.

ENDOVASCULAR TECHNIQUES (see also Chap. 42) .

One of the more promising avenues of investigation is the use of endovascular techniques for treating high-risk patients with aortic dissection. For example, because patients with renal or visceral artery compromise from dissection have operative mortality rates exceeding 50 percent,[185] [186] alternative management strategies are desirable. Two endovascular techniques have been used in many centers to manage patients with acute vascular complications secondary to aortic dissection. The first is balloon fenestration of the intimal flap, which involves crossing an intact intimal flap with a wire, passing a balloon-tipped catheter over the wire, and then expanding the balloon to tear a hole in the intimal flap. The hole acts as a site of reentry to allow blood to flow from the false into the true lumen, thereby decompressing the distended false lumen. The second technique involves percutaneous stenting of an affected arterial branch whose flow has been compromised by the dissection process. Slonim and coauthors reported the use of percutaneous management of ischemic complications of aortic dissection in a series of 22 patients.[186] Sixteen patients were treated with endovascular stents, 3 with balloon fenestration of the intimal flap, and 3 with fenestration in combination with stenting of the aorta or its branches; revascularization with clinical success was achieved in all 22 patients, with excellent long-term outcomes. The utility of aortic intimal flap fenestration in restoring blood flow to hypoperfused organs has also been demonstrated in animal models.[187] In the large IRAD series of acute aortic dissection, 3.2 percent of patients were treated with percutaneous fenestration procedures.[112]

More definitive endovascular techniques have also been introduced. Sutureless intraluminal prostheses placed during cardiopulmonary bypass are intended to improve outcome by decreasing intraoperative and postoperative bleeding complications. These devices have been used successfully with good outcomes in two small series of patients with proximal aortic dissection.[188] [189]

More recently, intraluminal stent-grafts placed percutaneously by the transfemoral catheter technique have been introduced as a potential alternative to aortic repair.[190] [191] [192] The purpose of this procedure is to close the site of entry into the false lumen (intimal tear), decompress and promote thrombosis of the false lumen, and relieve any obstruction of branch vessels that may accompany the dissection. It is hoped that this approach will reduce the morbidity and mortality of aortic dissection and reduce the risk of subsequent aneurysm formation. Nienaber and colleagues compared the use of stent-graft placement with standard surgical repair in a group of 24 patients with subacute or chronic type B aortic dissection and a patent false lumen.[191] No procedural complications occurred among the 12 patients undergoing stent-graft treatment, and when compared with the surgical group, the stent-graft group had a significantly shorter hospital stay, lower morbidity, and lower 1-year postprocedural mortality. Dake and colleagues inserted stent-grafts in the descending thoracic aortas of 19 patients with acute aortic dissection and a patent false lumen who suffered from obstruction of branch vessels, acute aortic rupture, or persistent back pain.[192] Endovascular stent-graft deployment was successful in all cases, with complete thrombosis of the false lumen in 79 percent and partial thrombosis in the remaining 21 percent. Restoration of flow to ischemic arterial branches with relief of corresponding symptoms occurred in 76 percent of obstructed branches. The results of these two series are extremely promising, but larger studies with more patients and longer follow-up will be required before stent-graft therapy becomes an accepted therapy for aortic dissection.[193]

DEFINITIVE MEDICAL MANAGEMENT.

The indications for definitive medical therapy are summarized in Table 40-4 . As discussed above, we prefer medical therapy for stable patients with uncomplicated acute distal dissection given that the 30-day survival rate for those with distal dissection treated medically is 92 percent.[112] However, surgery clearly must be performed in cases of medical management failure, such as in the presence of rupture or impending rupture, progression of the dissection with vital organ compromise, an inability to control pain with medicines, or retrograde progression of a type B dissection into the ascending aorta. Because of the extreme difficulty of surgery to repair the aortic arch when it is involved by the dissection, medical therapy is also usually advocated for distal dissections that either originate in the arch or extend retrograde into the arch. Operative therapy is again reserved for those with serious complications. Medical therapy is also generally recommended for patients with chronic aortic dissection, whether proximal or distal, unless late complications of the dissection, such as aortic regurgitation or localized aneurysm formation, necessitate surgery.

Severe hypertension is relatively common during the period of hospitalization after acute aortic dissection and may be seen even in patients without a history of significant hypertension. The etiology for this hypertensive response is unclear but it may reflect a marked increase in sympathetic tone triggered by the severe inflammation of the aortic wall that accompanies dissection. While such hypertension often prompts clinicians to order a CT or MR angiogram to rule out renal artery compromise by the dissection, in our experience, renal ischemia is rarely the cause.[194] In most cases, blood pressure begins to fall and becomes more easily controlled about 5 to 7 days after onset of the aortic dissection.

Long-Term Therapy and Late Follow-Up

Late follow-up of patients leaving the hospital with treated aortic dissection shows an actuarial survival rate not much worse than that of individuals of comparable age without dissection. No significant differences are seen among discharged patients when comparing proximal versus distal dissection, acute versus chronic dissection, or medical versus surgical treatment.[128] Five-year survival rates for all these groups are typically 75 to 82 percent.[128] [174] [178] Thus, the initial success of surgical or medical therapy is usually sustained on long-term follow-up. Late complications include aortic regurgitation, recurrent dissection, and aneurysm formation or rupture.

Long-term medical therapy to control hypertension and reduce dP/dt is indicated for all patients who have sustained an aortic dissection, regardless of whether their in-hospital definitive treatment was surgical or medical. Indeed, one study found that late aneurysm rupture after aortic dissection was 10 times more common in patients with poorly controlled hypertension than in those with controlled blood pressure,[195] which dramatically demonstrates the importance of aggressive lifelong antihypertensive therapy. Systolic blood pressure should be maintained at or below 130 mm Hg. The preferred agents are beta blockers or, if contraindicated, other agents with a negative inotropic as well as a hypotensive effect such as verapamil or diltiazem. Pure vasodilators, such as dihydropyridine calcium channel antagonists or hydralazine, may cause an increase in dP/dt and should therefore be used only in conjunction with adequate beta blockade. ACE inhibitors are attractive

antihypertensive agents for treating aortic dissection and may be of particular benefit in those with some degree of renal ischemia as a consequence of the dissection.

Up to 29 percent of late deaths following surgery result from rupture of either the dissecting aneurysm or an another aneurysm at a remote site. Moreover, the incidence of subsequent aneurysm formation at a site remote from the surgical repair is 17 to 25 percent,[108] [196] with these remote aneurysms accounting for many of the rupture-related deaths. The mean time interval from primary aortic dissection to the appearance of subsequent aneurysms is 18 months, with the majority appearing within 2 years.[196] Many such aneurysms occur from dilatation of the residual false lumen in the more distal aortic segments not resected at the time of surgery. Because the dissected aneurysm wall is relatively thin and consists of only the outer half of the original aortic wall, these aneurysms rupture more frequently than do typical atherosclerotic thoracic aneurysms.[78] [196] Thus, an aggressive approach to treating such late-appearing aneurysms may be indicated.

The high incidence of late aneurysm formation and rupture

emphasizes both the diffuse nature of the aortic disease process in this population and the tremendous importance of careful follow-up. The primary goal of long-term surveillance is the early detection of aortic lesions that might require subsequent surgical intervention, such as the appearance of new aneurysms or rapid aneurysm expansion, progression or recurrence of dissection, aortic regurgitation, or peripheral vascular compromise.

Follow-up evaluation of patients after aortic dissection should include careful and repeated physical examinations, periodic chest roentgenograms, and serial aortic imaging with TEE, CT,[175] or MRI.[170] [197] We generally prefer MRI for serially monitoring these patients because it is completely noninvasive and provides excellent anatomical detail that may be exceedingly helpful in evaluating interval changes.[198] Patients are at highest risk immediately after hospitalization and during the first 2 years, with the risk progressively declining thereafter. It is therefore important to have more frequent early follow-up; for example, patients may be seen at 3 and 6 months initially and then return every 6 months for 2 years, after which time they may be reevaluated at 6- to 12-month intervals, depending on the given patient's risk.

Atypical Aortic Dissection

In recent years it has become increasingly clear that in addition to aortic dissection as classically described, two other diseases of the aorta are closely related, *intramural hematoma* of the aorta and *penetrating atherosclerotic ulcer* of the aorta. These two conditions share with aortic dissection many of the predisposing risk factors and initial symptoms, and indeed, both may lead to either classic aortic dissection or aortic rupture. In light of their clinical similarities, it is appropriate to consider classic aortic dissection and its variants collectively among the "acute thoracic aortic syndromes," a category that also includes traumatic aortic transection and rupture, contained rupture (pseudoaneurysm), or acute expansion of thoracic aortic aneurysms.

INTRAMURAL HEMATOMA.

Intramural hematoma is essentially a hemorrhage contained within the medial layer of the aortic wall. Although the pathogenesis of intramural hematoma is still uncertain, rupture of the vasa vasorum is believed to be the initiating event and results in hemorrhage into the outer media and extending into the adventitia.[199] This complication may produce a localized or discrete hematoma, but more often the hemorrhage extends for a variable distance by dissecting along the outer media beneath the adventitia.[200] Intramural hematoma is distinguished from typical aortic dissection by the lack of an associated tear in the intima or direct communication between the media and aortic lumen; hence, some have termed it *aortic dissection without intimal rupture.* [199] Previous pathological studies of what were considered clinically to be aortic dissections have found that 3 to 13 percent did not have an identifiable intimal tear,[106] [107] [201] and it is possible that such cases were in fact actually intramural hematomas. Moreover, it remains uncertain whether intramural hematoma is a distinct pathological entity or instead represents a reversible precursor of classic aortic dissection.

Clinically, intramural hematoma may be indistinguishable from true aortic dissection. In the IRAD series of 464 patients with the clinical diagnosis of acute aortic dissection, 10 percent were found by imaging studies to have an intramural hematoma rather than classic dissection and two-thirds of these intramural hematomas were classified as type B.[112] The majority of patients are elderly with a history of hypertension and typically have extensive aortic atherosclerosis.[202] [203] Almost all patients have the chest and back

Figure 40-19 Intramural hematoma of the descending thoracic aorta. *A,* An axial CT scan without contrast enhancement demonstrates crescentic thickening of the aortic wall that is of increased density (H), consistent with an intramural hematoma of the aorta. A left pleural effusion (E) is also present. *B,* Subsequent contrast-enhanced images of the same patient demonstrating a contrast-filled aortic lumen with dark crescentic thickening of the aortic wall (H) that does not enhance, confirming the presence of an intramural hematoma that does not communicate with the aortic lumen. Note that neither the size nor the shape of the aortic lumen is distorted the way it would typically be in the presence of a classic aortic dissection.

pain symptoms typical of classic aortic dissection. Aortic regurgitation and pulse deficits may be present. One-half of patients may have an associated left pleural effusion[199] [202] that may not appear until several days after the hematoma develops.[199] Pericardial effusion may appear when the ascending aorta is involved.[202]

Intramural hematoma is best diagnosed by CT scanning. On a non-contrast-enhanced CT scan (Fig. 40-19 *A*) it appears as a continuous, crescentic, high-attenuation area along the aortic wall without evidence of an intimal tear, false lumen, or associated intimal atherosclerotic ulcer.[200] This first examination is followed by a contrast-enhanced CT scan (Fig. 40-19 *B*), which demonstrates failure of the intramural hematoma to enhance (appearing as a darker crescentic thickening of the aortic wall), thereby excluding communication with the aortic lumen. In some cases it may be difficult to distinguish intramural hematoma from aortic dissection with thrombosis of the false lumen or from mural thrombus within an aortic aneurysm.[199] However, with an intramural hematoma, the aortic lumen retains its overall size and shape, unlike the case with aortic dissection.

On MRI, an intramural hematoma appears as a crescentic high-intensity area along the aortic wall.[199] On TEE, it is manifested as a continuous crescentic or nearly concentric circular thickening of the aortic wall that in some cases may be difficult to distinguish from severe atherosclerotic thickening of the aortic wall.[204] [205] Aortography, on the other hand, often fails to detect the presence of an intramural hematoma because no contrast escapes the aortic lumen and the intramural hematoma does not usually compress the aortic lumen to produce recognizable aortographic signs such as seen with aortic dissection.[199] In fact, the sensitivity of aortography for detecting intramural hematoma is as low as 19 percent[206] ; therefore, while a negative aortogram may exclude the presence of classic aortic dissection, it does not reliably exclude the important variant of intramural hematoma.

The natural history of intramural hematoma is not yet well defined. Involvement of the ascending aorta appears to carry a high risk of death or complications requiring surgical repair, whereas hematomas of the descending aorta have a more favorable prognosis. In a retrospective series, Nienaber and coworkers determined that 13 percent of 195 patients with aortic dissection-like syndromes in fact had intramural hematoma.[204] The actuarial survival rates were similar for the groups with intramural hematoma and overt aortic dissection.[204] Of patients with proximal intramural hematoma, 30-day mortality was 80 percent for those treated medically versus 0 percent for those undergoing early repair. On the other hand, early mortality for distal intramural hematoma was 9 percent and did not differ significantly between medical and surgical treatment.

Intramural hematomas may regress with time or even completely resolve on follow-up imaging.[199] However, should the intramural hematoma completely resolve, the affected portion of the aorta is still at risk for progressive enlargement and fusiform aneurysm formation.[207] Alternatively, intramural hematoma may progress to overt aortic dissection within days[204] to months of initial examination.[200] Nienaber and colleagues found progression to overt dissection, aortic rupture, or cardiac tamponade in one-third of their patients.[204]

The limited data on the natural history of intramural hematoma suggest that it behaves very much like classic aortic dissection and should therefore be treated in a similar fashion. Thus, surgical therapy is best for proximal hematomas, whereas medical therapy is reasonable for distal hematomas. Physicians should have a low threshold, however, for proceeding to surgery in distal disease if symptoms persist or evidence of progression is seen. Medical management should therefore include serial imaging studies to monitor progression or regression of the intramural hematoma.

PENETRATING ATHEROSCLEROTIC ULCER.

Penetrating atherosclerotic ulcer, first defined in the literature in 1986 by Stanson and coauthors in 1986,[208] is an ulceration of an atherosclerotic lesion of the aorta

that penetrates the internal elastic lamina and allows hematoma formation within the media of the aortic wall (Fig. 40-20) (Figure Not Available) . Although such ulcerations occur almost exclusively in the descending thoracic aorta,[209] they may also occur in the arch or rarely in the ascending aorta.[210] [211] The hematoma that results from a penetrating atherosclerotic ulcer usually remains localized or extends several centimeters in length, but a false lumen typically does not develop.[212] However, it has also been suggested that some cases of intramural hematoma of the aorta may in fact be secondary to small penetrating atherosclerotic ulcers that have escaped detection on imaging studies but are later identified at the time of surgery.[213]

Atherosclerotic aortic ulcers penetrate through the media in one-quarter of cases to cause aortic pseudoaneurysms or through the adventitia in 8 percent to cause transmural aortic rupture[210] (Fig. 40-20) (Figure Not Available) . Rarely, a penetrating atherosclerotic ulcer may progress to an extensive classic aortic dissection.[211] Over time, penetrating atherosclerotic ulcers frequently lead to the formation of saccular or fusiform aortic aneurysms.[214]

Patients in whom penetrating atherosclerotic ulcers develop tend to be elderly with a history of hypertension and

Figure 40-20 (Figure Not Available) Evolution of a penetrating atherosclerotic ulcer of the aorta. Once an intimal ulcer has formed, it may then progress to a variable depth. Penetration through the intima causes a medial hematoma, while penetration through the media leads to the formation of a pseudoaneurysm, and perforation through the adventitial layer results in aortic rupture. *(From Stanson AW, Kazmier FJ, Hollier LH, et al: Penetrating atherosclerotic ulcers of the thoracic aorta: Natural history and clinicopathological correlations. Ann Vasc Surg 1:15, 1986.)*

Figure 40-21 Thoracic aortogram demonstrating a penetrating atherosclerotic ulcer of the distal end of the descending aorta (arrow). The hematoma of the aortic wall is evident as a localized contrast-filled outpouching of the aorta. The remainder of the aorta is diffusely atherosclerotic.

evidence of other atherosclerotic cardiovascular disease.[209] Initial symptoms include chest and back pain similar to that of aortic dissection, and the majority are hypertensive at initial evaluation.[209] However, since penetrating atherosclerotic ulcers tend to be localized, the vascular compromise or aortic regurgitation that often complicates aortic dissection does not develop.[208]

Chest roentgenograms often demonstrate a dilated descending thoracic aorta as well as left-sided or bilateral pleural effusions.[209] Aortography is the diagnostic standard for detecting a penetrating atherosclerotic ulcer, with the lesion appearing as a contrast-filled outpouching in the descending aorta in the absence of an intimal flap or false lumen[210] (Fig. 40-21) . On CT scanning or MRI the lesion appears as a focal ulceration, with thickening of the aortic wall and inward displacement of intimal calcification consistent with intramural hematoma. TEE may identify the presence of a culprit atherosclerotic ulcer in the setting of a visible intramural hematoma,[215] but diagnosis is difficult. [154]

The natural history of a penetrating atherosclerotic ulcer remains largely unclear, and at present no definitive treatment strategy is available. Certainly, patients who are hemodynamically unstable or who have evidence of pseudoaneurysm formation or transmural rupture should undergo urgent surgical repair. Continued or recurrent pain, distal embolization, and progressive aneurysmal dilatation are also indications for surgery.[212] In the near future, transluminal placement of an endovascular stent-graft may become an alternative to surgery in such patients.[216] Those without such complications should be treated with antihypertensive medications and monitored closely with follow-up imaging studies, similar to the management of a patient with a distal aortic dissection.

Aortic Trauma

See Chapter 51 .

AORTIC ATHEROMATOUS DISEASE (see also Chap. 41)

AORTOGENIC ATHEROTHROMBOTIC EMBOLI.

The clinical importance of atherosclerotic disease of the aorta has long been recognized inasmuch as atheromatous or fibrinous material, thrombi, or cholesterol particles dislodged from atherosclerotic plaque may cause cerebral or peripheral embolic phenomena.[217] However, assessing the degree of such atherosclerotic disease antemortem has been limited by the inability of the several imaging modalities to directly visualize the aortic intima.[218] Aortography demonstrates the aortic lumen rather than the aortic walls themselves and can thus detect only gross atherosclerotic changes, whereas CT scanning or MRI rarely detects protruding atheromas because the normal pulsatile motion of the aorta may limit definition of the aortic wall on the tomographic images. On the other hand, TEE is uniquely suited to assess atherosclerotic disease of the aorta in real time and has been demonstrated to have greater sensitivity for aortic arch atherosclerosis than is the case with chest roentgenography, aortography, or CT scanning.[218] On echocardiography, mild atherosclerosis appears as intimal thickening, irregularity, and calcification, whereas more severe disease appears as thick plaque with protruding atheromas (Fig. 40-22) . In some cases, protruding lesions have highly mobile components that probably represent atheroma with superimposed thrombus.[219]

Risk factors for aortic atherosclerosis include age, hypertension, diabetes,[220] hyperlipidemia,[221] and other vascular disease. [222] Through the use of TEE, the prevalence and extent of macroscopic atherosclerotic disease have now been documented in a variety of patient populations. Atheromatous disease is least common in the ascending aorta, more common in the arch, and most common in the descending thoracic aorta.[223] [224] While aortic atheromas are detected in as few as 2 percent of patients without a history of stroke or known aortic disease, they are found in 38 percent of those with significant carotid artery disease,[225] 60 percent of those with ischemic stroke,[223] and up to 90 percent of those with obstructive coronary artery disease.[226]

In an autopsy series, Amarenco and colleagues found that the presence of ulcerated plaque in the aortic arch was a significant independent risk factor for stroke, particularly cryptogenic stroke,[222] and multiple clinical studies using

Figure 40-22 Cross-sectional transesophageal echocardiogram of the descending thoracic aorta demonstrating extensive atherosclerotic disease. This patient had recently suffered an embolic stoke of uncertain etiology. Multiple atheromatous plaques up to 7 mm in thickness protrude into the aortic lumen. When viewed in real time, two plaques (arrows) had small mobile intraluminal components.

TEE have found an association between aortic atherosclerosis and stroke, as well as other peripheral embolic events.[217] [221] [227] In both retrospective and prospective studies, protruding aortic atheromas are detected in 7 to 8 percent of patients undergoing routine TEE,[217] [228] with about a 33 percent incidence of embolic vascular events over a 2-year follow-up period.[228] The embolic risk is even higher in patients with pedunculated or mobile lesions and those undergoing invasive aortic procedures.[217]

In a prospective case-control study, Amarenco and associates found atherosclerotic plaque measuring 4 mm or greater in the ascending aorta or proximal arch in 14 percent of patients with ischemic stroke as compared with only 2 percent of controls. After adjustment for atherosclerotic risk factors, the odds ratio for stroke was 9.1 for ischemic stroke and 4.7 for cryptogenic stroke, with an even higher risk ratio for complex atheromas than for simple ones.[223] However, the increased risk of stroke was associated only with large atheromas involving the ascending aorta and proximal arch, not with atheromas in the distal arch or descending aorta,[223] thus supporting the hypothesis that atheromas in the ascending aorta and proximal portion of the aortic arch embolize directly into the cerebral circulation and cause ischemic strokes in such patients.[229]

Little is known about the natural history of atheromatous lesions[230] of the aorta, although one prospective trial has demonstrated that individual lesion morphology is dynamic in that mobile components both form on some atheromas and resolve on others during the same time period.[231] At present, therapeutic strategies are limited. Potential approaches for chronic management include the use of antithrombotic[232] [233] or antiplatelet[230] therapy to prevent thrombus formation. In two recent prospective but nonrandomized studies, patients having aortic plaque 4 mm or more in thickness or mobile aortic atheromas on TEE examination were found to have a high rate of recurrent vascular events. Of these study subjects, those subsequently treated with warfarin therapy had a significantly lower rate of recurrent embolic events than did those treated with antiplatelet therapy, which suggests that warfarin may be efficacious in this high-risk population.[234] [235] A prospective randomized trial is clearly needed to confirm the benefits of oral anticoagulant therapy for aortic atheromas. Some investigators have reported the surgical removal, under hypothermic circulatory arrest, of protruding atheromas detected in patients after embolic events.[227] However, this surgery carries the risk of an early adverse outcome,

and at present no controlled data suggest that it actually reduces the incidence of future embolization in this population.

CARDIAC SURGERY AND ATHEROEMBOLISM.

Perioperative dislodgement with embolization of atherosclerotic material from the aorta is a well-recognized hazard of cardiac surgery and has been increasingly implicated as an important cause of postoperative stroke and other embolic events in these patients. The incidence of cerebral ischemic events after cardiac surgery typically ranges from 1 to 3 percent, with an increased risk among the elderly.[220] [236] In an autopsy series of patients who underwent cardiac surgery, Blauth and colleagues identified atheroemboli in 22 percent of cases.[237] Atheroembolic events occurred in 37 percent of those with severe atherosclerosis of the ascending aorta versus only 2 percent of those without significant ascending aortic atherosclerosis. Moreover, 96 percent of patients with perioperative atheroemboli had severe atherosclerosis of their ascending aorta.[237] Mobile pedunculated lesions appear more prone to embolize.[217]

Mechanisms by which aortic atherosclerotic debris may be dislodged during cardiac surgery include external manipulation of the aorta during palpation,[236] cross-clamping, cannula placement, anastomosis of the bypass grafts to the aorta,[220] and the "sandblasting" effect of the high-velocity jet of blood that exits the aortic cannula and strikes the atherosclerotic intima of the opposite aortic wall.[236] [237] Although surgeons have long relied on direct digital palpation to detect the presence of atherosclerosis in the ascending aorta, this method underestimates the incidence, severity, and extent of atherosclerotic disease.[238] In contrast, ultrasonography is superior for delineating the presence and severity of atherosclerotic disease of the ascending aorta,[217] with intraoperative epi-aortic ultrasound found to be even more sensitive than TEE.[239]

Several studies have examined the potential role of aortic ultrasonography in identifying patients at highest risk for perioperative atheroemboli. In 8 to 17 percent of cases, the ultrasonographic findings led to modifications in surgical technique such as changing the sites of aortic cannulation (with cannulation of the distal aorta or femoral artery instead), cross-clamping, or anastomosis of vein grafts.[220] [236] [238] [240] The results of such procedural modifications have been promising, with several reports showing a trend toward a reduction in stroke rates.

CHOLESTEROL EMBOLIZATION SYNDROME (see also Chap. 41) .

Cholesterol embolization syndrome is caused by distal showering of cholesterol crystals from ulcerated atheromatous plaque in the aorta or iliac and proximal femoral arteries in patients with diffuse atherosclerosis. These cholesterol crystals then obstruct small peripheral arteries (100 to 300 mum in size), where they cause local tissue ischemia or necrosis and frequently induce a local inflammatory reaction that may contribute to the arteriolar occlusive process.[241]

The precise mechanisms that precipitate cholesterol embolization are unclear. The syndrome is most commonly seen following instrumentation of the aorta, such as with cardiac catheterization, percutaneous transluminal coronary angiography, angiography, or intraaortic balloon pump insertion.[242] The overall incidence following cardiac catheterization was 0.1 percent in the Coronary Artery Surgery Study.[243] Cholesterol embolization may also complicate aortic surgery or cardiopulmonary bypass. At times, cholesterol embolization syndrome may occur spontaneously. Studies have suggested a possible causal relationship between warfarin therapy and such spontaneous cholesterol embolization.[244]

The clinical manifestations depend on the organs affected. Cutaneous manifestations, typically of the lower extremities, are most common and include livedo reticularis, gangrene, cyanosis, and ulceration. Acute onset of pain with digital ischemia and small areas of cutaneous gangrene is often referred to as the "blue toe" or "purple toe syndrome"[244] (see Fig. 41-23) . The presence of preserved pedal pulses in the setting of peripheral ischemia distinguishes this syndrome from embolic occlusion of larger arteries.

Acute nonoliguric renal failure with or without hypertension is a common consequence of renal emboli, often seen as a rise in creatinine over several weeks, followed by a slow but progressive worsening of renal function that may become severe and irreversible. Cholesterol embolization to the central nervous system is quite uncommon and may be manifested as focal neurological deficits, amaurosis fugax from retinal emboli, paralysis from spinal cord emboli, or a diffuse encephalopathy. Mesenteric embolization may cause abdominal pain, gastrointestinal bleeding, or pancreatitis. Finally, multiple organ systems may be simultaneously involved and mimic vasculitis or bacterial endocarditis.[241]

When the cholesterol embolization syndrome occurs as the consequence of an invasive procedure, the temporal relationship of events often suggests the diagnosis. In the case of spontaneous embolization, however, recognizing the syndrome remains extremely challenging, and diagnosis in the absence of cutaneous manifestations is especially difficult. An elevated erythrocyte sedimentation rate, eosinophilia, and a reduced complement level are helpful in suggesting the diagnosis, but making a definitive diagnosis requires tissue biopsy. Paraffin-fixed sections reveal needle-shaped

clefts in the arteriolar lumina that represent the spaces occupied by cholesterol particles before fixation.

No specific therapy effectively treats cholesterol embolization syndrome. Because cholesterol embolization resembles other atheroembolic phenomena, some have advocated the use of anticoagulant therapy. However, such therapy is typically unsuccessful and may even exacerbate the condition,[245] whereas discontinuing anticoagulation may improve the condition in some cases.[246] Glucocorticoid therapy has also been tried without success. Surgical therapy is generally limited to the amputation of an ischemic or gangrenous extremity. Overall, the prognosis for those suffering cholesterol embolization syndrome is quite poor, with a mortality rate of 38 to 80 percent.[247] [248]

ACUTE AORTIC OCCLUSION

Acute aortic occlusion is an infrequent, but potentially catastrophic, condition with an early mortality of 31 to 52 percent. [249] [250] [251] It is caused by either embolic occlusion of the infrarenal aorta at the bifurcation, known as a "saddle embolus," or acute thrombosis of the abdominal aorta. At least 95 percent of aortic emboli originate from the left side of the heart,[250] typically as a thrombus from the left atrium secondary to atrial fibrillation, particularly in the setting of rheumatic mitral stenosis, or from the left ventricle secondary to myocardial infarction, aneurysm, or dilated cardiomyopathy. Less common cardiac sources of emboli include atrial myxoma, prosthetic valve thrombus, and acute bacterial or fungal endocarditis.[252] Primary thrombosis accounts for the remaining 35 to 92 percent of acute aortic occlusions.[249] [250] Seventy-five to 80 percent of thrombotic aortic occlusions occur in the setting of underlying severe aortoiliac occlusive disease and are frequently precipitated by a low-flow state secondary to heart failure or dehydration. In those without aortoiliac occlusive disease, a hypercoagulable state may precipitate thrombosis of an abdominal aortic aneurysm and lead to aortic occlusion.[249] [250]

Acute aortic occlusion is in most cases heralded by the sudden onset of excruciating bilateral lower extremity pain--usually radiating from the midportion of the thigh distally--associated with weakness, numbness, and paresthesias. Nonclassic manifestations include sudden onset of bilateral lower extremity weakness, severe hypertension from renal artery involvement, and abdominal pain from mesenteric ischemia. Persistent ischemia may lead to myonecrosis with secondary hypotension, hyperkalemia, myoglobinuria, and acute tubular necrosis. If perfusion is not reestablished within hours, death is almost inevitable.

DIAGNOSIS.

Physical examination reveals cold pale extremities that are cyanotic and often exhibit a mottled, reticulated, and reddish blue appearance that may progress to the blue-black color of gangrene. Pulses are notably absent below the abdominal aorta, and capillary refill is absent. Signs of ischemic neuropathy are present and include symmetrical weakness, loss of all modalities of sensation (usually with demarcation at the level of the midthigh), and diminished or absent deep tendon reflexes. When neurological symptoms predominate, patients are often mistakenly thought to have spinal cord infarction or compression and their ischemic symptoms may initially be overlooked. In fact, as many as 11 to 17 percent of such patients may first undergo neurological or neurosurgical evaluation before the vascular etiology is recognized.[249] [250]

The diagnosis of acute aortic occlusion is confirmed by aortography. While some suggest that all stable patients should undergo the procedure,[249] others advise prompt surgical intervention without angiography if the diagnosis is strongly suspected since added delays increase the likelihood of irreversible ischemic damage to the limbs.[250] [251] Aortography is desirable in the presence of concomitant abdominal pain, hypertension, or anuria to evaluate the possibility of renal and mesenteric arterial involvement.[250]

MANAGEMENT.

Once a clinical diagnosis of acute aortic occlusion is made, intravenous heparin therapy should be initiated while awaiting immediate surgery. A saddle embolus can be

removed by using Fogarty balloon-tipped catheters inserted through a transfemoral arterial approach under local anesthesia. If the embolus cannot be retrieved with Fogarty catheters, removal by direct transabdominal aortotomy is undertaken. Patients with thrombotic occlusion generally undergo either direct aortic reconstruction or revascularization with aortofemoral or axillofemoral bypass. Operative mortality for acute aortic occlusion is 31 to 40 percent[250] [251] and as high as 85 percent among those with severe left ventricular dysfunction or a hypercoagulable state.[249] Limb salvage rates are as high as 98 percent.[250] [251] Lifelong anticoagulant therapy is necessary following surgery in almost all cases to prevent recurrent emboli.[253]

AORTOARTERITIS SYNDROMES

See also Chapter 47 .

BACTERIAL INFECTIONS OF THE AORTA.

Infected aortic aneurysms are rare, with as few as one case per year recently reported from a large medical center.[254] In an effort to avoid confusion with infections truly of fungal origin, the term "infected aneurysm" has gradually replaced the original designation "mycotic aneurysm" used by Osler to define localized dilatation in the wall of the aorta caused by sepsis. While saccular aneurysms are seen most commonly, infections can also cause fusiform and false aneurysms. In a minority of cases, infection may arise in a pre-existent aortic aneurysm, typically atherosclerotic ones. Rarely, one may encounter nonaneurysmal bacterial aortitis.[254] [255]

Pathogenesis.

Aortic infection may arise by several mechanisms. A septic embolus from bacterial endocarditis was once the most common etiology but has become rare in the era of efficacious antibiotic treatment of septicemia. Contiguous spread of infection from adjacent sites is also infrequently seen. The most common cause of an infected aneurysm is direct deposition of circulating bacteria in a diseased, atherosclerotic, or traumatized aortic intima,[254] after which organisms penetrate the aortic wall through breeches in intimal integrity to cause microbial arteritis. Recent reports suggest that the majority of aortic infections occur in patients with impaired immunity as a consequence of chronic disease, immunosuppressive therapy, or immune deficiency.[254] [256]

Microbiology.

Although virtually any organism may infect the aorta, certain bacteria seem to have a proclivity for this site. *Staphylococcus aureus* and *Salmonella* species are consistently the most frequently identified organisms.[257] [258] *Salmonella* commonly infects atherosclerotic arteries[255] but may also adhere to a normal aortic wall and directly penetrate an intact intima.[259] In fact, secondary aortic infection may develop in as many as one-quarter of patients older than 50 years who experience *Salmonella* bacteremia.[259] Other gram-positive organisms, particularly *Pneumococcus*, and gram-negative organisms may also cause infected aortic aneurysms. *Pseudomonas*, *Bacteroides fragilis*, *Campylobacter fetus*, *Neisseria gonorrhoeae*, and fungal infections are seen less often.[254] Aortic infections with unusual organisms are now seen with increasing frequency in the overtly immunocompromised population.[254]

Clinical Manifestations.

Most patients with infected aortic aneurysm are febrile, with extremely high fevers and rigors being common. Symptoms may arise from localized expansion of an infected aneurysm, which is palpable in as

many as 50 percent of patients and almost always tender.[260] A tender and pulsatile abdominal mass in a febrile patient should therefore be considered an infected aneurysm until proved otherwise.

Leukocytosis and an elevated erythrocyte sedimentation rate are present in most cases. When positive, blood cultures are helpful in suggesting the diagnosis and identifying the pathogen. In any patient with fever of unknown origin and documented *Salmonella* bacteremia, an arterial source of infection should be considered.[255] The absence of positive blood cultures, however, does not exclude the diagnosis of infected aortic aneurysm because cultures have been found to be negative in 25 percent of cases.

Although abdominal ultrasonography may identify the presence of an aortic aneurysm, CT scanning is superior in demonstrating associated pathological findings suggestive of an infectious etiology.[261] However, sometimes the aorta is normal in size when bacterial aortitis is first evaluated, so lack of aneurysmal dilatation does not exclude the diagnosis.[257] In such cases, if a patient's fever, leukocytosis, and pain persist, follow-up imaging should be performed because the aorta may rapidly dilate during the course of the infection. Aortography may also be used to make the diagnosis and is generally performed preoperatively to assist in surgical planning.

The natural history of infected aortic aneurysms is that of expansion and eventual rupture, with extremely rapid progression.[254] [257] *Salmonella* and gram-negative infections have a greater tendency to early rupture and death.[260] Overall mortality from infected aortic aneurysms is over 50 percent despite advances in therapy.[255] [262]

Management.

Infected aortic aneurysms are treated with intravenous antibiotics and surgical excision. The standard surgical approach involves resection of the infected aneurysm and infected retroperitoneal tissue, oversewing of the native aorta as stumps, and restoration of distal perfusion by placement of an extraanatomical bypass graft tunneled through unaffected tissue planes to avoid placing a graft in a contaminated region. Antibiotic therapy must be continued postoperatively for at least 6 weeks. Several reports suggest that in selected patients with localized infection and no gross pus, an effective and simpler surgical approach is in situ reconstruction of the aorta with a prosthetic graft.[256] [262]

PRIMARY TUMORS OF THE AORTA

Primary tumors of the aorta are quite rare, with only 47 cases reported in the literature from 1873 to the present. The frequency of such reports has increased significantly over the past decade, probably as a result of improvements in noninvasive imaging techniques. Most are diagnosed in the seventh to eighth decades of life. The thoracic aorta and abdominal aorta are involved with equal frequency. In several cases, aortic tumors have appeared in association with previously inserted Dacron aortic grafts.[263] Histologically, the majority of primary aortic tumors are classified as sarcomas, with the malignant fibrous histiocytoma subtype especially common.

The majority of primary aortic tumors arise in the intima[264] and grow along the intimal surface and into the aortic lumen to form polypoid masses (often with superimposed thrombus), but they tend to not invade the aortic wall. Intimal tumors may be characterized by symptoms of vascular obstruction from narrowing of the aortic lumen or, more typically, by signs and symptoms of peripheral embolization identical to those of atherothrombotic emboli. Emboli are commonly a mixture of tumor and thrombus, and the correct diagnosis may remain obscure until histological analysis of an embolectomy specimen is completed.

Figure 40-23 Transesophageal echocardiogram in a long-axis view of the descending thoracic aorta demonstrating a primary tumor of the aorta (arrows) protruding into the lumen. The tumor, which is 3.5 cm in length, involves the intimal layer but does not appear to be invading any farther into the aortic wall.

Less commonly, aortic tumors arise in the medial or adventitial layers of the aortic wall. Such tumors tend to not invade the aortic lumen but, instead, behave as aggressive mass lesions and cause constitutional symptoms or back pain.

Since primary aortic tumors are so uncommon and their features nonspecific, the diagnosis is rarely considered before surgical exploration or necropsy. However, several imaging modalities may be helpful in suggesting the diagnosis. Aortography demonstrates narrowing of the lumen or an intraluminal filling defect in the presence of an intimal tumor, but it may be negative if the tumor is adventitial.[265] Intraaortic biopsy of an intraluminal aortic mass with intravascular biopsy forceps guided by aortography has been reported.[266] [267] CT scanning can detect intimal tumors but may not easily differentiate these masses from protruding atheromas.[265] MRI may better define both the tumor anatomy and the extent of invasion.[268] Finally, the ability of TEE to image the aortic intima may make it especially useful in the

detection of intimal tumors of the thoracic aorta[269] (Fig. 40-23) .

Treatment of primary aortic tumors has met with little success. Because the majority of patients initially have metastatic disease, surgical approaches are often only palliative, i.e., to prevent further embolization. Many die secondary to the consequences of multiple emboli to vital organs. Of those undergoing surgical therapy, the large majority die within days to months postoperatively.

Acknowledgment

The author wishes to gratefully acknowledge the contributions of Drs. Kim A. Eagle, Roman W. DeSanctis, and Eve E. Slater to previous versions of this chapter in earlier editions of this text.

Chapter 41 - Peripheral Arterial Diseases

MARK A. CREAGER
PETER LIBBY

Peripheral Arterial Disease

The term *peripheral arterial disease* (PAD) generally refers to atherosclerosis when it obstructs the blood supply to the lower or upper extremities. Other nomenclature includes peripheral arterial occlusive disease and arteriosclerosis obliterans, although the latter term has fallen into disuse. The term *peripheral vascular disease* should be avoided when referring specifically to PAD since it fails to convey the nature of the problem and is more appropriately used to designate a group of diseases affecting blood vessels, including PAD, vasculitis, vasospasm, venous thrombosis, venous insufficiency, and lymphatic disorders.

Traditionally, cardiologists have devoted most of their efforts to diagnosis and treatment of arterial disease in the coronary tree. While diseases of the aorta have often been accorded a place in cardiology training and practice, focus on disease of the peripheral arteries has lagged. PAD is a strong marker of risk for major cardiovascular events since it is frequently associated with coronary and cerebral atherosclerosis. Moreover, symptoms of PAD, including intermittent claudication, jeopardize quality of life and independence for many patients. In contrast to coronary artery afflictions, PAD is commonly underdiagnosed and undertreated. Thus, practitioners of cardiology have increasing interest in the diagnosis and management of PAD. This chapter aims to provide a framework for an approach to the diagnosis and management of patients with PAD.

EPIDEMIOLOGY

The prevalence of PAD depends on the population studied, the diagnostic method used, and whether symptoms are included to derive estimates. Most epidemiologic studies have used a noninvasive measurement, the ankle/brachial index (ABI), to diagnose PAD. The ABI is the ratio of ankle to brachial systolic blood pressure and is described in greater detail on p. 1464. In relatively large population-based studies conducted in the United States, Europe, and the Middle East, the prevalence of PAD based on an abnormal ABI ranged from 4.6 to 19.1 percent (Table 41-1) .[1] [2] [3] [4] [5] [6] [7] In a free-living population participating in a lipid research clinic protocol, PAD was detected in less than 3 percent of those younger than 60 but in more than 20 percent of those 75 years and older and was 27 percent more prevalent in men than women.[1] In other studies, however, the prevalence was similar or greater in women.[2] [5] Taking these aggregate data into consideration, approximately 8 to 10 million individuals in the United States have PAD.

The prevalence of symptomatic disease in these populations can be assessed by questionnaires specifically designed to elicit symptoms of intermittent claudication. Estimates have varied depending on the age and gender of the population but generally indicate that only one-third to one-half of patients with PAD have symptoms of claudication. In the Whitehall Study of 18,388 male civil servants living in London and aged 40 to 64 years, approximately 1 percent were thought to have claudication.[8] Other estimates of claudication range from 1.6 to 4.5 percent of a population typically older than 40 years.[1] [3] [5] [6] [9] [10] [11] In the Edinburgh Artery Study of 1592 subjects aged 55 to 74 years, 116 new cases of claudication developed over a 5-year period, for an incidence of claudication of 15.5 per 1000 patient-years.[12] The prevalence and incidence of claudication increase with age (Fig. 41-1) and are greater in men than in women in most, but not all studies.[1] [2] [3] [5] [11] [13] [14] [15] In the Framingham Study of 5209 subjects aged 35 to 84 years, the 2-year incidence of claudication was 7.1 per 1000 for men and 3.6 per 1000 for women.[16]

Less information is available regarding the incidence of critical limb ischemia. In a prospective 7-year study of hospitals in northern Italy, the incidence of critical limb ischemia was 450 per million population per year, and the incidence of amputation was 112 per million per year.[17] Similarly, the Vascular Surgery Society of Great Britain estimated the incidence of critical limb ischemia in Britain and Ireland at 400 cases per million population per year. In Denmark, approximately 250 per million population per year underwent amputation because of critical limb ischemia.[18]

Contribution of Risk Factors

The well-known modifiable risk factors associated with coronary atherosclerosis also contribute to atherosclerosis of the peripheral circulation. Cigarette smoking, diabetes mellitus, dyslipidemia, hypertension, and hyperhomocysteinemia increase the risk of PAD (Table 41-2) .

SMOKING.

Data derived from several observational studies (including the Edinburgh Artery Study, the Framingham

Figure 41-1 Age-related incidence of intermittent claudication derived from large population-based studies. (From Dormandy JA, Rutherford RB: Management of peripheral arterial disease [PAD]. TASC Working Group. J Vasc Surg 31[Suppl]:1-296, 2000.)

Heart Study, and the Cardiovascular Health Study, among others) indicate a twofold to fivefold increased risk of PAD in smokers.[2] [4] [10] [11] [14] [19] [20] [31] In the Whitehall Study, approximately 84 percent of patients with claudication were current smokers or ex-smokers,[8] and in another large recent study, 90 percent of patients with PAD were current or former smokers.[32] Progression of disease to critical limb ischemia and limb loss is more likely to occur in patients who continue to smoke than in those who stop.[33] Smoking may even increase the risk of development of PAD more than it does coronary artery disease.[19] [34]

DIABETES MELLITUS.

In patients with diabetes mellitus, PAD is often extensive and severe, and these patients have a greater propensity for vascular calcification. Involvement of the femoral and popliteal arteries is similar to that of nondiabetic persons, but distal disease affecting the tibial and peroneal arteries occurs more frequently. The risk of development of PAD increases threefold to fourfold in patients with diabetes mellitus.[4] [14] [16] [19] [21] In the Framingham cohort, glucose intolerance contributed more as a risk factor for claudication than it did for coronary artery disease or stroke.[34]

LIPID DISORDERS.

Abnormalities in lipid metabolism are also associated with an increased prevalence of PAD. Elevations in total or low-density lipoprotein (LDL) cholesterol increased the risk of PAD and claudication in some studies but not in others.[2] [10] [13] [14] [35] In a large Israeli study involving 10,059 men aged 40 to 65 years, the odds ratio for development of claudication was 1.35 for each increase in serum cholesterol of 50 mg/dl.[10] Similar observations were made in the Framingham Heart Study, in which the odds ratio for claudication was 1.2 for each 40-mg/dl increase in total cholesterol.[14] In a cohort of patients participating in a lipid research clinic protocol, however, LDL cholesterol was not associated with PAD based on a multiple logistic regression analysis that included cigarette smoking, blood pressure, glucose, and obesity. Hypertriglyceridemia independently predicts risk for PAD.[36] [37] Increased levels of lipoprotein (a) impart a twofold increased risk of PAD, with

TABLE 41-2 -- RISK OF PERIPHERAL ARTERIAL DISEASE IN PERSONS WITH MODIFIABLE RISK FACTORS

RISK FACTOR	ESTIMATED RELATIVE RISK
Cigarette smoking[2] [4] [10] [19] [20]	2.0-5.0
Diabetes mellitus[4] [14] [16] [19] [21]	3.0-4.0
Hypertension[14] [16] [19]	1.1-2.2
Hypercholesterolemia (per 40- to 50-mg/dl increase in total cholesterol)[10] [14]	1.2-1.4
Fibrinogen (per 0.7-gm/liter increase in fibrinogen)[22] [23] [24] [25] [26]	1.35
C-reactive protein[27]	2.1
Hyperhomocysteinemia[28] [29] [30]	2.0-3.2

higher levels associated with a greater risk for critical limb ischemia.[38]

HYPERTENSION.

Hypertension increased the risk of claudication 2.5-fold in men and 4-fold in women in the Framingham Heart Study,[16] and the risk increased proportionally with the severity of hypertension.[14] [16] Similarly, in the Edinburgh Artery Study, elevations in systolic blood pressure correlated with PAD. However, this finding has not been consistently shown in all epidemiological studies. In the British Whitehall Study and a large Finnish study, hypertension was not found to be associated with claudication.[8] [13]

HYPERHOMOCYSTEINEMIA.

Hyperhomocysteinemia increases the risk of atherosclerosis by approximately twofold to threefold.[28] [29] [30] In a meta-analysis of studies relating homocysteine to atherosclerotic disease, the odds ratio for PAD in patients with increased homocysteine levels was 6.8.[30] High levels of homocysteine have been detected in 30 to 40 percent of patients with PAD.[39] [40] Prospective studies have not consistently confirmed a relationship of hyperhomocysteinemia with cardiovascular events, however (see Chap. 31) . Plasma levels of B complex vitamins, including folate, cobalamin, and pyridoxal 5
-phosphate, all inversely relate to the plasma homocysteine concentration, and patients taking B vitamin supplements have a lower risk of vascular disease.[29]

FIBRINOGEN.

An increase in fibrinogen is also associated with an increased risk of PAD.[11] [22] [23] [24] [41] The Edinburgh Artery Study noted a 35 percent increased risk for PAD over 5 years for each 0.70-gm/liter increase in fibrinogen.[25] [26] Patients with PAD have elevated levels of C-reactive protein, a serological marker of systemic inflammation. In the Physicians' Health Study, the relative risk of development of PAD among men in the highest quartile for C-reactive protein concentration was 2.1[27] (see also Chap. 31) .

The risk of PAD and intermittent claudication developing increases progressively with the burden of contributing factors. In the Framingham Heart Study, the occurrence of claudication in men whose risk factor was smoking versus nonsmoking was 2.6 versus 0.8 per 8 years per 1000 population.[16] In male smokers who were also hypertensive, hypercholesterolemic, and diabetic, the risk was 44.3 per 8 years per 1000 (Fig. 41-2) .[16] Similar observations have been made in women.

PATHOBIOLOGY

Heterogeneity of Blood Vessels in Different Circulatory Beds

Atherosclerosis preferentially affects certain locations in the circulation. As discussed in Chapter 30 , atheromatous lesions tend to form at flow dividers and branch points in arteries and usually spare veins. In the last several years, progress has been made in understanding the link between hydrodynamics of the circulation, the cellular and molecular

Figure 41-2 The incidence of intermittent claudication in the Framingham Heart Study in smokers and nonsmokers is compounded by an increased burden of risk factors. (From Murabito JM, D'Agostino RB, Silbershatz H, et al: Intermittent claudication. A risk profile from The Framingham Heart Study. Circulation 96:44-49, 1997. By permission of the American Heart Association, Inc.)

mechanisms of atherosclerosis, and the atheroprotective functions of vascular wall cells. Chapter 30 discusses the focality of atherosclerosis in terms of local hemodynamic differences. However, questions remain: Are blood vessels intrinsically different in different regions of the circulation? Do regional variations in the propensity for atherosclerosis merely depend on the external hemodynamic forces that impinge on them? Indeed, vessels in different beds have distinct morphology, physiology, and pharmacology and therefore intrinsic heterogeneity. Recent work has elucidated the biological basis of differences among blood vessels. This section will consider, in turn, new information regarding the development of blood vessels related to arterial heterogeneity, differences in functions of blood vessels depending on the circulatory bed, and finally, whether the mechanisms leading to clinical manifestations of arterial disease vary from one circulatory bed (e.g., the coronary circulation) to another and in different arteries (e.g., the carotid or the distal aorta).

DEVELOPMENTAL BIOLOGY OF HETEROGENEITY AMONG BLOOD VESSELS

Endothelial cells have a common origin but acquire bed-specific characteristics during development. The endothelial cells that form the inner lining of all blood vessels arise during embryogenesis from regions known as the blood islands located on the embryo's periphery. Angioblasts, which are predecessors of endothelial cells, share this site with the precursors of blood cells. Despite arising from the same site, cells display considerable heterogeneity even during embryological and early postnatal development. Although presumably derived from a common precursor, the signals that endothelial cells encounter during vessel development differ. As rudimentary blood vessels begin to form, endothelial precursors interact with the surrounding cells. This interchange permits spatial and temporal gradients of various stimuli and their receptors on endothelial cells, which leads to heterogeneity of this cell type in the adult.

Differential expression of endothelial genes in various types of blood vessels depend on transcriptional regulation by the local environment. For example, the promoter region of the gene that encodes von Willebrand factor directs expression of brain and heart microvessels in the endothelium but not in larger arteries.[42] Indeed, coculture of endothelial cells with cardiac myocytes, but not other cell types, could selectively activate a von Willebrand factor gene promoter construct. Likewise, endothelial nitric oxide synthase gene activity in the heart shows bed-specific regulation.[43] A recently recognized family of tyrosine kinase receptors known as EPH and their ligands known as epherins display heterogeneous expression in arterial versus venous endothelial cells during development.[44] These examples illustrate how the common precursor of endothelial cells shows molecular diversity early in life that depends on its location in the circulation.

SMOOTH MUSCLE CELLS DERIVE FROM MULTIPLE, LOCAL SOURCES DURING DEVELOPMENT

In contrast to endothelial cells, which derive from a common precursor, smooth muscle cells can arise from many sources. After endothelial cells form tubular anlage, or rudimentary, precursor of blood vessels, they recruit the cells that will become smooth muscle, or pericytes (smooth muscle-like cells associated with microvessels). In the descending aorta and arteries of the lower half of the body, regional mesoderm serves as the source of smooth muscle precursors. Mesodermal cells in somites give rise to the smooth muscle cells that invest much of the distal aorta and its branches. In arteries of the upper part of the body, however, smooth muscle cells actually derive from a completely different germ layer, neuroectoderm rather than mesoderm. Before the neural tube closes, neuroectodermal cells migrate and become the precursors of smooth muscle cells in the ascending aorta and some of its branches, including the carotid arteries.[45] Smooth muscle cells in the coronary arteries are derived from mesoderm, but in a special way. The precursors of coronary artery smooth muscle cells arise from a structure known as the proepicardial organ.[46] [47]

As in the case of endothelial cells, smooth muscle cells show molecular heterogeneity early during development. For example, the promoter of a characteristic smooth muscle gene known as SM22 drives gene expression in venous but not arterial smooth muscle cells during embryogenesis.[48] Much of the localization of structures in embryos depends on a family of genes known as homeobox genes. Deletion of a pair of homeobox genes known as *Prx1/Prx2* that are involved in mesenchymal pattern development causes selective impairment in development of the great vessels and the ductus arteriosus while sparing morphogenesis of other vessels.[49] Transcription factors also play an important role in determining the phenotype of cells. A specific transcription factor known as dHAND signals the recruitment of mesenchyme by endothelial cells in an anatomically heterogeneous manner during development. In particular, dHAND regulation selectively participates in the recruitment of mesenchyme in upper body blood vessels versus those of the more caudal portions of the embryo.[50]

CLINICAL IMPLICATIONS OF VASCULAR DEVELOPMENTAL BIOLOGY.

Far from being of mere theoretical concern, the developmental biology of the arterial tree has important clinical implications regarding issues that arise in daily practice. The distinct embryonic origins of smooth muscle cells in various arteries may help explain why some regions of the arterial tree are particularly prone to atheroma formation. While local hydrodynamics doubtless controls the expression of genes that protect against or promote atherogenesis (see Chap. 30) , the cellular substrate acted on by biomechanical forces varies as described above.

Intimal cushions, which consist of expanded regions populated by smooth muscle cells and extracellular matrix (Fig. 41-3) , develop in very interesting regions of the arterial tree early in life. Two regions of intimal cushion formation of particular consequence for cardiologists are the proximal left anterior descending coronary artery and the carotid siphon.[51] [52] The intimal cushion in the proximal left anterior descending coronary artery begins to form even during intrauterine life. It progresses rapidly in early postnatal life and leads to intimal cushions in the proximal left anterior coronary artery in all humans by 2 years of age.[51] It remains unclear to what extent lineage differences versus local hemodynamic forces contribute to the formation of these intimal cushions in arteries prone to the development of atherosclerosis. These cushions of smooth muscle and connective tissue form the "soil" in which atheromatous lesions can grow in later life.[53]

HETEROGENEITY IN VASCULAR FUNCTIONS.

The functions of blood vessels differ in various regions of the circulation as evidenced by the preferential effects of many vasoactive drugs commonly used in the practice of cardiology on selected vascular beds. Nitrates dilate both arteries and veins, whereas other vasodilators, such as hydralazine, act primarily as arterial vasodilators. The well-recognized differences in clinical outcomes of saphenous vein and internal mammary artery bypass grafts furnish another example

Figure 41-3 An intimal cushion shown in a cross section through the internal carotid artery of a 10-week-old male infant. Areas where intimal cushions form in early life are prone to the development of atheroma more commonly in later years. The bar shows 0.5 mm. (From Weninger WJ, Muller GB, Reiter C, et al: Intimal hyperplasia of the infant parasellar carotid artery: A potential developmental factor in atherosclerosis and SIDS. Circ Res 85:970-975, 1999. By permission of the American Heart Association, Inc.)

of clinically relevant heterogeneity among vessels. Internal mammary arteries release more nitric oxide than do saphenous veins. In addition, saphenous veins produce more vasoconstrictor endothelial-derived cyclooxygenase products than do internal mammary arteries. Such differences may help explain the superior clinical outcomes with internal mammary grafts versus autologous venous bypass grafts.[54]

Indeed, the reactions of blood vessels or vascular cells from various regions of the circulation sometimes differ directionally. The pulmonary vasoconstrictive versus systemic vasodilator response to hypoxia and the disparate response of the cerebral versus the systemic arterial circulation to carbon dioxide are commonly encountered examples. Neuroectoderm-derived smooth muscle cells in upper body blood vessels grow in response to transforming growth factor-beta; however, mesenchymal-derived smooth muscle cells from lower body arteries actually show growth inhibition when exposed to this mediator.[55] Perhaps, the different embryonic origins of smooth muscle cells in the ascending versus the descending aorta explain why certain gene defects express themselves primarily in the ascending aorta. In Marfan syndrome, for example, the fibrillin mutation characteristically involves the ascending aorta first (see also Chap. 56) . Likewise, in Williams syndrome, elastin is genetically defective throughout the body, yet the vascular phenotype of these patients is localized to the supervalvular portion of the ascending aorta.[45]

Heterogeneity of the Clinical Manifestations of Arterial Disease

The Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study collected arterial specimens from Americans younger than 35 years who died of non-cardiac causes. This study found that fatty streaks and raised arterial lesions initially localize in the dorsal portion of the abdominal aorta. Involvement of the thoracic aorta with fatty streaks or early atheroma follows lesion formation in the abdominal aorta. The PDAY data suggest that the formation of coronary atheroma actually lags behind the development of fatty lesions in the aorta.[56] [57]

The most dreaded clinical consequence of atherosclerosis is thrombosis, the cause of most myocardial infarctions and many strokes. Physical disruption of the atherosclerotic plaque causes most fatal coronary events. The role of plaque disruption as a cause of thrombosis in other arterial beds has received less attention. The discussion above has highlighted the developmental and anatomical reasons why coronary arteries may differ from peripheral arteries. In addition, the hemodynamic stresses impinging on lesions in the coronary versus the peripheral arterial tree differ as well. Notably, most coronary artery flow occurs during diastole, whereas peak pressure and flow in peripheral arteries occur during systole. Thus, the underlying mechanism of the thrombotic complications of atheroma might well differ in coronary versus peripheral arteries.

In the aorta, mural thrombi seldom develop into occlusive clots because of the high flow. Nonetheless, aortic plaque frequently ruptures, and aortic thrombi are recognized as a clinically important source of embolic disease (Fig. 41-4). (Figure Not Available) Plaque in the aorta encounters high "hoop" (circumferential) stress as a result of the large radius, according to the Laplace relationship. This difference may account for the prevalence of disrupted plaque in an atherosclerotic aorta. Recent evidence suggests that plaque rupture also underlies symptoms of carotid arterial disease. In one study, histopathological evaluation of carotid artery specimens

removed by endarterectomy revealed plaque rupture in 74 percent of symptomatic versus only 32 percent of asymptomatic patients.[58] The degree of stenosis was similar in both symptomatic and asymptomatic individuals in this study. Ulcerated plaque with superimposed thrombus was found in six of seven occluded internal carotid arteries in a neuropathological autopsy series.[59] Features

Figure 41-4 (Figure Not Available) Atherosclerotic aorta of a patient with atheroemboli. Multiple protruding, shaggy atheromas with superimposed mural thrombi are present. (Courtesy of R.M. Mitchell, M.D., Ph.D., Department of Pathology, Brigham and Women's Hospital, Boston.)

associated with vulnerability of coronary plaque, including foam cells and thinning of the fibrous cap, are more frequent in symptomatic than in asymptomatic carotid plaque.[58] As in unstable coronary plaque, inflammatory cells infiltrate and are activated (determined by expression of the histocompatibility antigen HLA-DR). The proportion of active inflammatory cells is consistently higher in ruptured plaque than in asymptomatic carotid plaque with a similar degree of stenosis.[60]

An independent line of clinical evidence supports a commonality in the mechanisms of complication shared by carotid and coronary arteries. A recent large study dichotomized patients with symptomatic carotid artery lesions into those with and those without irregularity of the carotid lesion by angiography. Over 10 years of follow-up, those with irregular carotid lesions had a greater than twofold higher cumulative incidence of non-stroke-related vascular death (mostly caused by coronary events) than did those with smooth lesions.[61] Nonvascular deaths and the risk factors assessed in this study did not differ between groups. Similar mechanisms are likely to account for acute thromboses in peripheral arteries, although detailed investigations are not available. Despite the considerable biological and functional heterogeneity among arterial beds, the mechanisms causing the most important clinical manifestations appear to be similar.

PATHOPHYSIOLOGY OF LIMB ISCHEMIA

Pathophysiological considerations in patients with PAD must take into account the balance of the circulatory supply of nutrients to the skeletal muscle and the oxygen and nutrient demand of skeletal muscle (Table 41-3) .

FACTORS REGULATING BLOOD SUPPLY(see alsoChap. 34)

The primary determinant of inadequate blood supply to the extremity is a flow-limiting lesion of a conduit artery. Flow through an artery is directly proportional to perfusion pressure and inversely proportional to vascular resistance. If atherosclerosis causes a stenosis, flow through the artery is reduced as described in the Poiseuille equation, in which Q=Delta$P$pir^4 8eta$l$, where Delta$P$ is the pressure gradient across the stenosis, r is the radius of the residual lumen, eta is blood viscosity, and l is the length of the vessel affected by the stenosis. As the severity of a stenotic lesion increases, flow becomes progressively reduced. The pressure gradient across the stenosis increases in a nonlinear manner, thus emphasizing the importance of a stenosis at high blood flow rates. Usually, a blood pressure gradient exists at rest if the stenosis reduces luminal diameter by more than 50 percent because kinetic energy is lost as turbulence develops.[62] A stenosis that does not cause a pressure gradient at rest may cause a gradient during exercise, when blood flow rises consequent to higher cardiac output and decreased vascular resistance. Thus, as flow through a stenosis increases, distal perfusion pressure is not maintained. Also, as the metabolic demand of exercising muscle outstrips its blood supply, local metabolites, including adenosine, nitric oxide, potassium, and hydrogen ion, accumulate and peripheral resistance vessels dilate.

TABLE 41-3 -- PATHOPHYSIOLOGICAL CONSIDERATIONS IN PERIPHERAL ARTERIAL DISEASE

Factors regulating blood supply to limb
Flow-limiting lesion (stenosis severity, inadequate collaterals)
Impaired vasodilation (decreased nitric oxide and reduced responsiveness to vasodilators)
Accentuated vasoconstriction (thromboxane, serotonin, angiotensin II, endothelin, norepinephrine)
Abnormal rheology (reduced red blood cell deformability, increased leukocyte adhesiveness, platelet aggregation, microthrombosis, increased fibrinogen)
Altered skeletal muscle structure and function
Axonal denervation of skeletal muscle
Loss of type II, glycolytic fast twitch fibers
Increased mitochondrial enzymatic activity

This response results in a further drop in perfusion pressure since the stenosis limits flow. In addition, intramuscular pressure rises during exercise and may exceed the arterial pressure distal to an occlusion and cause blood flow to cease.[62] Flow through collateral blood vessels is usually adequate to meet the resting metabolic needs of skeletal muscle tissue, but it is not enough during exercise.

Functional abnormalities in vasomotor reactivity may also interfere with blood flow. The vasodilator capability of both conduit and resistance vessels is impaired in patients with peripheral atherosclerosis. Normally, arteries dilate in response to pharmacological and biochemical stimuli, such as acetylcholine, serotonin, thrombin, or bradykinin, as well as in response to shear stress induced by increases in blood flow. This vasodilator response results from the release of biologically active substances from the endothelium, particularly nitric oxide (see also Chap. 34) . The vascular relaxation of a conduit vessel that occurs after a flow stimulus, such as that induced by exercise, may facilitate the delivery of blood to exercising muscles in healthy persons. Vasodilation subsequent to flow or pharmacological stimuli does not occur in the atherosclerotic femoral arteries and calf resistance vessels of patients with PAD.[63] This failure of vasodilation might prevent an increase in nutritive blood supply to exercising muscle since endothelium-derived nitric oxide has been shown to contribute to hyperemic blood volume following an ischemic stimulus.[63] [64] Preliminary studies have suggested that L-arginine, the precursor for endothelium-derived nitric oxide, increases muscle blood flow and improves claudication distance in patients with PAD, further supporting the contention that endothelium-dependent vasodilation is abnormal in these individuals.[65] [66] It is not known whether vasodilator function with respect to prostacyclin, adenosine, or ion channels is abnormal in peripheral atherosclerotic arteries. Endogenous vasoconstrictor substances such as prostanoids and other lipid mediators, thrombin, serotonin, angiotensin II, endothelin, and norepinephrine may interfere with vasodilation.

SKELETAL MUSCLE STRUCTURE AND METABOLIC FUNCTION

Electrophysiological and histopathological examination has found evidence of partial axonal denervation of skeletal muscle in legs affected by PAD.[67] Type I, oxidative slow-twitch fibers are preserved, but type II, or glycolytic, fast twitch fibers are lost in the skeletal muscle of patients with PAD.[68] Loss of type II fibers is associated with decreased muscle strength and reduced exercise capacity.[68] Within skeletal muscle, metabolism shifts to anaerobic earlier during exercise and it persists longer after cessation of exercise. Patients with claudication have increased lactate release and accumulation of acylcarnitines during exercise, indicative of ineffective oxidative metabolism.[69] [70] Yet, mitochondrial enzymatic activity is increased in the skeletal muscle of patients with claudication, possibly reflecting a metabolic adaptation to the reduced blood supply.[71] [72]

Pathophysiology of Critical Limb Ischemia

Abnormalities in the microcirculation contribute to the pathophysiology of critical limb ischemia. The number of perfused skin capillaries is reduced in patients with severe limb ischemia.[73] Other potential causes of decreased capillary perfusion in this condition include reduced red cell deformability, increased leukocyte adhesivity, platelet aggregates, fibrinogen, microthrombosis, excessive vasoconstriction, and interstitial edema (Fig. 41-5) .[74] [75] [76] Intravascular pressure may also be decreased because precapillary arterioles are dilated as a result of locally released vasoactive metabolites.[77]

CLINICAL FEATURES

Symptoms

INTERMITTENT CLAUDICATION.

The two cardinal symptoms of PAD are intermittent claudication and pain at rest. The term *claudication* is derived from the Latin word *claudicare,* to limp. Intermittent claudication is characterized by pain, ache, a sense of fatigue, or other discomfort that occurs in the affected leg during exercise, particularly walking, and resolves with rest. Claudication occurs when skeletal muscle oxygen demand during effort exceeds the blood supply and results from activation of local sensory receptors

Figure 41-5 Schematic representation of potential pathophysiological mechanisms that lead to microvascular obstruction in patients with critical limb ischemia. (From Second European Consensus Document on chronic critical leg ischemia. Circulation 84[Suppl 4]:1-26, 1991. By permission of the American Heart Association, Inc.)

by the accumulation of lactate or other metabolites. The location of the symptom often relates to the site of the most proximal stenosis. Buttock, hip, or thigh claudication is typical of patients with obstruction of the aorta and iliac arteries. Calf claudication occurs in patients with femoral and popliteal artery stenoses. The gastrocnemius muscle consumes more oxygen during ambulation than do other muscle groups in the leg and hence causes the most frequent symptom reported by patients. Ankle or pedal claudication occurs in patients with tibial and peroneal artery disease. Similarly, stenoses of the subclavian, axillary, and brachial arteries may cause shoulder, biceps, or forearm claudication, respectively. Symptoms should resolve several minutes following cessation of effort. Calf and thigh pain that occurs at rest, such as nocturnal cramps, should not be confused with claudication and is not a symptom of PAD. The history obtained from claudicants should note the distance walked, speed, and incline that precipitates claudication to evaluate disability and to provide a baseline qualitative measure with which to determine stability, improvement, or deterioration during subsequent encounters with the patient. Symptoms other than claudication can limit functional capacity.[78] Patients with PAD walk more slowly and have less walking endurance than do patients without PAD.[79] [80]

Several questionnaires have been developed to assess the presence and severity of claudication. The Rose Questionnaire was initially developed to diagnose both angina and intermittent claudication in epidemiological surveys.[81] It queries whether pain develops in either calf with walking and whether it occurs at rest, while walking at an ordinary or hurried pace, or when walking uphill. Several modifications of this questionnaire have been made, including the Edinburgh Claudication Questionnaire and the San Diego Claudication Questionnaire,[82] [83] which are both more sensitive and specific in comparison to a physician's diagnosis of intermittent claudication based on walking distance, walking speed, and nature of the symptoms. A more recently validated instrument, the Walking Impairment Questionnaire, asks a series of questions and assigns a point score based on walking distance, walking speed, and nature of the symptoms.[84]

Limb claudication may occasionally result from nonatherosclerotic causes of arterial occlusive disease (Table 41-4) . Several of these causes are discussed later in the chapter and include arterial embolism; vasculitides such as thromboangiitis obliterans (TAO), Takayasu arteritis, or giant cell arteritis; aortic coarctation; fibromuscular dysplasia; irradiation; and extravascular compression secondary to arterial entrapment or an adventitial cyst (see also Chap. 67) .

Several nonvascular causes of exertional leg pain should be considered in patients with symptoms suggestive of intermittent claudication (Table 41-4) . Lumbosacral radiculopathy resulting from degenerative joint disease, spinal stenosis, and herniated discs may cause pain in the buttock, hip, thigh, calf, and/or foot with walking, often after very short distances or even with standing.[85] [86] The term *neurogenic pseudoclaudication* has been used to describe this symptom. Lumbosacral spine disease and PAD each affect the elderly, and as such, both may be present in the same individual. Arthritis of the hips and knees also provokes leg pain with walking. Typically, the pain is localized to the affected joint and may be elicited on physical examination by palpation and range-of-motion maneuvers. Rarely, skeletal muscle disorders such as myositis can cause exertional leg pain. Muscle tenderness, abnormal neuromuscular examination findings, elevated skeletal muscle enzymes, and a normal pulse examination should distinguish myositis from PAD. McArdle syndrome, characterized by a deficiency of skeletal muscle phosphorylase, can cause symptoms mimicking the claudication of PAD. Patients with chronic venous regurgitation may complain of leg discomfort with exertion, a condition designated venous claudication.[87] [88] [89] Venous hypertension during exercise increases resistance and limits blood flow. In the case of venous insufficiency, the elevated extravascular pressure caused by interstitial edema further diminishes capillary perfusion. A physical examination demonstrating peripheral edema, venous stasis pigmentation, and occasionally, venous varicosities will identify this unusual cause of exertional leg pain.

REST PAIN.

Pain at rest occurs in patients with critical limb ischemia in whom the resting metabolic needs of the tissue are not adequately met by the available blood supply. Typically, patients complain of pain or paresthesias in the foot or toes of the affected extremity. This discomfort is worsened by leg elevation and improved by leg dependency, as might be anticipated by the respective effects of gravity on perfusion pressure. The pain may be particularly severe at sites of skin fissuring, ulceration, or necrosis. Of

ten, the skin is very sensitive, and even the weight of bedclothes or sheets elicits pain. Patients may sit on the edge of the bed and dangle their legs to alleviate the discomfort. However, patients with ischemic or diabetic neuropathy may have little or no pain despite the presence of severe ischemia.

Critical limb and digital ischemia may result from arterial occlusions other than those caused by atherosclerosis. Such conditions include vasculitides such as TAO, connective tissue disorders such as systemic lupus erythematosus and scleroderma, vasospasm, atheromatous embolism, and acute arterial occlusion caused by thrombosis or embolism. Many of these disorders are discussed later in this chapter. Acute gouty arthritis, trauma, and sensory neuropathy such as that caused by diabetes mellitus, lumbosacral radiculopathy, and reflex sympathetic dystrophy can cause foot pain. Leg ulcers also occur in patients with venous insufficiency and sensory neuropathy, particularly that related to diabetes. These ulcers are easily distinguished from arterial ulcers, which are described below. A venous ulcer is usually located near the medial malleolus, its border is irregular, and its base is pink with granulation tissue. The pain accompanying venous ulcers is milder than that of arterial ulcers. Neurotrophic ulcers occur with pressure or trauma, usually on the sole of the foot. These ulcers are deep, frequently infected, and not usually painful because of the loss of sensation (Fig. 41-6 , right panel).

Physical Findings

A careful vascular examination includes palpation of pulses and auscultation of accessible arteries for bruits. Pulses that are readily palpable in healthy individuals include the brachial, radial, and ulnar arteries of the upper extremity and the femoral, popliteal, dorsalis pedis, and posterior tibial arteries of the lower extremities. The aorta also can be palpated in asthenic persons. A decreased or absent pulse provides insight into the location of arterial stenoses. For example, a normal right femoral pulse but absent left femoral pulse suggests the presence of left iliofemoral arterial stenosis. A normal femoral artery pulse but absent popliteal artery pulse would indicate a stenosis in the superficial femoral artery or proximal popliteal artery. Similarly, disease of the anterior and posterior tibial arteries may be inferred when the popliteal artery pulse is present but the dorsalis pedis and posterior tibial pulses, respectively, are not palpable. Bruits are often indicative of accelerated blood flow velocity and turbulence at sites of stenosis. A stethoscope should be used to auscultate the supraclavicular and infraclavicular fossae for evidence of subclavian artery stenosis; the abdomen, flank, and pelvis for evidence of stenoses in the aorta and its branch vessels; and each groin for evidence of femoral artery stenoses. Pallor may be elicited on the soles of the feet of some patients with PAD by performing a maneuver in which the feet are elevated above the level of the heart and the calf muscles are exercised by repeated dorsiflexion and plantar flexion of the ankle. The legs are then placed in the dependent position and the time to the onset of hyperemia and venous distention is measured. Each of these parameters is dependent on the rate of blood flow, which is influenced by the severity of the stenosis and the adequacy of collateral vessels.

Muscle atrophy may be apparent in the legs of patients with chronic aortoiliac disease. Additional signs of chronic low-grade ischemia include hair loss, thickened and brittle toenails, smooth and shiny skin, and subcutaneous fat atrophy of the digital pads. The skin is cool in patients with severe limb ischemia, and they may have petechiae, persistent cyanosis or pallor, dependent rubor, pedal edema resulting from prolonged dependency, skin fissures, ulceration, or gangrene. Arterial ulcers typically have a pale base with irregular borders and usually involve the tips of the toes or the heel of the foot or develop at sites of pressure (Fig. 41-6, left panel). These ulcers vary in size and may be as small as 3 to 5 mm.

Categorization of PAD

Patients with PAD may be classified according to the severity of the symptoms and abnormalities detected on physical examination. Categorization of the clinical manifestations of PAD improves communication among professionals caring for these patients and provides a structure for defining guidelines for therapeutic intervention. The traditional scheme described by Fontaine classified patients in one of four stages progressing from asymptomatic to critical limb ischemia (Table 41-5) . A contemporary, more descriptive classification has been adopted by several professional vascular societies and includes asymptomatic patients, three

TABLE 41-5 -- FONTAINE CLASSIFICATION OF PERIPHERAL ARTERIAL DISEASE

STAGE	SYMPTOMS
I	Asymptomatic
II	Intermittent claudication
IIa	Pain free, claudication walking >200 meters
IIb	Pain free, claudication walking <200 meters
III	Rest and nocturnal pain
IV	Necrosis, gangrene

TABLE 41-6 -- CLINICAL CATEGORIES OF CHRONIC LIMB ISCHEMIA

GRADE	CATEGORY	CLINICAL DESCRIPTION
	0	Asymptomatic, not hemodynamically correct
I	1	Mild claudication
	2	Moderate claudication
	3	Severe claudication
II	4	Ischemic rest pain
	5	Minor tissue loss: nonhealing ulcer, focal gangrene with diffuse pedal ulcer
III	6	Major tissue loss extending above the transmetatarsal level, functional foot no longer salvageable

Adapted from Rutherford RB, Baker JD, Ernst C, et al: Recommended standards for reports dealing with lower extremity ischemia: Revised version. J Vasc Surg 26:517-538, 1997.

grades of claudication, and three grades of critical limb ischemia ranging from rest pain alone to minor and major tissue loss (Table 41-6) . [90]

DIAGNOSTIC TESTS

Segmental Pressure Measurement

One of the most useful and simplest noninvasive tests to evaluate the presence and severity of stenoses in the peripheral arteries is the measurement of systolic blood pressure along selected segments of each extremity. In the lower extremities, pneumatic cuffs are placed on the upper and lower portions of the thigh, on the calf, above the ankle, and often over the metatarsal area of the foot. Likewise, in the upper extremity, pneumatic cuffs are placed on the upper part of the arm over the biceps, on the forearm below the elbow, and at the wrist. Systolic blood pressure at each respective limb segment can be measured by first inflating the pneumatic cuff to suprasystolic pressure and then determining the pressure at which blood flow occurs during cuff deflation. The onset of flow can be assessed by placing a Doppler ultrasound flow probe over an artery distal to the cuff. In the lower extremities, it is most convenient to place the Doppler probe on the foot over the posterior tibial artery as it courses inferior and posterior to the medial malleolus or over the dorsalis pedis artery on the dorsum of the metatarsal arch. In the upper extremities, the Doppler probe can be placed over the brachial artery in the antecubital fossa or over the radial and ulnar arteries at the wrist.

Left ventricular contraction creates the kinetic energy for blood pressure, which is maintained throughout the large and medium-sized vessels. Systolic blood pressure in the more distal vessels may be higher than that in the aorta and proximal vessels because of reflection of blood pressure waves.[91] Stenosis can cause loss of pressure energy as a result of increased frictional forces and turbulence at the site of the stenosis. Approximately 90 percent of the cross-sectional area of the aorta must be narrowed before a pressure gradient develops. In smaller vessels such as the iliac and femoral arteries, a 70 to 90 percent decrease in cross-sectional area will cause a resting pressure gradient sufficient to decrease systolic blood pressure distal to the stenosis. Taking into consideration the precision of this noninvasive method and the variability in blood pressure over even short periods, a blood pressure gradient in excess of 20 mm Hg between successive cuffs is generally used as evidence of arterial stenosis in the lower extremity, whereas a 10-mm Hg gradient between sequential cuffs in the upper extremity is indicative of stenosis (Table 41-7) . Systolic blood pressure in the toes and fingers approximates 60 percent of the systolic blood pressure at the ankle and wrist, respectively, as additional pressure energy is lost in the smaller distal vessels.

Ankle/Brachial Index

Determination of the ABI furnishes a simplified application of leg segmental blood pressure measurements that can readily be used at the bedside. The ABI is the ratio of systolic blood pressure measured at the ankle to systolic blood pressure at the brachial artery. A pneumatic cuff placed around the ankle is inflated to suprasystolic pressure and subsequently deflated while the onset of flow is detected with a Doppler ultrasound probe placed over the dorsalis pedis and posterior tibial arteries, thus denoting ankle systolic blood pressure. Brachial artery systolic pressure can be assessed in routine manner by using either a stethoscope to listen for the first Korotkoff sound or a Doppler probe to listen for the onset of flow during cuff deflation. A normal ABI should be 1.0 or greater. However, in view of the variability intrinsic to sequential blood pressure measurements, an ABI less than 0.90 is considered abnormal and is 95 percent sensitive for angiographically verified peripheral arterial stenosis.[15] [92] The ABI is often used to gauge the severity of PAD. Patients with symptoms of leg claudication often have ABIs ranging from 0.5 t0 0.8, and patients

with critical limb ischemia usually have an ABI less than 0.5. In patients with skin ulcerations, ankle pressure less than 55 mm Hg predicts poor ulcer healing.[93] [94]

One limitation of leg blood pressure recordings is that they cannot be used reliably in patients with calcified vessels, as might occur in persons with diabetes mellitus or renal insufficiency. The calcified vessel cannot be compressed during inflation of the pneumatic cuff, and therefore the Doppler probe indicates continuous blood flow, even when the mercury manometer records pressure in excess of 250 mm Hg.

PULSE VOLUME RECORDING

The pulse volume recording graphically illustrates the volumetric change in a segment of the limb that occurs with each pulse. Plethysmographic instruments, typically with strain gauges or pneumatic cuffs, are used to transduce volumetric changes in the limb that can be displayed on a graphic recorder. These transducers are strategically placed along the limb to record the pulse volume in its different segments, such as the thigh, calf, ankle, metatarsal region, and toes, or the upper part of the arm, forearm, and fingers. The normal pulse volume contour is influenced by both local arterial pressure and vascular wall distensibility and resembles a blood pressure waveform. It

TABLE 41-7 -- LEG SEGMENTAL PRESSURE MEASUREMENTS (mm Hg) IN A PATIENT WITH BILATERAL CALF CLAUDICATION

Brachial artery	152/84
	RIGHT LEG	**LEFT LEG**
Upper thigh	160	162
Lower thigh	110	140
Calf	108	100
Ankle	64	78
A/B index	0.42	0.51

The right leg has pressure gradients between upper and lower parts of the thigh and between the calf and ankle. These gradients are indicative of stenoses in the superficial femoral artery and in the tibioperoneal arteries. The left leg has pressure gradients between the upper and lower parts of the thigh, between the lower part of the thigh and calf, and between the calf and ankle. These gradients are indicative of stenoses in the superficial femoral and popliteal arteries and in the tibioperoneal arteries.

A/B=ankle/brachial.

Figure 41-7 *Left panel,* Normal pulse volume recordings from the upper part of the thigh, lower part of the thigh, calf, and ankle showing a characteristic waveform consisting of a rapid systolic upstroke, a sharp peak, a dicrotic notch, and a concave downslope. *Right panel,* Abnormal pulse volume recordings showing a slower rate of rise, absence of a dicrotic notch, decreased amplitude, and slower descent.

comprises a sharp systolic upstroke that rises rapidly to a peak, a dicrotic notch, and a concave downslope that drops off gradually toward baseline (Fig. 41-7) .[94] [95] The contour of the pulse wave changes distal to a stenosis, with loss of the dicrotic notch, a slower rate of rise, a more rounded peak, and a slower descent. The amplitude becomes lower with increasing severity of disease, and the pulse wave may not be recordable at all in a critically ischemic limb.[94] Segmental analysis of the pulse wave may indicate the location of an arterial stenosis, which is likely to be found in the artery between a normal and abnormal pulse volume recording. The pulse volume wave also provides information regarding the integrity of blood flow when blood pressure measurements cannot be accurately obtained because of noncompressible vessels.

DOPPLER ULTRASOUND

Continuous-wave and pulsed-wave Doppler systems transmit and receive high-frequency ultrasound signals. The Doppler frequency shift caused by moving red blood cells is proportional to the velocity of blood flow. Typically, the perceived frequency shift is between 1 and 20 kHz and is within the audible range of the human ear. Therefore, placement of a Doppler probe along an artery enables the examiner to hear whether blood flow is present and the vessel is patent. Processing and graphically recording the Doppler signal permit more detailed analysis of the frequency components.

Doppler instruments can be used with or without gray-scale imaging to evaluate an artery for the presence of stenoses. The Doppler probe is positioned at approximately a 60-degree angle over the common femoral, superficial femoral, popliteal, dorsalis pedis, and posterior tibial arteries. A normal Doppler waveform has three components: a rapid forward flow component during systole, transient flow reversal during early diastole, and a slow antegrade component during late diastole. The Doppler waveform becomes altered if the probe is placed distal to an arterial stenosis and is characterized by deceleration of systolic flow, loss of the early diastolic reversal, and diminished peak frequencies. Arteries in a limb with critical ischemia may not show any Doppler frequency shift. As with pulse volume recordings, change from a normal to an abnormal Doppler waveform as the artery is interrogated more distally provides inferential evidence of the location of a stenosis.[95] [96]

DUPLEX ULTRASOUND IMAGING

Duplex ultrasound imaging provides a direct, noninvasive means of assessing both the anatomical characteristics of peripheral arteries and the functional significance of arterial stenoses. The methodology incorporates gray-scale B-mode ultrasound imaging, pulsed Doppler velocity measurements, and color coding of the Doppler shift information (Fig. 41-8). Real-time ultrasound scanners emit and receive high-frequency sound waves, typically ranging from 2 to 10 mHz, to construct an image. The acoustic properties of the vascular wall differ from those of the surrounding tissue, which enables them to be imaged easily. Atherosclerotic plaque may be present and visible on gray-scale images (Fig. 41-9) . Pulsed-wave Doppler systems emit ultrasound beams at precise times and can therefore sample the reflected ultrasound waves at specific depths, which enables the examiner to sample the blood cell velocity within the lumen of the artery. By positioning the pulsed Doppler beam at a known angle, blood flow velocity is calculated according to the equation $Df = 2VF\cos O/C$, where Df is the frequency shift, V is the velocity, F is the frequency of the transmitted sound, O is the angle between the transmitted sound and the velocity vector, and C is the velocity of sound in tissue. For optimal measurements, the angle of the pulsed Doppler beam should be less than 60 degrees. With color Doppler, the frequency shift information

Figure 41-8 Duplex ultrasound of the common femoral artery bifurcation into the superficial and deep femoral arteries. The *upper* image shows a normal gray-scale image of the artery in which the intima is not thickened and the lumen is widely patent. The *lower* image is a recording of the pulsed Doppler velocity sampled from the superficial femoral artery. The triphasic profile is apparent, the envelope is thin, and the peak systolic velocity is within normal limits.

within the entire field sampled by the ultrasound beam can be superimposed on the gray-scale image to provide a composite real-time display of flow velocity within the vessel.

Color-assisted duplex ultrasound imaging is an effective means of localizing peripheral arterial stenoses. Normal arteries have laminar flow with the highest velocity at the center of the artery. The representative color image is usually homogeneous, with relatively constant hue and intensity. In the presence of an arterial stenosis, blood flow velocity increases through the narrowed lumen. As the velocity increases, progressive desaturation of the color display can be noted, and flow disturbance distal to the stenosis causes changes in hue and color. Pulsed Doppler velocity measurements can be made along the length of the artery and particularly at areas of flow abnormalities suggested by the color images. A twofold or greater increase in peak systolic velocity at the site of an atherosclerotic plaque indicates a 50 percent or greater diameter stenosis (Fig. 41-9) .[97] [98] A threefold increase in velocity is suggestive of a 75 percent or greater stenosis. No Doppler signal is obtained if the artery is occluded. With contrast angiography used as a reference standard, the specificity and sensitivity of duplex ultrasound imaging for identifying sites of arterial

stenoses are approximately 95 and 80 to 85 percent, respectively.[97] [98] [99] [100] [101]

TREADMILL EXERCISE TESTING

Treadmill exercise testing is used to evaluate the clinical significance of peripheral arterial stenoses and to provide objective evidence of the patient's walking capacity. The initial claudication distance is defined as the point at which symptoms of claudication first develop, and the absolute claudication distance is the point at which the patient is no longer able to continue walking because of severe leg discomfort. This standardized and more objective measurement of walking capacity supplements the patient's history and thus provides quantitative assessment of the patient's disability, as well as a metric that can be monitored after therapeutic interventions.

Treadmill exercise protocols use a motorized treadmill that incorporates fixed or progressive speeds and angles of incline.[102] [103] [104] A fixed workload test usually maintains a constant grade of 12 percent and speed of 1.5 to 2.0 mph. A progressive, or graded, treadmill protocol typically maintains a constant speed of 2 mph while gradually increasing the grade by 2 percent every 2 to 3 minutes.[102] [103] Reproducibility of repeated treadmill tests is reportedly better with progressive-grade than with constant-grade protocols.[103] [105]

Treadmill testing provides a means to determine whether arterial stenoses contribute to the patient's symptoms of exertional leg pain. During exercise, blood flow through a stenosis increases as vascular resistance falls in the exercising muscle. According to Poiseuille's law, described previously, the pressure gradient across the stenosis increases in a manner that is directly proportional to flow. Thus, ankle and brachial systolic blood pressures are measured under resting conditions before treadmill exercise, within 1 minute after exercise, and repeatedly until baseline values are reestablished. Normally, the blood pressure increase that occurs during exercise should be the same in both the upper and lower extremities, with maintenance of constant ABI of 1.0 or greater. In the presence of peripheral arterial stenosis, the ABI decreases because the increase in blood pressure that is observed in the arm is not matched by a comparable increase in ankle blood pressure. A 25 percent or greater decrease in ABI after exercise in a patient whose walking capacity is limited by claudication is considered diagnostic and implicates PAD as a cause of the patient's symptoms.

Many patients with PAD also have coronary atherosclerosis. The addition of cardiac monitoring to the exercise protocol may provide adjunctive information regarding the presence of myocardial ischemia. A workload sufficient to increase myocardial oxygen demand and provoke myocardial ischemia may not be achieved in patients whose exercise capacity is limited by claudication. Nonetheless, electrocardiographic change, particularly during low levels of treadmill exercise, may provide evidence of severe coronary artery disease.

Figure 41-9 Duplex ultrasound of the common femoral artery. The *upper* image shows a gray-scale image of the artery in which plaque is present and encroaching on the lumen. The *lower* image is a recording of the pulsed Doppler velocity sampled from the common femoral artery. The peak velocity of 350 cm/sec is elevated. These features are consistent with significant stenosis.

Magnetic Resonance Angiography (see also Chaps. 10 and 42)

Magnetic resonance angiography (MRA) is a noninvasive means to visualize the aorta and the peripheral arteries. A detailed description of the instrumentation and technique is beyond the scope of this chapter. Resolution of the vascular anatomy with gadolinium-enhanced MRA approaches that of conventional contrast digital subtraction angiography (Fig. 41-10). Comparative studies have reported sensitivities of 93 to 100 percent and specificities of 96 to 100 percent for the aorta, iliac, femoral-popliteal, and tibial-peroneal arteries.[106] [107] [108] [109] Its current utility may be greatest for the evaluation of symptomatic patients to assist decision-making prior to performance of an endovascular intervention or in patients at risk for renal, allergic, or other complications during conventional angiography. As the technology improves, MRA may play a greater role in the preoperative evaluation of patients with PAD.

Contrast Angiography

Conventional angiography with a radioiodinated or other contrast agent is indicated for evaluation of arterial anatomy prior to a revascularization procedure. It is used occasionally when the diagnosis is in doubt. Most contemporary angiography laboratories use digital subtraction techniques after the intraarterial administration of contrast to enhance resolution. A retrograde transfemoral catheterization technique is generally used to evaluate the aorta and the peripheral

Figure 41-10 Gadolinium-enhanced two-dimensional magnetic resonance angiogram of both legs from the knee to above the ankle. Resolution of the popliteal and crural arteries is excellent.

arteries. Injection of the radiocontrast material into the aorta permits visualization of the aorta and iliac arteries, and injection of contrast into the iliofemoral segment of the involved leg permits optimal visualization of the femoral, popliteal, tibial, and peroneal arteries (Fig. 41-11) . In patients with aortic occlusion, catheterization of the fermoral arteries is not feasible. The aorta can be approached by brachial or axillary artery cannulation or, if necessary, directly by a translumbar approach.

PROGNOSIS

The prognosis of patients with PAD is affected by an increased risk for adverse cardiovascular events, as well as the risk of limb loss (Fig. 41-12) .[110] Patients with PAD frequently have concomitant coronary artery disease and cerebrovascular disease.[32] [111] The relative prevalence of each depends, in part, on the diagnostic criteria used to establish the diagnosis of each of these entities. In the Clopidogrel vs. Aspirin in Patients at Risk of Ischemic Events (CAPRIE) Trial, 21 percent of the patients with PAD had a history of myocardial infarction and 26 percent had angina. In the Cardiovascular Health Study, patients with abnormal ABIs were twice as likely to have a history of myocardial infarction, angina, congestive heart failure, or cerebrovascular ischemia as those with normal ABIs.[4] Approximately 15 to 25 percent of patients with PAD have significant carotid artery stenoses by duplex ultrasound. [112] [113] Epidemiological studies have found that the risk of death from cardiovascular causes is increased 2.5- to 6-fold in patients with PAD and the annual mortality rate is 4.3 to 4.9 percent.[4] [8] [12] [13] [32] [114] [115] [116] [117] [118] [119] [120] The risk of death is greatest in those with the most severe PAD, and mortality correlates with decreasing ABI (Fig. 41-13) . [121] [122] Approximately 25 percent of patients with critical limb ischemia die within 1 year, and the 1 year mortality rate in patients who have undergone amputation may be as high as 45 percent.[114] [123]

Angiographic progression of PAD occurs in over 60 percent of patients studied 5 years after the initial diagnosis.[124] Worsening symptoms develop in approximately 25 percent of patients with claudication[110] [125] Clinical progression to critical limb ischemia occurs in 7.5 to 8.0 percent of patients with claudication in the first year after diagnosis and approximately 2.2 percent each year thereafter.[12] [125] Both smoking and diabetes mellitus independently predict progression of disease.[33] [120] [126] [127] Of patients with PAD, those with diabetes mellitus have a 21 percent risk of major amputation as compared with 3 percent in non-diabetic persons.[127]

TREATMENT

The goals of therapy for PAD include a reduction in cardiovascular morbidity and mortality and improvement in quality of life by decreasing symptoms of claudication, eliminating rest pain, and preserving limb viability. Therapeutic considerations therefore include risk factor modification and antiplatelet therapy to reduce the risk of adverse cardiovascular events, such as myocardial infarction, stroke, and death. Symptoms of claudication can improve with pharmacotherapy or exercise rehabilitation, whereas optimal management of critical limb ischemia often includes endovascular interventions or surgical reconstruction to improve blood supply and maintain limb viability.

Risk Factor Modification (see also Chaps. 32 and 33)

Lipid-lowering therapy reduces the risk of adverse cardiovascular events in patients with coronary artery disease.

Figure 41-11 Angiogram of a patient with an ischemic right foot. *Left,* Complete occlusion of the right common iliac artery (arrow). *Right,* A 99 percent stenosis in the midportion of the superficial

femoral artery with reconstitution via collaterals.

Secondary prevention trials, which include the Scandinavian Simvastatin Survival Study (4S), Cholesterol and Recurrent Events (CARE), and the Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID), documented a reduced risk of nonfatal myocardial infarction or death from coronary artery disease by 24 to 34 percent (see also Chap. 33) .[128] [129] [130] No studies to date, however, have prospectively evaluated the effect of lipid-lowering therapy with 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors on these cardiovascular outcomes in patients with PAD. Pending such studies, recommendations for lipid-lowering therapy for patients with PAD are the same as recommendations for those with coronary artery disease. The National Cholesterol Education Program has advised that patients with atherosclerosis and hypercholesterolemia be treated with diet and drug therapy to achieve a target LDL cholesterol of 100 mg/dl or less.[131] Several clinical trials have found that lipid-lowering therapy with diet, niacin,

Figure 41-12 A schema of the natural history of patients with peripheral arterial disease emphasizing both the potential outcome of the affected limb and the cardiovascular prognosis. (From Weitz JI, Byrne J, Clagett GP, et al: Diagnosis and treatment of chronic arterial insufficiency of the lower extremities: A critical review. Circulation 94:3026-3049, 1996. By permission of the American Heart Association, Inc.)

Figure 41-13 Survival rates of patients with peripheral arterial disease (PAD) derived from a population-based study. PAD was diagnosed by measuring the ankle/brachial index. Just the presence of PAD, even in the absence of symptoms, was associated with decreased survival. Survival was poorest in patients with symptoms. (Reprinted, by permission, from Criqui M, Langer RD, Fronek A, et al: Mortality over a period of 10 years in patients with peripheral arterial disease. N Engl J Med 326:381-386, 1992.)

binding resins, or clofibrate reduces the progression of femoral artery atherosclerosis.[132] [133] In one study, the addition of probucol to cholestyramine did not affect femoral atherosclerosis.[134] Lipid-lowering therapy may also reduce the incidence or severity of claudication. The Program on the Surgical Control of the Hyperlipidemias (POSCH) found that partial ileal bypass surgery, a surgical procedure that lowers cholesterol levels, reduced the incidence of intermittent claudication or critical limb ischemia by 34 percent and reduced the risk of development of an abnormal ABI by 44 percent.[135] A post hoc analysis of the 4S found that simvastatin reduced the risk of new or worsening claudication by 38 percent in comparison to placebo (Fig. 41-14) .[136]

Smoking Cessation

Prospective trials examining the benefits of smoking cessation are lacking. However observational evidence unequivocally supports the notion that cigarette smoking increases the risk of atherosclerosis and its clinical sequelae. In patients with PAD, survival rates are better in nonsmokers than in those who have smoked or continue to smoke, and those who discontinue smoking have approximately twice the 5-year survival rate of those who continue to smoke.[137] [138] In one study of patients with PAD, the 10-year rate of myocardial infarction was 53 percent in smokers and 11 percent in nonsmokers.[33] Smoking cessation also lowers the risk for critical limb ischemia.[33]

Treatment of Diabetes (see also Chap. 63)

Aggressive treatment of diabetes decreases the risk for microangiopathic events such as nephropathy and retinopathy; however, only limited data support the benefit of aggressive treatment of diabetes on the clinical manifestations of atherosclerosis. In the Diabetes Control and Complications Trial (DCCT), which involved patients with type I diabetes mellitus, post hoc analysis found that intensive insulin therapy versus usual care caused a nonsignificant 42 percent reduction in cardiovascular events, including a 22 percent reduction in events related to PAD.[139] The United Kingdom Prospective Diabetes Study (UKPDS) of patients with type II diabetes mellitus found that intensive treatment with sulfonylureas or insulin was associated with

Figure 41-14 In the Scandinavian Simvastatin Survival Study, lipid-lowering therapy with simvastatin reduced the incidence of new or worsening claudication. (Adapted from Pedersen TR, Kjekshus J, Pyorala K, et al: Effect of simvastatin on ischemic signs and symptoms in the Scandinavian Simvastatin Survival Study (4S). Am J Cardiol 81:333-335, 1998.)

a 16 percent reduction in myocardial infarction, a finding of borderline statistical significance, and a trend for a decrease in death or amputation from PAD.[140]

Blood Pressure Control

Antihypertensive therapy reduces the risk of stroke, coronary artery disease, and vascular death.[141] It is not known whether antihypertensive therapy prevents the development or progression of PAD. It is conceivable, however, that treatment of hypertension may decrease perfusion pressure to extremities that are already compromised by peripheral arterial stenoses. In addition, concern has been raised regarding the potential adverse affects of beta-adrenergic receptor blockers on peripheral blood flow and symptoms of claudication or critical limb ischemia. Beta blockers have been found to worsen claudication in some trials, but not in others.[142] [143] [144] [145] [146] A meta-analysis that included 11 studies of beta blocker therapy in patients with intermittent claudication found no significant impairment in walking capacity in comparison to placebo.[147] Beta blockers have been shown to reduce the risk of myocardial infarction and death in patients with coronary artery disease, a problem affecting many patients with PAD.[148] [149] Thus, if clinically indicated for other conditions, these drugs should not be withheld in patients with PAD. The balance of evidence would support treatment of hypertension in patients with PAD according to established clinical guidelines (see Chap. 29) .[150]

Angiotensin-converting enzyme (ACE) inhibitors have been shown to reduce coronary events in patients with left ventricular dysfunction.[151] [152] In the Heart Outcomes Prevention Evaluation (HOPE) Study, the ACE inhibitor ramipril decreased the risk of vascular death, myocardial infarction, or stroke by 22 percent. Forty-four percent of the patients enrolled in the HOPE Trial had evidence of PAD as manifested by an ABI of less than 0.9. Ramipril reduced cardiovascular events in patients with PAD to a comparable degree as in those without PAD.[153]

Antiplatelet Therapy

Substantial evidence supports the use of antiplatelet agents to reduce adverse cardiovascular outcome in patients with atherosclerosis. A meta-analysis that included approximately 70,000 high-risk patients with atherosclerosis, including those with acute and prior myocardial infarction, stroke, and transient cerebrovascular ischemia, as well as other high-risk groups such as those with PAD, found that antiplatelet therapy was associated with a 27 percent odds reduction for subsequent vascular death, myocardial infarction, or stroke (see also Chap. 62) .[154] Of the 3295 patients with claudication included in this analysis, a statistically insignificant 18 percent reduction was noted in the risk of myocardial infarction, stroke, or death after 27 months of antiplatelet therapy.[155] The Swedish Ticlopidine Multicenter Study (STIMS) found that ticlopidine reduced mortality by 29 percent in patients with claudication. The CAPRIE Trial compared the efficacy of clopidogrel and aspirin in preventing ischemic events in patients with recent myocardial infarction, recent ischemic stroke, or PAD. Overall, an 8.7 percent relative risk reduction for myocardial infarction, ischemic stroke, or vascular death was seen in the group treated with clopidogrel.[32] Notably, of the 6452 patients in the PAD subgroup, clopidogrel treatment reduced adverse cardiovascular events by 23.8 percent.

Antiplatelet therapy also prevents occlusion in the peripheral circulation after revascularization procedures (Fig. 41-15). Of approximately 3000 patients with peripheral arterial procedures analyzed by the Antiplatelet Trialists Collaboration, the odds reduction for arterial or graft occlusion by antiplatelet therapy, primarily aspirin or aspirin plus dipyridamole, was 43 percent.[155] Ticlopidine also improves the long-term patency of peripheral saphenous vein bypass grafts.[156] Several studies have suggested that ticlopidine improves claudication or reduces the need for reconstructive vascular surgery, but these observations require confirmation in additional clinical trials.[157] [158]

Pharmacotherapy

The development of effective pharmacotherapy for treating symptoms of PAD has lagged substantially behind that for treating coronary artery disease. A report of 75 trials that included 33 drugs for the treatment of intermittent claudication found that approximately 75 percent of the trials were flawed by lack of a placebo control or

blinded randomization, inappropriate endpoints, or small sample size.[159] Published consensus guidelines for conducting clinical trials of pharmacological agents for the treatment of patients with PAD should provide common ground for the objective evaluation of new drugs.[160] [161] Most studies of vasodilator therapy have failed to demonstrate any efficacy in patients with intermittent claudication.[162] Several pathophysiological explanations may account for the failure of vasodilator therapy in PAD. During exercise, resistance vessels distal to a stenosis dilate in response to ischemia. Vasodilators would have minimal, if any, effect on these endogenously dilated vessels but would decrease resistance in other vessels and thereby create a relative steal phenomenon

Figure 41-15 Effect of antiplatelet therapy on arterial occlusion in patients with peripheral arterial disease based on the Antiplatelet Trialists' Collaboration. The odds ratios are shown for patients with claudication, infrainguinal bypass grafts, and percutaneous transluminal angioplasty. (From Antiplatelet Trialists' Collaboration. Collaborative overview of randomised trials of antiplatelet therapy--I: Prevention of death, myocardial infarction, and stroke by prolonged antiplatelet therapy in various categories of patients. BMJ 308:81-106, 1994.)

Figure 41-16 Effect of pentoxifylline on claudication distance based on a pooled analysis of two studies. ICD=initial claudication distance; ACD=absolute claudication distance. Number of patients = 278. (Data from Porter JM, Cutler BS, Lee BY, et al: Pentoxifylline efficacy in the treatment of intermittent claudication: Multicenter controlled double-blind trial with objective assessment of chronic occlusive arterial disease patients. Am Heart J 104:66-72, 1982; Lindgarde F, Labs KH, Rossner M: The pentoxifylline experience: Exercise testing reconsidered. Scandinavian Study Group. Circulation 80:1549-1556, 1989.)

that reduces blood flow and perfusion pressure to the affected leg. Moreover, in contrast to their effects on myocardial oxygen consumption in patients with coronary artery disease (because of afterload reduction), vasodilators do not reduce skeletal muscle oxygen demand.

In the United States, the Food and Drug Administration (FDA) has approved two drugs, pentoxifylline (Trental) and cilostazol (Pletal), for treating claudication in patients with PAD. Additional drugs have been approved by licensing bodies in Europe, Asia, and South America.

PENTOXIFYLLINE.

Pentoxifylline is a xanthine derivative that is used to treat patients with intermittent claudication. Its action is thought to be mediated via its hemorrheological properties, including its ability to decrease blood viscosity and improve erythrocyte flexibility.[163] It also has antiinflammatory and antiproliferative effects.[164] [165] Two prospective multicenter trials found that pentoxifylline increased absolute claudication distance after 24 weeks of treatment by approximately 20 percent (Fig. 41-16) .[166] [167] [168] Two meta-analyses of randomized placebo-controlled trials of pentoxifylline found that it increased initial claudication distance by approximately 20 to 30 meters and absolute claudication distance by approximately 45 to 50 meters.[169] [170] Another meta-analysis, however, concluded that the quality of reported data precluded a reliable estimate of pentoxifylline's efficacy.[171]

CILOSTAZOL.

This quinolinone derivative inhibits phosphodiesterase III, thereby decreasing cyclic adenosine monophosphate degradation and increasing its concentration in platelets and blood vessels. Although cilostazol inhibits platelet aggregation and causes vasodilation in experimental animals, its mechanism of action in patients with PAD is not known.[172] [173] Several trials have reported that cilostazol improves absolute claudication distance by 40 to 50 percent in comparison to placebo (Fig. 41-17) .[174] [175] Quality-of-life measures, as assessed by the Medical Outcomes Scale (SF-36) and the Walking Impairment Questionnaire, also improved. In addition, one study found that absolute walking distance improves more with cilostazol than with either pentoxyfilline or placebo, with the latter two having equivalent efficacy.[176] An advisory from the FDA has stated that cilostazol should not be used in patients with congestive heart failure since other phosphodiesterase III inhibitors have been shown to decrease survival in these patients.[177] [178] The effect of cilostazol on cardiac morbidity and mortality is not known.

OTHER DRUGS.

Many other drugs are under investigation for the treatment of either claudication or critical limb ischemia, including serotonin (5-hydroxytryptamine) antagonists, calcium channel blockers, L-arginine, carnitine derivatives, vasodilator prostaglandins, and angiogenic growth factors. One serotonin antagonist, ketanserin, did not improve claudication distance in a multicenter trial,[179] whereas another, naftidrofuryl, has been reported to improve symptoms of claudication in some trials and is currently available for use in Europe.[180] [181] L-Arginine, the precursor for endothelium-derived nitric oxide, was found to improve claudication distance after 3 weeks of intravenous therapy.[65] Propionyl L-carnitine, a cofactor for fatty acid metabolism, has also been reported to improve claudication, particularly in patients whose baseline maximum walking distance is less than 250 meters.[182] [183]

Therapy with vasodilator prostaglandins has been investigated in patients with intermittent claudication and in those with critical limb ischemia. Intravenous administration of prostaglandin E_1 (PGE_1) or its precursor improved claudication distance in preliminary trials.[65] [184] Phase III studies with oral prostacyclin derivatives in patients with intermittent claudication are in progress or have been completed recently, and the results are pending. In a large trial of 1560 patients with critical limb ischemia, PGE_1 administered intravenously for up to 28 days reduced the composite endpoint of death, major amputation, persistence of critical limb ischemia, acute myocardial infarction, and stroke at the time of hospital discharge from 73 to 64 percent, but its effect on this outcome was not significantly different from that of placebo at the 6-month time point.[185] Most of the benefit of PGE_1 in this trial was related to recovery from leg ischemia.

The therapeutic use of angiogenic growth factors has engendered considerable enthusiasm. Administration of basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF) as protein or gene therapy increases collateral blood vessel development, capillary

Figure 41-17 Effect of cilostazol versus pentoxifylline and placebo on maximal walking distance. (From Dawson DL, Cutler BS, Hiatt WR, et al: A comparison of cilostazol and pentoxifylline for treating intermittent claudication. Am J Med, in press.)

Figure 41-18 Effect of supervised exercise training on peak treadmill exercise time in patients with intermittent claudication. number, and blood flow in experimental models of hindlimb ischemia.[186] [187] [188] [189] [190] [191] Gene transfer of human plasmid phVEGF165 by an intraarterial catheter-based technique or by intramuscular injection into the ischemic extremity improved collateral blood vessel development in small case series.[192] [193] Placebo-controlled clinical trials of angiogenic growth factors in patients with either claudication or critical limb ischemia are in progress.

Exercise

Supervised exercise rehabilitation programs improve symptoms of claudication in patients with PAD (Fig. 41-18) .[194] A meta-analysis of 21 controlled studies of exercise rehabilitation found that a supervised exercise program increased the average distance walked to the onset of claudication by 179 percent and the maximal distance walked by 122 percent.[195] The greatest benefit occurred when sessions were at least 30 minutes in duration at least three times per week for 6 months and when walking was used as the mode of exercise. In a randomized study, exercise training resulted in greater improvement in maximal walking distance than did percutaneous transluminal angioplasty (PTA).[196]

The mechanisms through which exercise training improves claudication are not known. Studies in experimental models of hindlimb ischemia have suggested that regular exercise increases the development of collateral blood vessels.[197] [198] [199] Expression of angiogenic factors is increased by exercise, particularly in hypoxic tissue.[200] [201] [202] Exercise training has been shown to improve endothelium-dependent vasodilation of coronary arteries in patients with coronary atherosclerosis and in

the peripheral circulation of patients with congestive heart failure.[203] [204] [205] However, improvement in calf blood flow commensurate with improvement in walking distance has not been demonstrated in patients with claudication following exercise training.[194] [206] [207] To date, imaging studies demonstrating increased collateral blood vessels following exercise training in patients with PAD have not been reported.

The benefits of exercise training in patients with PAD may result from changes in skeletal muscle function, such as increased muscle mitochondrial enzyme activity and adenosine triphosphate production rate and decreased lactate production.[208] [209] In patients with PAD, improvement in exercise performance is associated with a decrease in plasma and skeletal muscle short-chain acylcarnitine concentrations, which indicate improvement in oxidative metabolism, as well as increased peak oxygen consumption.[194] [210] Training may also enhance biomechanical performance and enable patients to walk more efficiently with less energy expenditure.

Percutaneous Transluminal Angioplasty and Stents (see also pp. 1485-1488)

PTA and stent placement are being increasingly used in the management of patients with PAD, particularly those with disabling claudication and critical limb ischemia. Various endpoints have served to indicate the efficacy of these interventions, including the ABI, vessel patency by duplex ultrasound or conventional angiography, relief of symptoms, and limb salvage. In general, the efficacy of percutaneous interventions is better for treatment of stenoses than occlusions and when targeting vessels with good runoff (i.e., patent distal vessels) as opposed to poor runoff.[15] [211] [212] [213]

Iliac artery PTA alone is associated with 4- to 5-year patency rates of approximately 60 to 80 percent.[211] [214] [215] Iliac artery stent placement yields 4- to 5-year patency rates that range from 70 to 95 percent.[216] [217] [218] A meta-analysis of six iliac PTA studies comprising 1300 patients and eight iliac stent placement studies involving 816 patients found that the long-term patency rate was greater with stent placement than with PTA alone (Fig. 41-19) .[219] Overall, stent placement reduced late failure by 39 percent. The Dutch Iliac Stent Trial Group found that primary PTA followed by selective stent placement was more cost-effective than primary stent placement.[220] [221] Clinical success at 2 years was 78 percent for primary stent placement and 77 percent for selective stent placement. Quality of life improved comparably in each group.[221] [222] In a study comparing stent placement with surgery in patients with aortoiliac disease, the long-term patency rate was less in those who received stents.[223]

The overall efficacy of PTA of the femoral-popliteal arteries is less than that of the iliac arteries.[213] [216] [224] [225] [226] [227] Several large institutional series have found that primary patency rates 1, 3, and 5 years after femoral-popliteal PTA average 60, 50, and 45 percent, respectively.[224] [226] [227] [228] A life table based on a meta-analysis of seven femoral-popliteal PTA studies yielded a 5-year patency rate of approximately 45 percent.[229] An analysis comparing femoral-popliteal PTA with bypass surgery suggested that PTA was more cost-effective than surgery in patients with claudication who had either stenoses or occlusions and in patients with critical limb ischemia who had stenoses. Surgery, however, was more cost-effective than PTA in patients with critical limb ischemia who had arterial occlusions.[229] [230]

PTA of the tibial and peroneal arteries is technically more difficult and associated with a poorer outcome than is endovascular treatment of more proximal lesions,[213] possibly because most series included patients with critical limb ischemia who were considered high risk for bypass surgery. Long-term success appears to be greater in those with focal stenoses in whom distal perfusion is restored.[231] [232] [233] [234]

Figure 41-19 Four-year patency rate after percutaneous transluminal angioplasty (PTA) alone or stent placement for iliac artery lesions based on a meta-analysis of six iliac PTA studies and eight iliac stent studies. (From Bosch JL, Hunink MG: Meta-analysis of the results of percutaneous transluminal angioplasty and stent placement for aortoiliac occlusive disease. Radiology 204:87-96, 1997.)

Figure 41-20 Schematic of an aortobifemoral bypass. The infrarenal aorta has been transected and stapled closed. The proximal end of the graft is anastomosed end to end with the aorta. The distal limbs are anastomosed to the common femoral arteries via retroperitoneal tunnels. (From Whittemore AD, Mannick JA: Principles of vascular surgery. *In* Loscalzo J, Creager MA, Dzau VJ (eds): Vascular Medicine. 2nd ed. Boston, Little, Brown, 1996, pp 675-702.)

Limb salvage rates at 1 and 2 years ranged from 50 to 75 percent.[233] [235] [236] [237]

Innominate and subclavian artery PTA and stent placement are considered for localized lesions in patients with arm claudication or vertebrobasilar insufficiency secondary to subclavian steal. Initial success is achieved in approximately 80 to 90 percent of cases, and the 1-year patency rate averages 85 percent.[238] [239] [240]

Complications occur in approximately 4 to 6 percent of endovascular interventions and usually relate to the severity of arterial disease and the complexity of the procedure.[15] Local complications include thrombosis, dissection, hematoma, and pseudoaneurysm, and occasionally these complications require surgical repair.

Peripheral Arterial Surgery

Surgical revascularization is generally indicated to improve quality of life in patients with disabling claudication who are receiving maximal medical therapy and to relieve rest pain and preserve limb viability in patients with critical limb ischemia. The specific operation must take into account the anatomical location of the arterial lesions and the presence of comorbid conditions. The surgical procedure is planned after angiographic identification of the arterial obstruction to ensure sufficient arterial inflow to and outflow from the graft to maintain patency. Preoperative evaluation to assess the risk of vascular surgery should be performed since many of these patients have coexisting coronary artery disease. Guidelines for this evaluation have been established and are beyond the scope of this chapter (see Chap. 61) .[241]

Aortobifemoral bypass is the most frequent operation for patients with aortoiliac disease. Typically, a knitted or woven prosthesis made of Dacron or polytetrafluoroethylene (PTFE) is anastomosed proximally to the aorta and distally to each common femoral artery (Fig. 41-20) .[242] Occasionally, the iliac artery is used for the distal anastomosis to maintain antegrade flow into at least one hypogastric artery. A recent meta-analysis of aortic bifurcation grafts in 23 studies reported from 1970 to 1996 noted that 5- and 10-year limb patency rates were 91 and 87 percent for claudicants, respectively, and 88 and 82 percent for patients with critical limb ischemia, respectively.[243] Among the more recent series in this analysis, operative morbidity and mortality rates were 8.3 and 3.3 percent, respectively.[243]

Extraanatomical surgical reconstructive procedures for aortoiliac disease include axillobifemoral bypass, iliobifemoral bypass, and femorofemoral bypass. These bypass grafts, made of Dacron or PTFE, circumvent the aorta and iliac arteries and are generally used in high-risk patients with critical limb ischemia.[244] [245] Long-term patency rates are inferior to those of aortobifemoral bypass procedures. A recent Veteran's Administration Cooperative Study that included 340 femorofemoral bypass procedures and 79 axillofemoral or axillobifemoral bypass operations performed primarily in patients with critical limb ischemia reported a 5-year primary patency rate of approximately 50 percent. In other series, 5-year patency rates for axillobifemoral bypass operations have been reported to range from 50 to 70 percent, and those for femorofemoral bypass grafts have ranged from 70 to 80 percent.[246] [247] [248] [249] The operative mortality for extraanatomical bypass procedures is 3 to 5 percent, which reflects, in part, the serious comorbid conditions and advanced atherosclerosis of many of the patients who undergo these procedures.

Reconstructive surgery for infrainguinal arterial disease includes femoropopliteal, femorotibial, or femoroperoneal artery bypass. *In situ* or reversed autologous saphenous veins or synthetic grafts made of PTFE are used for the infrainguinal bypass. Patency rates for autologous saphenous vein bypass grafts are superior to those seen with PTFE grafts.[250] [251] [252] Also, patency rates are better for grafts in which the distal anastomosis is placed in the popliteal artery above the knee versus below the knee.[250] [251] [253] [254] [255] Five-year primary patency rates for femoropopliteal reconstruction in claudicants are approximately 80 and 75 percent for autogenous vein or PTFE grafts, respectively, and in patients with critical limb ischemia they are approximately 65 and 45 percent, respectively.[229] [253] [254] [255] [256] For femoral below-knee bypass, including tibioperoneal artery reconstruction, five-year patency rates for saphenous vein grafts in patients with claudication or critical limb ischemia are comparable to those of femoropopliteal above-knee grafts and range from 60 to 80 percent,[229] [244] [251] [253] [254] [255] [257] whereas 5-year patency rates for PTFE grafts in the infrapopliteal position are considerably inferior, approximating 65 percent in claudicants and 33 percent in patients with critical limb ischemia.[229] [244] [250] Operative mortality for infrainguinal bypass operations based on recent series is 1 to 2 percent.[258] [259] [260] [261]

Graft stenoses may result from technical errors at the time of surgery, such as retained valve cuffs or intimal flap or valvutome injury; from fibrous intimal hyperplasia, usually within 6 months of surgery; or from atherosclerosis, usually occurring within the vein graft at least 1 to 2 years after surgery.[255] [262] Institution of graft surveillance protocols using color-assisted duplex ultrasonography has enabled the identification of graft stenoses, thereby prompting graft revision and avoiding complete graft failure.[263] [264] [265] [266] [267] Several studies have reported improved graft outcome as a result of routine ultrasound surveillance.[263] [266]

Vasculitis (see also Chap. 67)

THROMBOANGIITIS OBLITERANS

TAO is a segmental vasculitis that affects the distal arteries, veins, and nerves of the upper and lower extremities. It typically occurs in young persons who smoke. A patient with characteristics of TAO was described initially by von Winiwater in 1879.[268] Leo Buerger coined the term "thromboangiitis obliterans" and described its pathology in 11 amputated limbs.[269]

PATHOLOGY AND PATHOGENESIS.

TAO primarily affects the medium and small vessels of the arms, including the radial, ulnar, palmar, and digital arteries, and their counterparts in the legs, including the tibial, peroneal, plantar, and digital arteries. The cerebral, coronary, renal,

mesenteric, aortoiliac, and pulmonary arteries may also be involved.[270] [271] [272] [273] The pathology is characterized by an occlusive, highly cellular thrombus composed of polymorphonuclear leukocytes forming microabscesses and, occasionally, multinucleated giant cells.[274] [275] The inflammatory infiltrate may also affect the vascular wall, but the internal elastic membrane remains intact. In the chronic phase of the disease, the thrombus becomes organized and the vascular wall becomes fibrotic.

The precise cause of TAO is not known. Tobacco use or exposure is present in virtually every patient.[274] [276] [277] [278] Potential immunological mechanisms include increased cellular sensitivity to type I and type III collagen or the presence of anti-endothelial cell antibodies.[279] [280] Decreased endothelium-dependent vasodilation to acetylcholine has been observed in both the affected and unaffected limbs of patients with TAO, which raises the possibility that reduced bioavailability of nitric oxide contributes to the disorder.[281]

CLINICAL FINDINGS.

The prevalence of TAO is greater in Asia than North America or Western Europe. In the United States, TAO occurs in approximately 13 per 100,000 population.[282] [283] [284] Most patients with TAO have symptoms before 45 years of age, and 75 to 90 percent are men.[284] [285]

Patients may have claudication of the hands, forearms, feet, or calves. The majority of patients with TAO have pain at rest and digital ulcerations. Often, more than one extremity is affected. Raynaud phenomenon occurs in approximately 45 percent of patients, and superficial thrombophlebitis, which may be migratory, occurs in approximately 40 percent of patients.[285]

The radial, ulnar, dorsalis pedis, and posterior tibial pulses may be absent if the corresponding vessel is involved. The clinical characteristics of critical limb ischemia and ischemic digital ulceration were described earlier in this chapter. The Allen test is abnormal in two-thirds of patients.[285] To perform this test, both the radial and ulnar arteries are compressed while the hand is clenched and then opened.[286] This activity causes palmar blanching. Release of compression from either pulse should normally produce palmar erythema if the palmar arches are patent. If they are occluded, pallor persists on the side where compression is maintained. Discrete, tender, erythematous subcutaneous cords, indicating a superficial thrombophlebitis, may be present on the distal aspects of the extremities.

DIAGNOSIS.

No specific laboratory tests, other than biopsy, can be used to diagnose TAO. Most tests, therefore, are required to exclude other diseases that might have similar clinical features, including autoimmune diseases such as scleroderma or systemic lupus erythematosus, hypercoagulable states, diabetes, or acute arterial occlusion secondary to embolism. The erythrocyte sedimentation rate and acute phase reactants, such as C-reactive protein, are usually normal. Serum immunological markers, including antinuclear antibodies, rheumatoid factor, and antiphospholipid antibodies, should not be present, and serum complement levels should be normal. If clinically indicated, a proximal source of embolism should be excluded by cardiac and vascular ultrasound or by arteriography. Arteriography of an affected limb supports the diagnosis of TAO if the patient has segmental occlusion of small- and medium-sized arteries, absence of atherosclerosis, and corkscrew collaterals circumventing the occlusion (Fig. 41-21). These same findings, however, may occur in scleroderma, systemic lupus erythematosus, mixed connective tissue disease, and antiphospholipid antibody syndrome. The pathognomonic test is a biopsy showing the classic pathological findings. Biopsy is otherwise rarely indicated, and biopsy sites may fail to heal because of severe ischemia. The diagnosis, therefore, is usually based on an age of onset younger than 45 years, a history of tobacco use, physical examination demonstrating distal limb ischemia, exclusion of other diseases, and if necessary, angiographic demonstration of typical lesions.[287] [288] [289]

TREATMENT.

The cornerstone of treatment is cessation of tobacco use. Amputation rarely ensues in patients without gangrene who stop smoking.[290] [291] In contrast, one or more amputations may ultimately be required in 40 to 45 percent of patients with TAO who continue to smoke.

Several drugs have been reported to benefit patients with TAO. The prostacyclin analogue iloprost administered 6 hours per day for 28 days was more effective than aspirin in relieving rest pain and healing ulcers.[292] In a multicenter trial, however, oral iloprost administered for 8 weeks was no more effective than placebo in healing ulcers, although it was somewhat more effective in relieving pain at low doses.[293] A naked plasmid DNA encoding vascular endothelial growth factor (phVEGF165) was intramuscularly injected into seven limbs of six patients with TAO, with subsequent healing of ulcers in three to five limbs and relief of rest pain in two others.[294]

Vascular reconstructive surgery is not usually a viable option because of the segmental nature of this disease and involvement of distal vessels. An autogenous saphenous vein bypass graft can be considered if a target vessel for the distal anastomosis is available. Long-term patency rates are better in ex-smokers than smokers.[295] [296]

Acute Limb Ischemia

Acute limb ischemia occurs when blood flow to the arm or leg is suddenly reduced by arterial occlusion. Perfusion is inadequate to meet the metabolic needs of the tissue, and limb viability is jeopardized. The clinical features of patients with acute limb ischemia are related to the location of the arterial occlusion and the resulting decrease in blood flow. Depending on the severity of ischemia, patients may note disabling claudication or pain at rest. Pain may develop over a short period and is manifested in the affected extremity distal to the site of obstruction. It is not necessarily confined to the foot or toes or to the hand or fingers as is usually the case in chronic limb ischemia. Concurrent ischemia of peripheral nerves causes sensory loss and motor dysfunction.

Physical examination findings may include absence of pulses distal to the occlusion, cool skin, pallor, delayed capillary return and venous filling, diminished or absent sensory perception, and muscular weakness or paralysis. This constellation of symptoms and signs is often recalled as the five P's: pain, pulselessness, pallor, paresthesias, and paralysis.

Prognosis

Comorbid cardiovascular disorders are usually present in patients with acute limb ischemia and may even be responsible for the event. As such, the long-term prognosis is limited in this population. Five-year survival rates after acute limb ischemia caused by thrombosis approximate 45 percent and after embolism are less than 20 percent.[297] The 1-month survival rate in persons older than 75 years with acute limb ischemia approximates 40 percent.[298] The risk of limb loss depends on the severity of the ischemia and the time elapsed before a revascularization procedure is undertaken. Amputation rates are approximately 6 percent if revascularization is performed within 12 hours of the onset of symptoms, 12 percent if performed between 12 and 24 hours, and 20 percent if delayed for more than 24 hours after symptom onset.[299]

A classification scheme that takes into consideration the severity of ischemia and viability of the limb, along with related neurological findings and Doppler signals, has been developed by the Society for Vascular Surgery and the International Society for Cardiovascular Surgery (Table 41-8) . A viable limb, category I, is not immediately threatened, has neither sensory nor motor abnormalities, and has blood flow detectable by Doppler. Threatened viability, category II, indicates that the severity of ischemia will cause limb loss unless the blood supply is restored promptly. The category is subdivided into marginally and immediately threatened limbs, the latter characterized by pain, sensory deficits, and muscular weakness. Arterial blood flow cannot be detected by Doppler. Irreversible limb ischemia leading to tissue loss and requiring amputation, category III, is characterized by loss of sensation, paralysis, and the absence of Doppler-detected blood flow in both arteries and veins distal to the occlusion.

Pathogenesis

The causes of acute limb ischemia include arterial embolism, thrombosis in situ, dissection, and trauma.[300] Most arterial emboli arise from thrombotic sources in the heart. Atrial fibrillation complicating valvular heart disease, congestive heart failure, coronary artery disease, and hypertension accounts for approximately 50 percent of cardiac emboli to the limbs. Other sources include rheumatic or prosthetic cardiac valves, ventricular thrombus resulting from myocardial infarction or left ventricular aneurysm, paradoxical embolism of venous thrombi through the intraatrial or intraventricular communications, and cardiac tumors such as left atrial myxomas. Aneurysms of the aorta or peripheral arteries may harbor thrombi that subsequently embolize to more distal arterial sites, usually lodging at branch points where the artery decreases in size.

Thrombosis in situ occurs in atherosclerotic peripheral arteries, infrainguinal bypass grafts, and peripheral artery aneurysms, as well as in normal arteries of patients with hypercoagulable states. In patients with peripheral atherosclerosis, thrombosis in situ may complicate plaque rupture and cause acute arterial occlusion and limb ischemia in a manner analogous to what occurs in coronary arteries in patients with acute myocardial infarction. Thrombosis complicating popliteal artery aneurysms is a much more common complication than rupture and may account for 10 percent of cases of acute limb ischemia in elderly men.[15] [301] Acute thrombotic occlusion of a normal artery is unusual but may occur in patients with procoagulant disorders such as antiphospholipid antibody syndrome, activated protein C resistance (factor V Leiden), deficiency of protein C or S, heparin-induced thrombocytopenia, essential thrombocythemia, and hyperhomocysteinemia. One of the most common causes of acute limb ischemia is thrombotic occlusion of an infrainguinal bypass graft, as discussed previously.

Diagnostic Tests

The history and physical examination usually establish the diagnosis of acute limb ischemia. Time available for diagnostic tests is often limited, and urgent revascularization

TABLE 41-8 -- CLINICAL CATEGORIES OF ACUTE LIMB ISCHEMIA (MODIFIED FROM THE SVS/ISCVS CLASSIFICATION)

		FINDINGS		DOPPLER SIGNALS	
CATEGORY	DESCRIPTION/PROGNOSIS	Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes) or none	None	(Often) inaudible	Audible
b. Immediately	Salvageable with immediate revascularization			(Usually) inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

procedures should not be delayed if limb viability is immediately threatened. The pressure in the affected limb and corresponding ABI can be measured if flow is detectable by Doppler ultrasound. A Doppler probe can be used to detect the presence of blood flow in peripheral arteries, particularly when pulses are not palpable. Color-assisted duplex ultrasonography can be used to determine the site of occlusion. It is particularly applicable for evaluation of the patency of infrainguinal bypass grafts. Contrast arteriography demonstrates the site of occlusion and provides an anatomical guide for revascularization.

Treatment

Analgesic medications should be administered to reduce pain. For patients with acute leg ischemia, the bed should be positioned such that the feet are lower than chest level, thereby increasing limb perfusion pressure via gravitational effects. Proper bed positioning can be accomplished by putting blocks under the posts at the head of the bed. Effort should be made to reduce pressure on the heels, on bony prominences, and between the toes by appropriate placement of soft material on the bed, such as sheepskin, and between the toes, such as lamb's wool. The room should be kept warm to prevent cold-induced cutaneous vasoconstriction.

Heparin is administered intravenously as soon as the diagnosis of acute limb ischemia is made.[15] The dose should be sufficient to increase the partial thromboplastin time by 1.5 to 2.5 times control values to prevent thrombus propagation or recurrent embolism. It is not known whether low-molecular-weight heparin would be as effective as unfractionated heparin in patients with acute limb ischemia.

Catheter-directed intraarterial thrombolysis is an initial treatment option for patients with category I and IIa acute limb ischemia if they have no contraindication to thrombolysis.[15] [302] Catheter-based thrombolysis can also be considered for patients with more severe limb ischemia who are considered high risk for surgical intervention. Long-term

Figure 41-22 Management algorithm for treatment of acute limb ischemia. (Adapted from Dormandy JA, Rutherford RB: Management of peripheral arterial disease [PAD]. TASC Working Group. J Vasc Surg 31[Suppl]:1-296, 2000.)

patency after thrombolysis is greater in patients with category I and II critical limb ischemia than in those with category III, in native arteries than in grafts, and in vein grafts than in prosthetic grafts.[303] [304] [305] Identification and repair of a graft stenosis after successful thrombolysis improve long-term graft patency.[306] [307] Thrombolytic regimens have used streptokinase, urokinase, recombinant tissue-type plasminogen activator (rt-PA), and reteplase. Outcome has varied among the published reports, but small studies have suggested that initial success in achieving graft patency is greater with urokinase than with streptokinase and greater with rt-PA than with urokinase.[306] [308] The duration of catheter-based thrombolytic therapy should generally be less than 48 hours to achieve optimal benefit and limit the risk of bleeding.

Surgical revascularization is indicated for patients with category IIb and early category III acute limb ischemia.[15] The surgical procedure depends on the nature and location of the arterial occlusion. Thromboembolectomy is the procedure of choice, particularly in patients whose acute limb ischemia is due to systemic embolism.[242] [309] [310] [311] After completion of an embolectomy procedure, angiography should be performed to search for residual thrombus, which can be treated with repeated passage of the balloon embolectomy catheter or by intraoperative thrombolysis. If thromboembolectomy is neither feasible nor successful, surgical reconstruction to bypass the occluded area should be performed. These techniques were discussed previously in this chapter.

Three prospective randomized trials have compared the benefits and risks of thrombolysis and surgical reconstruction in patients with acute limb ischemia (Table 41-9) . In the first of these, often referred to as the Rochester Trial, 114 patients with acute arterial occlusion secondary to thrombosis or embolism and involving either native arteries or bypass grafts were randomized to intraarterial urokinase or surgical revascularization.[312] After 1 year of follow-up, limb salvage rates were 82 percent in each group; however, the survival rate was only 58 percent in the group randomized to surgery versus 84 percent in the group receiving thrombolysis. The higher mortality rate in the surgical treatment group was attributed to cardiopulmonary complications.

The Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial compared thrombolysis with either rt-PA or urokinase to surgery after native artery or graft occlusion in patients with limb ischemia of less than 6 months' duration. The trial was stopped prematurely after enrollment of 393 patients. The composite outcome of death, ongoing or recurrent ischemia, major amputation, and major morbidity occurred in 62 percent of the group randomized to thrombolysis as compared with 36 percent of those randomized to surgery. Of patients who had symptoms for less than 14 days, however, amputation-free survival at 6 months was greater in patients treated with thrombolysis than in those treated with surgery.[313] In the Thrombolysis or Peripheral Arterial Study (TOPAS), intraarterial thrombolysis with urokinase was compared with surgery in 554 patients with acute limb ischemia of less than 14 days. Amputation-free survival rates at 6 and 12 months were 72 and 65 percent, respectively, in the thrombolysis group, and 75 and 70 percent, respectively, in the surgery group.[314] Taken together, the findings from these trials would suggest that catheter-based thrombolysis is an appropriate initial option in patients with category I and IIa acute limb ischemia of less than 7 days' duration, whereas surgical revascularization would be more appropriate for those with category IIb and early category III acute limb ischemia and in those whose symptoms have been present for more than 7 days (Fig. 41-22) .

Atheroembolism (see also Chap. 40)

Atheroembolism refers to the occlusion of arteries resulting from detachment and embolization of atheromatous debris, including fibrin, platelets, cholesterol crystals, and calcium fragments. Other terms include atherogenic embolism and cholesterol embolism. Atheroemboli originate most frequently from shaggy protruding atheromas of the aorta and less frequently from atherosclerotic branch arteries. The atheroemboli typically occlude small downstream arteries and arterioles of the extremities, brain, eyes, kidneys, or mesentery.[315]

The prevalence of atheroembolism in the general population is not known. Most affected individuals are men older than 60 who have clinical evidence of atherosclerosis.[316] [317] [318] The Dutch National Pathology Information System reported an incidence of atheroemboli of 6.2 patients per million per year, and atheroemboli were present in 0.3 percent of autopsy cases.[316] In autopsy series of persons older than 60 years, the incidence of atheroembolism has ranged from 0.8 to 2.4 percent.[319] [320] Atheroembolism accounted for 5 to 10 percent of acute renal failure encountered in a nephrology consulting service and was found in 1 percent of renal biopsy specimens obtained from patients with an unexplained decline in renal function.[321] [322]

Pathogenesis

The risk of atheroembolism is greatest in patients with aortic atherosclerosis characterized by large protuding atheromas (see Fig. 41-4) (Figure Not Available) . A strong association is observed between large aortic plaque identified by ultrasound and previous embolic disease.[323] [324] Similarly, identification of large protruding atheromas by transesophageal echocardiography predicts future embolic events.[323] [325] [326] Approximately 50 percent of atheroemboli involve vessels in the lower extremities.

Catheter manipulation is responsible for a large proportion of atheroemboli.[327] [328] [329] [330] [331] [332] Similarly, surgical manipulation of the aorta during cardiac or vascular operations may precipitate atheroembolism in 2 to 3 percent of patients.[333] [334] It remains controversial whether anticoagulants or thrombolytic drugs contribute to atheroembolism.[335] [336] [337] [338] In the Stroke Prevention and Atrial Fibrillation (SPAF) Study, atheroembolism occurred in 0.7 percent per patient-year in those assigned to adjusted-dose warfarin.[339] In the French Study of Aortic Plaques in Stroke Group, in no patient receiving warfarin did clinical evidence of atheroembolism develop.[326] Muscle biopsies at the time of coronary artery bypass surgery in patients with recent myocardial infarction detected atheroemboli in 14 percent of patients who received thrombolysis and in 10 percent of those who did not.[340] Atheroembolism may entail an inflammatory component inasmuch as cholesterol crystals can activate complement in vitro.[341] Hypocomplementemia can occur in patients with atheroembolism, an indication of complement activation in vivo.[315]

Clinical Findings

The most notable clinical features of atheroembolism to the extremities include painful cyanotic toes resulting in the appelation "blue toe syndrome" (Fig. 41-23). Livedo reticularis occurs in approximately 50 percent of patients.[342] Local areas of erythematous or violaceous discoloration may be present on the lateral aspects of the feet, on the soles, and also on the calves.[315] [343] Other findings include digital and foot ulcerations, nodules, purpura, and petechiae.[342] Pedal pulses are typically present since the emboli tend to lodge in the more distal digital arteries and arterioles. Symptoms and signs indicating additional organ involvement with atheroemboli should be sought. Hollenhorst plaque may be seen with funduscopic examination in patients with visual loss secondary to retinal ischemia or infarction. Renal involvement manifested by increased blood pressure and azotemia commonly occurs in patients with

Figure 41-23 Atheroemboli to the foot: "blue toe syndrome." Cyanotic discoloration of the first, fourth, and fifth toes is apparent as well as localized areas of violaceous discoloration along the lateral aspect of the foot. (From Halperin JL, Creager MA: Arterial occlusive diseases of the extremities. *In* Loscalzo J, Creager MA, Dzau VJ (eds): Vascular Medicine. 2nd ed. Boston, Little, Brown, 1996, pp 825-852.)

peripheral atheroemboli.[344] Patients may also have evidence of mesenteric or bladder ischemia and splenic infarction.

The clinical setting and findings are usually sufficient to diagnose atheroembolism. However, some of the manifestations of atheroemboli may be present with other diseases. As discussed previously, critical limb ischemia occurs in patients with severe peripheral atherosclerosis, and acute limb ischemia is a consequence of thrombembolism, each of which would be characterized by an abnormal pulse examination. Vasculitides secondary to connective tissue diseases, infections, drugs, polyarteritis nodosa, or cryglobulinemia, for example, may be characterized by multisystem organ damage and cutaneous findings of purpura, ulcers, and digital ischemia, similar to findings that result from atheroemboli (see also Chap. 67) . Procoagulant disorders such as antiphospholipid antibody syndrome, heparin-induced thrombocytopenia, and myeloproliferative disorders such as essential thrombocythemia can cause digital artery thrombosis with resultant digital ischemia, cyanosis, and ulceration.

Diagnostic Tests

Laboratory studies that are consistent with atheroembolism include an elevated erythrocyte sedimentation rate, eosinophilia, and eosinophiluria.[344] Other findings may include anemia, thrombocytopenia, hypocomplementemia, and azotemia. Imaging of the aorta with ultrasound, magnetic resonance angiography, or computed tomography may identify sites of severe atherosclerosis and shaggy atheroma indicative of a source for atheroemboli (see Fig. 40-22) . The only definitive test for atheroembolism is pathological confirmation by skin or muscle biopsy. Pathognomonic findings include elongated needle-shaped clefts in small arteries that are caused by cholesterol crystals, often accompanied by inflammatory infiltrates composed of lymphocytes and possibly giant cells and eosinophils, intimal thickening, and perivascular fibrosis.[315]

Treatment

No definitive treatment is known for atheroembolism. Analgesics should be administered for pain. Local foot care should be provided as described previously for patients with critical limb ischemia. It may be necessary to excise or amputate necrotic areas.

These patients are subject to recurrent atheroembolic events. Risk factor modification such as lipid-lowering therapy and smoking cessation may have favorable effects on the overall outcome from atherosclerosis, but it is not known whether such intervention will prevent recurrent atheroembolism. The use of antiplatelet drugs to prevent recurrent atheroembolism has been advocated by some and refuted by others.[345] [346] It is reasonable, however, to administer antiplatelet agents even in the absence of strong clinical evidence of efficacy since these agents will prevent other adverse cardiovascular events in patients with atherosclerosis. The use of warfarin is also controversial, and some have even suggested that anticoagulants precipitate atheroemboli.[323] [336] [347] Others have found that warfarin reduces atheroembolic events, particularly in patients with mobile aortic atheroma.[338]

Surgical removal of the source should be considered in patients with atheroembolism, particularly those in whom it recurs. Surgical procedures include excision and replacement of affected portions of the aorta, endarterectomy, and bypass operations.[348] Operative intervention is targeted to the site of the aorta or the iliac or femoral arteries where an aneurysm has formed or where obvious shaggy friable atherosclerotic plaque is present. Oftentimes, the aorta is diffusely affected by severe atherosclerosis and it is not possible to identify the precise segment that is responsible for atheroembolism. In addition, many of these patients are elderly and have coexisting coronary artery disease, which increases the risk associated with major vascular operations.

Chapter 42 - Extracardiac Vascular Interventions

SHAUN L. W. SAMUELS
MICHAEL D. DAKE

The exciting development and widespread use of endovascular procedures for managing extracardiac vascular disease are explained by several factors, including rising health care costs, advances in percutaneous catheter technology, and a high level of acceptance by patients of nonoperative interventions for the management of arterial occlusive disease, aneurysms, arterial hemorrhage, neoplastic disease, arterial-venous malformations, and venous disease. In this chapter we provide a review of the experience for each general topic along with the limitations and complications of these procedures. The application of various endovascular techniques, including percutaneous transluminal angioplasty (PTA), stents, and stent-grafts, to this wide spectrum of vascular disease is also addressed. It is beyond the scope of this presentation to discuss percutaneous procedures directed at dialysis access lesions, bypass graft stenoses, abnormalities affecting variant native anatomy, and uncommon causes of vascular disease.

Over the past decade a consensus has evolved regarding the indications and benefits of percutaneous treatment of extracardiac vascular disease. There is now a tremendous enthusiasm and potential for further growth of percutaneous endovascular therapies based on the ease, safety, short recuperation, and long-term results associated with these procedures.

ARTERIAL INTERVENTIONS

From the time of the great Charles Dotter, the father of interventional therapy, on, the focus of this therapy has been trained in on the problem of arterial occlusive disease. Atherosclerotic disease is the leading cause of death in the United States, and its presence in the heart reflects its presence elsewhere. The heart serves as a microcosm of the treatment of atherosclerosis in the periphery. The tools of the trade are essentially the same, and hence no detailed description of stents, thrombolytic agents, mechanical thrombectomy devices, or angioplasty balloons is provided in this chapter (see Chap. 38) . Whether in the coronary or extracardiac circulations, the bane of successful intervention is restenosis. For the most part, the approaches to restenosis in the coronary arteries should apply to the periphery. The early results of brachytherapy in the coronaries are promising.[1] Coated stents, local drug therapy, and gene therapy also deserve careful evaluation.

Iliac Interventions

If there is an ideal substrate for percutaneous intervention, it is the iliac artery. The iliac is a large vessel, it is close to the puncture site, and the surgical alternative to iliac interventions is usually a major operation. For all the apparent simplicity of percutaneous treatment, however, closer inspection reveals layers of complexity that make definitive answers about the specifics of the role of iliac intervention elusive. Thus, a brief primer on unresolved issues in the iliacs includes, but is not limited to: (1) surgery versus percutaneous intervention in complex iliac occlusions; (2) primary stenting versus secondary stenting for PTA failure; (3) the role of lesion morphology (i.e., eccentricity, degree of calcification, and tortuosity) in decision-making between PTA and stenting; (4) efficacy of treatment in stenoses versus occlusions; (5) the importance or lack thereof in maintaining the patency of the hypogastrics during interventions; (6) the role of thrombolysis in chronic occlusions; (7) the choice of stent from among a now dizzying variety; (8) the acceptable residual pressure gradient after iliac intervention; (9) the appropriate length of stent for a given lesion length; (10) the maximum lesion length that is appropriate for percutaneous therapy; (11) the optimum strategy for treating lesions at the aortic bifurcation; and (12) the conditions that make it appropriate to treat an iliac lesion through contralateral access. All of these issues have very practical implications on the daily decision-making facing an interventionalist who, in essentially every case involving treatment of the iliac segment, must address each of them in determining the appropriate therapy.

Rarely can the solutions to these problems be found in the literature. More often, one is left to confront them armed only with one's experience and the conflicting dogmas of various experts. Although iliac angioplasty/stenting is technically among the more straightforward arterial interventions, the issues surrounding such a seemingly well-explored territory reveal large gaps in our knowledge. As in many areas, the rapidity of technology development, the multiple competitive stent technologies, the plethora of variables to be controlled, and the many specific questions needing to be answered have conspired to make controlled, randomized studies of percutaneous iliac intervention daunting. At the same time, the absence of such trials will always provide ammunition to the skeptics who dismiss percutaneous iliac therapy as a quick fix.

Iliac angioplasty has been shown safe and effective (Fig. 42-1) , with impressive patencies, based on several studies.[2] [3] [4] The evidence for the efficacy of iliac stent placement also has been established through the many large series that have been published to date.[5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] Lack of standardized reporting and vast differences in technique, stents employed, and lesion type have made it difficult to draw conclusions from these studies (Table 42-1) . Bosch and Hunink [19] published a meta-analysis of iliac angioplasty and stent placement in an attempt to consolidate the findings of many series to yield meaningful information. It serves both as a

Figure 42-1 Iliac artery stent placement. *A,* Initial pelvic arteriogram demonstrates bilateral common iliac artery occlusions in a 52-year-old man with severe bilateral lower extremity claudication. *B,* After bilateral Palmaz stent (Johnson and Johnson, Miami Lakes, FL) placement, final arteriogram demonstrates restoration of normal-caliber common iliac arteries without residual stenosis. No pressure gradient was present after intervention.

useful review of studies done to that date and as a reasonable comparison of PTA with stent placement in the iliacs. The conclusion that there is a 39 percent reduction of late failure with stent placement as opposed to PTA gave comfort to those who intuitively believed that primary stent placement was a superior strategy. Those hopes were deflated by a later cost-effectiveness analysis by the same group[20] based on their meta-analysis[19] and an additional randomized trial of iliac PTA versus stent by the same group.[21] The cost-effectiveness evaluation[20] reveals that PTA with selective stent placement is a more cost-effective strategy than primary stent placement. This conclusion is based on stent and balloon costs in Holland, which the investigators acknowledge is higher than those in the United States. The findings are also based on patients being treated for claudication who are found to have stenotic disease rather than an occlusion. These caveats provide a glimmer of hope for proponents of the primary stent strategy in the United States.

Femoropopliteal Interventions

It is reasonable to question whether atherosclerotic disease of the superficial femoral artery (SFA) should be treated at all. This consideration has enormous implications: approximately 1 million people in the United States develop claudication each year.[22] The vessel may occlude and be asymptomatic in about 10 percent of those who progress to occlusion,[22] [23] or it may result in mild claudication, which improves with walking.[24] The profunda femoris artery shoulders the burden as a collateral in the case of SFA occlusion. The natural history of femoropopliteal (FP) disease is well documented.[23] [24] In the tabulations of McDaniel and Cronenwett, [23] the 5-year outcome for claudicators is as follows: mortality, 29 percent; need for operation, 25 percent; improved or stable, 55 percent; claudication worse, 16 percent; and amputation, 4 percent. Similar numbers have been confirmed in other published reports.[25] The high mortality in this population reflects the role of peripheral vascular disease as a marker for generalized atherosclerosis. These data, culled from a large number of first-rate studies that for the most part preceded the era of percutaneous therapy, are hardly compelling when used to support arguments for intervention in this population. A walking program may be as effective as more aggressive approaches,[24] [26] although the study of Price and associates [26] found that at 6 years the results of PTA and an exercise program were equivalent in their lack of benefit to the patient. The message has emerged that conservative therapy is appropriate for patients with stable claudication. Intervention is usually warranted for patients with progressive claudication, severe life-style limitation, or critical ischemia (rest pain, tissue loss); it is this population that gives rise to the debate over appropriate treatment.

Approaching the field of PTA of the FP segment invites confusion. A wide array of reports have come from many quarters with disparate results. Reporting methods and definitions vary. The word "patency", for example, takes on all shades of meaning, prompting some authors to discuss at considerable length what is meant by the term. PTA in the FP segment has been accepted by most, albeit begrudgingly by some, as a useful tool in the treatment of chronic lower extremity ischemia. The appropriate use of this procedure remains an issue clouded by the glaring disparity in quoted patency rates in the literature.

At latest follow-up interval

Fortunately, the amassed body of experience is large enough to allow reasonable conclusions about indications for FP PTA. An exhaustive analysis of PTA and surgical revascularization is provided by Hunink and coworkers,[27] who set out to establish when PTA and when bypass surgery is the preferred method of FP level revascularization. This analysis in turn was based on data from a prior meta-analysis by the same investigators[28] that summarized the results of 7 series of PTA and 10 series of bypass surgery to determine patency rates. The metric used to evaluate outcome in this study is the quality-adjusted life-year (QALY). The data were deemed appropriate or not based on the reporting methods used, and only those studies adhering to the chosen reporting criteria were included. Several large series, therefore, were excluded.[29] Using a theoretical model, the authors determined that, for a 65-year-old man with life style-limiting claudication or chronic critical ischemia (tissue loss or rest pain) and a *stenotic* lesion in the FP segment, PTA was the more cost-effective strategy. For the same cohort with claudication and an *occlusion*, PTA was also the optimal strategy. For chronic critical ischemia and FP occlusion, bypass surgery is the optimal initial strategy. The population is narrowly defined and the results based on assumptions, but the methods employed in this analysis were stringent. This generalized conclusion notwithstanding, application of such rules in individual patients, with a host of medical and social factors influencing treatment choices, may be extremely difficult.

The degree to which anatomical and technical factors sway one in choosing a method of revascularization cannot be overestimated. The larger series include subgroup analyses of impressive specificity. For example, the series by Capek and colleagues[30] breaks down the data in terms of presenting symptoms, risk factors, lesion number and distribution, lesion length and severity, lesion characteristics (calcification, eccentricity, irregularity), and runoff status. Life table analyses are performed on several variables. Those factors having a statistically significant impact on outcome included presence of other vascular disease, diabetes, severity of presenting symptoms, eccentricity of lesion, degree of stenosis, and lesion length. The effect of lesion length is further subdivided, with all the permutations, among lesions of 0 to 2 cm, 2 to 5 cm, 5 to 10 cm, and larger than 10 cm. Comparisons among all these groups reveal a significant difference in outcome between lesions 0 to 2 cm and those larger than 10 cm and between those 2 to 5 cm and those larger than 10 cm. Given the multiplicity of factors analyzed, it is striking that the greatest statistical significance ($p<0.001$) was found for presence of a palpable pulse at the conclusion of the procedure as a predictor of good outcome. This finding is highly reassuring to those of us for whom the first move after performing SFA PTA is to check for a pedal pulse by physical examination. Interestingly, if technical failures are omitted from the numbers for interventional treatment of FP occlusions, there is no statistical difference in patency between stenosis and occlusion. The 5-year patency of 42 percent for FP PTA is comparable with other recent large series,[31] [32] in which secondary patencies range from 38 to 45 percent. The complication rate for FP PTA is about 10 percent.[25] [33] Of these, only about 2 percent require surgical intervention and 0.2 percent result in death.[25] The specific techniques of PTA are rarely a focus of various studies, although differences in technique may account for the wide variation in patency. Proper balloon sizing and balloon length are important factors in angioplasty success, but they are seldom described in sufficient detail to be of use to the reader. In addition, some adjunctive techniques, such as prolonged balloon inflation to improve the result following suboptimal initial PTA, have been published.[34]

The role of stents in the FP segment is uncertain. One large study by Henry and associates[5] reported a 4-year secondary patency rate of 95 percent for SFA stents. These results have not been duplicated by others.[9] [35] The consensus appears to be that stents are only warranted for salvage in the FP segment for a PTA failure.[9]

Infrapopliteal Interventions

Anatomy, the limitations of technology, and a misplaced sense of futility have until recently kept the infrapopliteal vessels beyond the reach of the interventionist. Anatomy continues to be an obstacle, whereby occlusion of the main conduit, the FP segment, thwarts efforts to treat lesions below the knee. As for equipment limitations, the balloon technology has improved immensely and multiple low-profile, highly flexible balloon catheters are now available on long shafts to access the

trifurcation vessels. Digital angiography provides excellent anatomical detail and superb real-time fluoroscopic guidance enhanced by angiographic image overlay ("roadmapping"); and steerable guidewires, with liberal use of intraarterial vasodilators, have allowed access to the ankle and beyond.

The nihilistic attitude adopted by some when treating infrapopliteal disease does not hold up to scrutiny. Usually called on in a last ditch effort at limb salvage, after surgery has been ruled out or failed, tibial angioplasty is performed on a skewed population of those with the most severe critical ischemia, facing imminent amputation, and frequently having the most significant comorbid conditions. Such heroic interventions are occasionally doomed to failure by the underlying anatomy but attempted nonetheless, the interventionalist responding to pressure from the referring surgeon or from the patient to salvage the limb. In spite of these obstacles, many series report an impressive limb salvage rate given the circumstances. Saab and coworkers[36] reported on 14 tibial PTA procedures with technical success in 10, of which seven patients were spared amputation. Bakal and colleagues,[37] in a series of 53 patients, achieved a successful clinical response in 67 percent of patients overall, 85 percent of whom were diabetic, and in 97 percent of patients in whom straight line flow to the foot was restored through PTA. The series of Matsi and colleagues[38] had a technical success rate of 83 percent of 84 limbs treated for tibial disease, with a limb salvage rate of 63 percent at 2 years among those in whom one to three calf vessel runoff was restored. Schwarten reported a 2-year limb salvage rate of 83 percent in his series of 96 patients.[39] His series imposed restrictions on suitability for angioplasty: a maximum of five lesions and a maximum occlusion length of 5 cm. Other large series[40] [41] also report respectable limb salvage rates.

There are those who still challenge the appropriateness of infrapopliteal angioplasty.[42] [43] A vigorous defense is delivered by Bakal and coworkers,[44] who offer an excellent review of the literature and rebuttal of the juxtaposed submission by Fraser and associates.[42] There is agreement that uniform reporting standards and improved patient selection would aid in analysis of the published data and that a controlled randomized trial would be helpful in determining the cost-effectiveness of PTA versus surgery for infrapopliteal disease. Such trials are more easily designed than done, as partisans of one modality or the other often have little enthusiasm for enrolling patients.

Aortic Interventions

The large caliber of the aorta can mask significant atherosclerotic disease. Stenotic disease, resulting in a pressure gradient, is therefore uncommon, especially in a location not contiguous with the aortic bifurcation.

Reasonable concerns about angioplasty or stenting the infrarenal abdominal aorta, where vessel rupture could be rapidly fatal, have

not been validated by the few series thus far published. Hallisey and coworkers[45] reported a series of 14 patients in which 100 percent technical success was achieved, with clinical success in 93 percent and no significant complications.

Infrarenal aortic stent placement was reported in a small series by Long and colleagues,[46] also achieving a 0 percent morbidity rate. The clinical success in the series of seven patients was more difficult to deduce because of associated iliac segment disease. Comparison of aortic PTA and stenting was made through analysis of a subgroup of the SCVIR Transluminal Angioplasty and Revascularization (STAR) registry.[47] Stent placement, at least in the short term, bestowed no clinical benefit in the retrospective analysis of 25 patients.

Renal Artery Interventions (See also Chap. 48)

Several aspects of renovascular disease (RVD) make its treatment unique among those discussed here. The outcome measures are systemic physiological parameters (blood pressure, serum creatinine concentration) rather than improvement of a specific symptom. As paired organs, often with multiple arteries feeding each, the kidneys may play a sort of anatomical shell game, through which it may be difficult to determine which kidney or which artery is the culprit in a hypertensive patient. To complicate matters, renal artery stenosis (RAS) has a domino effect, whereby the stenotic lesion provokes a humoral response leading to hypertension and this hypertension proceeds to nephropathy in the seemingly uninvolved kidney. Furthermore, in addition to eliciting a hyperreninemic response, decreased blood flow to the kidney causes a separate ischemic nephropathy, leading to a loss of glomeruli and renal mass. Ischemia often causes shrinkage of the affected kidney. It is these secondary effects of RAS that probably lead to the occasionally tepid responses to interventional therapy. The damage to the kidney has already been done, and the intervention merely retards further deterioration. On the other hand, somewhat mysteriously, patients with severe RAS, involving one or both kidneys, may be normotensive and have normal function. Other factors, such as renal size, differential function, and the importance of nonatherosclerotic stenosis (fibromuscular dysplasia, Takayasu's arteritis), further distinguish RAS from stenotic disease elsewhere in the arterial system.

RVD is common, occurring in 27 percent of the population evaluated arteriographically for atherosclerotic disease in the lower extremities, in whom RVD was unexpected.[48] Given the prevalence of hypertension and the aging population, this subgroup constitutes a large cohort. Furthermore, the rapid progression of disease with deterioration of renal function is documented in the same study.[48] Aortorenal bypass surgery produces good clinical results, but at the cost of relatively high morbidity, length of hospital stay, and cost.

Renal angioplasty and stent placement have emerged as elegant solutions to the problems imposed by RVD (Fig. 42-2) . Numerous studies have been done to date supporting the effectiveness of percutaneous intervention for RAS.[49] [50] [51] [52] [53] [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] The results of several of the more recent series on renal artery stent placement may be found in Table 42-2 . Many of the findings of these studies have also been summarized in the excellent review article by Rees and associates,[64] which also includes data from the U.S. multicenter trial of stents in renal arteries. The data presented therein are striking: the technical success for renal stent placement approaches 100 percent benefit; achieved in 61 percent of patients treated for hypertension and improvement or stabilization of renal function in 70 percent of patients after stenting. The beneficial effects of stent placement on azotemia are particularly well displayed in a series by Harden and associates,[51] in which reciprocal serum creatinine plots dramatically flatten at the time of stent placement. One recent trial deemed the effectiveness of renal artery angioplasty vs. antihypertensive drug therapy similar.[64A] However, the follow-up of these patients was limited to 12 months, the use of stents does not reflect current practice, and there was a high degree of "cross-over" to PTCA from the drug-treated group, tempering the ability to generalize these results.[64B] [64C]

With regard to the issue of angioplasty versus stenting, a recent randomized study by van de Ven and colleagues[65] suggests that primary renal artery stenting is a superior strategy for ostial atherosclerotic RAS when compared to angioplasty with selective stent placement for angioplasty failure. The relative roles of angioplasty and stent placement in *nonostial* atherosclerotic RAS are not as clear-cut and probably favor initial angioplasty with selective stenting. One recent retrospective analysis[66] comparing renal PTA, renal stenting, and aortorenal bypass surgery provides evidence that percutaneous therapy is more cost effective and that PTA is probably the procedure of choice in nonostial RAS. In renal stent procedures, the complication rate hovers around 20 percent, including both major and minor complications.[67] The complication rate depends, however, on operator experience.[64] Aspects of this procedure aided by operator experience include exercising judgment in case selection, choice of access, what procedure to perform, and when to desist.

In summary, it stands to reason that improvement of renal blood flow is desirable, not only to improve function and ameliorate hypertension but also to spare renal parenchyma. It can be argued that early intervention for RAS may be warranted even *before* azotemia has occurred and in normotensive patients. Although this is far from proven, and renal intervention in the absence of these known indications is often eschewed, delaying renal artery interventions until clear end-organ damage has been done seems analogous to allowing asymptomatic patients with carotid disease to progress to stroke before action is taken. Clearly, the timing of intervention in this context warrants careful study.

Visceral Artery Interventions

Occlusive disease of the visceral vessels does not often lead to mesenteric ischemia, owing primarily to the redundancy in the system. Multiple collateral pathways exist among the celiac artery, superior mesenteric artery (SMA), and inferior mesenteric artery (IMA). When mesenteric ischemia does occur, it is rarely thought of a priori because the symptoms mimic those of peptic ulcer disease and because the frequent accompanying weight loss usually precipitates a work-up for malignancy. A careful history, however, usually reveals that patients maintain their appetites but experience such excruciating pain after eating that they avoid food altogether.

Patients with the classic symptoms and endoscopic evidence of bowel ischemia have a high likelihood of having significant stenotic disease of at least two of three mesenteric vessels on angiography.[68] If a single vessel is involved, however, it is usually the SMA, which is almost invariably involved when patients have confirmed visceral ischemia. It should be noted that both computed tomographic angiography and magnetic resonance angiography are of sufficient quality to be used as screening tests for stenotic disease of the visceral vessels. Surgical treatment of this disease has a high incidence of morbidity, given the patients' generally advanced age and diffuse atherosclerotic disease. Mateo and coworkers[69] reported an 8 percent mortality rate and a 45 percent complication rate among 85 patients in their series. These were similar to numbers reported by Kihara and colleagues.[70]

The common refrain is again sounded that less invasive

Figure 42-2 Renal artery stent placement. *A,* Initial renal arteriogram demonstrates a critical left renal artery ostial stenosis in a 48-year-old man with renal insufficiency and hypertension. *B,* Arteriogram obtained after stent placement demonstrates no significant residual stenosis. No pressure gradient was detectable after stent placement. *C,* The patient also received a stent in the right renal artery and was able to be taken off dialysis with a creatinine level stabilized in the 3 to 4 mg/dl range.

therapy should go a long way toward improving on these high rates of surgical morbidity (Fig. 42-3) . To that end, several series of both angioplasty[68] [71] [72] [73] [74] and stent placement (Table 42-3) [75] in the visceral vessels have demonstrated a high degree of technical success and clinical effectiveness. The complication rate and the mortality rate are not inconsequential, although both are lower than that presented in surgical series. A skewing of the populations can be seen as a result of patient selection, with patients undergoing percutaneous therapy if deemed poor operative candidates. This is the case in the series by Allen and associates, for example. The results of percutaneous therapy might well have been even more impressive were all patients with mesenteric ischemia, irrespective of comorbidities, given that option.

Supraaortic Interventions

The treatment of occlusive disease of the brachiocephalic vessels has followed the typical progression from surgical management, to PTA, to stent placement, all within the past decade. Percutaneous intervention has been advocated as the primary treatment for symptomatic subclavian artery stenosis or occlusion.[76] [77] Treatment of common carotid lesions is somewhat more problematic, especially when combined with carotid endarterectomy at the bifurcation.[78] The treatment of carotid bifurcation lesions by stent placement is addressed below. The innominate artery tends to be included in reports of subclavian artery intervention,[78] although separate reports of innominate stenting contain excellent results.[79] [80]

*Stent study.

Figure 42-3 Recanalization and stent placement for superior mesenteric artery (SMA) occlusion in a 78-year-old man with recent 30-lb. weight loss, severe postprandial pain, and food avoidance. *A,* Lateral abdominal aortogram demonstrates occlusion of the SMA 4 mm beyond its origin. Faint reconstitution of the SMA can be seen (arrowhead). Severe stenosis at the origin of the celiac axis can also be seen (curved arrow). *B,* After recanalization and primary stent placement, antegrade flow in the SMA has been restored without significant residual stenosis. The patient's symptoms resolved immediately, and he gained back much of the weight he lost.

Crucial to patient selection in the treatment of subclavian occlusive disease is establishing the presence of symptoms referable to the lesion. When proximal subclavian occlusion occurs it is often asymptomatic. In such cases, intervention is not warranted. Upper extremity claudication and vertebrobasilar insufficiency are the most common presenting symptoms.[78] [81] [82] [82A] Technique for recanalization of occlusions may involve femoral and/or brachial access. Results of PTA alone in the subclavian show a clinical success rate of 68 to 92 percent.[76] [82] [83] For subclavian stent placement, clinical success ranged from 83 to 100 percent.[78] [84] [85] [86] [86A] The much-feared complication of embolization into the vertebral artery has only rarely occurred in these series. Some protection from this is naturally afforded by the delay in reversal of flow in the vertebral artery after antegrade subclavian flow is reestablished.

A separate and expanding indication for left subclavian intervention follows the advent of left internal mammary artery (LIMA) coronary artery bypass grafting (CABG). Several case reports and small series have been published describing the syndrome of coronary steal and its treatment by percutaneous therapy, with generally excellent results.[87] [88] [89] [90] [91] [92] [93] [94] [95]

Common carotid artery interventions are uncommon and are usually done in conjunction with planned carotid bifurcation surgery to guarantee adequate postoperative inflow. PTA or stenting of the proximal common carotid is most frequently performed intraoperatively with direct carotid puncture. In this fashion the technical difficulty

introduced by navigating from the groin is obviated and distal control of the vessel may be obtained to prevent embolization at the time of intervention.

Vertebral artery PTA and stenting are rarely performed. The single small series in the literature does, however, demonstrate an adjunctive role for vertebral artery stenting.[96]

Carotid Interventions

One look at the inside of a carotid bifurcation gives one a good idea why surgeons are skeptical about carotid angioplasty and stenting. The plaque is usually an ulcerated, pockmarked, craggy mess, with friable wisps of thrombus and tenuously attached fronds of atheroma. The suggestion that someone should pass a large-caliber catheter through this figurative minefield, inflate a balloon, and then deploy a stent over the path of destruction seems unthinkable. Contrary to expectation, however, this procedure is feasible and unexpectedly safe (Fig. 42-4) . As with most procedures in interventional radiology, what remains to be seen is how well it works, and for how long.

Few areas have provoked more controversy. Editorials concerning carotid interventions flood the literature.[97] [98] [99] [100] [101] [102] [103] [104] [105] [106] [107] [108] [109] Several things about carotid interventions specifically make it a hotbed of controversy. Compare it, for example, to iliac interventions. Unlike iliac percutaneous interventions, those in the carotid eliminate the need for an operation of very *low* morbidity and mortality.[110] [111] [112] [113] As opposed to aortofemoral surgery, hospital stays for carotid surgery are generally

Figure 42-4 Internal carotid artery stent placement. *A,* Common carotid arteriogram identifies smooth concentric narrowing of the proximal internal carotid artery in a patient with a history of two neurologic episodes corresponding to the distribution of this vessel. *B,* After placement of a self-expanding Wallstent, no residual stenosis is noted.

short. In the iliacs, intervention does not burn any surgical bridges. In the carotid, stent placement makes surgery at the very least difficult and perhaps impossible. Emboli precipitated by iliac interventions can usually be managed percutaneously and rarely have long-term sequelae. In the carotid, emboli can be catastrophic, for obvious reasons. Fear of downstream embolization has led, in fact, to a burgeoning industry in various filtering or blocking devices deployed distal to the carotid bifurcation during interventions to trap emboli.

Careful scrutiny of the carotid endarterectomy trials[112] [113] reveals that a large number of patients were excluded from them for a variety of comorbid conditions. It is often precisely these patients who are offered carotid stent placement, and it is therefore not surprising that the complication rate may be higher in this population. Furthermore, stent technology is evolving, techniques are improving, and operator skills have been honed. As a result, it stands to reason that results of carotid stent placement will only improve. There have been few recent innovations in carotid surgery. At the same time, those series that have involved carotid stents in high-risk patients have demonstrated favorable results, certainly better than those of the medical alternative.[114] [115] [116] One aborted randomized trial,[117] in which 5 of 7 patients suffered strokes in the early stent experience, is difficult to reconcile with the superb results published in other series.[118] [119] Clinical and angiographic criteria may help in selecting patients at risk for complications of carotid interventions.[119A] In one large series, Yadav and colleagues treated 126 carotid arteries in 107 consecutive patients. The patients were often in a risk category that would have excluded them from the North American Symptomatic Carotid Endarterectomy Trial (NASCET)[112] or Asymptomatic Carotid Atherosclerosis Study (ACAS)[113] by virtue of their carotid arterial anatomy and/or preexisting medical conditions. Despite this relatively high risk group, the overall 30-day stroke plus death rate was 9.3 percent, and the major stroke plus death rate was 2.8 percent. These numbers compare favorably with surgical complication rates sufficiently well to justify further investigation.

A randomized trial of carotid stenting versus carotid endarterectomy has recently been funded by the National Institutes of Health. The Carotid Revascularization Endarterectomy versus Stent (CREST) trial has enrolled sites and will soon be under way. Such a controlled, randomized trial should help clarify the role of percutaneous carotid intervention, an issue that involves hundreds of thousands of patients each year and has huge repercussions as a major health care concern.

Disease of the Aorta

Aortic Dissection (See also Chap. 40)

There is currently much discussion among vascular interventionalists over the percutaneous therapy for aortic dissection, an unusual but potentially devastating complication of arterial disease. Even the most vehement naysayers concerning endovascular therapies must acknowledge the inroads interventionalists have made on the management of aortic dissection. Surgical results in this disease are mediocre;

and although medical control of hypertension is of great importance still in preventing extension of the dissection, current data support the role of interventional treatment of the ischemic complications. Aortic dissection frequently causes acute ischemia in the renal, mesenteric, and lower extremity vascular beds.

The largest series published to date is that of Slonim and associates,[120] in which 40 patients were treated for ischemic complications of aortic dissection by stent placement and/or percutaneous balloon fenestration of the dissection flap. Ninety-three percent were successfully revascularized, although 25 percent died within 30 days, most often due to irreversible ischemic damage acquired before revascularization. These results were closely matched by those of Williams and colleagues.[121]

The latest innovation in the treatment of acute aortic dissection is the use of stent-grafts to cover the primary entry tear.[122] In one series of 19 patients, 76 percent had restoration of flow to the ischemic bed by placement of the stent-graft alone and there was 100 percent technical success in stent-graft placement.

INTERVENTIONS FOR ANEURYSMAL DISEASE

The covered stent, or stent-graft, represents the next great area of promise in minimally invasive therapy. At present, it cannot be referred to as *percutaneous* therapy, because currently available devices require a cutdown for arterial access. However, with the technology advancing at a rapid pace, minification of the equipment to percutaneously manageable sizes is inevitable. The current reservations over this approach involve the training of individuals who should place stent-grafts and technical limitations of current devices. Increasingly, case reports of late endoleaks (see later) have called into question the long-term viability of the technology in its current form. As in other arenas of vascular intervention, more comparative data will be required to evaluate the role of surgical and interventional approaches to abdominal aortic aneurysm treatment.

ABDOMINAL AORTIC ANEURYSM.

Abdominal aortic aneurysm (AAA) is a significant health care issue in terms of the prevalence of the problem and the expense to treat it (see Chap. 40) . As the population ages, and for unknown other reasons, the incidence of AAA is increasing.[123] [124] Standard therapy, open surgical excision of the aneurysm, is well tolerated in most patients, but significant morbidity occurs in a large percentage of patients.[125] The pressure applied by increased health care costs has driven physicians to seek less invasive, less morbid, and less costly procedures to meet this demand. The standard set by surgical treatment, however, is a high one, and surgeons have had about 40 years to perfect their craft.

The patent literature on endoluminal aneurysm repair dates to 1979, but it was not until Parodi's first series in humans that interest broadened in this approach.[126] Recognizing the aforementioned pressures and the presence of an untapped market, industry and vascular specialists have moved rapidly to address the need. As a result, a daunting profusion of devices has become available. Stiff competition has emerged to enroll patients in trials of various devices. The lay press has entered the fray, and many patients

Figure 42-5 Modular, bifurcated endovascular grafts for the treatment of abdominal aortic aneurysm. *A,* Talent endograft (World Medical, Inc./AVE Inc., Sunrise, FL) is constructed with a series of serpentine nitinol self-expandable springs attached to a polyester surgical graft by a continuous series of polyester sutures. The Talent system allows for transrenal fixation of the device using a proximal bare stent design. This may help to secure the position of the endograft in patients with short (less than 15 mm) infrarenal aneurysm necks. *B,* Excluder endograft (W. L. Gore and Associates,

Inc., Sunnyvale, CA) is composed of thin-wall polytetrafluoroethylene graft material that lines a self-expanding nitinol stent exoskeleton. The modular bifurcated design includes proximal hooks to provide enhanced fixation to the proximal neck and a polytetrafluoroethylene cuff to prevent leaks. *C,* Zenith prosthesis (Cook, Inc., Bloomington, IN) is constructed with a series of Z-stents and polyester graft material. This device utilizes a proximal uncovered stent framework with hooks to secure attachment of the endograft to the aortic wall and allow treatment of relatively short proximal aneurysm necks.

express interest in innovative and less invasive alternatives to surgery.

Whereas open surgical repair has stood the test of time, current follow-up of endoluminal repair is necessarily shorter, with measures of effectiveness given for 2-year, rather than 10-year, follow-up. However, prolonged follow-up of patients with endoluminal AAA repair will help establish the utility of such procedures with time.

The natural history of untreated AAA is fairly well documented,[127] and its unpredictability has led to a gradual, but stepwise, reduction in the size of an aneurysm at which elective repair should be recommended.[128] With the advent of a new technology that promises greatly decreased morbidity, the bar may be lowered farther. The issue remains, however, to what extent the placement of an endoluminal graft alters the long-term natural history of AAA. A new array of problems has accompanied the emergence of endoluminal aneurysm repair, problems only recognizable because of the superb imaging capabilities of computed tomography, ultrasonography, and digital subtraction angiography.

Aneurysm elongation, widening of the infrarenal neck, increasing tortuosity, persistence of collaterals through the IMA and lumbars, and incomplete apposition of the proximal and/or distal fixation of a device, all can be determined with serial imaging, and the information has identified a new problem: the "endoleak." Endoleaks are continued flow within the aneurysm sac, external to the device, after endoluminal repair. The degree to which an endoleak may be tolerated is unknown currently, although it is the object of intense scrutiny.[129] [130] [131] [132] [133] [134] [135] [136] [137] [138] Endoleaks may resolve spontaneously, but they may also persist,[139] and the specter of continued rupture risk looms in such situations. Unfortunately, even when aneurysm size decreases after stent-graft repair, there is still a risk of rupture.[140]

DEVICES AVAILABLE FOR AORTIC ENDOLUMINAL REPAIR.

Appreciation of the rarity of having a distal aneurysm neck has dictated the terms of stent-graft design. The two major categories of devices are (1) aortounilateral iliac with contralateral blocker and (2) bifurcated. Most of the commercially developed devices are bifurcated (Fig. 42-5) . Most are composed of either polyester or polytetrafluoroethylene (PTFE), with a fully supported endoskeleton of either nitinol or stainless steel. The main exception is the EGS (Endovascular Technologies, Menlo Park, CA) device, that incorporates self-expanding metallic cuffs with radially arrayed hooks at the fixation points and is not fully supported. Some evidence has been published that suggests advantages to a system that is fully supported[141] (Fig. 42-6) . Each device, used under a U.S. Food and Drug Administration (FDA)-approved protocol or on a compassionate use basis, has its own set of imaging criteria to determine which patients have anatomy suitable for inclusion, primarily focusing on infrarenal neck length, diameter, and angulation, as well as diameter and tortuosity of the iliac arteries.

DEVICE INTRODUCTIONS.

Devices all require introduction through a sheath, usually 18 to 24 French. This is

Figure 42-6 Endovascular stent-graft management of an abdominal aortic aneurysm. *A,* Abdominal aortogram demonstrates a large eccentric infrarenal abdominal aortic aneurysm before stent-graft deployment. An Excluder (W. L. Gore and Associates, Inc., Sunnyvale, CA) constrained on its delivery catheter (arrow) is located in the abdominal aorta before deployment. *B,* Completion abdominal aortogram after placement of the modular, bifurcated stent-graft demonstrates good flow through the prosthesis without evidence of an endoleak into the aneurysm sac.

done by femoral cutdown, although modifications of technique involving iliac or direct aortic access are sometimes necessary. Procedures are performed under general or spinal anesthesia, either in the operating room or in the angiography suite equipped with operating room-quality air. Combined suites are being built in many centers. Correct positioning of the device is critical, requiring both knowledge of the underlying anatomy and the characteristics of the particular device's deployment. Malpositioning of the device may lead to occlusion of the renal arteries or caudal placement too near the aneurysm sac, the latter necessitating addition of extender cuffs. Open repair, for the most part, does not impose the same anatomical constraints on selection of aneurysm.

All currently available devices, because of the similarity of their construction, have similar shortcomings. None of the devices can be repositioned after deployment. Most of them have a self-expanding metal frame that springs into place, often very rapidly and without opportunity to alter the position during deployment. Many of the devices flare proximally during placement, creating a potential "windsock" effect, through which aortic flow pushes against the briefly occlusive, partially opened stent-graft. This tends to push the device caudally, and this displacement may result in a suboptimal final position. Although some of the devices can be partially pulled back during deployment, none can be significantly advanced once deployment has begun. Therefore, correction of this caudal shift during placement requires additional devices, as mentioned earlier. Reports of material failure and device migration have surfaced,[134] [138] [140] [142] and this may in part result from the somewhat awkward juxtaposition of the graft and metallic components, which do not lend themselves easily to bonding. In addition, sutures holding the two components together must endure significant cumulative stress for years, perhaps decades, after implantation. Anatomical constraints have eliminated many patients from being considered for endoluminal repair. Inadequate infrarenal aneurysm proximal neck is invoked most frequently, and devices most often require 1.5 to 2.0 cm of relatively normal caliber aorta to facilitate sealing.[143] [144] Until devices can be designed that duplicate the security of a surgically constructed suture line, these limitations will continue to cast doubt on the long-term effectiveness of the technology as it stands.

RESULTS.

Despite the above reservations, endoluminal AAA repair displays promising results.[139] [145] [146] [147] [148] [149] [150] [151] [152] [153] Irrespective of the particular product involved, technical success rate is high, aneurysm exclusion is achieved 80 to 95 percent of the time, and conversion to open repair is rare. Complications are not uncommon, however. Numerous case reports and small series of various complications have emerged,[131] [132] [134] [135] [154] [155] [156] and some of these report relatively late sequelae. The degree to which these late complications affect patients with stent-graft AAA repair will determine which device or devices, if any, will prove superior and guide the development of second generation stent-graft systems.

THORACIC ANEURYSMS (see also Chap. 40) .

Open repair of thoracic aortic aneurysms is a major surgical undertaking with an attendant high morbidity and mortality rate. This fact, coupled with the development of stent-graft technology,[126] [157] [158] has led inexorably to the application of stent-graft technology to thoracic aneurysm repair.

As in most stent-graft applications, the underlying lesional anatomy imposes great challenges. In the case of thoracic aortic aneurysms, it is the frequent juxtaposition of the aneurysm to the left subclavian artery that restricts the use of the device, or forces adjunctive surgical transposition of the left subclavian to left carotid (Fig. 42-7). Furthermore, the large caliber of the thoracic aorta in general challenges the limits of deliverability, because one can only percutaneously introduce devices through sheaths up to about 30 French. Moreover, the natural curvature of the aortic arch and proximal descending thoracic aorta must be accommodated by the device, which in its current incarnations contains a metal skeleton limited in its ability to handle such curves. Finally, there is concern about the occlusion of intercostal arteries, anastomoses from which may supply the spinal cord.

Despite these potential pitfalls, the procedure has been used with success in several series.[159] [160] [161] [161A] In the largest of these, Mitchell and colleagues report the results of 103 patients receiving stent-grafts for treatment of aneurysms of the descending thoracic aorta.[159] Sixty percent of these patients were not deemed operative candidates. Primary success was achieved in 73 percent of patients, and secondary success occurred in another 12 percent, but only 53 percent of patients were free of treatment failure at 3.7 years. Complications were common, and major perioperative morbidity occurred in 31 patients. Paraplegia occurred in 3 patients, and was associated with concomitant or preceding abdominal aortic aneurysm repair. There was one conversion to open repair in the series, and 5 patients required late operative intervention for persistent endoleaks. The patient population offered endoluminal repair was obviously a skewed one, with coexistent disease severe enough to exclude well over half from consideration for open surgery. Nonetheless, the results underscore the challenge of treating this disease for the reasons outlined earlier and that the technology must undergo further refinement if it is to become the mainstay of treatment. In a more selected patient population, the results were much

better.[161]

Stent-grafts have also been used with success in the treatment of mycotic aneurysms of the thoracic aorta[162] and in patients with acute rupture of the thoracic aorta, even in those with traumatic rupture.[163]

ILIAC ANEURYSMS

Isolated iliac aneurysms are uncommon. When they occur, however, they may be very dangerous, with an unpredictable course. They are not easily detected on physical examination, and rupture may not be discovered until it is too late because the diagnosis was not considered. Even in elective cases the mortality of open surgical repair is relatively high; and in emergency cases it is about 50 percent.[164] [165]

Several investigators have now demonstrated that stent-graft repair of isolated iliac artery aneurysms is feasible.[166] [167] [168] [169] All studies demonstrated 100 percent technical success with the exception of a single patient in the series by Quinn and coworkers,[168] the single failure attributed to marked tortuosity of the iliac artery. All but one patient has achieved complete aneurysm exclusion in these series, although the follow-up periods are generally short. Complications in all series were rare.

Stent-grafts have also been used to exclude isolated internal iliac aneurysms.[170] The outflow of the internal iliac artery is coil embolized, and the origin of the internal iliac is then occluded by placement of a stent-graft across it, from the common to external iliac artery. This approach effectively excludes the aneurysm by shutting off both inflow and outflow.

OTHER APPLICATIONS OF STENT-GRAFTS

Stent-grafts have been used in a variety of clinical applications beyond those discussed earlier. The repair of aneurysms and arteriovenous fistulas in the region of the subclavian artery[171] [172] has proven successful. In fact, the first report of placement of a covered stent in a patient documented use of a silicone-coated balloon expandable stent in the subclavian artery.[173] Marin and associates [172] have also reported on repair of femoral pseudoaneurysms with stent-grafts. Autologous vein-stent combinations have also been used for the treatment of internal carotid pseudoaneu

Figure 42-7 Stent-graft placement for treatment of a fusiform aneurysm involving the descending thoracic aorta. *A,* Thoracic aortogram in a left anterior oblique projection shows a large aneurysm of the proximal descending thoracic aorta associated with a relatively short proximal neck distal to the left subclavian artery. *B,* After placement of a thoracic Excluder (W. L. Gore and Associates, Inc., Sunnyvale, CA), a balloon is inflated within the proximal aspect of the device to fully expand the prosthesis within the proximal neck and smooth out any graft wrinkles. *C,* Similar left anterior oblique projection of a thoracic aortogram after stent-graft placement shows no further filling of the aneurysm sac and good positioning of the device.

rysm [174] and pseudoaneurysm of the SMA.[175] Covered stents have been used with reasonable success in transjugular intrahepatic portosystemic shunt (TIPS) treatment of patients with complications of portal hypertension, a procedure associated with considerable restenosis.[176]

VENOUS INTERVENTIONS

The conventional wisdom regarded venous interventions with considerable skepticism. The venous endothelium was considered too delicate, the flow too slow, and the walls of the veins too flimsy for seemingly crude techniques applied to the more robust arterial circulation. Surgeons learned this lesson long ago. It is with surprise, then, that vascular specialists have found that the veins can prove quite responsive to interventions. Especially surprising are the results seen in aggressive treatment of lower extremity deep venous thrombosis (DVT). Important roles are also played by interventionalists in treating upper extremity venous thrombosis and in the management of superior vena cava (SVC) syndrome. As on the arterial side, it appears that the size of the conduit and restoration of in-line, anatomical flow channels are the crucial factors in maintaining patency.

LOWER EXTREMITY VENOUS INTERVENTIONS.

Lower extremity deep venous thrombosis (LEDVT) is a common disease. Pulmonary embolus (PE) is the most dangerous consequence of LEDVT. However, the post-thrombotic syndrome, resulting in chronic pain and leg swelling, causes considerable morbidity and a decrease in quality of life. Although warfarin anticoagulation can limit PE, it does little to alter the course of post-thrombotic syndrome. The presence of clot within the veins eventually leads to inflammation and scarring, causing permanent damage to the venous valves and rendering them incompetent. It is the aim of more aggressive therapy of LEDVT to intervene before the onset of irreversible valve damage, and thereby salvage venous valve function.

Thrombolysis.

The mainstay of this more aggressive therapy is thrombolysis. Lysis potentially clears the vein of

clot, restores flow, and hence aborts the cycle of events leading to valve damage. Furthermore, many patients who develop LEDVT have an underlying anatomical lesion leading to thrombosis. Lysis of clot uncovers these lesions, which may then be treated by stenting. Semba and Dake published the first large series using lytic agents for the treatment of iliofemoral DVT and produced excellent results,[177] and this prompted the creation of a national venous registry. The preliminary results of that registry, representing 287 patients subjected to lysis, have confirmed the efficacy of this more aggressive approach to LEDVT.[178] What has emerged is an understanding of the importance of early treatment of DVT. Patients in whom evidence of chronic DVT was found demonstrated less complete lysis and less impressive patency rates than those with acute DVT.[178] The overall 1-year primary patency was 60 percent. Following these patients for several years will be necessary to establish the impact of treatment on the development of post-thrombotic syndrome. Fatal complications occurred in 2 of 287 patients (<1 percent), and 6 patients had pulmonary emboli.

INTERVENTIONS FOR PAGET-SCHROETTER SYNDROME.

Effort vein thrombosis, or Paget-Schroetter syndrome, occurs as a result of mechanical trauma to the subclavian vein at the thoracic outlet. It can occur at any age but has a predilection for young, athletic individuals. A developmental anomaly resulting in impingement on the vein may be present.[179] The natural history of the disorder is typically one of chronic venous obstruction with development of a painful, swollen extremity.

A multidisciplinary approach to its management has emerged, in which thrombolysis is performed in the acute setting and surgical decompression is performed after a variable interval of oral anticoagulation.[180] [181] [182] [183] PTA of the subclavian vein may prove a useful adjunct as well.[180] [181] Other studies, however, found no benefit to PTA in this setting.[184] The role of stent placement in this region is controversial. An emerging consensus that stenting is to be avoided has arisen from experience with stent fracture in this region. Encouraging results of stent placement for Paget-Schroetter syndrome, however, have been reported.[185] [186]

INTERVENTIONS IN SUPERIOR VENA CAVA SYNDROME.

Obstruction of the superior vena cava (SVC) is most frequently a result of malignant disease invading the mediastinum (see also Chap. 69) . To an increasing extent, however, benign causes are responsible, especially obstruction secondary to multiple central venous catheter placements. Not all patients with SVC obstruction are symptomatic. When symptoms do occur, however, they are dramatic: intense facial and upper extremity swelling gives patients a gargoyle-like appearance, which is intensely uncomfortable and unsettling not only to the patient but to the family as well. Patients also suffer from intense headaches, exacerbated while supine, making sleep difficult. Cognitive dysfunction occasionally occurs because of progressive brain edema brought on by venous obstruction. Although patients with malignant SVC syndrome generally have a short life expectancy, the quality of that life is abysmal if the obstruction is untreated. It is in that spirit that aggressive palliative therapy is offered.

Radiation therapy has been the mainstay of treatment for malignant SVC syndrome. The occasionally slow response to radiation and the achievement of maximum

radiation dosages without relief have prompted a gradual shift away from brachytherapy to initial percutaneous interventional therapy when it is available. Although some small series of surgical treatment of malignant SVC syndrome report excellent results,[187] such interventions are proposed with curative intent, only applicable in a small minority of patients with malignant mediastinal involvement with tumor.

SVC stent placement has been demonstrated in numerous reports to provide rapid relief of symptoms of SVC syndrome[188] [189] (Fig. 42-8) . The largest series in the literature was produced by Kee and coworkers,[188] in which a series of 59 patients, 16 of whom had a benign etiology, presented with SVC syndrome. Occlusion of the SVC was found in 31 of these patients, of whom 28 underwent catheter directed thrombolysis before stent placement. In patients with malignant disease, the clinical patency rate was 93 percent; and in those with benign disease, it was 85 percent. Relief of symptoms is often instantaneous and dramatic. Even in patients with a short life expectancy, SVC stent placement greatly improves the quality of their remaining time. In patients with benign disease, patency is comparable to surgery, with less morbidity. In institutions where expertise is available, stent placement is a reasonable first choice in the treatment of SVC syndrome.

Venous Filtration (See also Chap. 52)

Inferior vena cava (IVC) filter placement is one of the more common venous interventions. The utility of such devices would be even broader pending development of temporary and/or retrievable filters, the applications of which could be far reaching in trauma and perioperative management.

IVC FILTERS.

Although there remains some uncertainty about the indications for IVC filter placement, there is general agreement on the core indications: (1) contraindication to anticoagulation; (2) failure of anticoagulation; (3) complication of anticoagulation; and (4) free-floating iliocaval thrombus. The use of filters for prophylaxis against PE in the absence of documented DVT is controversial. Four filter designs are in wide use in the United States, all with purported advantages relative to other designs. Each has been subjected to scrutiny through both single center experiences[190] [191] [192] [193] [194] and review articles.[195] [196]

The major advantage of the Simon Nitinol filter (Nitinol Medical Technologies, Woburn, MA) is its flexibility and low profile (9F), allowing introduction through an antecubital vein.[193] This is particularly useful in patients with coagulopathy or on anticoagulation, in whom the risk of bleeding is higher. Antecubital veins are easily compressed, and there is less risk of clinically significant hematoma than in a jugular or femoral puncture.

The Vena Tech LGM (B. Braun Vena Tech, Evanston, IL) filter is the easiest to place, according to the manufacturer's advertising and in the opinion of many interventionalists. Questions have been raised about the rate of caval occlusion with Vena Tech filters,[194] which have been addressed in later publications.[192] Filter retraction has also been reported.[192]

The Bird's Nest Filter (Cook, Bloomington, IN) can be deployed in IVCs up to 40 mm in diameter, significantly larger than the 28-mm maximum of the other filters. It is also typically less expensive than the other filters. Arguably, a Bird's Nest Filter designed for jugular access is appropriate for treating any patient requiring a filter.

The titanium Greenfield filter (Medi-Tech/Boston Scientific, Watertown, MA) is the more sleek offspring of the earlier stainless steel Greenfield filter (Medi-Tech/Boston Scientific, Watertown, MA). The latest incarnation of this filter allows for delivery over the wire, although this apparently offers no advantage over standard deployment.[191]

All filters are reasonably effective in their primary function of preventing PE, with recurrent PE rates ranging from 1 to 5 percent.[195] The rate of development of caval thrombus is difficult to accurately ascertain but appears to be on the order of 5 to 25 percent.[195]

The introduction of an effective temporary filter would go a long way toward solving the problem of filter placement for prophylaxis. To date, no temporary filters are approved, although some are undergoing trials. Experimental results with one retrievable filter are encouraging.[197]

Figure 42-8 Endovascular stent placement for management of venous obstruction in a 68-year-old man with symptoms of superior vena cava syndrome. *A,* Right arm venogram demonstrates obstruction of the right subclavian and brachiocephalic veins with a highly developed collateral network that includes chest wall veins. *B,* Left internal jugular venogram identifies occlusion of the left jugular system and brachiocephalic vein. *C,* Chest radiograph demonstrates a series of balloon expandable stents (Corinthian, Cordis, Inc., Miami, FL) placed in the right subclavian, right brachiocephalic, left brachiocephalic, and superior vena cava. *D,* Bilateral upper extremity venogram performed after stent placement demonstrates reestablished flow within the previously occluded mediastinal veins. Full expansion of the stented segments is apparent, and a paucity of collateral flow is evident.

Part V - DISEASES OF THE HEART, PERICARDIUM, AND PULMONARY VASCULAR BED

Chapter 43 - Congenital Heart Disease in Infancy and Childhood

WILLIAM F. FRIEDMAN
NORMAN SILVERMAN

General Considerations

DEFINITION

Congenital cardiovascular disease is defined as an *abnormality in cardiocirculatory structure or function that is present at birth, even if it is discovered much later.*[1A] [1B] Congenital cardiovascular malformations usually result from altered embryonic development of a normal structure or failure of such a structure to progress beyond an early stage of embryonic or fetal development. The aberrant patterns of flow created by an anatomical defect may, in turn, significantly influence the structural and functional development of the remainder of the circulation. For instance, the presence in utero of mitral atresia may prohibit normal development of the left ventricle, aortic valve, and ascending aorta. Similarly, constriction of the fetal ductus arteriosus may result directly in right ventricular dilatation and tricuspid regurgitation in the fetus and newborn, it may contribute importantly to the development of pulmonary arterial aneurysms in the presence of ventricular septal defect (VSD) and absent pulmonic valve, or, further, it may result in an alteration in the number and caliber of fetal and newborn pulmonary vascular resistance vessels.

POSTNATAL EVENTS.

These may markedly influence the clinical presentation of a specific "isolated" malformation. Infants with Ebstein's malformation of the tricuspid valve may improve dramatically as the magnitude of tricuspid regurgitation diminishes with normal fall in pulmonary vascular resistance after birth; infants with hypoplastic left heart syndrome or interrupted aortic arch may not exhibit circulatory collapse; and infants with pulmonic atresia or severe stenosis may not become cyanotic until normal spontaneous closure of a patent ductus arteriosus occurs. Ductal constriction many days after birth also may be a central factor in some infants in the development of coarctation of the aorta. Still later in life, patients with a VSD may experience spontaneous closure of the abnormal communication or may develop right ventricular outflow tract obstruction and/or aortic regurgitation or pulmonary vascular obstructive disease. These selected examples serve to emphasize that anatomical and physiological changes in the heart and circulation may continue indefinitely from prenatal life in association with any specific congenital cardiocirculatory lesion.

Certain congenital defects are not apparent on gross inspection of the heart or circulation. Examples include the electrophysiological pathways for ventricular preexcitation or interruptions in the cardiac conduction system giving rise to paroxysmal supraventricular tachycardia or congenital complete heart block, respectively. Similarly, abnormalities in the development of myocardial autonomic innervation or in the ultrastructure of myocardial cells may ultimately prove to contribute to asymmetrical septal hypertrophy and left ventricular outflow tract obstruction. These examples make clear that occasional difficulties arise in distinguishing between congenital anomalies that are readily apparent at or shortly after birth and lesions that may have as their basis a subtle or undetectable abnormality that is present at birth.

INCIDENCE.

The true incidence of congenital cardiovascular malformations is difficult to determine accurately, partly because of the difficulties in definition discussed earlier. About 0.8 percent of live births are complicated by a cardiovascular malformation.[1] This figure does not take into account what may be the two most common cardiac anomalies: the congenital, nonstenotic bicuspid aortic valve[2] and the leaflet abnormality associated with mitral valve prolapse.[3] Moreover, the widely quoted 0.8 percent incidence figure fails to include small preterm infants, almost all of whom have persistent patent ductus arteriosus. Further, if the calculations were to include stillbirths and abortuses, the incidence would be greatly increased. Cardiac malformations occur 10 times more often in stillborn than in liveborn babies, and many early spontaneous abortions are associated with chromosomal defects (see Chap. 56).[1] Thus, it is clear that past statistical analyses have seriously *underestimated* the incidence of congenital heart disease.

Precise data concerning the frequency of individual congenital lesions also are lacking, and the results of many analyses differ, depending on the source (living or dead) and the selection of the study population. Table 43-1 is a compilation from both clinical and pathological studies that approximates the frequency of occurrence of specific cardiovascular malformations.[4] [5] [6]

Considered in toto, children with congenital heart disease are predominantly male. Moreover, specific defects may show a definite gender preponderance; patent ductus

TABLE 43-1 -- RELATIVE FREQUENCY OF OCCURRENCE OF CARDIAC MALFORMATIONS AT BIRTH

DISEASE	PERCENTAGE
Ventricular septal defect	30.5
Atrial septal defect	9.8
Patent ductus arteriosus	9.7
Pulmonic stenosis	6.9
Coarctation of the aorta	6.8

Aortic stenosis	6.1
Tetralogy of Fallot	5.8
Complete transposition of the great arteries	4.2
Persistent truncus arteriosus	2.2
Tricuspid atresia	1.3
All others	16.5
Data based on 2310 cases.	

arteriosus, Ebstein's anomaly of the tricuspid valve, and atrial septal defect are more common in *females,* whereas valvular aortic stenosis, coarctation of the aorta, hypoplastic left heart, pulmonary and tricuspid atresia, and transposition of the great arteries are more common in *males.*[7]

Extracardiac anomalies occur in about 25 percent of infants with significant cardiac disease,[10] and their presence may significantly increase mortality. The extracardiac anomalies often are multiple, in part involving the musculoskeletal system; one-third of infants with both cardiac and extracardiac anomalies have some established syndrome.

ETIOLOGY

Malformations appear to result from an interaction between multifactorial genetic and environmental systems too complex to allow a single specification of cause[8] ; in most instances, a causal factor cannot be identified. However, the explosion of new genetic research suggests that genetic causes are far more common than thought previously.[8] [9] Maternal rubella, ingestion of thalidomide and isotretinoin early during gestation, and chronic maternal alcohol abuse are environmental insults known to interfere with normal cardiogenesis in humans.[10] [11] *Rubella syndrome* consists of cataracts, deafness, microcephaly, and, either singly or in combination, patent ductus arteriosus, pulmonic valvular and/or arterial stenosis, and atrial septal defect. *Thalidomide* exposure is associated with major limb deformities and, occasionally, with cardiac malformations without predilection for a specific lesion. Tricuspid valve anomalies are associated with ingestion of *lithium* during pregnancy. The *fetal alcohol syndrome* consists of microcephaly, micrognathia, microphthalmia, prenatal growth retardation, developmental delay, and cardiac defects. The latter--often defects of the ventricular septum--occur in about 45 percent of affected infants. *Maternal lupus erythematosus* during pregnancy has been linked to congenital complete heart block. Animal experiments have incriminated hypoxia, deficiency or excess of several vitamins, intake of several categories of drugs, and ionizing irradiation as teratogens capable of causing cardiac malformations. The precise relation of these animal teratogens to human malformations is not clear.

The genetic aspects of congenital heart disease are discussed extensively in Chapter 56 . A single gene mutation may be causative in the familial forms of atrial septal defect with prolonged atrioventricular (AV) conduction, mitral valve prolapse, VSD, congenital heart block, situs inversus, pulmonary hypertension, and the syndromes of Noonan, LEOPARD, Ellis-van Creveld, and Kartagener. The genes responsible for several defects have either been mapped (e.g., long QT syndrome, Holt-Oram syndrome) or identified (e.g., Marfan syndrome, hypertrophic cardiomyopathy, supravalvular aortic stenosis). Contiguous gene defects on the long arm of chromosome 22 likely underlie the conotruncal malformations of the DiGeorge and velocardiofacial syndromes.[12] Table 43-2 (Table Not Available) provides a partial list of syndromes in which cardiovascular anomalies may be manifestations of the pleiotropic effects of single genes or examples of gross chromosomal defects. At present, less than 15 percent of all cardiac malformations can be accounted for by chromosomal aberrations or genetic mutations or transmission.

The finding that, with some exceptions, only one of a pair of monozygotic twins is affected by congenital heart disease indicates that the vast majority of cardiovascular malformations are not inherited in a simple manner.[13] However, this observation may have led, in the past, to an underestimation of genetic contribution, because most recent twin studies reveal more than double the incidence of

TABLE 43-2 -- SYNDROMES WITH ASSOCIATED CARDIOVASCULAR INVOLVEMENT

(Not Available)

Modified from Friedman WF, Child JS: Congenital heart disease. In Fauci A,, Braunwald E, Isselbacher KJ, et al (eds): Harrison's Principles of Internal Medicine. 14th ed. New York, McGraw-Hill, 1998, p 1300. © 1998 The McGraw-Hill Companies, Inc.

heart defects in monozygotic twins but usually in only one of the pair.[14] Family studies indicate a 2-fold to 10-fold increase in the incidence of congenital heart disease in siblings of affected patients or in the offspring of an affected parent. Malformations often are concordant or partially concordant within families.[15] [16] Because the incidence of congenital heart disease in the offspring or siblings of an index patient is only 2 to 10 percent, it is seldom wise to discourage

Figure 43-1 Diagrammatic representation of the atrial septa at 30 days *(A)*, at 33 days *(B)*, at 33 days (seen from the right side) *(C)*, at 37 days *(D)*, and in the newborn *(E)*; the newborn atrial septum viewed from the right *(F)*. *(From Clark EB, Van Mierop LHS: Development of the cardiovascular system. the parents of one affected child from having additional children if either parent is free of a cardiovascular anomaly.[1] Moreover, the low recurrence rate and the increasing possibilities for effective treatment for nearly all cardiac lesions usually justify a positive approach to family counseling. When two or more members of the family are affected, the recurrence risk may be quite high, and a pedigree should be obtained before further counseling. If a dominant or recessive mendelian pattern is established, the mendelian laws apply, and the risk of recurrence in each pregnancy is equal.

PREVENTION

The feasibility of preventive programs depends on what is learned in the future about the 85 percent or more of cardiovascular anomalies for which no cause currently is known. Strict animal testing of new drugs that may be teratogenic when taken during pregnancy may be expected to reduce the chances of another thalidomide tragedy. In this regard, the dictum cannot be emphasized too strongly that no medication should be taken during pregnancy without prior consultation with a physician. Physicians who deal with pregnant women should be aware of known teratogens as well as drugs that may have a functional rather than a structural damaging influence on the fetal and newborn heart and circulation, and they should recognize that for many drugs, information about their teratogenic potential is inadequate. Similarly, appropriate radiological equipment and techniques for reducing gonadal and fetal radiation exposure should always be used to reduce the potential hazards of this likely cause of birth defects.

Detection of abnormal chromosomes in fetal cells obtained from amniotic fluid or chorionic villus biopsy (see Chap. 56) may predict cardiac malformation as one component of the multisystem involvement that may exist in such syndromes as Down, Turner's, or trisomy 13-15 (D1) or 16-18 (E). Similarly, identification in such cells of the enzyme disorders observed in the mucopolysaccharidoses, homocystinuria, or type II glycogen storage disease may allow one to predict the ultimate presence of cardiac disease. Finally, immunization of children with rubella vaccine will avoid the effects of maternal rubella and its cardiac consequences.

Although fetal echocardiography may allow the identification of congenital heart disease, it is not yet clear if this modality will improve survivability.[17] [18] It is apparent, however, that a prenatal diagnosis of serious cardiac disease has resulted in a decision by some families to terminate pregnancies.

EMBRYOLOGY

NORMAL CARDIAC DEVELOPMENT.

Correlation of anatomical features of malformed hearts and embryonic cardiac morphology allows a developmental analysis of various anomalies.[19] Detailed accounts of the normal development of the cardiovascular system are provided elsewhere.[20] In brief, during the first month of gestation, the primitive, straight cardiac tube is formed, comprising the sinuatrium, the primitive ventricle, the bulbus cordis, and the truncus arteriosus in series, from cephalad to caudad. In the second month of gestation, this tube doubles over on itself to form two parallel pumping systems, each with two chambers and a great artery. The two atria develop from the sinuatrium, the AV canal is divided by the endocardial cushions into tricuspid and mitral orifices, and the right and left ventricles develop from the primitive ventricle and bulbus cordis. Differential growth of myocardial cells causes the straight cardiac tube to bear to the right, and the bulboventricular portion of the tube doubles over on itself, bringing the ventricles side by side. Migration of the AV canal to the right and of the ventricular septum to the left serves to align each ventricle with its appropriate AV valve. At the distal end of the cardiac tube, the bulbus cordis divides into a subaortic muscular conus and a subpulmonic muscular conus; the subpulmonic conus elongates and the subaortic conus resorbs, allowing the aorta to move posteriorly and connect with the left ventricle.

ABNORMAL DEVELOPMENT.

A host of anomalies may result from defects in this basic developmental pattern. Thus, double-inlet left ventricle is observed if the tricuspid orifice does not align over the right ventricle. The various types of persistent truncus arteriosus result from failure of the truncus to divide into the main pulmonary artery and aorta. Double-outlet anomalies of the right ventricle are produced by failure of either the subpulmonic or subaortic conus to resorb, whereas resorption of the subpulmonic instead of the subaortic conus may be central to transposition of the great arteries.

THE ATRIA.

The primitive sinuatrium is separated into right and left atria by the downgrowth from its roof of the septum primum toward the AV canal, thereby creating an inferior intraatrial ostium primum opening (Fig. 43-1) . Numerous perforations form in the anterosuperior portion of the septum primum as the septum secundum begins to develop to the right of the former. The coalescence of these perforations forms the ostium secundum. The septum secundum completely separates the atrial chambers except for a central opening--the fossa ovalis--which is covered by tissue of the septum primum, forming the valve of the foramen ovale.

Fusion of the endocardial cushions anteriorly and posteriorly divides the AV canal into tricuspid and mitral inlets (Fig. 43-2) . The inferior portion of the atrial septum, the superior portion of the ventricular septum, and portions of the septal leaflets of both the tricuspid and mitral valves are formed from the endocardial cushions. The integrity of the atrial septum depends on growth of the septum primum and septum secundum and proper fusion of the endocardial cushions. Atrial septal defects and various degrees of endocardial cushion defect are the result of developmental deficiencies of this process.

THE VENTRICLES.

Partitioning of the ventricles occurs as cephalic growth of the main ventricular septum results in its fusion with the endocardial cushions and the infundibular or conus septum. Defects in the ventricular septum may occur owing to a deficiency of septal substance; malalignment of septal components in different planes, preventing their fusion; or an overly long conus, keeping the septal components apart. Isolated defects probably result from the first

Figure 43-2 Frontal section through the heart of a 9-mm embryo *(A)* and 15-mm embryo *(B)*. At 9 mm, development of the cushions in the atrioventricular canal is noted, and the truncus and conus swellings are visible. At 15 mm, the conus septum is completed; note the septation in the atrial region. *(From Clark EB, Van Mierop LHS: Development of the cardiovascular system. In Adams FH, Emmanouilides GC, Riemenschneider TA, et al [eds]: Moss' Heart Disease in Infants, Children, and Adolescents. 4th ed. Baltimore, © Williams & Wilkins, 1989.)*

mechanism, whereas the latter two appear to generate the ventricular defects in tetralogy of Fallot and transposition complexes.

THE LUNGS.

These structures arise from the primitive foregut and are drained early in embryogenesis by channels from the splanchnic plexus to the cardinal and umbilicovitelline veins. An outpouching from the posterior left atrium forms the common pulmonary vein, which communicates with the splanchnic plexus, establishing pulmonary venous drainage to the left atrium. The umbilicovitelline and anterior cardinal vein communications atrophy as the common pulmonary vein is incorporated into the left atrium. Anomalous pulmonary venous connections to the umbilicovitelline (portal) venous system or to the cardinal system (superior vena cava) result from failure of the common pulmonary vein to develop or establish communications to the splanchnic plexus. Cor triatriatum results from a narrowing of the common pulmonary vein-left atrial junction.

THE GREAT ARTERIES.

The truncus arteriosus is connected to the dorsal aorta in the embryo by six pairs of aortic arches. Partition of the truncus arteriosus into two great arteries is a result of the fusion of tissue arising from the back wall of the vessel and the truncus septum. Rotation of the truncus coils the aorticopulmonary septum and creates the normal spiral relation between the aorta and pulmonary artery. Semilunar valves and their related sinuses are created by absorption and hollowing out of tissue at the distal side of the truncus ridges. Aorticopulmonary septal defect and persistent truncus arteriosus represent various degrees of partitioning failure.

Although the six aortic arches appear sequentially, portions of the arch system and dorsal aorta disappear at different times during embryogenesis (Fig. 43-3) . The first, second, and fifth sets of paired arches regress completely. The proximal portions of the sixth arches become the right and left pulmonary arteries, and the distal left sixth arch becomes the ductus arteriosus. The third aortic arch forms the connection between the internal and external carotid arteries, and the left fourth arch becomes the arterial segment between the left carotid and subclavian arteries; the proximal portion of the right subclavian artery forms from the right fourth arch. An abnormality in regression of the arch system in a number of sites can produce a wide variety of arch anomalies, whereas a failure of regression usually results in a double aortic arch malformation.

FETAL AND TRANSITIONAL CIRCULATIONS

Although the illness created by the presence of a cardiac malformation is almost always recognized only after an affected baby is born, important effects on the circulation have existed from early in pregnancy until the time of delivery. Thus, knowledge of the changes in cardiocirculatory structure, function, and metabolism that accompany development is central to a systematic comprehension of congenital heart disease.

FETAL CIRCULATORY PATHWAYS.

Dynamic alterations occur in the circulation during the transition from fetal to neonatal life when the lungs take over the function of gas exchange from the placenta. The single fetal circulation consists of parallel pulmonary and systemic pathways (Fig. 43-4) in contrast to the two-circuit system in the newborn and adult, in whom the pulmonary vasculature exists in series with the systemic circulation. Prenatal survival is not endangered by major cardiac anomalies as long as one side of the heart can drive blood from the great veins to the aorta; in the fetus, blood can bypass the nonfunctioning lungs both proximal and distal to the heart.

Oxygenated blood returns from the placenta through the umbilical vein and enters the portal venous system. A variable amount of this stream bypasses the hepatic microcirculation and enters the inferior vena cava by way of the ductus venosus. Inferior vena caval blood flows from the ductus venosus, hepatic vein, and lower body venous drainage, which is summarily deflected to a significant extent across the foramen ovale into the left atrium. Almost all superior vena caval blood passes directly through the tricuspid valve, entering the right ventricle. Most of the blood that reaches the right ventricle bypasses the high-resistance, unexpanded lungs and passes through the ductus arteriosus into the descending aorta. The right ventricle contributes about 55 percent and the left 45 percent to the total fetal cardiac output. The major portion of blood ejected from the left ventricle supplies the brain and upper body, with lesser flow to the coronary arteries; the balance passes across the aortic isthmus to the descending aorta, where it joins with the large stream from the ductus arteriosus before flowing to the lower body and placenta.

FETAL PULMONARY CIRCULATION.

In fetal life, pulmonary arteries and arterioles are surrounded by a fluid medium, have relatively thick walls and small lumina, and resemble comparable arteries in the systemic circulation. The low pulmonary blood flow in the fetus (7 to 10 percent of the total cardiac output) is the result of high pulmonary vascular resistance. Fetal pulmonary vessels are highly reactive to changes in oxygen tension or in the pH of blood perfusing them as well as to a number of other physiological and pharmacological influences.

EFFECTS OF CARDIAC MALFORMATIONS ON THE FETUS.

Although fetal somatic growth may be unimpaired, the hemodynamic effects in utero of many cardiac malformations may alter the development and structure of the fetal heart and circulation.[22] Thus, total anomalous pulmonary venous connection in utero may result in underdevelopment of the left atrium and left ventricle, and premature closure of the foramen ovale may result in hypoplasia of the left ventricle. Moreover, postnatally, the caliber of the aortic isthmus may be reduced in the presence of lesions in utero that create left ventricular hypertrophy, such as aortic stenosis, and impede filling because of reduced compliance of that chamber. It may also be reduced in the presence of a lesion that interferes with left ventricular filling directly (e.g., mitral stenosis) or indirectly by diverting a proportion of left ventricular output away from the ascending aorta while increasing right ventricular output and ductus arteriosus flow (e.g., AV septal defect with left ventricular-right atrial shunt or aortic or subaortic stenosis with VSD). Similarly, obstruction in utero to right ventricular outflow is associated with an increase in proximal aortic flow and diameter and almost never with aortic coarctation. Ebstein's malformation of the tricuspid valve is more commonly recognized in the fetus than ex utero. Death with severe hydrops in utero or early in postnatal life may account for a much lower frequency of this lesion in data gathered after birth. The anomaly, which produces fetal AV valvar regurgitation, a large right-to-left atrial shunt, and ineffective pulmonary flow compromising pulmonary vasculature development, is one of the most significant causes of fetal hydrops, heart failure, and loss. Similar tricuspid valve hemodynamic consequences can also occur in pulmonary atresia with intact ventricular septum.[17] [21] In these and other examples, it is important to recognize that malformations compatible with fetal survival may nonetheless result in abnormal development of the circulation in utero and also affect circulatory adjustments after birth.[23]

FUNCTION OF THE FETAL HEART.

Compared with the adult heart, the fetal and newborn heart is unique with respect to its ultrastructural appearance[24] its mechanical and biochemical properties,[25] [26] [27] [28] [29] [30] and autonomic innervation.[31] During late fetal and early neonatal development, there is maturation of the excitation-contraction coupling process[32] [33] and the biochemical composition of the heart's energy-utilizing myofibrillar proteins and of adenosine triphosphate and creatine phosphate energy-producing proteins.[29] Moreover, fetal and neonatal myocardial cells are small in diameter and reduced in density, so that the young heart contains relatively more noncontractile mass (primarily

Figure 43-3 Transformation of the aortic arches and dorsal aorta into the definitive vascular pattern is a process of fusion and segmental resorption of the paired first to sixth branchial arches with the paired dorsal aorta. *(From Castaneda A, Jonas RA, Mayer JE Jr, et al: Cardiac Surgery of the Neonate and Infant. Philadelphia, WB Saunders, 1994, p 398.)*

Figure 43-4 The fetal circulation; arrows indicate the directions of flow. A fraction of umbilical venous blood enters the ductus venosus and bypasses the liver. This relatively highly oxygenated blood flows across the foramen ovale to the left heart, preferentially perfusing the coronary arteries, head, and upper trunk. The output of the right ventricle flows preferentially across the ductus arteriosus and circulates to the placenta, as well as to the abdominal viscera and lower trunk. *(Courtesy of Dr. David Teitel.)*

mitochondria, nuclei, and surface membranes) than later in postnatal life. As a result, force generation and the extent and velocity of shortening are decreased, and stiffness and water content of ventricular myocardium are increased in the fetal and early newborn periods.

The diminished function of the young heart is reflected in its limited ability to increase cardiac output in the presence of either a volume load or a lesion that increases resistance to emptying.[34] Although functional integrity of efferent and afferent cardiac autonomic pathways exists early in life, fetal and newborn myocardium lacks the complete development of sympathetic but not cholinergic innervation. Thus, adaptation to cardiocirculatory stress in fetal or early newborn life may be less effective than in adulthood.

CHANGES AT BIRTH.

The fundamental change that normally occurs at birth is a division of the single parallel fetal circulation into separate, independent circulations. Inflation of the lungs at the first inspiration produces a marked reduction in pulmonary vascular resistance, owing partly to the sudden suspension in air of fetal pulmonary vessels previously supported by fluid media. The reduced extravascular pressure assists new vessels to open and already patent vessels to enlarge. The rapid decrease in pulmonary vascular resistance is related more importantly to vasodilatation owing to the increase in oxygen tension to which pulmonary vessels are exposed rather than to physical expansion of alveoli with gas. Defining the role of nitric oxide in the mediation of changes in pulmonary vascular tone in these events is of great interest.[35] Pulmonary arterial pressure falls, and pulmonary blood flow increases greatly. Systemic vascular resistance rises when clamping of the umbilical cord removes the low-resistance placental circulation. Increased pulmonary blood flow increases the return of blood to the left atrium and raises left atrial pressure, which in turn closes the foramen ovale.

The shift in oxygen dependence from the placenta to the lungs produces a sudden increase in arterial blood oxygen tension, which, in concert with alterations in the local prostaglandin milleu, initiates constriction of the ductus arteriosus.[36] Pulmonary pressure falls further as the ductus constricts. In healthy mature infants, the ductus arteriosus is profoundly constricted at 10 to 15 hours and is closed functionally by 72 hours, with total anatomical closure following within a few weeks by a process of thrombosis, intimal proliferation, and fibrosis. Preterm infants have a high incidence of persistent patency of the ductus arteriosus because of an immaturity of those mechanisms responsible for constriction. In surviving preterm infants, the ductus arteriosus spontaneously closes within 4 to 12 months of birth.

The ductus venosus, ductus arteriosus, and foramen ovale remain potential channels for blood flow after birth. Thus, persistent patency of the ductus venosus may mask the most marked signs of pulmonary venous obstruction in infants with total anomalous pulmonary venous connection below the diaphragm. Similarly, lesions producing right or left atrial volume or pressure overload may stretch the foramen ovale and render incompetent the flap valve mechanism for its closure. Anomalies that depend on patency of the ductus arteriosus for preserving pulmonary or systemic blood flow remain latent until the ductus arteriosus constricts. A common example is the rapid intensification of cyanosis observed in infants with tetralogy of Fallot when the magnitude of pulmonary hypoperfusion is unmasked by spontaneous closure of the ductus arteriosus. Moreover, increasing evidence shows that ductal constriction is a key factor in the postnatal development of coarctation of the aorta. Finally, it should be recognized that because the ductus arteriosus is potentially patent after birth and the pulmonary resistance vessels are hyperreactive, hypoxic pulmonary vasoconstriction of diverse causes may result in a right-to-left shunt through the ductus.

Pathological Consequences of Congenital Cardiac Lesions

CONGESTIVE HEART FAILURE

Although the basic mechanisms of cardiac failure, as outlined in Chapter 16 , are similar for all ages, pediatric cardiologists should clearly recognize that the common causes, time of onset, and often the approach to treatment vary with age.[37] [38] The development of fetal echocardiography has allowed the diagnosis of intrauterine cardiac failure.[21] [39] The cardinal findings of fetal heart failure are scalp edema, ascites, pericardial effusion, and decreased fetal movements. Although abnormalities in several organ systems may result in nonimmunological fetal hydrops, cardiac causes include a host of structural, functional, rhythm, and metabolic disturbances of the heart. Infants younger than 1 year and having cardiac malformations account for 80 to 90 percent of pediatric patients who develop congestive failure. Moreover, cardiac decompensation in an infant is a medical emergency necessitating immediate treatment if the patient is to be saved.

CAUSES OF HEART FAILURE.

In preterm infants, especially less than 1500-gm birth weight, persistent patency of the ductus arteriosus is the most common cause of cardiac decompensation, and other forms of structural heart disease are rare.[40] In full-term newborns, the earliest important causes of heart failure are the hypoplastic left heart and coarctation of the aorta syndromes, sustained tachyarrhythmia, cerebral or hepatic arteriovenous fistula, and myocarditis. Among the lesions commonly producing heart failure beyond age 1 to 2 weeks, when diminished pulmonary vascular resistance allows substantial left-to-right shunting, are VSD and atrioventricular septal defects, transposition of the great arteries, truncus arteriosus, and total anomalous pulmonary venous connection, often with pulmonary venous obstruction. Although heart failure usually is the result of a structural defect or of myocardial disease, it should be recognized that the newborn myocardium may be severely depressed by such abnormalities as hypoxemia and acidemia, anemia, septicemia, marked hypoglycemia, hypocalcemia, and polycythemia. In older children, heart failure often is due to acquired disease (see Chap. 45) or is a complication of open-heart surgical procedures. In the acquired category are rheumatic and endomyocardial diseases, infective endocarditis, hematological and nutritional disorders, and severe cardiac arrhythmias.

CLINICAL MANIFESTATIONS IN THE INFANT.

The clinical expression of cardiac decompensation in infants consists of distinctive signs of pulmonary and systemic venous congestion and altered cardiocirculatory performance that resemble, but often are not identical to, those of older children or adults (Table 43-3) .[37] [41] These reflect the interplay between the hemodynamic burden and adaptive responses. Common symptoms and signs are feeding difficulties and failure to gain weight and grow, tachypnea, tachycardia, pulmonary rales and rhonchi, liver enlargement, and cardiomegaly. Less frequent manifestations include peripheral edema, ascites, pulsus alternans, gallop rhythm, wheezing, and inappropriate sweating. Pleural and pericardial effusions are exceedingly rare. The distinction between left and right heart failure is less obvious in infants than in older children or adults because most lesions that create a left ventricular pressure or volume overload also result in left-to-right shunting of blood through the foramen ovale and/or patent ductus arteriosus as well as pulmonary hypertension owing to elevated pulmonary venous pressures. Conversely, augmented

TABLE 43-3 -- FEATURES OF HEART FAILURE IN INFANTS

Poor feeding and failure to thrive
Respiratory distress--mainly tachypnea
Rapid heart rate (160 to 180 beats/min)
Pulmonary rales or wheezing
Cardiomegaly and pulmonary edema on radiogram
Hepatomegaly (peripheral edema unusual)
Gallop sounds
Color--ashen pale or faintly cyanotic
Excessive perspiration
Diminished urine output

filling or elevated pressure of the right ventricle in infants reduces left ventricular compliance disproportionately when compared with older children or adults and gives rise to signs of both systemic and pulmonary venous congestion.[37]

Fatigue and dyspnea on exertion express themselves as a feeding problem in infants. Characteristically, the respiratory rate in heart failure is rapid (50 to 100 breaths/min). In the presence of left ventricular failure, interstitial pulmonary edema reduces pulmonary compliance and results in tachypnea and retractions. Excessive pulmonary blood flow by way of significant left-to-right shunts may further decrease lung compliance. Moreover, upper airway obstruction may be produced by selective enlargement of cardiovascular structures. In patients with large left-to-right shunts and left atrial and main pulmonary artery enlargement, the left main stem bronchus may be compressed, resulting in emphysematous expansion of the left upper or lower lobe or left lower lobe collapse.[42] Respiratory distress with grunting, flaring of the alae nasi, and intercostal retractions is observed when failure is severe and especially when pulmonary infection precipitates cardiac decompensation, which often is the case. Under these circumstances, pulmonary rales may be due to the infection, failure, or both. A resting heart rate with little variability is also characteristic of heart failure. Hepatomegaly is common in infants in failure, although liver tenderness is uncommon. Cardiomegaly may be assessed roentgenographically, but it must be recognized that in normal newborn infants, the cardiac diameter may be as much as 60 percent of the thoracic diameter, and the large thymus gland in infants occasionally interferes with evaluation of heart size. Two-dimensional and Doppler echocardiography provide a reliable estimate of cardiac performance and chamber dimensions, and values may be compared with data derived from normal infants.[43] [44] [45]

Cardiac decompensation may progress with extreme rapidity in the first hours and days of life, producing a clinical picture of advanced cardiogenic shock and a profoundly obtunded infant. The presence of marked hepatomegaly and gross cardiomegaly usually allows distinction from noncardiac causes of diminished systemic perfusion.

CYANOSIS

Cyanosis is produced by reduced hemoglobin in cutaneous vessels in excess of approximately 3 gm/dl (see p. 1539). Peripheral cyanosis usually reflects an abnormally great extraction of oxygen from normally saturated arterial blood, commonly the result of peripheral cutaneous vasoconstriction. Central cyanosis is a result of arterial blood oxygen unsaturation, most often in patients with congenital heart disease caused by shunting of systemic venous blood into the arterial circuit. Infants especially (as compared with adults) may appear cyanotic when in heart failure because of both peripheral and central factors[46] ; the latter may include severe

impairment of pulmonary function that commonly exists with alveolar hypoventilation, ventilation-perfusion inequality, or impaired oxygen diffusion.

In patients with central cyanosis owing to arterial oxygen unsaturation, the degree of cutaneous discoloration depends on the absolute amount of reduced hemoglobin, the magnitude of the right-to-left shunt relative to systemic flow, and the oxyhemoglobin saturation of venous blood. The last of these depends in turn on the tissue extraction of oxygen. Cyanosis commonly appears or intensifies with physical activity or exercise as the saturation of systemic venous blood declines concurrent with an increase in right-to-left shunting across a defect as peripheral vascular resistance decreases. Oxygen transfer to the tissues is affected by shifts in the oxygen-hemoglobin dissociation relation, which may be altered by blood pH and levels of red blood cell 2,3-diphosphoglycerate concentration.

CLUBBING AND POLYCYTHEMIA/ERYTHROCYTOSIS.

Prominent accompaniments of arterial hypoxemia are polycythemia and clubbing of the digits. The latter is associated with an increased number of capillaries with increased blood flow through extensive arteriovenous aneurysms and an increase of connective tissue in the terminal phalanges of the fingers and toes. Polycythemia is a physiological response to chronic hypoxemia that stimulates erythrocytosis. The extremely high hematocrits observed in patients with arterial oxygen unsaturation cause a progressive increase in blood viscosity. Because the relationship is nonlinear between hematocrit and blood viscosity, relatively small increases beyond packed blood cell volumes of 60 percent result in large increases in viscosity. Also, the apparent viscosity of blood increases in the microcirculation, where lower shear rates exist, an increasingly important factor as the hematocrit exceeds 70 percent.

Both the hematocrit and the circulating whole blood volume are increased in polycythemia accompanying cyanotic congenital heart disease; the hypervolemia is the result of an increase in red blood cell volume. The augmented red blood cell volume provoked by hypoxemia provides an increased oxygen-carrying capacity and enhanced oxygen supply to the tissues. The compensatory polycythemia often is of such severity that it becomes a liability and produces such adverse physiological effects as hyperviscosity, cellular aggregation, and thrombotic lesions in diverse organs and a hemorrhagic diathesis.[47] In this regard, oral steroid contraceptives are contraindicated in adolescent cyanotic females because of the enhanced risk of cerebral thrombosis.

Management.

Red blood cell volume reduction and replacement with plasma or albumin (erythropheresis) lower blood viscosity and increase systemic blood flow and systemic oxygen transport; they thus may be helpful in the treatment of patients with severe hypoxic polycythemia (hematocrit
65 percent). A final hematocrit of 55 to 63 percent should be achieved; the higher level is necessary in patients with low initial oxygen saturation to avoid a severe reduction in arterial oxygen content. Acute phlebotomy without fluid replacement is contraindicated.

CEREBRAL AND PULMONARY COMPLICATIONS.

Cerebrovascular accidents and brain abscesses occur particularly in cyanotic patients with substantial arterial desaturation.[48] [49] *Cerebral thrombosis* is most common before age 2 years in severely cyanotic children, even in the presence of relatively low hematocrits, and occurs especially in a clinical setting in which oxygen requirements are raised by fever or, if blood viscosity is increased, dehydration.

Brain Abscess.

This is an important complication of cyanotic heart disease.[49] Such abscesses are rare before 18 months of age and commonly are of insidious onset marked by headache, low-grade fever, vomiting, and a change in personality. Seizures or paralysis less frequently herald the onset of a brain abscess. Abscess must be suspected in any cyanotic child with focal neurological signs. Morbidity and mortality are related inversely to oxygen saturation levels. Brain abscess is thought to occur in about 2 percent of the population with cyanotic congenital heart disease; a mortality rate of 30 to 40 percent often is related to delay in diagnosis and treatment.

Paradoxical Embolus.

This is a rare complication of cyanotic heart disease, usually observed only at necropsy.[50] Emboli arising in systemic veins may pass directly to the systemic circulation, because right-to-left intracardiac shunts allow venous blood to bypass the normal filtering action of the lungs.

Retinopathy.

Dilated tortuous vessels progressing to papiliedema and retinal edema occasionally are observed in cyanotic patients and appear to be related to decreased arterial oxygen saturation and/or to erythrocytosis but not to hypercapnia.

Hemoptysis.

This is an uncommon but major complication in cyanotic patients with congenital heart disease; it occurs most often in the presence of pulmonary vascular obstructive disease or in patients with an extensive bronchial collateral circulation or pulmonary venous congestion.[51] Massive hemoptysis almost always represents rupture of a dilated bronchial artery.

SQUATTING.

After exertion, patients with cyanotic heart disease, especially tetralogy of Fallot, typically assume a squatting posture to obtain relief from breathlessness.[52] Squatting appears to improve arterial oxygen saturation by increasing systemic vascular resistance, thereby diminishing the right-to-left shunt, and by the pooling of markedly desaturated blood in the lower extremities. In addition, systemic venous return, and therefore pulmonary blood flow, may increase.

HYPOXIC SPELLS.

Hypercyanotic or hypoxemic spells commonly complicate the clinical course in younger children with certain types of cyanotic heart disease, especially tetralogy of Fallot.[52] The spells occur commonly in the morning and are characterized by anxiety, hyperpnea, and a sudden marked increase in cyanosis; they are the result of an abrupt reduction in pulmonary blood flow. Unless terminated, the hypercyanotic episodes may lead to convulsions and may even be fatal. The sudden reduction in pulmonary blood flow may be precipitated by fluctuations in arterial P_{CO_2} and pH, a sudden fall in

systemic or increase in pulmonary vascular resistance, or an acute increase in the severity of right ventricular outflow tract obstruction, either by augmented contraction of the hypertrophied muscle in the right ventricular outflow tract or by a decrease in right ventricular cavity volume owing to tachycardia.

Treatment.

This consists of oxygen administration, placing the child in the knee-chest position, and administration of morphine sulfate. Additional medications that may prove of value include intravenous administration of sodium bicarbonate to correct the accompanying acidemia, alpha-adrenoceptor stimulants such as phenylephrine hydrochloride (Neo-Synephrine) or methoxamine to raise peripheral resistance and diminish right-to-left shunting, and beta-adrenoceptor blocking agents, which reduce cardiac sympathetic tone, depress cardiac contractility directly, and increase ventricular volume by reducing heart rate.

ACID-BASE IMBALANCE

Disturbances in blood gas and acid-base equilibrium are noted particularly in infants with either congestive heart failure or cyanosis.[53] Large-volume left-to-right shunts, especially with pulmonary edema, may be associated with moderate respiratory acidemia and a lowering of arterial oxygen tensions, reflecting an increase in the alveolar-arterial oxygen tension gradient and ventilation-perfusion imbalance. Interference with carbon dioxide transport implies moderate to severe failure in these infants. Lesions associated with a reduced systemic cardiac output, such as severe coarctation of the aorta or critical aortic stenosis in infancy, often present as cardiac failure complicated by a severe metabolic acidemia and relatively high values of arterial oxygen tension. The latter finding, even in the presence of right-to-left shunting

across a patent ductus arteriosus, is a result of diminished systemic perfusion and an elevated pulmonary-systemic blood flow ratio.

Respiratory acidemia and depressed levels of oxygen tension are observed in infants with obstruction to pulmonary venous return and right-to-left atrial shunting. Many infants with severe hypoxemia caused by lesions such as transposition of the great arteries or pulmonic atresia show metabolic acidemia and marked reductions in carbon dioxide tension secondary to hyperventilation, resulting from hypoxic stimulation of peripheral chemoreceptors.

IMPAIRED GROWTH

Impaired growth and physical development and delayed onset of adolescence are common features of many cyanotic and, to a lesser extent, acyanotic forms of congenital heart disease.[54] [55] Mental development seldom is affected. The severity of growth disturbance depends on the anatomical lesion and its functional effect. Most children with mild defects grow normally. Weight gain is commonly slower than linear growth in acyanotic patients with large left-to-right shunts, whereas in cyanotic congenital heart disease, height and weight usually parallel each other. Boys appear to be more retarded in growth than girls, especially in the second decade of life. Skeletal maturity (i.e., bone age) is delayed in cyanotic children in relation to the severity of hypoxemia.

In some children, prenatal factors such as intrauterine infection and chromosomal or other hereditary and nonhereditary syndromes are responsible for growth retardation. In other patients, extracardiac malformations may contribute to poor weight gain and linear growth. Additional explanations for the mechanisms of growth interference have implicated malnutrition as a result of anorexia and inadequate nutrient and caloric intake, hypermetabolic state, acidemia and cation imbalance, tissue hypoxemia, diminished peripheral blood flow, chronic cardiac decompensation, malabsorption or protein loss, recurrent respiratory infections, and endocrine or genetic factors. In some instances, the underdevelopment is influenced little by operative correction of the underlying cardiac anomaly.

Among factors that may be responsible for persistent growth retardation postoperatively are age at operation, hemodynamically significant residual lesions, and sequelae or complications of operation. As a general rule, it is unwise preoperatively to guarantee to the parents of a child with heart disease that surgery will result in accelerated growth and development.

PULMONARY HYPERTENSION (See also Chap. 53)

Pulmonary hypertension is a common accompaniment of many congenital cardiac lesions, and the status of the pulmonary vascular bed often is the principal determinant of the clinical manifestations, the course, and whether surgical treatment is feasible.[56] Increases in pulmonary arterial pressure result from elevations of pulmonary blood flow and/or resistance, the latter sometimes caused by an increase in vascular tone but usually the result of underdevelopment and/or obstructive, obliterative structural changes within the pulmonary vascular bed.[57] [58] [59]

Pulmonary vascular resistance normally falls rapidly immediately after birth, owing to onset of ventilation and subsequent release of hypoxic pulmonary vasoconstriction. Subsequently, the medial smooth muscle of pulmonary arterial resistance vessels thins gradually. This latter process often is delayed by several months in infants with large aorticopulmonary or ventricular communications, at which time levels of pulmonary vascular resistance are still somewhat elevated. In patients with high pulmonary arterial pressure from birth, failure of normal growth of the pulmonary circulation may occur, and anatomical changes in the pulmonary vessels in the form of proliferation of intimal cells and intimal and medial thickening often progress, so that in an older child or adult vascular resistance ultimately may become fixed by obliterative changes in the pulmonary vascular bed. The causes of pulmonary vascular obstructive disease remain unknown, although increased pulmonary arterial blood pressure, elevated pulmonary venous pressure, polycythemia, systemic hypoxia, acidemia, and the nature of the bronchial circulation all have been implicated. Quite likely, injury to pulmonary vascular endothelial cells initiates a cascade of events that involve the release or activation of factors that alter the extracellular matrix, induce hypertrophy, cause proliferation of vascular smooth muscle cells, and promote connective tissue protein synthesis. Considered together, these may permanently alter vessel structure and function.[60] [61]

Many patients with pulmonary vascular obstruction have a cardiac anomaly that places them at particular risk early in life, precluding survival to adulthood. Patients at particularly high risk for the development of significant pulmonary vascular obstruction are those with certain forms of cyanotic congenital heart disease, such as complete transposition of the great arteries with or without VSD or patent ductus arteriosus, single ventricle without pulmonary stenosis, double-outlet right ventricle, and truncus arteriosus.[62] Other conditions in which pulmonary vascular obstruction appears to progress rapidly include large VSD, as well as the less common conditions of unilateral pulmonary artery absence, congenital left-to-right shunts in an environment of high altitude or in association with the Down syndrome of trisomy 21, and complete AV canal defects, even those unassociated with a chromosomal anomaly.

MECHANISMS OF DEVELOPMENT.

Intimal damage appears to be related to shear stresses because endothelial cell damage occurs at high-flow shear rates. A reduction in pulmonary arteriolar lumen size due to either thickened medial muscle or vasoconstriction increases the velocity of flow. Shear stress also increases as blood viscosity rises; therefore, infants with hypoxemia and high hematocrits as well as increased pulmonary blood flow are at increased risk of developing pulmonary vascular disease. In patients with left-to-right shunts, pulmonary arterial hypertension, if not present in infancy or childhood, may never occur or may not develop until the third or fourth decade or later. Once developed, intimal proliferative changes with hyalinization and fibrosis are not reversible by repair of the underlying cardiac defect. In severe pulmonary vascular obstructive disease, arteriovenous malformations may develop and predispose to massive hemoptysis.

Most vexing is the variability among patients with the same or similar cardiac lesions in both the time of appearance and rate of progression of their pulmonary vascular obstructive process. Although genetic influences may be operative (an example is the apparent acceleration of pulmonary vascular disease in patients with congenital heart disease and trisomy 21), evidence is now accumulating for important prenatal and postnatal modifiers of the pulmonary vascular bed that appear, at least in part, to be lesion dependent. Thus, a quantitative variability exists in the pulmonary vascular bed related to the *number,* not just the size and wall structure, of arterial vessels within the pulmonary circulation.[63] [64]

Modeling of the blood vessels occurs proximal to and within terminal bronchioles (preacinar and intraacinar vessels, respectively) continuously from before birth. The intraacinar vessels, in particular, increase in size and number from late fetal life throughout childhood, with minimal muscularization of their walls. The ensuing increase in the cross-sectional area of the pulmonary arterial circulation allows

the cardiac output to rise substantially without an increase in pulmonary arterial pressure. If, however, the presence of a cardiac lesion interferes with the normal growth and multiplication of these most peripheral arteries, the resulting elevation of pulmonary vascular resistance may first be related to failure of the Intraacinar pulmonary circulation to develop fully, and then secondarily to the morphological changes of obliterative vascular disease--medial thickening, intimal proliferation, hyalinization and fibrosis, angiomatoid and plexiform lesions, and ultimately, arterial necrosis.[59]

In essence, the morphometric framework adds an important dimension--that of growth and development of the pulmonary circulation--to the traditional view of pulmonary vascular obstructive disease occurring primarily as a result of anatomical changes in the individual pulmonary arterioles. Research attention currently focuses on the cellular and molecular biology of the vessel wall and abnormalities in endothelial cell-smooth muscle interactions in pulmonary hypertension.

ASSESSMENT OF THE PATIENT WITH PULMONARY HYPERTENSION.

It is important to understand the difficulties that exist with standard methods of assessing the severity of pulmonary vascular obstructive disease. Clinical and electrocardiographic (ECG) observations do not distinguish between reversible and irreversible elevations in pulmonary vascular resistance. Echocardiography and Doppler interrogation of the heart may enable one to diagnose the presence of pulmonary hypertension but do not provide an accurate estimate of pressure or a reliable calculation of pulmonary vascular resistance. The pulmonary systolic pressure is predicted from the velocity of tricuspid regurgitation using the modified Bernoulli equation, which is susceptible to error if the right atrial pressure is elevated. The mean pulmonary regurgitant velocity can also be relatively predictive of the mean pulmonary artery pressure. Thus, hemodynamic measurements at cardiac catheterization are the mainstay in assessing the pulmonary vascular bed, especially its reactivity. The premium on accuracy is high because the presence, degree, and reactivity of pulmonary vascular obstruction determine the feasibility and long-term outcome of operation. Surgery must not be offered to patients with severe, fixed pulmonary vascular obstruction, even when the cardiac defect is anatomically correctable. Such patients either do not survive operation or, if they do, are not benefited and more often than not are harmed.

The aims of hemodynamic study are to quantify and compare the pulmonary and systemic flows and resistances and to determine the reactivity of the pulmonary vascular bed in patients with pulmonary hypertension. Because resistance to pulmonary blood flow cannot be measured directly, it is calculated from the ratio of pressure gradient to flow across the pulmonary bed according to Poiseuille's equation, which refers to steady flow of a newtonian fluid through straight, rigid tubes.

There are potential errors in applying the equation and errors inherent in the methods of measurement. Furthermore, it is not possible in every patient to catheterize the pulmonary artery; when this is the case, pulmonary venous wedge pressures may be used, but they are not always reliable indicators of pulmonary artery pressure, and the moment of hemodynamic evaluation may not be representative of potentially variable states of the pulmonary circulation. Nonetheless, a practical index of pulmonary vascular resistance can be established from measurements of pulmonary and systemic arterial pressures and calculated flows. One can then determine whether administration of drugs or oxygen or nitric oxide reduces the pulmonary vascular resistance, implying that the resistance is not fixed and therefore may decrease or at least not progress after successful operation.[65] A reduction in calculated pulmonary vascular resistance in response to oxygen or nitric oxide inhalation or pharmacological intervention does not preclude coexisting anatomical pulmonary vascular disease but does imply a component of potentially reversible vasoconstriction contributing to the high resistance.

OTHER DIAGNOSTIC METHODS.

Because of the aforementioned shortcomings, additional methods have been developed to study the morphology of the small pulmonary arteries in patients with pulmonary hypertension. An example is the use of high-resolution magnification for *pulmonary wedge angiography* to determine the presence and extent of obstructive pulmonary vascular changes.[66] Pulmonary wedge angiograms, assessed quantitatively, appear to correlate well with both hemodynamic findings and histological observations of the structural state of the pulmonary vascular bed. Of additional interest is the current practical application of morphometric structural analyses that attempt to identify for operation patients whose postoperative pulmonary hemodynamics might be expected to improve, if not normalize.[67] Thus, preoperative or intraoperative *lung biopsy* has been proposed for patients with equivocal hemodynamic data to aid in determining whether to proceed with operation in reasonable anticipation of postoperative regression of elevated pulmonary vascular resistance.[68]

THE MORPHOMETRIC APPROACH.

Decisions on optimal timing of operations often are difficult because of the varying rates of development of pulmonary vascular disease in different patients with the same anomaly and because evaluation of pulmonary vascular resistance and reactivity in the catheterization laboratory is a less than perfect science. Preoperative lung biopsy using the Heath-Edwards criteria has enjoyed little popularity, especially because sampling errors may result from the scatter of different grades of lesion in different parts of the lung. Accordingly, it is attractive to seek an alternative method that would obviate these problems. In this regard, application of a morphometric approach holds promise because the described changes in pulmonary vessel morphological characteristics are more uniformly distributed throughout the lung and, importantly, lend themselves to quantification.

Three abnormalities have been identified as anatomical markers of elevated pulmonary vascular resistance: (1) an excessive and premature extension of vascular smooth muscle into intraacinar pulmonary arteries, (2) failure of preacinar arterial wall thickness to regress normally, and (3) failure of pulmonary arteries to grow and proliferate normally during postnatal development. Frozen-section lung biopsy provides a firmer basis for judgment of whether reparative or palliative operation should proceed. The technique has proved useful in patients with univentricular hearts or tricuspid atresia in determining the feasibility of a Fontan procedure and in patients with lesions known to exhibit early and rapidly progressive pulmonary vascular disease such as complete transposition of great arteries, complete AV canal defect, and nonrestrictive VSD.[68] [69]

CLINICAL MANIFESTATIONS OF PULMONARY HYPERTENSION.

When this condition is associated with a large left-to-right shunt, the clinical manifestations reflect the specific malformation responsible. When pulmonary vascular resistance is elevated and a significant right-to-left shunt exists, the patient is cyanotic, and polycythemia and clubbing are noted. A dominant *a* wave in the jugular venous pulse may be seen, reflecting vigorous right atrial contraction caused by diminished compliance of the right ventricle. In some instances there are large systolic *c-v* waves, which suggest tricuspid regurgitation. A prominent right ventricular parasternal lift and palpable systolic expansion of the pulmonary artery are present. A soft pulmonary systolic ejection murmur preceded by an ejection sound and followed by a markedly accentuated pulmonic component of the second heart sound often is audible on auscultation; an early diastolic decrescendo blowing murmur of pulmonary regurgitation may be heard. If right ventricular failure and dilatation supervene, the systolic murmur of tricuspid regurgitation may be audible at the lower left sternal border. Right ventricular enlargement may be evident on the chest roentgenogram and ECG. The former examination also reveals a conspicuously enlarged pulmonary artery, prominent hilar pulmonary vascular markings, and attenuated peripheral vessels. The presence of pulmonary hypertension is suggested by analysis of Doppler waveforms of right and left ventricular ejection. The site of the underlying defect may be localized by means of two-dimensional and Doppler echocardiography and/or cardiac catheterization and angiocardiography. Pressures in the right side of the heart are essentially identical to systemic pressures in cyanotic patients if the shunt is at the ventricular or aorticopulmonary

levels, but they usually are lower than systemic pressures in patients with an intraatrial shunt. Efforts continue to identify a specific treatment for obstructive pulmonary vascular disease.[70] [71]

This fact underscores the importance of efforts to define the optimal age at operation to provide the highest probability of postoperative normalization of the pulmonary vascular bed. It is important to emphasize that almost all congenital cardiovascular defects are amenable to surgical repair in infancy, and it is likely that the surgical art will progress to the point that virtually all patients with lesions associated with pulmonary hypertension will be operated on within the first 3 to 18 months of life. When this goal is reached without increased operative mortality, the incidence of postoperative pulmonary vascular obstruction may well achieve the status of a bygone concern.

OTHER CONSEQUENCES OF CONGENITAL HEART DISEASE

INFECTIVE ENDOCARDITIS (see also Chap. 47).

Infective endocarditis is uncommon before age 2 years and thereafter most often affects children with tetralogy of Fallot (especially after systemic-pulmonary anastomosis), VSD, aortic stenosis, and patent ductus arteriosus. Postsurgical patients with prosthetic heterograft or homograft valves or conduits are at particular risk. Infants and children with normal cardiac anatomy are at increased risk now that the use of central venous catheters is routine, and drug addiction in adolescents is an emerging risk factor.[72]

A causative organism can be isolated in about 90 percent of children, usually either alpha streptococci (usually *Streptococcus viridans*) or *Staphylococcus aureus,* although uncommon organisms may also be identified.[73] [74] [75] Fungal endocarditis is quite rare in the pediatric age group. Mortality appears to be highest when coagulase-positive *Staphylococcus* is the offending organism and when the endocarditis involves the left, rather than the right, side of the heart. Most recent data suggest 75 to 80 percent overall survival. Factors predisposing to endocarditis may be identified in about one-third of cases. These include cardiovascular surgery with infection during the perioperative period, respiratory tract infections, and ear, nose, throat, and dental procedures. Less often, contamination during a surgical procedure or cardiac catheterization or an infection involving the skin, genitourinary tract, or other organ system has been the cause.

Although routine antimicrobial prophylaxis is recommended for all children with congenital heart disease and for the majority of patients alter operative repair of the lesion,[74] [74A] it should be recognized that many different microbes are responsible for the disease and that an effective preventive approach ultimately may center on active immunization rather than antibiotics. Antibiotic prophylaxis currently is recommended for all dental procedures known to induce gingival or mucosal bleeding, including cleaning, oral trauma, and other procedures such as tonsillectomy, gastrointestinal surgery, genitourinary surgery, and incision and drainage of infected tissue (Table 43-4) . The risk of endocarditis is undoubtedly related both to the magnitude of bacteremia and to the type of underlying heart disease. Because infection on a prosthetic heart valve or conduit may be devastating, combinations of antibiotics given parenterally are advisable in these patients.

CHEST PAIN (see also Chap. 3).

Angina pectoris is an uncommon symptom of cardiac disease in infants and children, occurring in association with anomalous pulmonary origin of a coronary artery or, occasionally, in association with severe aortic stenosis, pulmonic stenosis, or pulmonary hypertension owing to pulmonary vascular obstruction. Cardiac pain in infants with anomalous coronary artery usually takes the form of irritability and crying during feeding or straining at bowel movement. In children with severe or right ventricular outflow tract obstruction, chest pain commonly follows effort and is identical to angina observed in adults. Cardiac pain associated with *pulmonary vascular obstruction* may be anginal in nature but often is evanescent and pleuritic in type. Atypical forms of chest pain associated with the syndrome of *mitral valve prolapse* are much less usual in children than in adults. A sensation of chest discomfort or cardiac awareness frequently is interpreted as pain by the parents of children with cardiac arrhythmias. Careful questioning serves to identify palpitations rather than pain as the symptom and often elicits an additional history of anxiety, pallor, and sweating. Pain caused by *pericarditis* is commonly of acute onset and associated with fever, and it can be identified by specific physical, roentgenographic, and

echocardiographic findings.

Most commonly, chest pain in children is *musculoskeletal* in origin and may be reproduced on upper extremity movement or by palpation; chest wall pain often is the result of *costochondritis.* [75] Finally,

TABLE 43-4 -- PROPHYLACTIC ANTIBIOTICS FOR PROTECTION FROM BACTERIAL ENDOCARDITIS

PROPHYLACTIC REGIMENS FOR DENTAL, ORAL, RESPIRATORY TRACT, OR ESOPHAGEAL PROCEDURES*

Standard General Prophylaxis for Patients at Risk

Amoxicillin: adults, 2.0 gm (children, 50 mg/kg) PO 1 hr before procedure.

Unable to Take Oral Medications

Ampicillin: adults, 2.0 gm (children, 50 mg/kg) IM or IV within 30 min before procedure.

Amoxicillin/Ampicillin/Penicillin-Allergic Patients

Clindamycin: Adults, 600 mg (children, 20 mg/kg) PO 1 hr before procedure.

or

Cephalexin* or cefadroxil
: adults, 2.0 gm (children, 50 mg/kg) PO 1 hr before procedure.

or

Azithromycin or clarithromycin: Adults, 500 mg (children, 15 mg/kg) PO 1 hr before procedure.

Amoxicillin/Ampicillin/Penicillin-Allergic Patients Unable to Take Oral Medications

Clindamycin: adults, 600 mg (children, 20 mg/kg) IV within 30 min before procedure.

or

Cefazolin: adults, 1.0 gm (children, 25 mg/kg) IM or IV within 30 min before procedure.

PROPHYLACTIC REGIMENS FOR GENITOURINARY/GASTROINTESTINAL PROCEDURES

High-Risk Patients

Ampicillin plus gentamicin: ampicillin (adults, 2.0 gm; children, 50 mg/kg) plus gentamicin 1.5 mg/kg (for both adults and children, not to exceed 120 mg) IM or IV within 30 min before starting procedure. 6 hr later, ampicillin (adults, 1.0 gm; children, 25 mg/kg) IM or IV, or amoxicillin (adults, 1.0 gm; children, 25 mg/kg) PO.

High-Risk Patients Allergic to Ampicillin/Amoxicillin

Vancomycin plus gentamicin: vancomycin (adults, 1.0 gm; children, 20 mg/kg) IV over 1-2 hr plus gentamicin 1.5 mg/kg (for both adults and children, not to exceed 120 mg) IM or IV. Complete injection/infusion within 30 min before starting procedure.

Moderate-Risk Patients

Amoxicillin: adults, 2.0 gm (children, 50 mg/kg) PO 1 hr before procedure.

or

Ampicillin: adults, 2.0 gm (children, 50 mg/kg) IM or IV within 30 min before starting procedure.

Moderate-Risk Patients Allergic to Ampicillin/Amoxicillin

Vancomycin: adults, 1.0 gm (children, 20 mg/kg) over 1-2 hr. Complete infusion within 30 min before starting procedure.

*Follow-up dose no longer recommended.

Total children's dose should not exceed adult dose.

Cephalosporins should not be used in patients with immediate-type hypersensitivity reaction to penicillins.

children, like adults, may suffer chest pain of nonspecific form owing to *anxiety,* with or without hyperventilation; a history often is elicited of a family member or friend who had recently died of or suffered myocardial infarction.

SYNCOPE (see also Chap. 27).

Syncope is an unusual feature of heart disease in children; its presence suggests specific diagnoses, the most common being an arrhythmia. The symptom is observed in patients with long QT syndrome and in children with complete AV block that is less often of congenital origin than a sequela of cardiac

operation. Syncope caused by abrupt episodes of either bradycardia or tachycardia occurs in association with the sick sinus syndrome. The latter is most commonly produced in children after surgical procedures that involve the region of the sinoatrial node, e.g., atrial septal defect closure or Mustard's venous switch procedure for transposition of the great arteries. Syncope is an occasional but ominous symptom if associated with severe aortic stenosis, pulmonary vascular obstruction, or a left atrial myxoma that transiently occludes left ventricular inflow.[76]

In children with an anatomically normal heart, transient episodes of vasovagally mediated hypotension and bradycardia (neurocardiogenic syncope) may be diagnosed by autonomic function testing and head-upright tilt-table testing (see Chap. 27). The latter is especially helpful in assessing the adequacy of prophylactic therapy, usually by volume expansion (e.g., salt and fludrocortisone), or by beta-adrenergic blockade or alpha-adrenergic agonist or serotonin reuptake inhibitor therapy.[77]

SUDDEN DEATH (see also Chap. 24).

The sudden infant death syndrome is not likely due to a cardiac cause but rather to pulmonary and/or central nervous system causes. In contrast to adults, children seldom die suddenly and unexpectedly of cardiovascular disease.[78] Arrhythmias, hypoxemia, and coronary insufficiency secondary to left ventricular outflow tract obstruction are the most frequent causes of death. Sudden death most often is reported in patients with postoperative heart disease or dilated cardiomyopathy. It is also observed in patients with aortic stenosis or hypertrophic obstructive cardiomyopathy, primary pulmonary hypertension, Eisenmenger's syndrome of pulmonary vascular obstruction, myocarditis, congenital complete heart block, primary endocardial fibroelastosis, anomalies of the coronary arteries, and cyanotic congenital heart disease with pulmonic stenosis or atresia. A relation exists between strenuous exercise and sudden death in patients with aortic stenosis or obstructive cardiomyopathy, thus providing justification for restricting patients with these lesions from gymnastic activities and strenuous competitive sports.[79]

Congenital long QT syndrome is most often inherited as an autosomal dominant trait and is associated with malignant arrhythmias. It is characterized by a prolonged Q-T interval in the surface ECG, syncope, seizures, and sudden death caused by ventricular tachyarrhythmias. On a molecular level, a great many mutations in four ion channel genes have thus far been identified in these patients[80] (see chaps. 23 and 25).

The High-Risk Infant with Congenital Heart Disease

Without prompt recognition, accurate diagnosis, and treatment, about one-third of all infants born with congenital heart disease die in the first months of life. Heart failure and cyanosis are the two cardinal signs in high-risk infants with heart disease, and this section provides an approach to the management of each.

HEART FAILURE

Care of infants with heart failure must include careful consideration of the underlying structural or functional disturbance. The general aims of treatment are to achieve an increase in cardiac performance, augment peripheral perfusion, and decrease pulmonary and systemic venous congestion.[37] It must be emphasized, however, that under many conditions medical management cannot control the effects of the abnormal loads imposed by a host of congenital cardiac lesions. Under these circumstances, cardiac diagnosis and interventional catheter or operative intervention may be urgently required. Thus, initial therapy is aimed at stabilizing an infant's condition for diagnostic ultrasonography or hemodynamic or angiocardiographic study as soon as possible. In almost all situations, the decision to intervene surgically or to continue medical management requires a definitive anatomical diagnosis.

RESERVE MECHANISMS IN THE NEONATAL HEART

Pediatricians in particular should be aware of the important concept of cardiac reserve because it is in this regard that important differences exist between the young heart (of the preterm or newborn infant) and the fully developed heart of the older child, adolescent, and adult (Fig. 43-5) .

Clinicians have long recognized the unique fragility and lability of the neonatal circulation in response to disease states and various physiological stimuli. Moreover, it often is apparent that newborns may exhibit suboptimal therapeutic responses to drugs such as digitalis, which directly stimulate cardiac contractility. The age dependence of these observations has its basis in the reduced ability of the hearts of premature and full-term newborns, when compared with the hearts and circulation of older children or adults, to call on a functional reserve capacity to adapt to stress.[37] [81] [82]

Studies from our and other laboratories have shown that structural, functional, biochemical, and pharmacological properties of the young heart differ considerably from those of its older counterpart.[21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] The young heart contains fewer myofilaments to generate force with and to shorten during contraction. In addition, the chamber stiffness of the young heart's ventricles is greater than that later in life.

PRELOAD RESERVE.

Any increase in ventricular filling or volume in the small, young heart results in a disproportionately greater rise in

Figure 43-5 Schema of reduced cardiac reserve in fetal and newborn hearts compared with an adult's. In a newborn infant, resting cardiac muscle performance *(top panel)* is close to the peak of ventricular function because of limitations in diastolic, systolic, and heart rate reserve. Similarly, pump reserve *(bottom panel)* early in life is limited by these factors, as well as by a much higher resting cardiac output relative to body weight, compared with an adult.

ventricular wall tension or stress. Similarly, it takes a smaller increase in ventricular filling to reach the limits of assistance given to cardiac pump and muscle function by stretching the myofilaments; that is, *preload or diastolic reserve is limited.*

The young heart generates relatively less force; it cannot generate the same ventricular systolic pressure or wall tensions, or obtain the same stroke volume augmentation from any initial stretch, as can the older heart. With these facts in mind, it must be remembered that the oxygen consumption of a normal newborn is considerably higher than later in life; accordingly, a newborn at rest has a much higher cardiac output per square meter than a child or adult. Thus, even in the absence of stress, the young heart must function near peak performance just to satisfy the normal demands of the peripheral tissues. Because newborn cardiac performance at rest is so close to its celling, or limits of function, little *systolic reserve* is available to adapt to an acute or chronic stress such as pressure or volume load from an obstructive lesion or left-to-right circulatory shunt, respectively, or asphyxia.

HEART RATE RESERVE.

This consists of the ability of the heart to change its rate of pumping to raise the level of cardiac output. In this regard, newborns also are limited because in this age group the intrinsic heart rate normally is high. In addition, heart failure per se raises the frequency of contraction even further, primarily as a result of high circulating levels of catecholamines. In this sense, a newborn's heart rate also is closer than a child's or adult's to its ceiling, or upper limits of effectiveness. Furthermore, increases in heart rate occur largely at the expense of diastolic filling time. Thus, at very rapid heart rates, there is a disproportionately diminished diastolic time and therefore diminished time for perfusion of the myocardium by its own coronary arterial system. In addition. rapid heart rates result in elevated myocardial energy expenditure and increased myocardial demand for oxygen. The sum of these considerations indicates that newborn *heart rate reserve* is reduced.

TREATMENT (see also Chap. 18).

Table 43-5 lists supportive and pharmacological measures in the treatment of newborns with heart failure. The supportive measures are designed to increase tissue oxygen supply, decrease tissue oxygen consumption, and correct metabolic abnormalities. Digitalis glycosides, preload reduction with certain diuretic agents, and afterload reduction with angiotensin-converting enzyme inhibitors provide the most important elements of medical therapy, but it is important to recognize that the

TABLE 43-5 -- TREATMENT OF CONGESTIVE HEART FAILURE

GENERAL INTERVENTIONS
Rest (occasional sedation)
Semi-Fowler's position
Temperature and humidity control
Oxygen
Decrease sodium load

Avoid aspiration	
Treat infection, if present	
SPECIFIC INTERVENTIONS	
Preload manipulation	
Move ventricular function curve up by volume infusion to increase venous return	
Move ventricular function curve down with diuretics, venodilators	
Afterload reduction	
Facilitate ventricular emptying by reducing wall tension	
Reduce blood viscosity	
Drugs, arteriolar dilators, mechanical counterpulsation	
Inotropic stimulation	
Improve physical and metabolic milieu: pH, Pa_{O_2}, glucose, calcium, hemoglobin	
Inotropic drugs: digitalis, catecholamines, dobutamine, dopamine, levodopa	
Heart rate	
Control rhythm disturbances with pacing, drugs	
Other	
Mechanical ventilation	
Prostaglandin manipulation	
Peritoneal dialysis	
INTERVENTIONAL CATHETER-DIRECTED THERAPY or SURGERY (may include transplantation)	

TABLE 43-6 -- DIURETIC AND DIGITALIS DOSAGES FOR INFANTS

PREPARATION	DOSAGE AND ROUTE OF ADMINISTRATION
Furosemide	IV, 1 mg/kg/dose; PO, 2-6 mg/kg/d
Ethacrynic acid	IV, 1 mg/kg/dose; PO, 2-3 mg/kg/d
Hydrochlorothiazide	PO 2-5 mg/kg/d
Spironolactone	PO 1-3 mg/kg/d
Triamterene	PO 2-4 mg/kg/d
Digoxin	
Elixir	0.05 mg/ml
Parenteral	0.10 mg/ml

AGE AND WEIGHT	DOSE AND ROUTE*	
	Acute Digitalization	Maintenance
Premature <1.5 kg	10-20 mug/kg IV TDD: ½, ¼, ¼ of dose q8h	4 mug/kg/d IV (may increase to 4 mug/kg q12hr at age 1 mo)
1.5-2.5 kg	Same as above	4 mug/kg q12hr IV
Full-term newborns	30 mug/kg IV, TDD	4-5 mug/kg q12hr IV
Infants (1-12 mo)	35 mug/kg IV, TDD	5-10 mug/kg q12hr IV
>12 mo	40 mug/kg IV, TDD (maximum 1.0 mg)	5-10 mug/kg q12hr IV
Older children (>20 kg)	1.0-2.0 mg IV, TDD	0.125-0.250 mg IV
	over 48 hr	qd

TDD=Total digitalizing dose.

*PO=Oral dose approximately 20 percent greater than IV dose except in "older children." In older children, IV=oral dose.

dosage regimen of drugs administered to young patients must be adjusted to take into account the age and size of the patient and the maturity-dependent pharmacological properties of cardioactive drugs. Because this is especially true in early infancy, Table 43-6 provides the dosages of digoxin and diuretics commonly used for infants.

Digitalis and Diuretics.

Digoxin is the glycoside used exclusively to treat pediatric patients in most cardiac centers because it is readily absorbed, available in convenient dosage form, and excreted rapidly from the body. The efficacy and safety of digitalis remain topics of debate, although on balance, continued use is warranted. Premature infants are more sensitive to digitalis than are full-term newborns, who, in turn, are more sensitive than older infants. Infants absorb and excrete digoxin as well as adults do, and their relative distribution of the glycoside to different body tissues is also similar. The prevailing dose schedules for digoxin produce higher serum concentrations in infants than would be considered optimal for adults.[83] The basis for the higher digitalis requirement in infancy is unclear, although it may relate to an age-dependent alteration in the sensitivity of the myocardium per se to the glycosides. In this regard, infants tolerate higher serum digoxin concentrations than adults without developing signs of toxicity. In adults, the usual therapeutic concentrations of digoxin are less than 2 ng/ml blood, and toxicity commonly occurs above that level. In contrast, in infants, therapeutic levels of digoxin range from 1 to 5 ng/ml (mean = 3.5), and toxicity is associated with concentrations in excess of 3 ng/ml. Older children have therapeutic and toxic levels similar to those of adults.[84]

A restricted fluid intake (65 ml/kg/day) and a low-sodium diet (1 to 2 mEq/kg/day) should accompany diuretic therapy in the most seriously ill infants with heart failure. Furosemide is the agent of choice when the rapid elimination of excess salt and water is needed. Hydrochlorothiazide, occasionally in conjunction with spironolactone or triamterene to reduce potassium loss and sodium retention, is convenient for long-term therapy.

TABLE 43-7 -- DOSAGE REGIMENS: INOTROPIC AGENTS

DRUG	DOSE	COMMENTS
Epinephrine (Adrenalin)	0.05-1.0 mug/kg/min IV	May cause hypertension and cardiac arrhythmias; inactivated in alkaline solution
Isoproterenol (Isuprel)	0.05-0.5 mug/kg/min IV	May decrease coronary blood flow; results in peripheral and pulmonary vasodilation

Norepinephrine (Levophed)	0.05-0.5 mug/kg/min IV	Causes significant vasoconstriction
Dobutamine (Dobutrex)	2-10 mug/kg/min IV (max 40 mug/kg/min)	No direct effect on renal perfusion, little or no peripheral vasodilatation or tachycardia
Dopamine (Intropin)	2-20 mug/kg/min IV (max 50 mug/kg/min)	Significant renal vasodilatation
	2-5 mug/kg/min	Inotropic±heart rate acceleration
	5-8 mug/kg/min	Significant heart rate acceleration
	>8 mug/kg/min	±Vasoconstriction
	>10 mug/kg/min	Significant vasoconstriction
	15-20 mug/kg/min	
Levodopa	40-80 mg/kg/d PO; maximum single dose 1 gm q6h	Administer with pyridoxine 0.7 mg/kg/d (maximum 25 mg) and metoclopramide 0.1 mg/kg/dose, 1 hr before levodopa dose
	(Above dose/effect relations speculative in neonates)	
Amrinone	Dose schedule not well established for infants and children	May cause thrombocytopenia, hepatic and gastrointestinal disturbance, fever, and arrhythmias
	40-75 mug/kg/min IV for 2-3 min, then maintenance at 3-10 mug/kg/min; Dose not to exceed 10 mg/kg/24 hr	
Milrinone	Dose schedule not established for infants and children	See Amrinone
	Adults: bolus 50 mug/kg maintenance 0.375-0.75 mug/kg/min	

Modified from Friedman WF, George BL: New concepts and drugs in the treatment of congestive heart failure. Pediatr Clin North Am 31:1197, 1984.

Other Pharmacological Approaches.

These may prove to be of significant benefit in selected instances in which digitalis and diuretics are relatively ineffective. In situations in which cardiac decompensation is not the result of an obstructive lesion, catecholamines may be used temporarily to alleviate cardiac failure while the patient is awaiting more definitive operative treatment (Table 43-7) .[81] In infants with the coarctation of the aorta syndrome, in whom ductal constriction unmasks the aortic branch point, producing aortic narrowing, or with aortic arch interruption, heart failure may be reversed dramatically by intravenous infusion of prostaglandin E_1 (0.03 to 0.1 mg/kg/min), which results in dilatation of the ductus arteriosus and relief of the obstruction.[85] Conversely, in preterm infants in whom patent ductus arteriosus is responsible for profound cardiopulmonary deterioration, constriction of the ductus arteriosus may be accomplished by inhibition of prostaglandin synthesis with the nonsteroidal anti-inflammatory agent indomethacin (0.2 mg/kg intravenously).[86] [87]

Vasodilator therapy also is used in infants or children with heart disease in whom preload or afterload alterations may be expected to improve cardiac performance (Table 43-8) .[81] [88] Moreover, treatment of severe cardiac failure often requires combining inotropic and afterload-reducing agents (see Chap. 18). Combinations of dopamine, dobutamine, and nitroprusside have been used extensively and effectively in the pediatric population, primarily in the setting of low cardiac output after open-heart surgery.[89] [90] Use of oral afterload-reducing agents, e.g., hydralazine or captopril, in association with digoxin is worthwhile in the long-term therapy of outpatients with congestive cardiomyopathy and/or significant mitral or aortic regurgitation.[88]

Rapid developments in molecular biology have begun to revolutionize our understanding of cardiovascular regulation, both before and after birth and at all ages. As knowledge is gained about the mechanisms responsible for the variability of gene expression in the heart, it is apparent that the future holds the opportunity for clinicians to modify

TABLE 43-8 -- DOSAGE REGIMENS: VASODILATORS IN INFANTS AND CHILDREN

DRUG	DOSE AND ROUTE OF ADMINISTRATION	COMMENTS
Nitroglycerin	0.5-20 mug/kg/min IV (max 60 mug/kg/min IV)	Dosage schedule for IV and other routes of administration not well established for children
Hydralazine (Apresoline)	0.5 mg/kg/d PO q6-8hr (max 200 mg/d or 7 mg/kg/d)	May cause tachycardia, gastrointestinal symptoms, neutropenia, lupus-like syndrome
	1.5 mug/kg/min IV or 0.1-0.5 mg/kg/dose IV q6hr (max 2 mg/kg q6hr)	
Captopril (Capoten)	0.1-0.4 mg/kg/dose PO given q6-24hr as needed	May cause neutropenia/proteinuria
Enalopril (Vasotec)	0.1 mg/kg/24 hr PO; increase as needed over 2 wk (max 0.5 mg/kg/24 hr IV: 0.01 mg/kg/dose q8-24 hr)	
Nitroprusside (Nipride)	0.5-8 mug/kg/min IV	May result in thiocyanate or cyanide toxicity if used in high doses or for prolonged periods; light sensitive
Prazosin (Minipress)	1st dose: 5 mug/kg PO (max 25 mug/kg/dose q6hr)	Initial dose used to elevate hypotensive effects; orthostatic hypotension, attenuation of hemodynamic effects may occur

Modified from Friedman WF, George BL: New concepts and drugs in the treatment of congestive heart failure. Pediatr Clin North Am 31:1197, 1984.

gene expression in ways that will importantly enhance the heart's ability to respond to both the heart failure state and those diseases that are responsible for the abnormalities leading to cardiac disease.[91]

CYANOSIS (See also p. 1617)

Cyanosis in infants often presents as a diagnostic emergency, necessitating prompt detection of the underlying cause. The schema in Figure 43-6 outlines a general approach to diagnosis. The cardiologist must distinguish between three types of cyanosis--peripheral, differential, and central--while recognizing that cyanosis may accompany diseases of the central nervous, hematological, respiratory, and cardiac systems.

PERIPHERAL CYANOSIS.

Peripheral cyanosis (normal arterial oxygen saturation and widened arteriovenous oxygen differences) usually indicates stasis of blood flow in the periphery. The level of reduced hemoglobin in the capillaries of the skin usually exceeds 3 gm/100 dl. The most prominent causes of peripheral cyanosis in newborns are autonomically controlled alterations in the cutaneous distribution of capillary blood flow (acrocyanosis) and septicemia associated with evidence of a low cardiac output, i.e., hypotension, weak pulse, and cold extremities. In many instances, peripheral cyanosis is clearly the result of a cold environment or high hemoglobin content. When cyanosis is caused by the former, vasodilatation produced by immersing the extremity in warm water for several minutes reverses the cyanosis.

CENTRAL CYANOSIS.

Oxygen unsaturation in central cyanosis may result from inadequately oxygenated pulmonary venous blood, in which case inhalation of 100 percent oxygen may diminish or clear the discoloration (discussed later). Conversely, in instances in which cyanosis is due to an intracardiac or extracardiac right-to-left shunt, pulmonary venous blood is fully saturated, and inhalation of 100 percent oxygen usually does not improve the infant's color. It is necessary to qualify the latter statement because oxygen may act directly in infants with elevated pulmonary vascular resistance to dilate the pulmonary blood vessels and thus reduce the magnitude of the venoarterial

shunt. Central cyanosis also may be due to the replacement of normal by abnormal hemoglobin, as in methemoglobinemia.

Several factors influence the oxygen saturation produced at any given arterial P_{O_2} . These include temperature, pH, ratio of fetal to adult hemoglobin, and erythrocyte concentration of 2,3-diphosphoglycerate. For example, fetal hemoglobin has a higher affinity for oxygen than does adult hemoglobin and therefore would be more highly saturated at any given P_{O_2} . Thus, determination of the systemic arterial oxygen tension may provide a more accurate picture of the underlying pathophysiology than simply measuring the oxygen saturation.[46] [92]

DIFFERENTIAL CYANOSIS.

Differential cyanosis virtually always indicates the presence of congenital heart disease, often with patency of the ductus arteriosus and coarctation of the aorta as components of the abnormal anatomical complex. If the upper part of the body is pink and the lower part of the body blue, coarctation of the aorta or interruption of the aortic arch is probable, with oxygenated blood supplying the upper body and desaturated blood supplying the lower body by way of right-to-left flow through the ductus arteriosus. The latter also occurs in patients with patent ductus arteriosus and markedly elevated pulmonary vascular resistance. A patient with transposition of the great arteries and coarctation of the aorta with retrograde flow through a patent ductus arteriosus demonstrates the reverse situation, i.e., the lower part of the body is pink and the upper part blue. Simultaneous determinations of oxygen saturation in the temporal or right brachial artery and the femoral artery are helpful in confirming the presence of differential cyanosis.

Differentiating Between Pulmonary and Cardiac Causes of Cyanosis

The distinction between respiratory signs and symptoms arising from cyanotic cardiac disease and those associated with a primary pulmonary disorder is an important challenge to the cardiologist.[41] Upper airway obstruction precipitates cyanosis by producing alveolar hypoventilation owing to reduced pulmonary ventilation. Mechanical obstruction may occur from the nares to the carina, and the important diagnostic possibilities among congenital abnormalities are choanal atresia, vascular ring, laryngeal web, and tracheomalacia. Acquired causes include vocal cord paresis, obstetrical injury to the cricothyroid cartilage, and

Figure 43-6 Flow chart for the evaluation of cyanotic infants. Tests to be done are listed at the left. The response to each of these tests leads along the line to the proper diagnostic category. CHD = congenital heart disease; CHF = congestive heart failure; CNS = central nervous system; Hct = hematocrit; PDA = patent ductus arteriosus; T/GA = transposition of great arteries; Coarct=coarctation; Rm=room. *(From Kirkpatrick SE, Friedman WF, Pitlick P, et al: Differential diagnosis of congenital heart disease in the newborn--University of California, San Diego, School of Medicine, and University Hospital, San Diego [Specialty Conference]. West J Med 128:127, 1978.)*

TABLE 43-9 -- ARTERIAL BLOOD GAS PATTERNS IN VARIOUS DISORDERS CAUSING CYANOSIS IN INFANTS

PATTERN	pH	P_{O_2}	P_{CO_2}	RESPONSE TO O_2	VENOUS pH	SUGGESTED CONDITION
1						Hyaline membrane or other pulmonary parenchymal disease
2						Hypoventilation

4			--	--		Decreased or ineffective pulmonary blood flow
5			--	--		Systemic hypoperfusion

-- = no effect. For description of patterns, see pp. 1524 ff.

foreign body. Structural abnormalities in the lungs resulting from intrapulmonary disease are more frequently a basis for cyanosis among newborns than is upper airway obstruction. Hyaline membrane disease, atelectasis, or pneumonitis causing inflammation, collapse, and fluid accumulation in the alveoli results in reduction of the oxygenation of blood reaching the systemic circulation.

Successfully distinguishing among these various causes of cyanosis depends on interpretation of the respiratory pattern, the cardiac physical examination, evaluation of arterial blood gases (Table 43-9) , and interpretation of the ECG, chest radiograph, and echocardiogram.

RESPIRATORY PATTERNS.

The key to differential diagnosis at the bedside commonly is the proper evaluation of the pattern of respiration. Term infants normally exhibit a progressive reduction in respiratory rate during the first day of life from 60 to 70 breaths/min to 35 to 55 breaths/min. Moreover, mild intercostal retractions and minimal expiratory grunting disappear within several hours of birth. An increased depth of respiration in the presence of cyanosis but without other signs of respiratory distress often is associated with congenital cardiac disease in which inadequate pulmonary blood flow is the most important functional component.

Apnea.

The most important variations from normal respiratory patterns are apnea, bradypnea, and tachypnea. Intermittent apneic episodes are common in premature infants with central nervous system immaturity or disease. In addition, higher centers may be depressed as a result of severe hypoxemia, acidemia, or administration of pharmacological agents to mother or baby. The association of apneic episodes, lethargy, hypotonicity, and a reduction of spontaneous movement most often points to intracranial disease as an underlying cause.

Tachypnea.

Diverse conditions result in tachypnea in the newborn period. Tachypnea in the presence of intrinsic pulmonary disease with upper or lower airway obstruction usually is accompanied by flaring of the alae nasi, chest-wall retractions, and grunting. In contrast, tachypnea associated with intense cyanosis in the absence of obvious respiratory distress suggests the presence of cyanotic congenital heart disease. In general, highest respiratory rates (80 to 110 breaths/min) occur in association with primary lung disease, not heart disease. Initial chest radiography frequently is diagnostic, especially if the problem is aspiration, mucous plug, adenomatoid malformation, lobar emphysema, diaphragmatic hernia, pneumothorax, lung agenesis, pulmonary hemorrhage, or an abnormal thoracic cage configuration. Choanal atresia may be precluded by passing a feeding tube through the nares, and the more common types of esophageal atresia and tracheoesophageal fistula may be excluded by passing the tube farther into the stomach.

CARDIAC EXAMINATION.

Specific findings on cardiovascular examination may direct attention to a cardiac cause of cyanosis. Peripheral perfusion is poor in the presence of severe primary myocardial disease or the hypoplastic left heart syndrome. In contrast, peripheral pulses are bounding and the dorsalis pedis and palmar pulses are easily palpable in infants with patent ductus arteriosus, truncus arteriosus, or aorticopulmonary window. A marked discrepancy between upper and lower extremity blood pressures helps

to identify infants with coarctation of the aorta. Inspection and palpation of the precordium allow an overall estimate of cardiac activity. A thrill in the suprasternal notch and/or over the precordium occasionally may be felt in infants with patent ductus arteriosus, critical aortic stenosis, or coarctation of the aorta. Characterization of the second heart sound may be of help because it often is single in infants with a hypoplastic left heart complex, pulmonary atresia with or without an intact ventricular septum, or truncus arteriosus. Wide splitting of the second heart sound may occur in infants with total anomalous pulmonary venous return. Ejection sounds often are detectable in infants with persistent truncus arteriosus and occasionally with critical aortic or pulmonic stenosis. The presence of a third heart sound is normal, but a gallop rhythm may provide a clue to myocardial failure. Wide splitting of the first and second heart sounds may produce the characteristically rhythmic auscultatory cadence of Ebstein's anomaly of the tricuspid valve (see Chaps. 25 and 44). The presence of a cardiac murmur may point clearly to underlying cardiac disease, but the absence of a murmur does not preclude a cardiac malformation. Moreover, cardiac murmurs of specific anomalies often are atypical in the newborn period. However, certain cardiac murmurs such as the decrescendo holosystolic murmur of tricuspid regurgitation in Ebstein's anomaly or the transient tricuspid regurgitation of infancy may point clearly to an accurate diagnosis. Auscultation of the head and abdomen may detect the murmur of an arteriovenous malformation at those sites in infants who present with findings of severe heart failure.

BLOOD GAS AND pH PATTERNS.

Arterial blood gas analysis may be a reliable method of evaluating cyanosis, suggesting the type of altered physiology, and assessing responses to therapeutic maneuvers.[53] Specimens for blood gas analysis should be obtained in room air and in 100 percent oxygen. Stick capillary samples from the patient's warmed heel may be used, although determinations obtained by arterial puncture are preferable for evaluation of oxygenation because they are less susceptible to alterations in regional blood flow in critically ill infants. Sampling of right radial or temporal arterial blood is preferable because these sites are proximal to flow through a ductus arteriosus and do not reflect right-to-left ductal shunting, as would a sample from the descending aorta obtained by means of an umbilical artery catheter. A trial of continuous positive airway pressure may improve oxygenation in infants with either hyaline membrane disease or pulmonary edema.

Arterial blood gas patterns in various pathophysiological conditions are listed in Table 43-9 . Pattern 1 typically is observed in infants with ventilation-perfusion abnormalities resulting from primary respiratory disease, often associated with elevated pulmonary vascular resistance and venoarterial shunting across a patent foramen ovale or patent ductus arteriosus. Pulmonary hypoventilation with carbon dioxide retention produces pattern 2. In the presence of a lesion causing obligatory venous admixture, such as total anomalous

pulmonary venous connection (pattern 3), the response to oxygen may reflect an increase in pulmonary venous return secondary to a fall in pulmonary vascular resistance. Pattern 4 typically is seen in infants with a cardiac malformation that results in reduced pulmonary blood flow. Oxygen administration in these infants does not alter the arterial P_{O_2} . The alterations of pattern 5 are observed when systemic hypoperfusion is the principal hemodynamic problem. In these babies, the arteriovenous oxygen difference is high, and the acidemia may be progressive and unrelenting.

ELECTROCARDIOGRAM (see also Chap. 5).

ECG is less helpful in suggesting a diagnosis of heart disease in premature and newborn infants than in older children. Right ventricular hypertrophy is a normal finding in neonates, and the range of normal voltages is wide. However, specific observations can offer major clues to the presence of a cardiovascular anomaly. A counterclockwise, superiorly oriented frontal QRS loop with absent or reduced right ventricular forces suggests the diagnosis of tricuspid atresia. In contrast, when the QRS axis is normal but left ventricular forces predominate, the diagnosis of pulmonic atresia must be considered. The counterclockwise, superior QRS orientation also is observed in infants with an endocardiac cushion defect and in some with double-outlet right ventricle; right ventricular forces in these babies are increased.

The initial septal vector should be assessed from the ECG. Q waves often are not clearly seen in the lateral precordial leads in the first 72 hours of life. A leftward, posteriorly directed septal vector giving rise to Q waves in the right precordial leads is abnormal and suggests the presence of marked right ventricular hypertrophy, single ventricle, or inversion of the ventricles. T wave alterations may be seen on a normal neonatal ECG and may be of no particular consequence. By 72 hours of age, however, the T waves should be inverted in V_3 and V_1 and upright in the lateral precordium; persistently upright T waves in the right precordial leads are a sign of right ventricular hypertrophy. Depressed or flattened T waves in the lateral precordium may suggest subendocardial ischemia and a left heart outflow tract obstructive lesion, electrolyte disturbance, acidosis, or hypoxemia. An ECG pattern of myocardial infarction suggests a diagnosis of anomalous pulmonary origin of the coronary artery. Finally, rhythm disturbances such as complete heart block or supraventricular tachycardia (see Chap. 25) can be detected readily by ECG.

RADIOGRAPHIC EXAMINATION (see also Chap. 8).

Chest radiography often is useful in differentiating between respiratory and cardiac causes of cyanosis in the newborn period. Determination of a normal cardiac and abdominal situs aids in ruling out several kinds of complex cyanotic cardiac malformations associated with asplenia or polysplenia with abdominal heterotaxy and dextrocardia. The distinct appearance of pulmonary parenchymal disease, such as the classic reticulogranular pattern of hyaline membrane disease, may allow a specific radiological diagnosis. In those premature infants with a large ductus arteriosus, the radiographic appearance often evolves from the typical findings of hyaline membrane disease to increased pulmonary vascular markings and finally to perihilar and generalized pulmonary edema.

Most important, the pediatric cardiologist depends heavily on the evaluation of pulmonary vascular markings to categorize neonatal congenital cardiac malformations according to function. In the presence of cyanosis, diminished pulmonary vascular markings call attention to the group of anomalies that includes tetralogy of Fallot, pulmonic stenosis with intact ventricular septum, pulmonic atresia, tricuspid atresia, and Ebstein's malformation of the tricuspid valve. Reduced pulmonary blood flow is responsible for the systemic arterial desaturation in these babies. Increased pulmonary vascular markings in cyanotic infants are associated with lesions in which an obligatory admixture of systemic venous and pulmonary venous blood occurs. The more common anomalies in this category include transposition of the great arteries, hypoplastic left heart syndrome, truncus arteriosus, and total anomalous pulmonary venous drainage.

As mentioned earlier, overall heart size in normal newborn infants is greater than in older children, and cardiothoracic ratios up to 0.60 are within normal limits. The thymus shadow occasionally obscures the cardiac silhouette and prohibits accurate estimation of heart size. An enlarged heart on x-ray examination suggests a cardiac disorder. However, in the presence of severe respiratory difficulties with an increase in carbon dioxide tension and a decrease in both pH and arterial oxygen tension, cardiomegaly may be only moderate. A right aortic arch suggests the presence of either tetralogy of Fallot or persistent truncus arteriosus. An ovoid heart with a narrow base associated with increased pulmonary vascular marking is typical of transposition of the great arteries. A boot-shaped heart with concavity of the pulmonary outflow tract suggests tetralogy of Fallot, pulmonic atresia, or tricuspid atresia.

LABORATORY STUDIES IN CONGENITAL HEART DISEASE

FETAL ECHOCARDIOGRAPHY (see also Chap. 7).

Ultrasound technology now allows examination of human fetal cardiac development and function in utero.[39] [93] [94] [95] Diagnostic-quality images of the fetal heart in utero can be obtained as early as 16 weeks of gestation. Cardiac structures are imaged primarily by cross-sectional echocardiography and augmented by a combination of range-gated pulsed Doppler ultrasonography, Doppler color flow imaging, and M-mode echocardiography. Analysis of the structure and function of the fetal heart during the second and third trimesters of pregnancy has allowed cardiologists to counsel prospective parents and, in a number of instances, to formulate management plans for pregnancy, delivery, and the immediate postnatal period. Using fetal echocardiography, major forms of congenital heart disease have been diagnosed in utero and cardiac rhythm abnormalities have been detected, permitting direct efforts at transplacental therapy. In particular, it has been established that a high incidence of cardiac pathology exists in the presence of nonimmune fetal hydrops. It appears clear that hydrops fetalis often represents end-stage fetal cardiac decompensation (Fig. 43-7) . AV

Figure 43-7 Fetal echocardiogram taken transabdominally through the uterus and the placenta shows a fetus lying with its head to the right hand side of the figure and demonstrates a pericardial (Peric) effusion (arrows). The right ventricle (RV), the aorta (AO), and the left atria (LA) are seen within the cardiac silhouette.

valve insufficiency often causes fetal right ventricular volume overload and systemic venous hypertension, leading to hydrops fetalis.

Pulsed Doppler and color flow mapping ultrasound examination of the fetus importantly supplement the echocardiographic findings in identifying the responsible defects, such as Ebstein's malformation of the tricuspid valve, atrial isomerism with AV septal defects, and the absent pulmonary valve and hypoplastic left heart syndromes.

Fetal cardiac ultrasonography is of special importance in analyzing disturbances of fetal cardiac rhythm, which usually are first suspected on the basis of auscultatory findings. Transabdominal ECG cannot identify atrial depolarization and is of limited value in the analysis of cardiac arrhythmias in utero. However, M-mode recordings of cardiac motion versus time allow conclusions about electrical events in the fetal heart, as they are reflected by the mechanical responses that are recorded echocardiographically. Supraventricular tachyarrhythmias are a common cause of nonimmune fetal hydrops (Fig. 43-8) . Detection is of practical use in the treatment of these patients because the arrhythmia is treatable with the use of various antiarrhythmic drugs, such as digoxin, procainamide, propranolol, and flecainide, administered to the mother and reaching the fetus transplacentally or, rarely, under sonographic guidance, by injecting drugs, such as amiodarone, into the umbilical vein.[96]

ECHOCARDIOGRAPHY IN THE NEONATE.

Echocardiography is of immense value in differentiating between heart disease and lung disease in newborns.[97] [97A] Indeed, it has become the standard for the diagnosis of virtually all cardiovascular malformations. A great many infants are now referred directly after ultrasound study for operative repair, without intervening cardiac catheterization. Echocardiographic diagnoses that often can be made with certainty include coarctation of the aorta, interruption of the aortic arch, patent ductus arteriosus, hypoplastic left heart syndrome, aortic valve stenosis, membranous and fibromuscular subvalvular aortic stenosis, aortic coarctation, hypertrophic cardiomyopathy, cor triatriatum, total anomalous

Figure 43-8 M-mode echocardiogram at 35 weeks' gestation, showing fetal supraventricular tachycardia and pericardial effusion (PEff). The tracing, taken at the midventricular level, allows the heart rate to be calculated from atrioventricular valve (AVV) motion (250 beats/min). *(Courtesy of Dr. Charles Kleinman.)*

pulmonary venous connection, atrial septal defect, tricuspid atresia, Ebstein's anomaly of the tricuspid valve, valvular pulmonic stenosis, AV septal defect, single ventricle, double-outlet right ventricle, transposition of the great arteries, and patent ductus arteriosus. The echocardiogram provides suggestive and often conclusive evidence for tetralogy of Fallot, truncus arteriosus, and pulmonary atresia with an intact ventricular septum, as well as pulmonary atresia with a VSD and a patent ductus arteriosus.

Doppler ultrasonography (see Chap. 7) supplements the two-dimensional echocardiographic examination by its ability to quantify valve gradients, cardiac output, blood flow patterns in the cardiac chambers and great arteries, and often shunt size.[98] [99] For example, the pulmonary-systemic blood flow ratio can be calculated by multiplying the square of the ratio of the great vessel diameters by the ratio of the peak systolic flow velocities, the pulmonary variable being the numerator in each ratio. The coupling of Doppler ultrasonographic techniques with the two-dimensional echocardiogram, and the representation in color of abnormalities in flow, volume, and direction (see Chap. 7), greatly improve diagnostic accuracy. Magnetic resonance imaging (see Chap. 10) can also be useful.[99A]

DIAGNOSTIC CARDIAC CATHETERIZATION (see also Chap. 11).

If certain cardiac anomalies are identified by noninvasive studies or if a clear-cut differentiation cannot be made between cardiac and pulmonary disease, heart catheterization and angiocardiography may be necessary to define the underlying state precisely. However, fewer cardiac catheterizations have been performed in infants and children of all ages since the beginning of aggressive pursuit of preoperative diagnoses by noninvasive imaging modalities, particularly two-dimensional Doppler flow echocardiography.[99] [100] Hemodynamic study of newborn infants carries a small but distinct risk.[101] As a general rule, cardiac catheterization is not performed unless the information sought is central to treatment of the infant. Most infants with serious heart disease require therapeutic intervention, and thus catheterization should be performed only when surgical support is readily available. Cardiac catheterization is often performed in newborns who experience congestive heart failure in the first days after birth if the cause is an anatomical abnormality rather than an arrhythmia or a metabolic disturbance. Preferably, medical measures will have been instituted to stabilize the clinical state before a hemodynamic study is performed.

Some newborns with cyanotic congenital heart disease require prompt cardiac catheterization because of the considerable risk of rapid deterioration. Under these circumstances, hemodynamic and angiographic studies may not only provide the anatomical diagnosis required before emergency operation but also allow the opportunity for therapeutic maneuvers such as balloon atrial septostomy to facilitate intercirculatory mixing in patients with complete transposition of the great arteries or to augment interatrial shunting in patients with a restrictive patent foramen ovale and either tricuspid, pulmonic, or mitral atresia or total anomalous pulmonary venous connection. Selective intravenous infusion of low doses of prostaglandin E_1 (0.05 to 0.1 mug/kg/min) has been used before and at cardiac catheterization for the emergency palliation of ductus-dependent cardiac lesions such as pulmonary atresia, aortic coarctation, and interruption of the aortic arch. Because a patent ductus arteriosus maintains pulmonary and systemic blood flow, respectively, in these infants, dilatation of the ductus with vasodilatory prostaglandins may retard their clinical deterioration. Thus, prostaglandin E_1 infusion has been shown to be an effective short-term measure to correct hypoxemia and acidemia and to improve the preoperative and intraoperative status of infants who require surgical relief of the congenital cardiac lesion that is causing pulmonary or systemic hypoperfusion.

THERAPEUTIC CATHETERIZATION (see also Chap. 38).

Balloon atrial septostomy was the first catheter intervention that proved useful in treating congenital heart disease, and it remains the standard initial palliation in infants with complete transposition of the great arteries unless the arterial switch operation is performed imminently.[102] Many additional transcatheter techniques are now used successfully to treat congenital heart disease. These include knife blade atrial septostomy; umbrella or coil closure of patent ductus arteriosus; self-expanding and centering Amplatzer occluding device, or buttoned or modified clamshell or umbrella device closure of atrial septal defect; balloon-expandable intravascular stents for peripheral pulmonary artery and selected postoperative stenoses; and balloon and coil embolization of large systemic pulmonary artery collateral vessels and arteriovenous fistulas.[103] [104] [105] Other procedures that have expanded the role of the cardiac catheter from a diagnostic tool to a therapeutic instrument include transvenous or transarterial pacemaker insertion and retrieval of foreign bodies from the cardiovascular system. Transluminal balloon angioplasty currently is used principally in pediatrics for dilation of pulmonic and aortic valve stenoses, native and recoarctation of the aorta, and peripheral pulmonary artery stenosis. Questions about transluminal angioplasty in native neonatal coarctation, tetralogy of Fallot, and congenital subaortic and mitral stenoses remain unresolved. Finally, electrode catheter radiofrequency ablative techniques for the treatment of tachycardias are now performed routinely in centers with pediatric electrophysiology programs.[106]

ELECTROPHYSIOLOGICAL STUDIES (see also Chap. 23).

The cardiac catheterization laboratory also is being used with increasing frequency to define the anatomical and physiological diagnoses of arrhythmias, thus facilitating an accurate prognosis and providing a rational basis for pharmacological, catheter ablation, or surgical treatment.[107] [108] [109] Catheter ablation approaches to tachyarrhythmias are now standard pediatric procedures (see Chaps. 23 and 25). The invasive electrophysiological approach provides unique information that cannot be obtained noninvasively. This includes determination of conduction times of individual components of the conducting system and measurement of refractory periods for structures such as the AV node, His bundle, and bundle branches. In addition, one can determine the origin or anatomical circuit, sustaining mechanisms, and possible perturbations that terminate the arrhythmia. This last maneuver is particularly important because it may enable the planning of effective drug treatment. It also may determine the advisability of catheter ablation, pacemaker control, or surgical treatment of the rhythm disturbance.

Specific Cardiac Defects

Many classifications of congenital cardiovascular lesions have been proposed on the basis of hemodynamic, anatomical, and radiographic factors. Although the groups overlap, the following arrangement of cardiac anomalies is used in this chapter: (1) communications between the systemic and pulmonary circulations without cyanosis (left-to-right shunts), (2) obstructing valvular and vascular lesions with or without associated right-to-left shunt, (3) abnormalities in the origins of the great arteries and veins (the transposition complexes), (4) malpositions of the heart and cardiac apex, and (5) miscellaneous anomalies.

LEFT-TO-RIGHT SHUNTS

Atrial Septal Defect (See also p. 1593)

MORPHOLOGY.

Atrial septal defect is one of the most commonly recognized congenital cardiac anomalies in adults but is very rarely diagnosed and even less commonly results in disability in infants.[110] The anatomical sites of interatrial defects are shown in Figure 43-9 . Defects of the sinus venosus type are high in the atrial septum near the entry of the superior vena cava and may be created by a deficiency in the wall that normally separates the pulmonary veins from the right lung and the superior vena cava and right atrium, thereby also resulting in partial anomalous pulmonary venous drainage.[111] The atrial septal defect most often involves the fossa ovalis, is midseptal in location, and is of the ostium secundum type. This type of defect is a true deficiency of the atrial septum and should not be confused with a patent foramen ovale. Embryologically, the left side of the atrial septum is derived from the septum primum, which possesses an opening--the interatrial ostium secundum (see Fig. 43-1). The ostium secundum lies forward and superior to the position of the foramen ovale. The latter is formed by the septum secundum and occupies the right side of the atrial septum. Tissue of the septum primum lying to the left of the foramen ovale

Figure 43-9 Diagrammatic representation of open right atrium (RA) and right ventricle (RV) showing the position of the various types of interatrial communications. The superior vena cava (SVC), inferior vena cava (IVC), and right atrial appendage (RAA) define the areas of the right atrium. There are five potential spaces of interatrial communication. The classic ostium secundum (OS) atrial septal lies within the fossa ovalis. The second most frequent defect is an ostium primum (OP) atrial communication, followed by the superior vena caval type of sinus venosus (SV) defect lying posteriorly within the right atrium at the junction of the SVC and pulmonary veins. An IVC sinus venosus (SV) defect lies at the junction of the right atrium with the IVC. The last communication is through the coronary sinus (CS).

serves as a flap valve that usually becomes fused postnatally with the side of the foramen ovale, yielding an anatomically closed or sealed foramen. "Probe patency," or an incomplete seal of the foramen ovale, occurs in about 25 percent of adults. A widely patent foramen ovale may be considered an acquired form of atrial septal defect that occurs especially when a disproportion exists between the size of the foramen ovale and the effective length of its valve. Enlargement of the foramen ovale per se is commonly associated with obstructive lesions on the right side of the heart, whereas a short valve relative to the size of the foramen often attends large-volume left-to-right shunts in which left atrial dilatation is prominent.

Ostium primum atrial septal anomalies are a form of AV septal defect and are dealt with in the next section. Lutembacher's syndrome is a designation applied to the rare combination of atrial septal defect and mitral stenosis, which is almost invariably the result of acquired rheumatic valvulitis.[112] Ten to 20 percent of patients with ostium secundum atrial septal defect also have prolapse of the mitral valve as an associated anomaly.[113]

HEMODYNAMICS.

The magnitude of the left-to-right shunt through an atrial septal defect depends on the size of the defect, the relative compliance of the ventricles, and the relative resistance in both the pulmonary and the systemic circulation.[114] In patients with a small atrial septal defect or patent foramen ovale, the left atrial pressure may exceed the right by several millimeters of mercury, whereas the mean pressures in both atria are nearly identical when the defect is large. Left-to-right shunting occurs predominantly in late ventricular systole and early diastole with some augmentation during atrial contraction. The shunt results in diastolic overloading of the right ventricle and increased pulmonary blood flow. During the first few days and weeks of life, pulmonary resistance falls and systemic resistance rises, facilitating right ventricular emptying and impeding left ventricular emptying; the left-to-right shunt rises. Early in infancy, left-to-right flow through even a large interatrial communication commonly is limited by both the reduced chamber compliance of the thick neonatal right ventricle and the elevated pulmonary and reduced systemic vascular resistance of the neonate. The pulmonary vascular resistance commonly is normal or low in older infants or children with atrial septal defect, and the volume load usually is well tolerated, even though pulmonary blood flow may be two to five times greater than systemic. A transient and small right-to-left shunt occurring with the onset of left ventricular contraction and especially during respiratory periods of decreasing intrathoracic pressure is common in patients with ostium secundum defect, even in the absence of pulmonary hypertension.

CLINICAL FINDINGS.

Patients with atrial septal defect usually are asymptomatic early in life, although occasional reports describe congestive heart failure and recurrent pneumonia in infancy.[110] Children with atrial septal defect may experience undue fatigue and exertional dyspnea. They tend to be somewhat underdeveloped physically and prone to respiratory infection. Atrial arrhythmias, pulmonary arterial hypertension, development of pulmonary vascular obstruction, and heart failure are exceedingly uncommon in the pediatric age range, in contrast to their common appearance in adults with atrial septal defect. In the former group, diagnosis often is entertained after detection of a heart murmur on routine physical examination prompts a more extensive cardiac evaluation. Small defects, less than 4 to 8 mm, have a modest probability of spontaneous closure.[115]

Physical Examination.

Common findings include a prominent right ventricular cardiac impulse and palpable pulmonary artery pulsation. The first heart sound is normal or split, with accentuation of the tricuspid valve closure sound. Increased flow across the pulmonic valve is responsible for a midsystolic pulmonary ejection murmur. After the normal postnatal decline in pulmonary vascular resistance, the second heart sound is split widely and is relatively fixed in relation to respiration in patients with normal pulmonary pressures and low pulmonary vascular impedance because of a delay in pulmonic valve closure. With pulmonary hypertension, the splitting interval is a function of the electromechanical intervals of each ventricle; wide splitting occurs with shortening of the left and/or lengthening of the right ventricular electromechanical interval.[116] If the shunt is large, increased blood flow across the tricuspid valve is responsible for a mid-diastolic rumbling murmur at the lower left sternal border. In patients with associated prolapse of the mitral valve, an apical holosystolic or late systolic murmur radiating to the axilla often is heard, but a midsystolic click may be difficult to discern. Moreover, left ventricular precordial overactivity usually is absent because mitral regurgitation is mild in most patients.

In teenage patients, the physical findings may be altered when an increase in pulmonary vascular resistance results in diminution of the left-to-right shunt. Both the

pulmonary and the tricuspid murmurs decrease in intensity, whereas the pulmonic component of the second heart sound becomes accentuated and the two components of the second heart sound may fuse; a diastolic murmur of pulmonic incompetence appears. Cyanosis and clubbing accompany development of a right-to-left shunt.

Electrocardiogram.

In patients with an ostium secundum defect, the ECG usually shows right-axis deviation, right ventricular hypertrophy, and rSR
or rsR
pattern in the right precordial leads with a normal QRS duration (Fig. 43-10 ; see also Fig. 44-1). It is not clear whether the delay in right ventricular activation is a manifestation of right ventricular volume overload or a true conduction delay in the right bundle branch and peripheral Purkinje system. An early notch (triphasic "crochetage") pattern on the R wave in inferior limb leads is as sensitive an indicator of atrial defect as incomplete right bundle branch block.[117] Left-axis

Figure 43-10 Typical electrocardiographic tracing in secundum atrial septal defect showing right-axis deviation, rSR in the right pericordial leads, and right ventricular hypertrophy. *(Courtesy of Dr. Delores A. Danilowicz.)*

deviation of the P wave in the frontal plane (manifested by a negative P wave in lead III) suggests the presence of a sinus venosus rather than an ostium secundum type of atrial septal defect. Left-axis deviation and superior orientation and counterclockwise rotation of the QRS loop in the frontal plane suggest the presence of either an ostium primum defect or a secundum atrial septal defect in association with mitral valve prolapse. Prolongation of the PR interval may be seen with all types of atrial septal defects; the prolonged internodal conduction time may be related to both the increased size of the atrium and the increased distance for internodal conduction produced by the defect itself.[117]

Chest Roentgenogram (see Fig. 44-2).

This usually reveals enlargement of the right atrium and ventricle, dilatation of the pulmonary artery and its branches, and increased pulmonary vascular markings. Dilatation of the proximal portion of the superior vena cava occasionally is noted in patients with a sinus venosus defect. Left atrial dilatation is extremely rare but may be observed when significant mitral regurgitation exists.

Echocardiographic Features.

These include pulmonary arterial and right ventricular dilatation and anterior systolic (paradoxical) or "flat" interventricular septal motion if significant right ventricular volume overload is present.[98] The defect may be visualized directly by two-dimensional echo imaging, particularly from a subcostal view of the interatrial septum (Fig. 43-11 ; also see Chap. 7). Transesophageal color-coded Doppler echocardiography and color flow provides excellent visualization of defects of the atrial septum.[118] [119] Associated mitral valve prolapse also may be identified by echocardiographic examination (see Chap. 7). Findings on ultrafast computed tomographic (CT) scanning are discussed in Chapter 10 .

Two-dimensional echocardiography, supplemented by conventional or color-coded Doppler flow and/or contrast echocardiography, has supplanted cardiac catheterization as the confirmatory test for atrial septal defect.[120] Cardiac catheterization is then used if inconsistencies exist in the clinical data or if significant pulmonary hypertension is suspected.

Cardiac Catheterization.

Diagnosis may be readily confirmed by passage of the catheter across the atrial defect. The site at which the catheter crosses, if high in the cardiac silhouette, may suggest a sinus venosus defect; if midseptal, a patent foramen ovale or ostium secundum defect; or, if low, a primum defect.[121] Serial determinations of the oxygen saturation or indicator dilution curve techniques may

Figure 43-11 Subcostal coronal view showing a secundum atrial septal defect between the left atrium (LA) and the right atrium (RA). The right upper pulmonary vein (PV) is seen entering the left atrium. This view is posterior to the major portion of the ventricles; the left ventricle (LV) is seen, but only a small portion of the right ventricle (unlabeled) is apparent. I = inferior; L = left; R = right; S = superior.

be used to estimate the magnitude of the shunt. In the absence of pulmonary hypertension, pressures on the right side of the heart often are normal, despite a large shunt. When a high oxygen saturation is found in the superior vena cava or when the catheter enters pulmonary veins directly from the right atrium, a sinus venosus defect is likely, and indicator dilution curves and selective angiography aid in identifying the number and location of the anomalous veins. *Partial anomalous pulmonary venous connection,* although usually associated with sinus venosus defect, may accompany secundum defects. Selective left ventricular angiography identifies prolapse of the mitral valve and allows assessment of the magnitude of mitral regurgitation that may be present in such patients.[128]

MANAGEMENT.

In contrast to adults, children with sinus venosus or secundum types of atrial septal defect seldom require treatment for heart failure or antiarrhythmic medications for atrial fibrillation or supraventricular tachycardia. Respiratory tract infections should be treated promptly. Although the risk of infective endocarditis is low, antibiotics should be administered prophylactically before dental procedures.

Operative or Transcatheter Repair.

This should be advised for all patients with uncomplicated atrial septal defects and evidence of significant left-to-right shunting, i.e., with pulmonary-systemic flow ratios exceeding about 1.5:1.0. Ideally, this should be carried out in those 2 to 4 years of age. Rarely, an atrial septal aneurysm is seen in association with a secundum-type atrial septal defect.[122] Such patients may experience spontaneous closure and may be monitored more conservatively until an older age before advising operation. Whether by median sternotomy or by minimally invasive transxiphoid techniques,[123] the defect is closed by suture or with a patch of prosthetic material with the patient on cardiopulmonary bypass. Earlier surgical repair is definitive treatment for the small number of infants and young children with significant symptoms or congestive failure. The surgical mortality rate is less than 1 percent, and results usually are excellent. Although the mitral valve may be examined directly at operation, it seldom is necessary in childhood to attempt plication or replacement of a ballooning or prolapsing mitral valve.

Operation should *not* be carried out in patients with small defects and trivial left-to-right shunts (pulmonary-systemic flow ratio
1.5:1.0) or in those with severe pulmonary vascular disease (pulmonary-systemic resistance ratio
0.7:1.0) without a significant left-to-right shunt.[124] Although still investigational, considerable experience exists with transcatheter closure by a variety of occluding devices using fluoroscopic or transesophageal echocardiographic imaging guidance[125] [126] [127] (Fig. 43-12) . Limitations include difficulties in centering the device, the size of the sheath delivery system, the need to have more than a 4-mm separation between the edges of the defect and other important cardiac structures, and the inability to close defects whose stretched diameter exceeds 22 mm.

Subtle evidence of left ventricular dysfunction may be observed preoperatively at cardiac catheterization in children with isolated large atrial septal defects but without overt left or right ventricular failure.[128] Thus, decreased left ventricular stroke volume and cardiac output have been observed in children with both low and normal left ventricular end-diastolic volumes. In routine catheterization studies carried out on patients whose atrial septal defects were closed during preadolescence or later, a residual reduced cardiac output response to intense upright exercise in the absence of residual shunts, arrhythmias, or pulmonary arterial hypertension has been observed.[129] Normal myocardial function is preserved in patients in whom the defects were closed in early childhood.[130]

Electrophysiological Abnormalities.

Intracardiac electrophysiological studies reveal a high incidence of intrinsic

Figure 43-12 Clamshell umbrella occlusion of an ostium secundum atrial septal defect. A long sheath is positioned in the left atrium *(A). B,* The distal umbrella arms are opened in the left atrium and the umbrella and sheath are pulled back together to the atrial septum. *C,* The proximal set of arms is then delivered on the right atrial side of the atrial septum. The correct position of the device is confirmed by fluoroscopy, angiography, and echocardiography before the device is released. *(From Castaneda A, Jonas AR, Mayer JE Jr, et al: Cardiac Surgery of the Neonate and Infant. Philadelphia, WB Saunders, 1994, p 136.)*

dysfunction of the sinoatrial and AV nodes, which persists after surgical repair. These intrinsic nodal abnormalities are more common in sinus venosus than in ostium secundum defects[131] but occur in both varieties. There also is evidence that the type of venous cannulation at the time of operative repair may contribute to the incidence and severity of arrhythmias observed at long-term follow-up.[132]

Atrioventricular Septal Defect (See also p. 1596)

AV septal defects account for 4 to 5 percent of congenital heart defects and comprise a range of malformations characterized by various degrees of incomplete development of the inferior portion of the atrial septum, the inflow portion of the ventricular septum, and the AV valves (see Figs. 43-1 and 44-3). These anomalies also have been called endocardial cushion defects and AV canal defects. The basic defect is a deficiency of the AV septum, which separates the left ventricular inlet from the right atrium; it causes anomalies that range in severity from a small ostium primum atrial defect to a complete AV septal malformation that also involves defects in the interventricular septum and the mitral and tricuspid valves. The latter often are abnormal to various degrees, with five or six leaflets of variable size present, and variability also in the completeness of their commissures. AV septal defects are often encountered in association with other congenital abnormalities, such as asplenia or polysplenia syndromes, trisomy 21 (Down syndrome), and Ellis-van Creveld syndrome of ectodermal dysplasia and polydactyly.

Ostium Primum Defect (Partial AV Canal)

Ostium primum atrial septal defects lie immediately adjacent to the AV valves, either of which may be deformed and incompetent. Most often, only the anterior or septal leaflet of the mitral valve is displaced, and it commonly is cleft; the tricuspid valve usually is not involved. A cleft often is considered to be present in the mitral valve, although it is likely that the valve is in fact a trileaflet structure, with the cleft representing an abnormal commissure. The interatrial defect often is large, and the size of the left-to-right interatrial shunt in these patients is controlled by the same factors that exist in patients with ostium secundum atrial septal defect. Moreover, the clinical features are quite similar and principally consist of right ventricular precordial hyperactivity, a wide and persistently split second heart sound, a right ventricular outflow tract systolic ejection murmur, and a mid-diastolic tricuspid flow rumble. The murmurs of AV valve regurgitation may be audible if either valve is significantly abnormal; however, serious AV valve regurgitation usually is absent. In the occasional patient, mitral regurgitation is substantial and creates prominent signs of left ventricular overload.

Chest roentgenography usually reveals right atrial and ventricular cardiomegaly, prominence of the right ventricular outflow tract, and increased pulmonary vascular markings. The *ECG findings* (see Fig. 44-4) are characteristic and show a right ventricular conduction defect accompanied by left anterior division block, left-axis deviation, and superior orientation and counterclockwise rotation of the QRS loop in the frontal plane (see Chap. 5). Hemodynamic factors do not appear to be important in producing the characteristic ECG appearance. Rather, the superior QRS vector in patients with a shortened H-V interval appears to be related to early activation of the posterobasal left ventricular wall; in other patients with a normal conduction time between the bundle of His and the ventricles, the counterclockwise superior inscription of the frontal plane vector appears to be related to late activation of the anterolateral left ventricular wall.[133] A prolonged P-R interval is observed in many patients with an ostium primum atrial septal defect; prolonged internodal conduction may be related to displacement of the AV node in a posteroinferior direction in some patients and/or to the enlarged right atrium.

ECHOCARDIOGRAPHY.

Two-dimensional echocardiography is considered the standard for the diagnosis of all forms of AV septal defect (see Chap. 7). Important features include enlargement of both the right ventricle and the pulmonary artery, systolic anterior ventricular septal motion, prolonged mitral-septal apposition in diastole, and various abnormalities in mitral valve motion.[134] The defect is clearly visualized from the precordial apical and subxiphoid positions, with the latter views best demonstrating the relation between the atrial defect, the AV valves, and the interventricular septum (Fig. 43-13) . Doppler color flow enhances these relations. Interatrial septal tissue is absent in the region of the crest of the interventricular septum; the trileaflet configuration of the mitral valve also may be identified. The subxiphoid long-axis view of the left ventricular outflow tract exhibits the gooseneck deformity in a manner similar to that with a right anterior oblique left ventricular angiogram. Echocardiography is particularly useful for detecting and characterizing double-orifice mitral valve, an association in about 3 percent of patients with ostium primum atrial defect. It also allows detection of

Figure 43-13 *Top panel,* Transesophageal echocardiogram taken from a subcostal transgastric plane in a patient with tetralogy of Fallot and type C complete atrioventricular septal defect. A secundum atrial septal defect (upper smaller arrow) is also seen in the left panel, and the ostium primum component of the complete atrioventricular canal is seen below (larger lower arrow). The right frame shows the complete atrioventricular septal defect with the anterosuperior bridging leaflet (arrow) straddling between the left and right ventricles (LV, RV) without attaching to the interventricular septum. The left pulmonary artery (LP) is seen behind the ascending aorta (AO). *Bottom panel,* Four-chamber transesophageal plane demonstrates a communication above the anterior and bridging leaflets (ABL and PBL) in the right- and left-hand frames, respectively. The small arrow indicates the typical position of an ostium primum atrial septal defect lying immediately below the rim of the atrial septum and above the valve tissue. LA = left atrium; RA = right atrium.

single left ventricular papillary muscle, hypoplasia of the left ventricle, and coarctation of the aorta, seen especially in symptomatic infants with an ostium primum atrial defect but without trisomy 21.[135] The *angiographic features* resemble those in the complete form of AV septal defect and are discussed later.

Complete AV Septal Defect

MORPHOLOGY.

The complete form of the AV septal defect includes, in addition to the ostium primum atrial septal defect, a VSD in the posterior basal inlet portion of the ventricular septum and a common AV orifice.[136] The common AV valve usually has six leaflets: left superior and inferior, left and right lateral, and right superior and inferior. The left and right superior leaflets together often are referred to as the "anterior" bridging leaflet. No attachment exists between the left superior and inferior leaflets and the right superior and inferior leaflets. The left superior leaflet may cross the crest of the ventricular septum to reside partially on the right ventricular side. A classification of complete AV canal defect into types A, B, and C reflects the variability and the degree of anterior leaflet bridging of the ventricular septum (see Fig. 43-13). Thus, in type A, the anterior leaflet is almost entirely committed to the left ventricle and is attached by chordae tendineae to the crest of the ventricular septum. In type C there is marked rightward displacement of the anterior bridging leaflet, which floats freely over the crest of the ventricular septum and is not attached to it by chordae tendineae. In type B, chordal attachments extend medially to an anomalous papillary muscle adjacent to the septum in the right ventricle.

A high incidence (about 35 percent) of additional cardiovascular lesions exists in patients with common AV canal. Principal among those associated with type C are tetralogy of Fallot, double-outlet right ventricle, transposition of the great arteries, and asplenia and polysplenia syndromes. Moreover, the type A complete AV septal anomaly commonly is seen in patients with Down syndrome.

The designation *unbalanced atrioventricular canal* is applied to the condition in which one ventricle is hypoplastic and the other receives most of the common AV valve. Subaortic obstruction may be due to abnormal features of the left side of the common AV valve or to hypoplasia of the left ventricle. The left-sided (mitral) component may also be the site of a potential form of double-orifice mitral stenosis postoperatively.

DIAGNOSIS.

Patients with common AV septal defects present clinically before age 1 year with a history of frequent respiratory infections and poor weight gain. Heart failure in infancy is extremely common. The *physical findings* are similar to those observed in patients with ostium primum atrial septal defect but may include as well the holosystolic, lower left sternal border murmur of an interventricular communication and/or the decrescendo, holosystolic apical murmur of mitral regurgitation. The ECG features of complete AV canal defects resemble those in the partial ostium primum variety of AV septal anomalies (see Fig. 43-10). *Radiographically,* the usual findings are generalized cardiomegaly and engorged pulmonary vessels.

Two-dimensional echocardiography is diagnostic (see Chap. 7).[134] Apical and subcostal views are used to determine the size of the septal defects, the commitment of valve tissue and chordal attachments to the ventricles, ventricular size, the magnitude of AV valve insufficiency, and the anatomy of the left ventricular outflow tract. The subcostal oblique coronal view is often best to evaluate the commitment of AV valve tissue to each ventricle. Patterns of shunting and the number and magnitude of regurgitant jets are best evaluated by using pulsed, continuous-wave, and color flow Doppler imaging. On *hemodynamic study,* patients with persistent common AV canal invariably have elevated pulmonary arterial pressures; after age 2 years, a significant number of these patients have progressively severe pulmonary vascular obstructive disease.

Diagnosis also is reliably established by selective left ventricular *angiocardiography* using rapid injection of relatively large quantities of contrast material.[137] The findings include an absence of the AV septum and a deficiency of the inlet portion of the ventricular septum, with elongation of the left ventricular outflow tract in relation to the inflow tract. The aortic valve is elevated and displaced anteriorly relative to the AV valves, changing the relation between the anterior components of the left AV valve and the aorta, which produces a pathognomonic gooseneck deformity seen angiographically in diastole.

MANAGEMENT.

In patients with complete AV canal, cardiac decompensation should be controlled initially. Even with an adequate response to medical therapy early in life, operation should be considered before age 6 months because infants with a complete form of the AV septal defect are at high risk of obstructive pulmonary vascular disease. The level of major shunting should be determined by echocardiographic-Doppler data, or less often during initial hemodynamic and angiographic studies, because if it is mainly at the ventricular level, pulmonary artery banding occasionally may be advised for intractable heart failure and failure to thrive. Often, however, there is a significant left ventricular-right atrial shunt either directly or indirectly by way of mitral regurgitation and left-to-right interatrial shunting, which will be unaffected by pulmonary artery banding and requires complete surgical correction.

Surgical Repair.

Operative repair of uncomplicated primum defects is, for the most part, simple and yields good results. Left AV valve regurgitation and subaortic stenosis can be late complications amenable to reoperation. In most centers, primary repair in patients who have intractable heart failure, growth failure, or severe pulmonary hypertension is the preferred approach at any age.[138] Mild to moderate regurgitation often persists after surgical repair, particularly if significant AV valve incompetence existed preoperatively.[139] Rarely, if left AV leaflet tissue is remarkably deficient or deformed, mitral valve replacement may be required. Advances in the surgical approach to complex forms of AV septal defects have greatly improved the outlook for patients born with this malformation.[140] [141] These include better reconstruction of the mitral valve (Fig. 43-14) and more precise preoperative detection of such anatomical features as additional muscular VSDs, malalignment

Figure 43-14 A suture technique is illustrated for repair of a cleft mitral valve *(A)*. Absolute alignment of the cleft in all its dimensions is of critical importance with placement of the sutures where the edges naturally coapt *(B)*. *C*, The cleft repair is accompanied by annuloplasty. *(From Castaneda A, Jonas RA, Mayer JE Jr, et al: Cardiac Surgery of the Neonate and Infant. Philadelphia, WB Saunders, 1994, p 174.)*

of the complete AV septum, and left ventricular hypoplasia. Operative improvement is primarily related to a clearer understanding of the anatomy of this complex lesion and to the ability to reconstruct the left AV valve, often by splitting of papillary muscles and shortening of chordae tendineae, with or without annuloplasty. Many surgeons prefer to close the septal defects with a single patch rather than separating ventricular and atrial patches. Suture placement is avoided in the region of the AV node and the bundle of His.

Figure 43-15 *A,* The four components of the ventricular septum viewed from the right ventricular side. I = inlet component, which extends from tricuspid annulus to attachments of the tricuspid valve; T = trabecular septum, which extends from the inlet out to the apex and up to the smooth-walled outlet; O = outlet septum or infundibular septum, which extends up to the pulmonary valve and membranous septum. *B,* The anatomical position of ventricular septal defects. a = outlet defect; b = papillary muscle of the conus; c = perimembranous defect; d = marginal muscular defects; e = central muscular defects; f = inlet defect; g = apical muscular defects. *(From Graham TP Jr, Gutgesell HP: Ventricular septal defects. Ventricular Septal Defect (See also p. 1595)

MORPHOLOGY.

Among the most prevalent of cardiac malformations, defects of the ventricular septum occur commonly, both as isolated anomalies and in combination with other anomalies. The ventricular septum is made up of four compartments: the membranous septum, the inlet septum, the trabecular septum, and the outlet, or infundibular, septum. Defects result from a deficiency of growth or a failure of alignment or fusion of component parts. Defects most commonly are classified as occurring in or adjacent to one or more of the septal components (Fig. 43-15) . [142] [143]

The most common defects occur in the region of the membranous septum and are referred to as *paramembranous* or *perimembranous defects* because they are larger than the membranous septum itself and are associated with a muscular defect at a portion of their perimeter. They also are known as infracristal, subaortic, or conoventricular defects. These perimembranous defects also can be defined by their adjacent areas as inlet, trabecular, or outlet. A second type of defect is one with an entirely muscular rim. Such muscular defects also can be defined as inlet, trabecular, central, apical, marginal or Swiss cheese, or outlet and vary greatly in size, shape, and number. A third type of defect occurs when the outlet septum is deficient and commonly is referred to as supracristal, subpulmonary, outlet, infundibular, or conoseptal. Because the aortic and pulmonary valves are in fibrous continuity, this type of defect also may be referred to as doubly committed subarterial. A septal deficiency of the site of the AV septum characterizes defects called AV septal, AV canal, or inlet septal defects.

The other feature of any defect may be a malalignment of the septal components. Either the inlet or the outlet septum can be malaligned. Malalignment of the inlet septum produces either mitral or tricuspid valve override and/or straddle. Malalignment of the outlet septum can be to the right or the left of the trabecular septum; when to the left of the trabecular septum, the VSD is characteristic of tetralogy of Fallot, double-outlet ventricle, truncus arteriosus, and, in some cases, transposition of the great arteries.

ECHOCARDIOGRAPHY.

Two-dimensional and Doppler color flow mapping identify the type of defect in the ventricular septum (Fig. 43-16) .[144] [145] [146] Perimembranous VSDs are identified by septal dropout in the area adjacent to the septal leaflet of the tricuspid valve and below the right border of the aortic annulus. The subaortic or anterior malalignment type of VSD appears just below the posterior semilunar valve cusps, entirely superior to the tricuspid valve. The subpulmonary VSD appears as echo dropout within the outflow septum and extending to the pulmonary annulus. One or two of the aortic cusps may be seen to be protruding through the defect into the right ventricular outflow tract. The inlet AV septal-type of VSD extends from the fibrous annulus of the tricuspid valve into the muscular septum and often is entirely beneath the septal tricuspid leaflet. Muscular defects may appear anywhere throughout the ventricular septum and may be either large and single or small and multiple. Anatomical localization of all VSDs is facilitated by coupling two-dimensional ultrasound images (see Chap. 7) with a Doppler system and by superimposing a color-coded direction and velocity of blood flow on the real-time images.

Figure 43-16 Four-chamber echocardiographic view in anatomical position demonstrates the ventricular septal defect (arrows within the left ventricular [LV] cavity). The tricuspid valve (TV) is adjacent to the ventricular septal defect and billows into the right ventricle (RV), a feature consistent with typical tricuspid tissue tags associated with perimembranous ventricular septal defect (formerly called ventricular septal aneurysm). LA = left atrium; RA = right atrium.

Pulmonary and systemic blood flow can be calculated from arterial velocity profiles and cross-sectional areas of the great vessels.[147] Calculation of pulmonary/systemic flow ratios is reasonably accurate. Detection of jets within the right ventricle allows determination of right ventricular pressure by subtracting the product using the Bernoulli equation, which gives the pressure difference, from the systemic systolic blood pressure. Continuous-wave Doppler has been helpful in determining the right ventricular pressure from tricuspid regurgitation, which is found fairly often with VSDs. Many other techniques of Doppler measurement have been used with varying success in efforts to determine pulmonary arterial pressure accurately.

PATHOPHYSIOLOGY.

The functional disturbance caused by a VSD depends primarily on its size and the status of the pulmonary vascular bed rather than on the location of the defect. A small VSD with high resistance to flow permits only a small left-to-right shunt. A large interventricular communication allows a large left-to-right shunt only if there is no pulmonic stenosis or high pulmonary vascular resistance because these factors also determine shunt flow. Resistance to left ventricular emptying also affects shunt flow because it is an important factor in determining left ventricular pressure. Large defects allow both ventricles to function hemodynamically as a single pumping chamber with two outlets, equalizing the pressure in the systemic and pulmonary circulations. In such patients, the magnitude of the left-to-right shunt varies inversely with pulmonary vascular resistance. The natural history of VSDs has a wide spectrum, ranging from spontaneous closure to congestive cardiac failure and death in early infancy. Within this spectrum are possible development of pulmonary vascular obstruction, right ventricular outflow tract obstruction, aortic regurgitation, and infective endocarditis.[148] [149] [150] [151]

Infants

It is unusual for a VSD to cause difficulties in the immediate postnatal period, although congestive heart failure during the first 6 months of life is a frequent occurrence. Early diagnosis is helpful to ensure more careful observation of the affected infant.[148] The examining physician usually suspects the diagnosis because of a harsh systolic murmur at the lower left sternal border. The ECG and chest roentgenogram findings are within normal limits in the immediate neonatal period because appreciable left-to-right shunting occurs only after the pulmonary vascular resistance decreases as the pulmonary vessels lose their fetal characteristics. It is desirable to monitor these infants closely.

A VSD that either decreases in size or closes completely during the first year of life presents no problems to the practicing physician. Spontaneous closure occurs by age 3 years in about 45 percent of patients born with VSD; occasional patients, however, do not experience spontaneous closure until age 8 to 10 years or even later.[152] Closure is more common in patients born with a small VSD; nonetheless, about 7 percent of infants with a large defect and congestive heart failure early in life also may experience spontaneous closure. Partial rather than complete closure is common in patients with both large and small VSDs. Anatomically, reduction of the VSD often is based on adherence of the tricuspid valve to the defect, hypertrophy of septal muscle, or ingrowth of fibrous tissue. Rarely, closure of the VSD is the result of prolapse of an aortic cusp or infective endocarditis.[150] Some defects close when an aneurysm forms in the ventricular septum (see Fig. 43-16). On auscultation, a click may be heard in early systole as the aneurysm tenses toward the right; the septal aneurysm may be detected by echocardiography as an anterior systolic bulge in the right ventricular outflow tract. A persistent minute VSD is not life threatening unless infective endocarditis develops. With proper precautions (see Chap. 47), the incidence of this complication is less than 1 percent.

If a moderate or large defect maintains its size after birth, the net left-to-right shunt increases during the first month of life as pulmonary vascular resistance falls. *Physical examination* during this time usually reveals a thrill along the lower left sternal border, and the holosystolic murmur of flow across the interventricular defect is accompanied by a low-pitched diastolic rumble at the apex, reflecting increased flow across the mitral valve. *Chest roentgenograms* reveal increased pulmonary vascular markings; evidence of left or biventricular hypertrophy may be observed on the ECG. Infants with a large left-to-right shunt tend to fare poorly, with recurrent upper and lower respiratory tract infections, failure to gain weight, and congestive heart failure. Congestive heart failure may be severe and intractable despite intensive medical management.

MANAGEMENT.

We currently recommend primary intracardiac repair of the VSD at any age rather than surgical banding of the pulmonary artery[153] to reduce pulmonary blood flow and alleviate heart failure. An exception is made for the rare infant with multiple VSDs and a sievelike septum, who is at higher risk for complications after operative repair. Operation usually is deferred, along with debanding of the pulmonary artery, until the child reaches 3 to 5 years. Primary closure of the VSD, preferably through the right atrium, may be performed in infancy using cardiopulmonary bypass, profound hypothermia and cardiocirculatory arrest, or a combination of the two techniques. Mortality approaches zero in major centers if the defect is isolated and uncomplicated but approaches 10 percent if many anomalies are present.[154]

Fortunately, medical treatment often is successful in controlling congestive heart failure. Nevertheless, these infants should be referred for cardiac catheterization to evaluate pulmonary vascular resistance and to detect associated defects that may require operation, such as patent ductus arteriosus and coarctation of the aorta.

Children

Beyond the first year of life, a variable clinical picture emerges in children with VSD.[148] [155] If a small defect is present, the child usually is asymptomatic, the ECG usually appears normal, and the chest roentgenogram shows normal or only a mild increase in pulmonary vascular markings. Effort intolerance and fatigue are associated with moderate left-to-right shunts. These children exhibit cardiomegaly with a forceful left ventricular impulse and a prominent systolic thrill along the lower left sternal border. The second heart sound normally is split, with moderate accentuation of the pulmonic component; a third heart sound and rumbling diastolic murmur that reflects increased flow across the mitral valve are audible at the cardiac apex. The characteristic murmur resulting from flow across the defect is harsh and holosystolic, is best heard along the third and fourth interspaces to the left of the sternum, and is widely transmitted over the precordium. A basal midsystolic ejection murmur due to increased flow across the pulmonic valve also may be heard. The ECG reveals left or combined ventricular hypertrophy, and the chest roentgenogram and CT scan (see Chap. 5) show cardiomegaly, left atrial enlargement, and vascular engorgement.

PULMONARY HYPERTENSION.

It is of utmost importance to identify patients who may develop irreversible pulmonary vascular obstructive disease (Eisenmenger's reaction).[155] [156] [157] [158] Retrospective analyses of children who develop this complication indicate that infants with systemic or near systemic pressures in the pulmonary artery at the time of initial hemodynamic study are most at risk. If early primary closure is not recommended, recatheterization before age 18 months and a second determination of pulmonary vascular resistance should be performed in these patients to decide whether surgical intervention is obligatory to prevent development of fixed obliterative changes in the pulmonary vessels.

Mechanisms.

It is likely that numerous factors are involved in the development of pulmonary vascular disease (see Chap. 53). The anatomically large VSD allows some or all of the systemic pressure to be transmitted to the pulmonary arteries, thereby retarding regression

of their muscular media. Medial hypertrophy in the first months of life is responsible for higher pulmonary vascular resistance than would be anticipated for the amount of pulmonary blood flow. The shearing forces created by the high velocity of flow through narrowed pulmonary arterioles cause endothelial damage that is progressive.

Although an elevation in left atrial pressure may contribute to the rise in pulmonary vascular resistance, it is not an essential factor because pulmonary venous pressures can be low in patients who later develop pulmonary vascular disease. Nonetheless, pulmonary venous hypertension also may contribute to pulmonary arterial vasoconstriction and thus to increased shear forces. In this same regard, pulmonary vasoconstriction enhancing the risk of pulmonary vascular obstruction also

may be caused by hypoxia due to either high altitude or lung disease. At high altitudes, large VSDs have higher pulmonary vascular resistances and smaller shunts than at low altitudes.

Clinical Features.

If a child who previously had a loud murmur and thrill associated with poor growth suddenly has a growth spurt, fewer respiratory infections, and a diminution of the intensity of the cardiac murmur and disappearance of the thrill, he or she may be developing severe obliterative changes in the pulmonary vascular bed. An increase in intensity of the pulmonic component of the second heart sound, a reduction in heart size on the chest roentgenogram, and more pronounced right ventricular hypertrophy on the ECG also are noted. These changes occur because the increased pulmonary vascular resistance causes a decrease in the left-to-right shunt. If these changes are suspected, cardiac catheterization should be repeated; if they are confirmed, prompt surgical repair is indicated before an inoperable predominant right-to-left shunt ensues. If operation is performed before age 2 years, pulmonary vascular resistance may be expected to fall to normal levels.[158]

In older patients, the degree to which pulmonary vascular resistance is elevated before operation is a critical factor determining prognosis. If the pulmonary vascular resistance is one-third or less of the systemic value, progressive pulmonary vascular disease after operation is unusual. However, if a moderate-to-severe increase in pulmonary vascular resistance exists preoperatively, either no change or progression of pulmonary vascular disease is common postoperatively. Moreover, the presence of increased pulmonary vascular resistance results in a higher immediate postoperative mortality rate for surgical closure of VSD. These observations make it clear that a large VSD should be approached surgically very early in life when pulmonary vascular disease is still reversible or has not yet developed (Fig. 43-17) .

RIGHT VENTRICULAR OUTFLOW TRACT OBSTRUCTION.

With time, the clinical picture changes in 5 to 10 percent of patients with VSD and a moderate to large left-to-right shunt early in life. It begins to resemble more closely the tetralogy of Fallot (see Chap. 44); i.e., subvalvular right ventricular outflow tract obstruction develops owing to progressive hypertrophy of the crista supraventricularis. Depending on the severity of the latter process, it ultimately may result in reduced blood flow and a right-to-left shunt across the VSD. As right ventricular outflow tract obstruction develops, the holosystolic murmur is replaced by the crescendo-decrescendo ejection systolic murmur of pulmonic stenosis, and the pulmonary closure sound becomes softer. Right ventricular hypertrophy is evident on the ECG, and the chest roentgenogram shows a reduction in pulmonary vascular markings and a smaller heart size with a right ventricular configuration. Infundibular

Figure 43-17 Early and late postoperative changes of pulmonary artery pressure after closure of ventricular septal defects in infants. *(From Castaneda A, Jonas RA, Mayer JE Jr, et al: Cardiac Surgery of the Neonate and Infant. Philadelphia, WB Saunders, 1994, p 200.)*

hypertrophy may progress quite rapidly within the first year of life, but the typical evolution to a clinical picture of cyanotic tetralogy of Fallot often takes 1 to 4 years. In those infants who develop right ventricular outflow obstruction, the incidence of spontaneous closure or reduction in size of a VSD is low.

VENTRICULAR SEPTAL DEFECT WITH AORTIC REGURGITATION.

This well-described complication of VSD occurs in about 5 percent of patients.[159] It usually is noted after age 5 years when a physician detects the early diastolic blowing murmur and wide pulse pressure of aortic regurgitation while monitoring a patient with a VSD. The diagnosis is readily confirmed by Doppler echocardiography. In such patients, aortic regurgitation may become the predominant hemodynamic abnormality. It is of interest that VSD with aortic regurgitation is rare in Europe and the United States, with an incidence of about 4 percent of all cases of isolated VSD, whereas in Japan the incidence is substantially higher (about 10 percent). In the Japanese, in particular, aortic regurgitation is the result of herniation of an aortic leaflet (usually the right coronary) through a subpulmonic supracristal VSD. In these patients, closure of the VSD may be all that is required to relieve aortic regurgitation. In many patients, however, especially in the Western world, the VSD is below the infundibular septum (crista supraventricularis). Although aortic leaflet herniation, especially of the right or noncoronary cusp, may occur in some of these patients, aortic regurgitation often results from a primary abnormality of the valve, usually one defective commissure. In the latter situation, plication of the elongated leaflet may lessen but not abolish the aortic regurgitation; in some patients, prosthetic aortic valve replacement may be necessary to provide hemodynamic relief.

In most patients with VSD and aortic regurgitation, the VSD is small to moderate in size, and mild right ventricular outflow tract obstruction exists. The latter is caused by either subpulmonic infundibular stenosis or projection of the herniated aortic cusp into the right ventricular outflow tract. The distinction between types of VSD with aortic regurgitation usually can be made by two-dimensional and Doppler echocardiography and by selective left ventricular angiocardiography to define the site of the interventricular communication in combination with retrograde aortography to assess the anatomy and competence of the aortic valve.[160]

Management.

Treatment of patients with VSD and aortic regurgitation is controversial. In patients with a large, hemodynamically significant left-to-right shunt, repair of the VSD is indicated, but aortic regurgitation is repaired only if at least moderate aortic regurgitation exists. If a supracristal VSD without aortic regurgitation is identified at cardiac catheterization in early childhood, a sensible argument for prophylactic closure of the VSD can be put forth to prevent the potential complication of aortic valve incompetence. In the presence of moderate or severe aortic regurgitation, valvuloplasty is preferred to valve replacement,[161] in recognition of the fact that the severity of aortic regurgitation may increase in subsequent years and that reoperation with valve replacement may be necessary. Operation should probably be deferred in asymptomatic patients with a subcristal VSD and an insignificant left-to-right shunt when aortic regurgitation is not severe. If the defect is supracristal in the same clinical setting, its closure may not alleviate the mild degree of aortic incompetence but may retard its progression.

OTHER FORMS OF VENTRICULAR DEFECT.

Unusual forms of VSD include numerous muscular defects and left ventricular-right atrial communications. Defects in the muscular ventricular septum frequently are several small fenestrations that produce a large net left-to-right shunt.[151] Their recognition is a necessary preliminary to successful operation because incomplete repair may result in postoperative cardiac failure and death. A shunt from the left ventricle to right atrium may occur with a VSD in the most superior portion of the ventricular septum because the tricuspid valve is lower than the mitral valve. The clinical, ECG, and radiological findings in these patients do not differ appreciably from those in patients with a simple VSD, although right atrial enlargement may provide a clue to correct diagnosis of left ventricular-right atrial communication.[162]

The pathophysiology of a single or common ventricle may resemble that of a large VSD, although these defects are dissimilar embryologically. The single chamber frequently is the morphological left ventricle; malposition of the great arteries is common. No cyanosis may be detectable if selective streaming and increased pulmonary blood flow rather than complete mixing occurs. Pulmonary hypertension invariably is present unless pulmonic stenosis exists. It is imperative to differentiate a single ventricle from a large VSD by echocardiography and angiography because the operative approaches to the former malformation require the atriopulmonary Fontan's connection.

MANAGEMENT.

It is rarely necessary to restrict the activities of a child with an isolated VSD. Infective bacterial endocarditis is always a threat, and antibiotic prophylaxis for dental procedures and minor surgery is indicated (see Table 43-4 , p. 1516). [163] Respiratory infections require prompt evaluation and treatment. These children should be seen at least once or twice yearly to detect changes in the clinical picture that suggest the development of pulmonary vascular obliterative changes.

SURGICAL TREATMENT.

When clinical findings suggest a moderate shunt but no pulmonary hypertension, elective hemodynamic evaluation should be undertaken before age 3 years. Of prime importance in the hemodynamic evaluation is determination of pressure and blood flow in the pulmonary artery.[164] Surgical treatment is not recommended for children who have normal pulmonary arterial pressures with small shunts (pulmonary-systemic flow ratios of less than 1.5 to 2.0:1).[165] In such patients, the remaining risk of infective endocarditis does not exceed the risk of operation. Moreover, although the inherent risk of operation is small, the possibility of postoperative heart block, infection, or other complications of operation and cardiopulmonary bypass dictates a conservative approach when the cardiac defect may be well tolerated for life.

In some centers, the use of intraoperative transesophageal echocardiography has provided accurate assessment of patch integrity and the presence of additional

muscular defects after termination of cardiopulmonary bypass.[166] [167]

With larger shunts, elective operation may be advised before the child enters school, thus minimizing any subsequent distinction of these patients from their normal classmates. Total assessment of the psychosocial dynamics of the family and child is helpful in determining the proper age for elective operation in each patient.

Under investigation is transcatheter closure by umbrella or clamshell occluder devices inserted by crossing the ventricular defect to guide a venous catheter through a long sheath and, ultimately, placing the device across the ventricular septum from the right ventricular side.[168] [169] [170] The use of such devices is limited to defects in the apical muscular septum, well distanced from the semilunar and AV valves.

Complete heart block is the most significant surgically induced conduction system abnormality, occurring immediately after surgery in fewer than 1 percent of patients. Late-onset complete heart block occasionally is a problem, especially in the 10 to 25 percent of patients whose postoperative ECG findings show complete right bundle branch block with left anterior hemiblock. When the latter ECG pattern is observed in patients with transient complete heart block in the early postoperative period, electrophysiological studies should be conducted at postoperative cardiac catheterization. Patients presenting postoperatively with right bundle block and left anterior hemiblock appear to fall into two populations, defined by either peripheral damage to the conduction system or damage to the bundle of His or its proximal branches. The former has not been associated with transient postoperative complete heart block, and these patients usually have a benign course. Trifascicular damage may be demonstrated in the latter population by a prolonged H-V interval, which implies a higher risk of complete heart block later in life. Although prophylactic use of permanent pacemakers in asymptomatic patients with evidence of trifascicular damage is not currently recommended, this group certainly requires careful follow-up and continued study.

Treadmill exercise studies of patients who preoperatively had normal or only moderately elevated pulmonary vascular resistance and essentially normal postoperative cardiac catheterization data may uncover late abnormalities in circulatory function.[171] Despite normal cardiac output at rest, an impaired cardiac output response to exercise is noted in some. Moreover, despite normal pulmonary arterial pressure at rest, markedly abnormal increases in pulmonary arterial pressure may be noted during exercise. These findings may be related to abnormal left ventricular function after closure of the VSD and/or to persistent pathological changes in the pulmonary arterioles or to abnormal pulmonary vascular reactivity.[172] A direct relation exists between age at operation and the magnitude of the pulmonary arterial pressure response to intense exercise, suggesting that early operation may prevent permanent impairment of the functional capacity of the myocardium and pulmonary vascular bed.

A child who has already developed pulmonary vascular obstruction and a net right-to-left shunt across the VSD may occasionally come to medical attention (see also p. 1614). Symptoms may consist of exertional dyspnea, chest pain, syncope, and hemoptysis; the right-to-left shunt leads to cyanosis, clubbing, and polycythemia. Little can currently be offered to this group of patients other than continuing support to the patient and family.

Patent Ductus Arteriosus (See also Chap. 44)

The ductus arteriosus normally exists in the fetus as a widely patent vessel connecting the pulmonary trunk and the descending aorta just distal to the left subclavian artery (see Fig. 43-4 , p. 1511). In a fetus, most of the output of the right ventricle bypasses the unexpanded lungs by way of the ductus arteriosus and enters the descending aorta, where it travels to the placenta, the fetal organ of oxygenation.

It was earlier assumed that during fetal life the ductus arteriosus is a passively open channel that constricted postnatally by means of undefined molecular mechanisms in response to the abrupt rise in arterial P_{O_2} accompanying the first breath of life.[173] Even in utero, the lumen of the ductus arteriosus may be influenced by vasoactive substances, particularly prostaglandins.[86] [87] [174] [175] [176] Thus, inhibition of prostaglandin synthesis causes profound constriction of the ductus arteriosus in the mammalian fetus that may be reversed by administration of vasodilatory E-type prostaglandins. Initial contraction and functional closure of the ductus arteriosus shortly after birth is related both to the sudden increase in the partial pressure of oxygen that accompanies ventilation and to changes in the synthesis and metabolism of vasoactive eicosanoids. Intimal proliferation and fibrosis proceed more gradually, so that anatomical closure may take as long as several weeks for completion.[177]

The ductus arteriosus is a unique structure after birth because its patency may, on the one hand, result in cardiac decompensation but may, on the other hand, provide the only life-sustaining conduit to preserve systemic or pulmonary arterial blood flow in the presence of certain cardiac malformations.[178] Appreciable left-to-right shunting across the patent ductus arteriosus frequently complicates the clinical course of infants born prematurely.[179] The ductal shunt has been implicated specifically in the deterioration of pulmonary function in infants with the respiratory distress syndrome; in these infants severe congestive heart failure often is unresponsive to digitalis and diuretics.[87]

A distinction should be made between patency of the ductus arteriosus in a *preterm* infant, who lacks the normal mechanisms for postnatal ductal closure because of immaturity, and a full-term newborn, in whom patency of the ductus is a true congenital malformation, probably related to a primary anatomical defect of the elastic tissue within the wall of the ductus.[177] In the former circumstance, delayed spontaneous closure of the ductus may be anticipated if the infant does not succumb to the cardiopulmonary difficulties caused by the ductus itself or to some lethal complication of prematurity, such as hyaline membrane disease, intraventricular hemorrhage, or necrotizing enterocolitis. In a similar manner, some full-term newborns have persistent patency of the ductus arteriosus for weeks or months because their relative hypoxemia contributes to vasodilatation of the channel. In the latter category are infants born at high altitude; those born with congenital malformations causing hypoxemia, such as pulmonary atresia with or without VSD; or those born with malformations in which ductal flow supplies the systemic circulation, such as hypoplastic left heart syndrome, interruption of the aortic arch, or some examples of coarctation of the aorta syndrome.

In the clinical settings in which the ductus preserves pulmonary blood flow, the essentially inevitable spontaneous closure of the vessel is associated with profound clinical deterioration. The latter may be reversed medically within the first 4 to 5 days of life by infusion of prostaglandin E_1 intravenously. By dilating the constricted ductus arteriosus, a temporary increase occurs in arterial blood oxygen tension and oxygen saturation and correction of acidemia.[178] These infants can then undergo operative repair or a palliative systemic-pulmonary anastomosis, under more optimal circumstances. Pharmacological dilation of the ductus arteriosus also is effective in preoperative restoration of systemic blood flow and alleviation of heart failure, especially in infants with aortic coarctation or hypoplastic left heart syndrome, and in infants with complete transposition of the great arteries in whom intercirculatory mixing is augmented.

PREMATURE INFANTS.

In most, if not all, preterm infants less than 1500-gm birth weight, persistence of a patent ductus arteriosus is prolonged, and in about one-third of these infants a large aorticopulmonary shunt is responsible for significant cardiopulmonary deterioration.[180] [181] Radiographic, echocardiographic, and Doppler ultrasound signs of significant left-to-right shunting usually precede the appearance of physical findings suggesting ductal patency. A significant increase in the cardiothoracic ratio is seen on sequential roentgenograms, as well as increased pulmonary arterial markings progressing to perihilar and generalized pulmonary edema. Serial echocardiographic evaluations that demonstrate increases in left ventricular end-diastolic and left atrial dimensions, especially when correlated with the aforementioned radiographic signs, are highly suggestive of a large shunt. Two-dimensional and Doppler echocardiography directly visualize and define the flow characteristics of the ductus arteriosus with great accuracy.[182]

Clinical Findings.

These include bounding peripheral pulses, an infraclavicular and interscapular systolic murmur (occasionally a continuous murmur), precordial hyperactivity, hepatomegaly, and either multiple episodes of apnea and bradycardia or respiratory dependence. Cardiac catheterization carries a high risk in preterm infants and seldom is indicated unless the diagnosis is obscure.

Treatment.

Treatment of preterm infants with a patent ductus arteriosus varies with the magnitude of shunting and the severity of hyaline membrane disease because the ductus may contribute importantly to mortality in the respiratory distress syndrome. Intervention in an asymptomatic infant with a small left-to-right shunt is unnecessary because the patent ductus arteriosus almost invariably undergoes spontaneous closure and does not require late surgical ligation and division. Those infants who demonstrate unmistakable signs of a significant ductal left-to-right shunt during the course of the respiratory distress syndrome often are unresponsive to medical measures to control congestive heart failure and require closure of the patent ductus arteriosus to survive. These infants are best treated within the first 2 to 7 days of life by pharmacological inhibition of prostaglandin synthesis with indomethacin to constrict and close the ductus[179] [183] [184] [185] ; surgical ligation is required in the estimated 10 percent of infants who are unresponsive to indomethacin.[186] Early intervention is advised to reduce the likelihood of necrotizing enterocolitis and of bronchopulmonary dysplasia related to prolonged respirator and oxygen dependence. Less often, indications for pharmacological or surgical closure of the ductus

consist of life-threatening episodes of apnea and bradycardia or a prolonged failure to gain weight and grow.

FULL-TERM INFANTS AND CHILDREN.

In full-term newborns and older infants and children, patency of the ductus arteriosus occurs particularly in girls and in the offspring of pregnancies complicated by first-trimester rubella. Although most frequent in isolated form, the anomaly may coexist with other malformations, particularly coarctation of the aorta, VSD, pulmonic stenosis, and aortic stenosis. Flow across the ductus is determined by the pressure relation between the aorta and the pulmonary artery and by the cross-sectional area and length of the ductus itself.[187] Pulmonary pressures most commonly are normal, and a persistent gradient and shunt from aorta to pulmonary artery exist throughout the cardiac cycle.

Physical examination reveals a characteristic thrill and a continuous machinery murmur, with a late systolic accentuation at the upper left sternal border. The left atrium and left ventricle enlarge to accommodate the increased pulmonary venous return, and flow murmurs across the mitral and aortic valves may be detected. With significant left-to-right shunting, the runoff of blood through the ductus causes a widened systemic pulse pressure and bounding peripheral pulses. The hemodynamic abnormality is reflected in the ECG by left ventricular and occasionally left atrial hypertrophy, and in the chest roentgenogram by left atrial and ventricular enlargement, prominent ascending aorta and pulmonary artery, and pulmonary vascular engorgement (see Chaps. 8 and 44).

The clinical diagnosis may be difficult when the findings do not conform to the classic presentation. As mentioned earlier, disappearance of the diastolic component of the murmur is common in premature infants because pulmonary arterial diastolic pressures are higher at that age. In older patients, both heart failure and pulmonary hypertension are associated with a reduction in the pressure gradient across the ductus arteriosus and result in atypical systolic murmurs. When severe pulmonary vascular obstructive disease results in reversal of flow through the ductus and preferential shunting of unoxygenated blood to the descending aorta, the toes, rather than the fingers, may show cyanosis and clubbing.

Full-term infants with patent ductus arteriosus may survive for a number of years, although a large defect occasionally results in heart failure and pulmonary edema early in life. The leading causes of death in older children are infective endocarditis and heart failure. Beyond the third

Figure 43-18 *Top panel,* High parasternal view of a patent ductus arteriosus in the sagittal plane demonstrating the classic position of a ductus arteriosus (D) lying between the pulmonary trunk (PT) and the descending aorta (DAO). The transverse aorta (TAO) giving rise to vessels to the head and neck is seen lying above the pulmonary trunk. The left atrium (LA) is seen inferiorly. The pulmonary trunk appears continuous with a wide patent ductus into the descending aorta just above the origin of the left pulmonary artery (L). *Bottom panel,* Patent ductus arteriosus (PDA) in a conventional parasternal short-axis view arising from the main pulmonary artery (MPA). The left pulmonary artery lies immediately to the right of the ductus and the left pulmonary artery lies adjacent to the ascending aorta (AO). The ductus is continuous with the descending aorta (DAO). The AO lies between the MPA anteriorly, the right atrium (RA) and LA posteriorly, and the right pulmonary artery laterally to the left.

Figure 43-19 Transcatheter closure of a patient ductus arteriosus is illustrated using the Rashkind double-umbrella technique. The catheter approaches the ductus via a long sheath advanced from the femoral vein. The *right panel* shows expansion of the distal umbrella. *(From Castaneda A, Jonas RA, Mayer JE Jr, et al: Cardiac Surgery of the Neonate and Infant. Philadelphia, WB Saunders, 1994, p 136.)*

decade of life, severe pulmonary vascular obstruction has been known to cause aneurysmal dilatation, calcification, and rupture of the ductus.[188]

The patent ductus can be directly visualized by two-dimensional echocardiography (Fig. 43-18) ; range-gated pulsed Doppler echocardiography shows the characteristic flow abnormalities across the ductus, as well as a continuous flow disturbance in the pulmonary artery. Cardiac catheterization may be indicated when additional lesions or pulmonary vascular obstruction is suspected.

Management.

In the absence of severe pulmonary vascular disease with predominant right-to-left shunting, the anatomical presence of a patent ductus usually is considered sufficient indication for closure. Ligation or division of the ductus carries a low risk, whether performed electively in an asymptomatic child or at any age if symptoms are present. The operative risk is reduced if heart failure can be compensated by medical measures before surgery. Operation should be deferred for several months in patients treated successfully for infective endarteritis because the ductus may remain somewhat edematous and friable. Rarely, when the infection does not subside with intensive antibiotic treatment, surgical ligation may be necessary to eradicate the infection.

Although strictly speaking still investigational, substantial experience exists with transcatheter closure of the patent ductus using various approaches, including coils, buttons, plugs, and umbrellas, with each occluder device introduced through a relatively large-diameter sheath from the femoral vein (Fig. 43-19) [189] [190] [191] [192] [193] [194] [195] (see Chap. 44). The approach is especially feasible in patients who weigh more than 10 kg and who have neither a long tubular ductus nor a ductus with a long, narrow aortic end. In experienced hands, initial occlusion is successful in 85 to 90 percent of patients; reocclusion adds 5 to 7 percent to the overall success rate. Potential complications in 5 to 10 percent of patients include embolization of the device, endocarditis, and hemolysis. Ductal closure by manually invasive surgery or thoracoscopy will undoubtedly undergo future evaluation.[196] [197]

Aorticopulmonary Septal Defect

Aorticopulmonary window or fenestration, partial truncus arteriosus, and aortic septal defect are other designations applied to this relatively uncommon anomaly. Septation of the aortopulmonary trunk occurs by fusion of the conotruncal ridges (see Fig. 43-2). The right and left sixth aortic arches, destined to become the pulmonary arteries, join the pulmonary artery to complete great artery development (see Fig. 43-5). Congenital defects between the ascending aorta and the pulmonary artery result from faulty development of this area during embryonic life. The typical aortopulmonary septal defect results because of incomplete fusion of the distal aortopulmonary septum.[198] Malalignment of the conotruncal ridges results in unequal partitioning of the aortopulmonary trunk, which may result in partial or complete fusion of the right pulmonary artery to the aorta.

The usual defect consists of a communication between the aorta and pulmonary artery just above the semilunar valves. Persistent patency of the ductus arteriosus is an associated lesion in 10 to 15 percent of cases. Less common accompanying cardiovascular lesions include VSD, aortic origin of the right pulmonary artery, aortic arch interruption, coarctation of the aorta, and right aortic arch. Aorticopulmonary septal defects usually are large and are accompanied by severe pulmonary arterial hypertension and early-onset pulmonary vascular obstruction.

PHYSICAL EXAMINATION.

The pulses typically are bounding, like those of a large patent ductus arteriosus. The murmur, however, seldom is continuous, and a basal systolic murmur is most common. Cardiomegaly is present, and pulmonary hypertension is reflected in a loud and palpable sound of pulmonary valve closure. Aorticopulmonary septal defect should be suspected whenever a large shunt into the pulmonary artery is demonstrated at catheterization. Diagnosis of the anomaly and its distinction from patent ductus and persistent truncus arteriosus usually can be done by two-dimensional echocardiography. Identification of the aortopulmonary window and associated malformations may also employ hemodynamic study and selective angiocardiography with the injection of contrast material into the left ventricle and/or the root of the aorta (Fig. 43-20) . Although some patients may survive to adulthood with uncorrected aorticopulmonary

Figure 43-20 Aortic root injection of contrast material in the frontal view produces simultaneous opacification of the aorta and pulmonary artery through a large aorticopulmonary septal defect (arrow). *(Courtesy of Dr. Robert White.)*

septal defect, most die early in life unless surgical treatment is undertaken. Rarely, transcatheter closure by insertion of an occluding device may be feasible in infants

with a small aortopulmonary window.[199] As a general rule, operative correction is indicated in all symptomatic infants when the diagnosis is made. Elective repair is advised at 3 to 6 months.[200] [201] Profound hypothermic total circulatory arrest or total cardiopulmonary bypass is required, and the defect is closed by way of a transaortic approach, usually with a prosthetic or xenograft pericardial patch.

Persistent Truncus Arteriosus

MORPHOLOGY.

Persistent truncus arteriosus is a rare but serious anomaly in which a single vessel forms the outlet of both ventricles and gives rise to the systemic, pulmonary, and coronary arteries.[202] The defect results from failure of septation of the embryonic truncus by the infundibular truncal ridges (see Fig. 43-4 , p. 1511). It is always accompanied by a VSD, frequently with a right-sided aortic arch. The VSD is due to the absence or underdevelopment of the distal portion of the pulmonary infundibulum. The truncal valve usually is tricuspid but is quadricuspid in about one-third of patients and rarely can be bicuspid. Truncal valve regurgitation and truncal valve stenosis are each seen in 10 to 15 percent of patients. There may be a single coronary artery, displacement of the coronary ostia (usually the left ostium posteriorly), or a single posterior descending coronary artery arising from the right coronary or, less often, from the left circumflex artery, especially in patients with a single coronary artery.[203]

Truncus malformations can be classified either anatomically according to the mode of origin of pulmonary vessels from the common trunk or from a functional point of view, based on the magnitude of blood flow to the lungs. In the common type (type I) of truncus arteriosus malformation, a partially separate pulmonary trunk of variable length exists because of the presence of an incompletely formed aorticopulmonary septum. The pulmonary trunk usually is very short and gives rise to left and right pulmonary arteries. When the aorticopulmonary septum is absent, there is no discrete main pulmonary artery component, and both pulmonary artery branches arise directly from the truncus.

In type II, each pulmonary artery arises separately but close to the other from the posterior aspect of the truncus (Fig. 43-21) . In type III, each pulmonary artery arises from the lateral aspect of the truncus. Less commonly, one pulmonary artery branch may be absent, with collateral arteries supplying the lung that does not receive a pulmonary artery branch from the truncus. Truncus arteriosus malformation should not be confused with "pseudotruncus arteriosus," which is the severe form of tetralogy of Fallot with pulmonary atresia in which the single aorta arises from the heart accompanied by a remnant of atretic pulmonary artery.

HEMODYNAMICS.

Pulmonary blood flow is governed by the size of the pulmonary arteries and the pulmonary vascular resistance. In infancy, pulmonary blood flow is usually excessive because pulmonary vascular resistance is not greatly increased. Thus, despite an obligatory admixture of systemic and pulmonary venous blood in the common trunk, only minimal cyanosis is present. Rarely, pulmonary blood flow is restricted by hypoplastic or stenotic pulmonary arteries arising from the truncus. Pulmonary vascular obstruction usually does not restrict pulmonary blood flow before 1 year of age.[204]

CLINICAL FEATURES.

Infants with truncus arteriosus usually present with mild cyanosis coexisting with the cardiac findings of a large left-to-right shunt. Symptoms of heart failure and poor physical development usually appear in the first weeks or months of life. The most frequent physical findings include cardiomegaly, a systolic ejection sound accompanied by a thrill, a loud single second heart sound, a harsh systolic murmur, and a low-pitched mid-diastolic rumbling murmur and bounding pulses. Truncus arteriosus often is a measure of the *DiGeorge's syndrome* (see Table 43-2 (Table Not Available)); thus, facial dysmorphism, a high incidence of extracardiac malformations (particularly of the limbs, kidneys, and intestines), atrophy or absence of the thymus gland, T-lymphocyte deficiency, and predilection to infection also may be features of clinical presentation.[205] Evidence suggests that genetically induced embryonic abnormalities in the cardiac neural crest play a major part in creation of the cardiovascular malformation as well as the other components of the syndrome[206] (see Chap. 56).

Truncal valve incompetence is suggested by the presence of a diastolic decrescendo murmur at the base of the heart. The physical findings are different if pulmonary blood flow is restricted by either high pulmonary vascular resistance or pulmonary arterial stenosis: Cyanosis is prominent, congestive failure is rare, and only a short systolic ejection may be audible, occasionally accompanied by continuous murmurs posteriorly of bronchial collateral flow.

Figure 43-21 *Top,* Subcostal coronal view of truncus arteriosus (Tr). The truncal valve lies above the ventricular septal defect (open arrow), which appears above the left ventricle (LV) and right ventricle (RV). The Tr is seen dividing into the transverse aortic arch (TAO), which gives rise to the vessels supplying the head and neck: the innominate artery (IA), the left carotid artery (LCA), and the left subclavian artery (LSA). *Bottom,* Doppler color flow image showing the superimposition of color flow into the truncus arteriosus, left pulmonary artery, transverse aorta, and branches to the head and neck.

ELECTROCARDIOGRAPHY AND RADIOGRAPHY.

Left ventricular hypertrophy alone or in combination with right ventricular hypertrophy is present electrocardiographically when a prominent left-to-right shunt exists; right ventricular hypertrophy is observed in patients with restricted pulmonary blood flow. The radiographic findings depend on the hemodynamic circumstances. Gross cardiomegaly with left or combined ventricular enlargement, left atrial enlargement, and a small or absent main pulmonary artery segment with pulmonary vascular engorgement are the usual radiographic features. A right aortic arch is common (25 to 30 percent of patients). When pulmonary blood flow is reduced, both heart size and pulmonary vascular markings are less prominent.

The *echocardiographic* features of truncus arteriosus (see Fig. 43-21) include a large truncal root overriding the ventricular septum and an outlet VSD. Additionally seen are

truncal valve abnormalities with a variable number of cusps and leaflets, often thickened with rolled edges, an increase in the right ventricular dimension, and mitral valve-truncal root continuity. Differentiation between truncus arteriosus and tetralogy of Fallot by ultrasonography may be difficult unless either the separate origin of the pulmonary arteries or a single trunk from the ascending portion of a single arterial root can he identified. The origin of the pulmonary arteries is detected from various imaging planes, including high short-axis views, scanning superiorly from the truncal valve, or from a subcostal view (see Fig. 43-21). Diagnosis should be suspected at cardiac catheterization if the catheter fails to enter the central pulmonary arteries from the right ventricle. Selective angiocardiography and retrograde aortography are necessary to establish a precise diagnosis and to reveal the common trunk arising from the heart and the origin of the pulmonary arteries from the truncus.[207]

The early fatal course as well as early development of pulmonary vascular obstructive disease in patients surviving infancy is responsible for the poor prognosis associated with truncus arteriosus. In infants and young children with large left-to-right shunts, surgical banding of one or both pulmonary arteries to reduce pulmonary flow has been used with little success. Corrective operation is indicated before age 3 months to avoid the development of severe pulmonary vascular obstructive disease.[208]

SURGICAL TREATMENT.

Operation consists of closure of the VSD, leaving the aorta arising from the left ventricle; the pulmonary arteries are excised from their truncus origin, and a valve-containing prosthetic conduit or aortic homograft valve conduit is used to establish continuity between the right ventricle and the pulmonary arteries (Fig. 43-22). Truncal valve insufficiency is a challenging problem and may require valve replacement or more moderate plastic repair to correct prolapse and improve central cusp coaptation. Important risk factors for perioperative death are severe truncal valve regurgitation, interrupted aortic arch, coronary artery anomalies, and age at operation greater than 100 days.[209] [210] Patients with only one pulmonary artery are especially prone to early development of severe pulmonary vascular disease but otherwise are not at increased risk from surgery.

With truncus arteriosus defects, the possible inequalities of pressure and flow between the two pulmonary arteries often make precise calculation of pulmonary resistance difficult. Corrective operation may be performed in patients with at least one adequate pulmonary artery having low distal pressure or arteriolar resistance. Conversely, significant systemic arterial desaturation in a patient with two pulmonary arteries and with neither pulmonary artery stenosis nor a previous pulmonary artery band signifies that high pulmonary vascular resistance exists and that the condition is probably inoperable. It is not yet clear how often and at what age the

conduit between the right ventricle and pulmonary artery must be replaced with a larger prosthesis because of either growth of the patient, in whom a small conduit causes eventual obstruction, heterograft valve degeneration, or obstruction created by neointimal proliferation within a prosthetic conduit.[211] When operation is carried out within a conduit in the first year of life, conduit replacement often is required within 3 to 5 years.

Coronary Arteriovenous Fistula

Coronary arteriovenous fistula (see also Chap. 44) is an unusual anomaly that consists of a communication between one of the coronary arteries and a cardiac chamber or vein. The right coronary artery, or its branches, is the site of the fistula in about 55 percent of cases; the left coronary artery is involved in about 35 percent, and both coronary arteries in 5 percent. Connections between the coronary system and a cardiac chamber appear to represent persistence of embryonic intertrabecular spaces and sinusoids. Most of these fistulas drain into the right ventricle, right atrium, or coronary sinus; fistulous communication to the pulmonary artery, left atrium, or left ventricle is much less frequent. The shunt through the fistula most often is of small magnitude, and myocardial blood flow is not compromised.[212] Rarely, spontaneous closure may occur. Potential complications include pulmonary hypertension and congestive heart failure if a large left-to-right shunt exists, bacterial endocarditis, rupture or thrombosis of the fistula or an associated arterial aneurysm, and myocardial ischemia distal to the fistula due to decreased coronary blood flow.

Most pediatric patients are asymptomatic and are referred because of a cardiac murmur that is loud, superficial, and continuous at the lower or midsternal border. The site of maximal intensity of the murmur is related to the site of drainage and usually is different from the second left intercostal space--the classic site of the continuous murmur of

Figure 43-22 Operative correction of truncus arteriosus, type III. The pulmonary arteries arise separately from the truncus. An anterior incision is made, and a segment of aorta containing the orifices of both pulmonary arteries is excised from the truncus *(a)*. The cuff of tissue containing the two pulmonary arteries is anastomosed to an extracardiac valved conduit *(b)*. Aortic continuity is restored by direct suture *(c)* or by interposing a preclotted graft *(d)*. The diagram does not show closure of the ventricular septal defect. *(From Stark J, deLaval M: Surgery for Congenital Heart Defects. New York, Grune & Stratton, 1983, p 420.)*

persistent ductus arteriosus--except when the fistula drains into the pulmonary artery or right ventricle. In the latter situation, the murmur is louder in diastole than in systole because of compression of the fistula by contracting myocardium. The ECG and chest roentgenogram findings often are normal and seldom show selective chamber enlargement or myocardial ischemia. A significantly enlarged feeding coronary artery can usually be detected by two-dimensional echocardiography. The entire course and site of entry of the AV fistula can be traced by combining two-dimensional echocardiography and Doppler color flow mapping and imaging techniques. The shunt entry site is characterized by a continuous turbulent systolic and diastolic flow pattern (see Chaps. 7 and 44). [212] [213] Multiplane transesophageal echocardiography also accurately defines the origin, course, and drainage site of the fistula.

Standard retrograde thoracic aortography, balloon occlusion angiography of the aortic root with a 45-degree caudal tilt of the frontal camera ("laid-back" aortogram),[214] or coronary arteriography can be used reliably to identify the size and anatomical features of the fistulous tract, which can be closed preferably by transcatheter coil embolization or suture obliteration in most cases.[215] [216] In the presence of a large left-to-right shunt and symptoms of heart failure, the decision to operate is clearly justified. The fistula most often is closed in asymptomatic patients to prevent future symptoms or complications, such as infective endocarditis. The prognosis after successful closure of a coronary artery-cardiac chamber fistula is excellent.

Anomalous Pulmonary Origin of the Coronary Artery

This rare malformation occurs in about 0.4 percent of patients with congenital cardiac anomalies. In almost all patients, the left coronary artery originates from the posterior sinus of the pulmonary artery.[217]

In unusual cases that have been reported, the right coronary artery, or the entire coronary artery system, originates from the main pulmonary trunk. Embryologically, the distal coronary artery system is formed by 9 weeks from solid angioblastic buds that extend throughout the epicardium to form the major coronary artery branches. Proximally, the coronary network forms a ring around the truncus arteriosus, joining with coronary buds from the primitive aortic sinuses as the truncus partitions to form the great arteries. The varieties of anomalous pulmonary origin of the coronary artery are the result of displacement in this proximal process.

PATHOPHYSIOLOGY.

During fetal life, pulmonary artery pressure is slightly greater than aortic pressure, and perfusion of the left coronary artery is antegrade (Fig. 43-23 *A*). After birth, when pulmonary artery pressure falls below aortic pressure, perfusion of the left coronary artery from the pulmonary artery ceases, and the direction of flow in the anomalous vessel reverses. Blood flows from the aorta to the right coronary artery, then through collateral channels to the left coronary artery, and finally to the pulmonary artery (Fig. 43-23 *B*). In effect, the left coronary artery behaves as a fistulous communication between the aorta and pulmonary artery. If adequate collateral channels exist or develop between the two coronary artery circulations, total myocardial perfusion through the right coronary artery increases (Fig. 43-23 *C*). In 10 to 15 percent of patients, myocardial ischemia never develops because extensive intercoronary collaterals allow survival to adolescence or adulthood. In fact, if collateral blood flow is considerable, patients may develop the clinical manifestations of a large arteriovenous shunt and a continuous or diastolic murmur.

By far the most common clinical presentation is that of an infant who suffers a myocardial infarction and develops congestive heart failure.[218] The infant syndrome usually becomes manifested at age 2 to 4 months with angina-like symptoms that may be misinterpreted as colic. Feeding and defecation often are accompanied by dyspnea, irritability and crying, pallor, diaphoresis, and occasional loss of consciousness. Older children or adults usually present with a continuous murmur or with mitral regurgitation resulting from dysfunction of ischemic or infarcted papillary muscles. In some instances, the coronary anomaly is unsuspected until a previously well adolescent or adult experiences angina, heart failure, or sudden death.

DIAGNOSIS.

The diagnosis of anomalous origin of the coronary artery is supported by ECG demonstration of deep Q waves in association with ST segment alterations and T wave inversions in leads I, aV_L , V_5 , and V_6 (Fig. 43-24) . These findings greatly assist the differentiation of this anomaly from myocarditis and dilated cardiomyopathy.[219] Chest roentgenograms show moderate to severe enlargement of the left atrium and ventricle. Echocardiography with Doppler color flow mapping has replaced cardiac catheterization as the standard method of diagnosis. The pulmonary

Figure 43-23 Anomalous origin of the left main coronary artery from the pulmonary artery. *A,* In a fetus, both right and left coronary arteries receive forward flow from their respective great arteries. *B,* Soon after birth, before collaterals are well developed, there may be an anterolateral infarct and slight retrograde flow from the left coronary artery to the pulmonary artery. *C,* After collaterals have enlarged, there is high flow in the enlarged right coronary artery and the collaterals and significant retrograde flow into the pulmonary artery. Dotted arrows indicate direction and approximate magnitude of flow in the right and left coronary arteries and the collaterals between them. PV = pulmonary vein; LA = left atrium; LAA = left atrial appendage; RA = right atrium; LMCA = left main coronary artery; LCx = left circumflex coronary artery; LAD = left anterior descending coronary artery; RCA = right coronary artery. *(From Hoffman JIE: In Emmanouilides GC, Riemenschneider TA, Allen HD, et al [eds]: Moss and Adams' Heart Disease in Infants, Children, and Adolescents. 5th ed. Baltimore, © Williams & Wilkins, 1994, p 776.)*

Figure 43-24 Typical electrocardiogram of an infant with anomalous left coronary artery before *(above)* and after *(below)* ligation of the anomalous left coronary artery. Note the abnormal Q waves in I, AVL, and V_6 . *(Courtesy of Dr. Delores A. Danilowicz.)*

origin of the anomalous left coronary artery is visualized from long- or short-axis views. Color flow mapping demonstrates retrograde flow in the left coronary system and an abnormal flow jet from the left coronary artery into the pulmonary trunk. Moreover, detection of anterograde flow in the left coronary system helps to preclude the diagnosis.[221] Color flow mapping of the jet from the origin of the left coronary artery as it enters the pulmonary artery is diagnostic. Detection of anterograde diastolic flow in the left coronary system virtually precludes this diagnosis.[220] If the echocardiographic diagnosis is unequivocal, coronary arteriography or aortography

is not required to make the diagnosis. The origin of the anomalous left coronary artery occasionally may be visualized echocardiographically from long- or short-axis views of the pulmonary artery.[221] Absence of the left coronary artery from its usual origin in the left sinus of Valsalva does not distinguish this lesion from single coronary artery. Color flow Doppler examination may also reveal associated mitral regurgitation. Ischemia or infarction is suggested by the echocardiographic findings of segmental wall motion abnormalities, particularly involving the anterolateral free wall of the left ventricle. Electron beam CT after intravenous contrast infection may accurately define the malformation (see Chap. 10). Stress thallium scintigraphy shows a characteristic defect of the anterolateral wall of the left ventricle. Positron emission tomography reveals both the perfusion defect and its metabolic consequences (Fig. 43-25).

Aortography or coronary angiography demonstrates the retrograde drainage of the coronary vessel into the pulmonary artery. It should be recognized that ventricular arrhythmias may complicate the course of hemodynamic study. The magnitude of shunting into the pulmonary artery may be determined by oximetry, indicator-dilution curves, or angiography.

MANAGEMENT.

Medical treatment is indicated in infants with myocardial infarction for congestive heart failure, arrhythmias, and cardiogenic shock. In patients with a small left-to-right shunt or no shunt at all, the prognosis is exceedingly poor with conservative management, justifying an attempt to reestablish a two-coronary artery system. The *operations* that have been used include reimplanting the left coronary artery into the aortic root, surgically creating an aortopulmonary window and a tunnel to convey blood from the window across the back of the pulmonary trunk to the origin of the anomalous left coronary artery, with reconstruction of the anterior wall of the pulmonary trunk, and anastomosis of the left coronary artery with the subclavian artery or with the aorta by means of a graft.[222] [223] If clinical deterioration occurs in infants with a sizable left-to-right shunt into the pulmonary artery, simple ligation of the left coronary artery at its origin prevents retrograde flow

Figure 43-25 Positron emission tomography (PET) transaxial images depict myocardial perfusion and glucose metabolism in a 7-month-old infant with anomalous origin of the left coronary artery (LCA) from the pulmonary artery. The ammonia (NH_3) scan demonstrates hypoperfusion *(left panel)*, whereas the fluorodeoxyglucose scan shows increased glucose metabolism *(right panel)* in the anterior lateral left ventricular wall (arrows) in the region perfused by the LCA. Under fasting conditions, normal myocardium has minimal glucose (FDG) uptake, whereas in this figure, hypoperfused myocardium preferentially metabolizes glucose. The "mismatch" pattern in this figure indicates ischemic but viable myocardium. This patient underwent reimplantation of the LCA with subsequent complete recovery of cardiac function and normalization of PET perfusion and metabolism. RV = right ventricle; LV = left ventricle; IVS = interventricular septum.

and allows perfusion of the left ventricle with blood supplied through anastomoses with the right coronary artery. If medical management stabilizes the infant with significant intercoronary collaterals, operation may be postponed to allow the patient to grow, because increased size of the vessels enhances the likelihood of successful reimplantation or coronary arterial bypass surgery. The outcome of surgery and ultimate prognosis are significantly influenced by the degree of myocardial damage suffered preoperatively.[224] Uncommonly, it is necessary to consider aneurysmectomy or mitral valve replacement. Cardiac transplantation has been suggested as an option only if recovery of myocardial function is poor.

Aortic Sinus Aneurysm and Fistula

Congenital aneurysm of an aortic sinus of Valsalva, particularly the right coronary sinus, is an uncommon anomaly that occurs three times more often in males than in females. The malformation consists of a separation, or lack of fusion, between the media of the aorta and the annulus fibrosis of the aortic valve.[225] The receiving chamber of the aorticocardiac fistula usually is the right ventricle, but occasionally, when the noncoronary cusp is involved, the fistula drains into the right atrium.

Five to 15 percent of aneurysms originate in the posterior or noncoronary sinus; seldom is the left aortic sinus involved. Associated anomalies are common and include bicuspid aortic valve, VSD, and coarctation of the aorta.

The deficiency in the aortic media appears to be congenital. Reports in infants are exceedingly rare[226] and are infrequent in children, because progressive aneurysmal dilatation of the weakened area develops but may not be recognized until the third or fourth decade of life, when rupture into a cardiac chamber occurs.

An *unruptured aneurysm* usually does not produce a hemodynamic abnormality, although pressure on the intracardiac conduction system by an unruptured aneurysm may be a rare cause of complete AV block; rarely, myocardial ischemia may be caused by coronary arterial compression. Rupture is often of abrupt onset, causes chest pain, and creates continuous arteriovenous shunting and volume loading of both right and left heart chambers, which results in heart failure. An additional complication is infective endocarditis, which may originate either on the edges of the aneurysm or on those areas in the right side of the heart that are traumatized by the jetlike stream of blood flowing through the fistula.

DIAGNOSIS.

The presence of this anomaly should be suspected in a patient with a history of chest pain of recent onset, symptoms of diminished cardiac reserve, bounding pulses, and a loud superficial continuous murmur accentuated in diastole when the fistula opens into the right ventricle, as well as a thrill along the right or left lower parasternal border. The *physical findings* can be difficult to distinguish from those produced by a coronary arteriovenous fistula. *Electrocardiography* shows biventricular hypertrophy, and chest roentgenography demonstrates generalized cardiomegaly. Two-dimensional and pulsed Doppler *echocardiographic* studies may detect the walls of the aneurysm and disturbed flow within the aneurysm or at the site of perforation, respectively.[227] *Transesophageal echocardiography* may provide more precise information than the transthoracic approach. *Cardiac catheterization* reveals a left-to-right shunt at the ventricular or, less commonly, the atrial level; the diagnosis may be established definitively by retrograde thoracic aortography (Fig. 43-26) .

MANAGEMENT.

Preoperative medical management consists of measures to relieve cardiac failure and to treat coexistent arrhythmias or endocarditis, if present. At operation, the aneurysm is closed and amputated, and the aortic wall is reunited with the heart, either by direct suture or with a prosthesis.[228] Every effort should be made to preserve the aortic valve in children because patch closure of the defect combined with prosthetic valve replacement greatly enhances the risk of operation in small patients.

VALVULAR AND VASCULAR LESIONS WITH OR WITHOUT RIGHT-TO-LEFT SHUNT

Aortic Arch Obstruction

The conventional anatomical and clinical divisions into preductal and postductal coarctation or infantile and adult types, respectively, are misleading because the anatomical localization is inaccurate and the age dependence of the clinical presentation does not hold true (i.e., the adult type often is seen in the first weeks of life). A spectrum of anatomical lesions exists, causing obstruction of the aortic arch or proximal portion of the descending aorta. These range from a localized coarctation or constriction of the lumen, most commonly located just distal to the origin of the left subclavian artery and closely related to the attachment of the ductus arteriosus with the aorta, to diffuse narrowing or interruption of a portion of the aortic arch. In this chapter, aortic arch obstruction is divided into three types: (1) localized juxtaductal coarctation, (2) hypoplasia of the aortic isthmus, and (3) aortic arch interruption. *Pseudocoarctation* is used synonymously with "kinking" or "buckling" of the aorta, which is a subclinical form of localized juxtaductal coarctation of the aorta.

Localized Juxtaductal Coarctation (See also p. 1600)

MORPHOLOGY.

This lesion consists of a localized shelflike thickening and infolding of the media of the posterolateral aortic wall opposite the ductus arteriosus; the wall of the aorta into which the ductus or ligamentum arteriosum inserts is not involved.[229] Juxtaductal coarctation occurs two to five times more commonly in males than in females, and there is a high degree of association with gonadal dysgenesis (Turner's syndrome) and bicuspid aortic valve.[230] Other common associated anomalies include VSD and

mitral stenosis or regurgitation. The most important extracardiac anomaly is aneurysm of the circle of Willis.

PATHOGENESIS.

Juxtaductal coarctation is probably related to an abnormality in the pattern of ductus arteriosus blood flow in utero, which in turn may be the result of associated intracardiac anomalies.[230] [231] Thus, in fetal life, blood flow through the aortic isthmus constitutes only 12 to 17 percent of the total cardiac output, whereas blood flow through the ductus arteriosus exceeds that across the aortic valve. The dorsal aortic wall directly opposite the ductus arteriosus resembles morphologically the apex of a normal branch point of the aorta if ductal flow pathways in utero diverge, with some flow directed cephalad into the aortic isthmus and the remainder proceeding into the descending aorta. The aortic branch point is identical histologically to the posterior shelf of juxtaductal aortic coarctation. A divergence of ductal flow is fostered by the presence of lesions in the fetus that create an imbalance between left and right ventricular outputs, with right-sided flow predominating (e.g., bicuspid aortic valve, mitral valve anomaly). In the absence of an anomaly fostering augmented ductal flow, a branch point may be created by an alteration in the angle at which the ductus arteriosus meets the aorta, pointing the ductal stream directly against the posterior aortic wall rather than obliquely down into the descending aorta. Cardiac anomalies that cause augmented ascending aortic blood flow (e.g., pulmonic atresia or stenosis, tetralogy of Fallot) prevent development of a branch point and indeed are almost never seen in association with juxtaductal coarctation of the aorta.

During fetal life, the posterior aortic shelf is not obstructive because blood may pass readily from the ascending aorta to the descending aorta by traversing the anterior aortic segment and the aortic end of the ductus arteriosus. Postnatally, however, when the ductus undergoes obliteration at its aortic end, the shelflike projection of the posterior aortic wall unmasks the obstruction to aortic flow (Fig. 43-27) . After pharmacological interventions that dilate the ductus arteriosus (prostaglandin E_1 infusion), the pressure difference may be obliterated across the site of coarctation because the fetal flow pattern is reestablished.[178] [232]

The pathogenesis of juxtaductal coarctation already described explains the prevalence of associated intracardiac anomalies that foster reduced ascending aortic flow and augmented ductus arteriosus flow in utero, as well as the absence of associated intracardiac anomalies in which the converse flow conditions exist in utero. The dependence of aortic obstruction on constriction of the ductus arteriosus postnatally explains the variable onset after birth of the clinical manifestations of coarctation, as well as the dramatic alleviation of the obstruction produced pharmacologically by dilatation of the ductus arteriosus.

CLINICAL FINDINGS.

The manifestations of juxtaductal coarctation of the aorta depend on the prominence of the posterolateral aortic shelf, which determines the intensity

Figure 43-27 Juxtaductal coarctation (COARCT) unmasked by constriction of the ductus arteriosus (DA). MPA = main pulmonary artery; D.Ao. = descending aorta; Ao.Isth. = aortic isthmus. *(Courtesy of Dr. Norman Talner.)*

of obstruction, and on the rapidity with which obstruction develops.

NEONATES AND INFANTS.

Rapid, severe obstruction in infancy is a prominent cause of left ventricular failure and systemic hypoperfusion. Substantial left-to-right shunting across a patent foramen ovale and pulmonary venous hypertension secondary to heart failure cause pulmonary arterial hypertension. Because little or no aortic obstruction existed during fetal life, the collateral circulation in the newborn period is often poorly developed. In these infants, peripheral pulses characteristically are weak throughout the body until left ventricular function is improved with medical management; a significant pressure difference then develops between the arms and the legs, allowing detection of a pulse discrepancy. Cardiac murmurs are nonspecific in infancy and commonly are derived from associated lesions.

The *ECG* shows the right-axis deviation and right ventricular hypertrophy; the *chest radiograph* shows generalized cardiomegaly and pulmonary arterial and venous engorgement. Two-dimensional and Doppler echocardiography provide an accurate noninvasive assessment of the anatomy and physiology in most patients. Hemodynamic study also allows delineation of the site and extent of aortic obstruction and detection of associated cardiac malformations. Most infants with early-onset severe heart failure respond poorly to medical management, and balloon angioplasty, surgical excision of the coarctation, or a subclavian flap angioplasty often is required. We prefer an operation consisting of excision of the area of coarctation and extended end-to-end repair or end-to-side anastomosis with absorbable sutures to allow remodeling of the aorta with time.[233]

Aortic obstruction may develop slowly in infants in whom the posterolateral aortic shelf is not prominent at birth and in whom ductus arteriosus constriction is gradual. In these babies, compensatory myocardial hypertrophy and an extensive collateral circulation have time to develop. If the obstruction does not intensify and cardiac failure does not occur by age 6 or 9 months, circulatory compensation is likely until adult life.

CHILDREN.

Most children with isolated juxtaductal coarctation are asymptomatic. Complaints of headache, cold extremities, and claudication with exercise may be noted, although attention usually is directed to the cardiovascular system by detection of a heart murmur of upper extremity hypertension on routine physical examination. Mechanical factors rather than those of renal origin play the primary role in the production of hypertension. Absent, markedly diminished, or delayed pulsations in the femoral arteries and a low or unobtainable arterial pressure in the lower extremities with hypertension in the arms are the basic clues to the diagnosis. A midsystolic murmur over the anterior chest, back, and spinous processes is most frequent, becoming continuous if the lumen is sufficiently narrowed to result in a high-velocity jet across the lesion throughout the cardiac cycle. Additional systolic and continuous murmurs over the lateral thoracic wall may reflect increased flow through dilated and tortuous collateral vessels.

ECG reveals left ventricular hypertrophy of various degrees, depending on the height of arterial pressure above the obstruction and the patient's age. Combined with right ventricular hypertrophy, this usually implies a complicated lesion. *Chest roentgenograms* (see Chaps. 8 and 44) can show a dilated left subclavian artery high on the left mediastinal border and a dilated ascending aorta. Indentation of the aorta at the site of coarctation and prestenotic and poststenotic dilatation (the "3" sign) along the left premediastinal shadow is almost pathognomonic. Poststenotic dilation also may be detected by indentation of the barium-filled esophagus. Notching of the ribs, an important radiographic sign, is due to erosion by dilated collateral vessels, increases with age, and usually becomes apparent between the 4th and 12th years of life. The aortic coarctation may be visualized directly by two-dimensional echocardiography from high parasternal or suprasternal notch views with short focused transducers and from the subxiphoid window with extended focal range transducers (Fig. 43-28) . Doppler examination reveals a flow disturbance and high-velocity jet at the site of obstruction and provides a reasonable estimate of the transcoarctation pressure gradient.[234] [235] CT, magnetic resonance imaging[235] [236] (Fig. 43-29 and Chap. 10), or cardiac catheterization and aortography (see Fig. 44-7 , p. 1601) also accurately localizes the site of

Figure 43-28 Aortic coarctation (Coarc) is visualized from the suprasternal notch. The aorta (Ao) can be traced from the ascending aorta (AAo). The aortic arch is somewhat narrowed, and the relationship of the left subclavian artery (LS) to the coarctation is identified clearly. LA = left atrium; PA = pulmonary artery; IA = innominate artery; LC = left carotid artery.

obstruction, determines the length of coarctation, and, particularly, identifies associated malformations. Preoperative catheterization is avoided for selected patients with typical clinical and two-dimensional and Doppler echocardiographic findings.[237] Intravascular ultrasonography provides interesting morphological images suitable especially for comparison with postoperative status.[238]

MANAGEMENT.

Controversy exists about the role of balloon angioplasty (see Chap. 38), with or without balloon-expandable stents, in the treatment of native coarctation, especially in neonates.[239] [240] [241] [241A] There is concern about residual pressure gradients, aneurysm formation, aortic dissection and rupture, and femoral arterial complications,

especially late after angioplasty. It is clear that angioplasty can effectively reduce obstruction in many patients, albeit with an unpredictable late outcome.

An extended end-to-end anastomosis with resection of the aortic isthmus and ductal tissue yields a low mortality and a low rate of recoarctation. It is now the procedure of

Figure 43-29 Three-dimensional computer reconstruction of magnetic resonance images in a child with discrete coarctation and numerous large collateral vessels, displayed in a lateral projection. Dilated brachiocephalic and internal mammary arteries are evident. *(Courtesy of Dr. W. James Parks, The Children's Heart Center, Emory University, Atlanta, GA.)*

choice at many centers.[242] Subclavian flap aortoplasty, particularly in neonates and infants, or surgical resection and end-to-end anastomosis of uncomplicated juxtaductal coarctation of the aorta can be accomplished with excellent results in most patients[243] ; some surgeons prefer an onlay patch across the site of obstruction. In children who are asymptomatic, it is preferable to delay surgery until age 4 to 6 years, at which time coarctation seldom recurs. Paradoxical hypertension of short duration often is noted in the immediate postoperative period, a phenomenon much less common after balloon angioplasty.[244] [245] [246] [247] A resetting of carotid baroreceptors and increased catecholamine secretion appears to be responsible for the initial phase of postoperative systemic hypertension, with a later, second phase of prolonged elevation of systolic and particularly diastolic blood pressure related to activation of the renin-angiotensin system. A necrotizing panarteritis of the small vessels of the gastrointestinal tract of uncertain cause occasionally complicates the course of recovery.

The risk of recurrent narrowing after repair of coarctation in infancy is 5 to 10 percent. Such narrowing is best detected by magnetic resonance imaging or Doppler ultrasonography.[235] This problem is treated most effectively by transcutaneous balloon angioplasty,[248] [248A] [249] which may be expected to markedly reduce but not entirely abolish the pressure differences across the site of recoarctation.

In those patients who survive the first 2 years of life, complications of juxtaductal coarctation are uncommon before the second or third decade. The chief hazards to patients with coarctation result from severe hypertension and include the development of cerebral aneurysms and hemorrhage, hypertensive encephalopathy, rupture of the aorta, left ventricular failure, and infective endocarditis. Systemic hypertension in the absence of residual coarctation has been observed in resting or exercise-stressed patients postoperatively and appears to be related to the duration of preoperative hypertension.[250] Lifelong observation is desirable because of the late onset of hypertension in some postoperative patients.[251]

Hypoplasia of the Aortic Arch

MORPHOLOGY.

The aortic isthmus, the portion of the aorta between the left subclavian artery and the ductus arteriosus, normally is narrowed in the fetus and newborn. The lumen of the aortic isthmus is about two-thirds that of the ascending and descending portions of the aorta until age 6 to 9 months, when the physiological narrowing disappears.[252] Pathological tubular hypoplasia of the aortic arch usually is noted in the aortic isthmus and often is referred to as preductal or infantile coarctation of the aorta.[253] Associated major cardiac malformations occur in virtually all such infants and include large VSD, AV septal defect, transposition of the great arteries, the Taussig-Bing type of anomaly, and double-outlet right ventricle. The VSD most often is subpulmonary, lying within the substance of the infundibular septum. Thus, muscle persists between the aortic and pulmonary valve leaflets, and when it is displaced leftward, it produces subaortic stenosis. Persistent patency of the ductus arteriosus commonly coexists, and right-to-left flow across the ductus arteriosus usually provides filling of the descending aorta. The adequacy of blood flow to the lower body depends on the degree of aortic hypoplasia, the caliber of the ductus arteriosus, and the relationship between pulmonary and systemic vascular resistance. Substantial right-to-left shunting through a wide-open ductus arteriosus minimizes the arterial blood pressure difference between the upper and lower body.

CLINICAL FINDINGS.

Differential cyanosis of the toes and feet with normal color of the fingers and hands may be difficult to discern because intracardiac left-to-right shunting and pulmonary edema attenuate the differences in oxygen saturation in the ascending and descending aorta. Clinical deterioration is associated with ductal constriction or a decline in pulmonary vascular resistance. Moreover, the clinical presentation often is dictated by the hemodynamic effects of complex associated intracardiac malformations. Infants most often present with findings of a large left-to-right intracardiac shunt, pulmonary hypertension, and marked cardiac decompensation. Although tubular hypoplasia is detectable by two-dimensional echocardiography, cardiac catheterization may be required to evaluate the full extent of intracardiac and extracardiac lesions. Surgical repair of aortic

Figure 43-30 An extended repair of aortic coarctation is used in the presence of a hypoplastic aortic arch. The broken lines in the *left panel* delineate resection sites of the coarcted segment. In the *right panel,* the ductus arteriosus has been ligated and the incisions are extended to the undersurface of the aortic arch and onto the distal aorta. When the suture line is completed, the reconstruction of the arch is generally excellent. *(From Stark J, deLaval M: Surgery for Congenital Heart Defects. 2nd ed. Philadelphia, WB Saunders, 1994, p 292.)*

arch hypoplasia usually must be accompanied by operative palliation or correction of associated intracardiac lesions. An extended end-to-end anastomosis (Fig. 43-30) , classic or reversed subclavian flap angioplasty, patch aortography, and bypass grafting are among the operative approaches to correct long segment narrowing.[247] Recoarctation is common and often necessitates transcatheter balloon aortoplasty and/or a second operation later in life to relieve anastomotic stenosis.[247] [248]

AORTIC ARCH INTERRUPTION.

Aortic arch interruption is a rare and usually lethal anomaly; unless treated surgically, almost all infants die within the first month of life.[254] Interruptions distal to the left subclavian artery (type A) occur with almost equal frequency to interruptions distal to the left common carotid artery (type B); interruptions distal to the innominate artery (type C) are extremely uncommon. The right subclavian artery often is of variable origin, frequently arising from the descending aortic segment distal to the interruption. The clinical presentation resembles that in tubular hypoplasia or severe juxtaductal coarctation of the aorta with a patent ductus arteriosus.

Virtually all patients have associated intracardiac anomalies. A patent ductus arteriosus almost always connects the main pulmonary artery with the descending aorta. With rare exceptions, patients with interrupted aortic arch have either a VSD (80 to 90 percent of cases) or an aorticopulmonary window (10 to 20 percent). Because the ductus arteriosus provides lower body blood flow, its spontaneous constriction results in profound clinical deterioration. The latter may be temporarily ameliorated by prostaglandin E_1 infusion. The VSD most often is subpulmonary, lying within the substance of the infundibular septum. Thus, muscle persists between the aortic and pulmonary valve leaflets; when the muscle is displaced leftward, it produces subaortic stenosis.[255] Other complex intracardiac malformations, such as transposition of the great arteries, aortopulmonary window, and truncus arteriosus, are common.

CLINICAL FEATURES.

An association is frequent with the genetic 22q11 deletion of DiGeorge's syndrome, a constellation of cardiac, parathyroid, thymic, and facial anomalies attributed to disruption of the interaction of premigratory neural crest cells with endodermal pharyngeal pouch cells. In this syndrome, thymic hypoplasia or aplasia is accompanied by immunological and hypocalcemia problems.[256] [257] The major clinical problem is severe congestive heart failure as a consequence of volume overload of the left ventricle resulting from an associated intracardiac left-to-right shunt and of pressure overload imposed by systemic hypertension.

Management.

The perioperative clinical condition of most patients can be improved by intensive medical management with mechanical ventilation, inotropic support, and prostaglandin infusion. Various forms of palliative operative techniques have fair to poor results. There has been increasing success with complete primary repair in infancy as the procedure of choice.[258] Greater mortality is associated when a two-stage approach with initial arch repair and pulmonary artery banding is followed by later repair of the intracardiac lesion. Recurrent narrowing at the aortic suture line can be treated by balloon angioplasty or reoperation.

Congenital Valvular Aortic Stenosis (See also p. 1599)

MORPHOLOGY.

Congenital valvular aortic stenosis is a relatively common anomaly, estimated to occur in 3 to 6 percent of patients with congenital cardiovascular defects. However, it must be appreciated that the true incidence of the malformation is probably grossly underestimated because the congenital bicuspid aortic valve may be undetected in early life and becomes stenotic and of clinical significance only in adult life, at a time when it may be indistinguishable from the acquired forms of aortic stenosis. Congenital valvular aortic stenosis occurs much more frequently in males than in females, with the gender ratio approximating 4:1. Associated cardiovascular anomalies have been noted in as many as 20 percent of patients.[259] Patent ductus arteriosus and coarctation of the aorta occur most frequently with valvular aortic stenosis; all three of these lesions may coexist (see also Chap. 44).

The basic malformation consists of thickening of valve tissue with various degrees of commissural fusion. The valve most commonly is the bicuspid, with a single fused commissure and an eccentrically place orifice. A third commissure, incomplete or rudimentary, is sometimes apparent. Less commonly, the valve has three fused cusps with a stenotic central orifice. In some patients, the stenotic aortic valve is unicuspid and dome shaped, with no or one lateral attachment to the aorta at the level of the orifice. In infants and young children with severe aortic stenosis, the aortic valve ring may be relatively underdeveloped. This lesion forms a continuum with the hypoplastic left heart syndrome and the aortic atresia and hypoplasia complexes. Secondary calcification of the valve is extremely rare in childhood, but the dynamics of blood flow associated with the congenitally deformed aortic valve ultimately lead to thickening of the cusps and calcification in adult life. When the obstruction is hemodynamically significant, concentric hypertrophy of the left ventricular wall and dilatation of the ascending aorta occur.

HEMODYNAMICS (see also Chaps. 11 and 46).

The hemodynamic abnormalities produced by obstruction to left ventricular outflow are discussed in Chapter 46 . A peak systolic gradient exceeding 75 mm Hg in association with a normal cardiac output or an effective aortic orifice less than 0.5 cm^2 /m body surface area is considered to reflect critical or severe obstruction to left ventricular outflow.[259] The normal outflow orifice approximates 2.0 cm^2 /m body surface area; areas of 0.5 to 0.8 cm^2 /m^2 signify moderate obstruction; when the area is larger than 0.8 cm^2 /m^2 , the obstruction is considered to be mild.

The resting cardiac output and stroke volume usually are within normal limits. During exercise, most children with critical stenosis show an elevation of the cardiac output and an associated elevation in the transvalvular pressure gradient.[260] When left ventricular failure occurs, cardiac output decreases and left atrial, left ventricular end-diastolic, and pulmonary vascular pressures increase.

Studies of left ventricular performance in children with aortic stenosis often reveal supernormal pump function, as

indicated by increases in ejection fraction and circumferential fiber shortening.[261] Despite high left ventricular systolic pressures, left ventricular wall stress appears to be lower than normal throughout systole, presumably because increases in wall thickness provide overcompensation for the pressure overload. Undoubtedly, a spectrum exists, from well-compensated patients at one end, who have supernormal pump function and normal contractile function, to patients with heart failure at the opposite end, who have both impaired pump function and a reduced contractile state.

While pressure overload hypertrophy can preserve systolic function, it can also result in abnormal left ventricular early diastolic filling.[262] Thus, clinical studies seeking to analyze the determinants of left ventricular filling by a separate assessment of dynamic (elastic recoil, ventricular relaxation rate, and atrial driving pressure) and static (chamber stiffness and left ventricular hypertrophy) determinants suggest that diastolic function most importantly varies according to the severity of left ventricular hypertrophy and systolic function. Studies of children suggest that hypertrophy is a more important factor than excessive wall stress and depressed ejection performance in accounting for abnormal diastolic filling.

The blood supply to the myocardium may be significantly compromised in infants and children with aortic stenosis, despite normal patency of the coronary arteries.[263] Coronary blood flow and arterial oxygen content are critical determinants of oxygen supply to the myocardium. Because intramyocardial compressive forces are greatest in the subendocardium, blood flow to that region of the left ventricle is entirely diastolic in the presence of elevated left ventricular systolic pressure. In patients with left ventricular outflow tract obstruction, coronary vasodilatation may give an inadequate response to an increase in the demands of the myocardium for oxygen at rest or with exercise. When subendocardial vessels are maximally dilated, the coronary artery driving pressure and the duration of diastole determine the magnitude of subendocardial flow. When the duration of systolic ejection lengthens across the stenotic orifice, diastole is shortened, especially at high heart rates. Moreover, a reduction occurs in coronary driving pressure if left ventricular end-diastolic pressure is high or if aortic diastolic pressure is low, e.g., with aortic regurgitation or heart failure. In patients with severe aortic stenosis, the redistribution of flow away from the subendocardium and the ischemia that results in that portion of ventricular muscle may be estimated by relating the diastolic pressure-time index (DPTI) (i.e., the area between the aortic and left ventricular pressures in diastole) to the systolic pressure-time index (SPTI) (a measure of myocardial oxygen demands). Inadequate subendocardial oxygen delivery has been shown to exist when the ratio [DPTI × arterial oxygen content/SPTI] falls below 10.[263]

NEONATES AND INFANTS

Reports exist of cardiac dysfunction and even nonimmunological fetal hydrops fetalis in association with severe aortic stenosis.[264] [265] [266] The hydrops can be the result of in utero left ventricular myocardial infarction or profound left ventricular systolic and diastolic dysfunction. Balloon dilation using coronary balloon catheters has been attempted via transabdominal echo-guided needle puncture of the fetal left ventricle. This approach is not established, and it is doubtful that it will become a management option.

Fortunately, isolated aortic valvular stenosis seldom causes symptoms in infancy.[267] This lesion, however, occasionally can be responsible for profound and intractable heart failure, even in fetal life. Despite normal coronary arterial anatomy, infarction of left ventricular papillary muscles may occur, resulting in an acquired form of mitral valvular regurgitation that intensifies the heart failure state. In addition, endocardial fibroelastosis may result from limited subendocardial oxygen delivery, and myocardial degeneration may be significant. Symptomatic infants with isolated valvular aortic stenosis are irritable, pale, and hypotensive and present with tachycardia, cardiomegaly, and pulmonary congestion manifested by dyspnea, tachypnea, subcostal retractions, and diffuse rales. Cyanosis may be observed secondary to pulmonary venous desaturation. The systolic murmur in infants often is atypical; it is best heard at the apex or along the lower left sternal border and may be confused with that caused by a VSD. In infants with heart failure, the murmur occasionally may be absent or extremely soft, becoming louder when myocardial contractility is improved with digitalis and other medical measures. Infants with heart failure frequently have a poor response to medical management.

The *ECG findings* may not be characteristic; left ventricular hypertrophy and/or strain as well as right atrial enlargement and right ventricular hypertrophy may be detected shortly after birth.[267] The latter signs of right heart involvement result from both pulmonary hypertension secondary to elevated left ventricular diastolic and left atrial pressures and from volume loading of the right ventricle caused by left-to-right shunting across the foramen ovale. Survival past the early neonatal period does not preclude subsequent difficulties, and clinical deterioration may recur with the onset of physiological anemia.

Management

Congenital aortic stenosis must be considered a medical emergency in a seriously ill newborn, and echocardiography, and sometimes cardiac catheterization and angiocardiography, may be indicated in the first 24 hours of life. Two-dimensional echocardiographic studies show a severe immobility of the aortic valve, with little or no systolic opening, poststenotic dilation of the aorta, left ventricular hypertrophy, right ventricular enlargement, and a severely disturbed Doppler-determined pattern of ascending aortic flow velocity. The echo-Doppler examination must also identify associated intracardiac and extracardiac anomalies, one of the most important of which is severe aortic arch obstruction.

Dilation of the ductus arteriosus with prostaglandin E_1 infusion may provide transitional support of the systemic circulation. In many centers, expeditious balloon aortic valvuloplasty follows the echo-Doppler examination in infants who are unstable and markedly symptomatic.[268] [269] [270] [271] [272] A number of approaches have been reported for performing this procedure, including the use of a carotid artery cutdown, which thus far does not appear to result in any abnormalities of the carotid pulse or any neurological sequelae. A transumbilical technique of balloon valvuloplasty can be performed quickly, safely, and effectively with preservation of the femoral artery. Because of a high risk of iliofemoral artery complications in infants with the transfemoral route to valvuloplasty, when this route is used it is advisable to use double-balloon techniques to allow insertion of small valvuloplasty catheters. The complications of balloon valvuloplasty are related to the small size and young age of the patient. Accordingly, if arterial access is a problem, and in infants younger than 1 month, surgical valvotomy remains a satisfactory option. Open repair under direct vision is the preferred type of operation.

Hemodynamic findings in neonates and infants frequently include left-to-right shunting at the atrial level, elevated left atrial and left ventricular end-diastolic pressures, and a small pressure drop across the aortic valve as a result of markedly reduced cardiac output. Right-to-left shunting across a patent ductus arteriosus is encountered occasionally. The lesion may be distinguished from the hypoplastic left heart syndrome echocardiographically and angiographically by the presence of normal or enlarged left ventricular cavity and normal or dilated ascending aorta.[273] [274] Establishment of the diagnosis and prompt catheter valvuloplasty or surgical valvotomy are justified because prolonged periods of stabilization are uncommon with medical therapy. Poor myocardial performance resulting from endocardial fibroelastosis, subendocardial ischemia, reduced left ventricular compliance, and inadequate relief of obstruction with or without aortic insufficiency are some of the factors accounting for high mortality and morbidity after catheter-directed treatment or operation.

At the extreme end of the spectrum of critical valvar aortic stenosis in newborns are patients with many small left-sided structures; in these patients, the adverse effects of small inflow, outflow, and/or cavity size of the left ventricle appear to be cumulative.[274] It is in this group that traditional treatment by aortic valvuloplasty or valvotomy, which is a two-sided ventricle repair, may be less effective than a multistaged Norwood approach.[274] The latter consists of an initial single-ventricle repair in which the main pulmonary artery is anastomosed to the aorta with creation of a systemic-to-pulmonary arterial shunt, followed later by a Fontan-type operation that creates an atriopulmonary connection, with or without a prior superior cava-pulmonary connection. The single-ventricle repair results in functional sacrifice of the left ventricle and the right ventricle supporting the systemic circulation without a pulmonary ventricle.

CHILDREN

Congenital aortic stenosis may be responsible for severe obstruction to left ventricular outflow in the absence of clinical symptoms of diminished cardiac reserve that are so frequent in other forms of congenital heart disease.[275] Most children with congenital aortic stenosis grow and develop normally and are asymptomatic. Attention usually is called to these children when a murmur is detected on routine examination. When symptoms occur, those noted most commonly are undue fatigue, exertional dyspnea, angina pectoris, and syncope. Less often described are abdominal pain, profuse sweating, and epistaxis. A symptomatic child usually has critical stenosis. There is a distinct threat of sudden death in patients with severe obstruction[276] (see Chap. 26). Although the precise cause is poorly understood, ventricular arrhythmias, perhaps initiated by acute myocardial ischemia, are probably the most common inciting event. It has been speculated that an abrupt rise in intracavity left ventricular systolic pressure elicits a reflex hypotensive syncope that promotes acute ischemia and ventricular fibrillation. Bacterial endocarditis occurs in about 4 percent of patients with congenital valvular aortic stenosis.[277]

DIAGNOSIS

Physical Findings.

When the magnitude of obstruction is significant, a left ventricular lift usually is palpable, and a precordial systolic thrill often is palpated over the base of the heart with transmission to the jugular notch and along the carotid arteries; presystolic expansion often is palpable. The obstruction usually is mild if neither a left ventricular lift nor a thrill is present.

Opening of the aortic valve produces a systolic aortic ejection sound that typically is present at the cardiac apex when the valve is mobile, particularly in patients with mild to moderate stenosis. A delay in closure of the stenotic aortic valve leads to a single or a closely split second heart sound, and paradoxical splitting may be present. A fourth heart sound normally is associated with severe obstruction. A loud, harsh, rhomboid-shaped systolic murmur starts after completion of left ventricular isometric contraction and is best heard at the base of the heart. The murmur, like the thrill, radiates to the suprasternal notch and carotid vessel as well as to the apex. An early diastolic blowing murmur of aortic regurgitation is present in some patients, but unless the valve leaflets have been eroded by bacterial endocarditis, the regurgitation usually is not hemodynamically significant; uncommonly, in patients with a congenitally bicuspid valve, aortic regurgitation may be severe and may predominate.

Electrocardiography.

ECG signs of left ventricular hypertrophy tend to vary with the severity of obstruction, although a normal or near-normal ECG does not preclude severe aortic stenosis, and excessive left ventricular voltages may be observed in children with mild obstruction.[275] The lack of close correlation between the ECG and the transvalvular pressure gradient emphasizes the potential hazard of relying on the ECG in patient care. The most reliable index of the severity of obstruction is the presence of a left ventricular "strain pattern," consisting of left ventricular hypertrophy combined with ST segment depressions and T wave inversion in the left precordial leads (Fig. 43-31) .

Roentgenography.

Overall heart size is normal or the degree of enlargement is slight in most children with congenital valvular aortic stenosis. Concentric left ventricular hypertrophy accompanies moderate or severe obstruction and is manifested by rounding of the cardiac apex in the frontal projection and posterior displacement in the lateral view.

Echocardiography.

Two-dimensional and Doppler echocardiography are the current methods of choice for defining the anatomy and the hemodynamic severity of valvular aortic stenosis.[278] [279] Real-time cross-sectional echocardiography reveals impaired mobility of cusp tissue, an alteration in the phasic movement of the aortic valve with reduced lateral and increased superior excursions of valve echoes, and an increase in the internal aortic root dimension beyond the level of the valve annulus.[259] Imaging of the valve must be performed many times in order to display the

Figure 43-31 Electrocardiogram in congenital aortic stenosis. This tracing shows left ventricular hypertrophy and the typical left ventricular "strain" pattern (V_6). *(Courtesy of Dr. Delores A. Danilowicz.)*

valve through the long axis of the left ventricular outflow tract and then through a plane parallel to the valve annulus. The long-axis view of the left ventricular outflow tract allows evaluation of the valve mobility and cusp separation; it is the best view for demonstrating doming of the aortic valve. The parasternal short-axis view bisects the face of the valve, demonstrating the anatomy of the commissures (Fig. 43-32) .

The echocardiogram also reveals associated left ventricular hypertrophy and the presence of endocardial fibroelastosis (seen as bright endocardial echoes). Further, measurements of mitral valve diameter, left ventricular enddiastolic dimension, and left ventricular cross-sectional area serve to distinguish those infants with critical aortic stenosis from those with a hypoplastic left ventricle.[274] Among these calculations suggesting the latter are an end-diastolic volume less than 20 ml/m^2 , an inflow dimension of 25 mm, a narrow ventricular aortic junction less than 5 mm, or a small mitral orifice less than 9 mm. Pulsed-wave Doppler echocardiography allows inspection of the pattern of flow velocity within the circulation. This technique detects the altered and disturbed turbulence of flow in patients with aortic stenosis. A highly accurate noninvasive approach to quantifying the severity of obstruction combines continuous-wave Doppler flow analysis with the cross-sectional echocardiographic determination of the area of the orifice.[280] A simplified Bernoulli equation uses the measurement of the maximum velocity of the aortic jet and time-averaged pressure drop obtained from planimetry of the maximal velocity spectral reading. A simpler estimate of the transvalvular gradient (in mm Hg) may be calculated as four times the square of the peak Doppler velocity (m/sec).

The Doppler method records a peak instantaneous pressure difference, which may differ importantly from the gradient recorded by a cardiac catheter, which is a peak-to-peak pressure difference.[281] Doppler mean gradient is more

Figure 43-32 Standard short-axis view of aortic cusps in the closed position in a patient with a bicuspid aortic valve. *Left frame,* The right (R) and noncoronary (NC) left (L) cusps are seen within the aortic root. The arrows indicate the points of adherence of the cusps to the aortic wall. The right ventricle (RV) is seen anteriorly; the right atrium (RA), and left atrium (LA) are seen posteriorly. *Middle*

frame, Same patient, with open valve leaflets in systole, shows fusion between the right and left coronary cusps. The fused raphe (arrow) between these cusps is typical of a bicuspid aortic valve. *Right frame,* Taken in systole from another patient with a bicuspid aortic valve, this frame demonstrates similar features but with a fused raphe (arrow) between the right and noncoronary cusps.

accurate than the instantaneous gradient when compared with the pressures found at cardiac catheterization. Management decisions often depend on estimation of the severity of obstruction, and all pressure gradient estimations depend on flow velocity across the valve, which may be confounded by low cardiac output or concomitant valvar regurgitation. Thus, an important argument can be made that the determination of the stenotic valve systolic area is often more important than calculation of a systolic gradient.[279] [280] [281]

The most widely accepted technique for correcting the gradient for flow is to use the continuity equation, which measures the flow velocity ratio across the aortic valve and therefore corrects for high and low flow rates. The continuity equation presumes that for flow in a series, the product of mean velocity and cross-sectional area is constant at all points in the flow circuit. In patients with aortic stenosis, the area of the left ventricular outflow tract is determined by two-dimensional echocardiography, the flow velocity of the outflow tract by pulsed-wave Doppler, and the flow velocity immediately above the valve by continuous-wave Doppler, all of which, taken together, allow determination of the valve area by the continuity equation: Aortic valve area: [(area)LVOT × V(LVOT)]/(V)AV (obtained by converting the diameter to area and assuming that it is circular); (V)LVOT = peak outflow tract velocity, and (V)AV = peak velocity across the aortic valve.

Transesophageal two-dimensional echocardiographic determination of aortic valve area has been applied in adults with aortic stenosis.[282] The approach offers considerably better resolution of cardiac anatomy than does conventional transthoracic two-dimensional echocardiography and may also prove to be more accurate in estimating pressure gradients and aortic valve areas. The approach is applicable to older children but has not yet been reported in young children in sufficient detail to make specific recommendations.

Diagnostic Cardiac Catheterization

Cardiac catheterization is now rarely used to establish the site and severity of obstruction to left ventricular outflow because the malformation is readily diagnosed and the evaluation of the intensity of stenosis is accurate by echo-Doppler examination.[283] Instead, catheterization is undertaken when therapeutic interventional transcatheter balloon aortic valvuloplasty is indicated.

During the catheterization procedure, cardiac output is measured by the indicator-dilution, thermodilution, or Fick technique. Retrograde left heart catheterization allows withdrawal pressure recordings across the site of stenosis, and left ventricular angiocardiography can be carried out, permitting an evaluation of the size of the left ventricular cavity, the thickness of the wall, the competence of the mitral valve, the patency of the coronary arteries, and the diameter of the aortic root and ascending aorta. If aortic insufficiency is thought to be present, cineaortography is performed with injection of contrast material into the aortic root. The severity of aortic insufficiency can be assessed qualitatively by cineaortography and quantitatively by ventriculography, with calculation of regurgitant volume by subtraction of net forward flow (calculated by the Fick method) from angiographically determined total forward flow. The typical angiocardiographic features of valvar stenosis are thickening of the aortic cusps, poststenotic dilation of the ascending aorta, and, occasionally, a jet of contrast material entering the ascending aorta through a central or eccentric narrowed valve orifice (Fig. 43-33) . The leaflets of the bicuspid valve are domed in systole, and a central jet corresponds to the orifice of the stenotic valve. In contrast, the stenotic orifice of the unicommissural valve can be visualized by the systolic jet in contact with the posterior wall of the aorta, with leaflet tissue and valve motion seen only anteriorly.[259]

Balloon Valvuloplasty.

Balloon dilatation may be indicated in any infant or child who has a clinical diagnosis of aortic stenosis and in whom the clinical examination, roentgenogram, resting or exercise ECG, or Doppler echocardiogram suggests the possibility of severe obstruction.[284] Even in the absence of such findings, balloon valvuloplasty may be performed if symptoms that might be related to aortic stenosis exist, such as dizziness, fainting, or angina.

We prefer to catheterize the left side of the heart via a retrograde approach by femoral percutaneous puncture. The goals of the study are to analyze the severity of obstruction and assess the function of the left ventricle. In most centers, balloon valvuloplasty is recommended if the severity of the aortic stenosis would otherwise require surgical treatment--that is, a peak systolic pressure gradient exceeding 70 mm Hg measured in the basal state or a calculated effective orifice less than 0.5 cm^2/m^2 of body surface area. In the

Figure 43-33 *A,* Left ventricular angiocardiogram obtained by the transseptal method in a patient with congenital valvular aortic stenosis. Ao = poststenotic dilatation of the aorta; LV = left ventricle. Arrow denotes the thickened valve cusp. *B,* Selective angiocardiogram in a patient with discrete subvalvular stenosis (bottom arrow). Associated mitral regurgitation is evident from the reflux of contrast material into an enlarged left atrium (LA). The aortic valve (top arrow) is normal, and the right coronary artery is visualized. *(From Friedman WF, Kirkpatrick SE: Congenital aortic stenosis. In Adams FH, Emmanouilides GC, Riemenschneider TA, et al: Moss' Heart Disease in Infants, Children, and Adolescents. 4th ed. Baltimore, © Williams & Wilkins, 1989.)*

presence of symptoms or left ventricular strain pattern on the ECG or an abnormal exercise ECG, there is less rigid regard to the hemodynamic assessment of the severity of stenosis. Further, some centers go forward with balloon valvuloplasty with peak systolic gradients greater than or equal to 50 mm Hg. There is general agreement that there be no significant aortic regurgitation (less than grade 2 of 4) and that other associated cardiac anomalies be absent, except aortic coarctation.

Balloon dilatation of the aortic valve began in the mid-1980s; truly long-term follow-up studies are not yet available. Early studies and our experience suggest that the diameter of the balloon should not exceed that of the aortic valve ring. Most centers prefer a balloon with a diameter 80 to 100 percent that of the aortic annulus or at least 1 mm smaller than it. The expected hemodynamic result is a reduction in the catheterization-measured peak-to-peak ejection gradient of about 60 to 70 percent. The appearance of aortic regurgitation or its progression is the major complication of valvuloplasty, although the aortic regurgitation is mild in the great majority of patients.[284] Significant aortic regurgitation appears to accompany the development of aortic valve prolapse, which is likely due to tearing of the valve cusp or its raphe or partial detachment of the valve from the valve ring, all of which undermine the support mechanism of the valve. In those patients whose balloon valvuloplasty has resulted in very significant aortic regurgitation, valve surgery may be required to either replace the valve or repair a tear in the valve. Other complications from balloon aortic valvuloplasty include bleeding, arrhythmias, cerebral vascular accidents, iliofemoral arterial complications, injury to the mitral valve, and, rarely beyond infancy, death.[284]

Natural History.

Congenital aortic stenosis frequently is a progressive disorder, even early in life, in a significant fraction of patients presenting initially with mild obstruction.[285] [286] [287] Thus, clinical deterioration may be anticipated because of an intensification in the severity of stenosis rather than the development of significant aortic regurgitation. Progression of obstruction usually is the result of the increase in cardiac output that occurs concurrently with increased body growth. Less often, a decrease in the area of the orifice is an added factor in the intensification of obstruction. The onset of symptoms or changes in the phonocardiogram or graphic pulse tracings, chest roentgenograms, ECGs, or vectorcardiograms cannot be depended on to indicate progressive obstruction in the individual patient; Doppler echocardiography is most reliable.

MANAGEMENT.

A malformed aortic valve is a potential site of bacterial infection; antibiotic prophylaxis is recommended for all patients, regardless of the severity of obstruction. Strict avoidance of strenuous physical activity is advised if severe aortic stenosis is present. Participation in competitive sports also should probably be restricted in patients with milder degrees of obstruction. Digitalis should be administered to patients who have symptoms of diminished cardiac reserve and also should be considered for patients with left ventricular hypertrophy, even if they are not in heart failure.

Surgery.

Percutaneous balloon aortic valvuloplasty is a useful palliation to delay open valvulotomy, the Ross procedure (see below), or valve replacement. For those patients in whom balloon valvuloplasty is unsuccessful, operation is carried out under direct vision after institution of cardiopulmonary bypass, and the fused commissures are opened. When this is done precisely and judiciously, the commissural incision enlarges the valve orifice and does not result in significant aortic regurgitation.[288] When operation is performed in childhood, a mortality rate of less than 2 percent can be expected.[289] Among the factors influencing the indications, techniques, and results of

operation are the patient's age, the nature of the valvar deformity, and the experience of the surgical team.

Long-term follow-up studies indicate that aortic valvotomy is a safe and effective means of palliative treatment with excellent relief of symptoms.[289] [290] Aortic insufficiency can occasionally be progressive and require valve replacement. Moreover, after commissurotomy, the valve leaflets remain somewhat deformed, and it is likely that further degenerative changes, including calcification, will lead to significant stenosis in later years.[259] Thus, prosthetic valve replacement is required in approximately 35 percent of patients within 15 to 20 years of the original operation. Because the valve is not rendered normal, antibiotic prophylaxis is indicated in postoperative patients, even if the systolic pressure gradient has been abolished. For those patients eventually requiring aortic valve replacement, the surgical options include replacement with a prosthetic aortic valve, an aortic homograft, or a pulmonary autograft in the aortic position. Accumulating evidence shows that the pulmonary autograft may ultimately be preferable to the aortic homograft for aortic reconstruction, and many surgeons

prefer the procedure to palliative surgical valvotomy as the initial operation of choice. In the pulmonary autograft, called the Ross procedure, the patient's pulmonary valve is removed and used to replace the diseased aortic valve, and the right ventricular outflow tract is reconstructed with a pulmnary valve allograft.[291] [292] [293] [294] We consider it likely that the Ross procedure will emerge as the approach of choice in the future. Neither homografts nor autografts require anticoagulation. There is a finite incidence of valve degeneration of approximately 2 percent per patient per year with the former, whereas primary tissue failure has not been observed among pulmonary autografts.

Discrete Subaortic Stenosis **(See also p. 1599)**

This malformation accounts for 8 to 10 percent of all cases of congenital aortic stenosis and occurs twice as frequently in males as in females. The lesion consists of a membranous diaphragm or fibrous ring encircling the left ventricular outflow tract or a long fibromuscular narrowing just beneath the base of the aortic valve. Subaortic stenosis is rarely diagnosed in infancy, when it is usually the result of a malalignment VSD with deviation posteriorly of the outlet septum into the left ventricular outflow tract, often associated with coarctation of the aorta or interruption of the aortic arch.

Distinction of subvalvular from valvular aortic stenosis is extremely difficult by means of clinical findings alone.[259] Rarely, a systolic ejection sound is heard, and the diastolic murmur of aortic regurgitation is more common than it is in valvular aortic stenosis. Dilatation of the ascending aorta is common, but valvular calcification is not observed.

Echocardiography is useful in differentiating between valvular and subvalvular stenosis (see Chap. 7).[295] The criterion for diagnosis of the latter is demonstration of a localized subvalvar discrete ridge or long segment narrowing in the left ventricular outflow tract. Further, because of the possibility of recurrence of subvalvular aortic stenosis, careful postoperative follow-up echocardiography is required. Two-dimensional echocardiographic studies from the apical two-chamber and left parasternal and subxiphoid long-axis views demonstrate persistent, prominent echoes in the subaortic left ventricle in both systole and diastole (Fig. 43-34) . Doppler sampling proximal to the aortic valve shows increased flow velocity.[295] Most important, echocardiography also can identify hypertrophic subaortic stenosis when it coexists with fixed subaortic stenosis and can differentiate between the two forms of obstruction.

Definitive distinction between valvular and subvalvular obstruction is also provided by transesophageal Doppler echocardiography[296] and by recording pressure tracings as a catheter is withdrawn across the outflow tract and valve, or by localizing the site of obstruction with selective left ventricular angiocardiography (see Fig. 43-33).

Mild degrees of aortic valvular regurgitation commonly are observed in patients with discrete subaortic stenosis and appear to be caused by thickening of the valve and impaired mobility of the cusps secondary to the trauma created by the high-velocity jet passing through the subaortic diaphragm. Further deformation of these abnormal valve cusps by the vegetations of bacterial endocarditis often results in severe aortic regurgitation.

MANAGEMENT.

Because of the likelihood of both progressive obstruction and aortic regurgitation, the presence of even mild or moderate subaortic stenosis warrants consideration of elective operation.[297] [298] [299] Reports describe transluminal balloon dilation for discrete subaortic stenosis, but it is unlikely that this palliative approach will be an acceptable alternative, since the relief of obstruction is not

Figure 43-34 Parasternal long axis (P Lax.) view of membranous subaortic stenosis. The ventricular septum (SEPT), right ventricle (RV), left ventricle (LV), and left atrium (LA), as well as the aorta (AO), are seen. The arrows indicate the attachments of the subvalvar membrane to the septum anteriorly and to the mitral valve posteriorly.

likely to be as complete or as long as in those patients undergoing surgical resection.

The risks of operation in patients with discrete subaortic stenosis and valvular aortic stenosis are essentially the same. Surgical treatment of discrete subaortic stenosis has evolved from simply excising the membrane or fibrous ridge to adding a generous ventricular myotomy and myectomy to the membranectomy.[300] Operation may be expected to improve the hemodynamic state substantially; it frequently is totally curative.

Evidence indicates that muscle resection combined with membrane excision lowers the risk of reoperation for recurrent subaortic stenosis.[301] Discrete membranous subaortic stenosis may tend to recur after operation, although we and others consider these recurrences to be often related, at least in part, to incomplete removal of the lesion at initial operation. Intraoperative echocardiography has been used as an adjunct to operation to enable immediate assessment of the adequacy of relieving obstruction. Studies have suggested that abnormal flow patterns may predispose to pathological proliferation of subvalvar aortic tissue, which reinforces the requirement that careful echocardiographic and surgical exploration of the outflow tract, even well below the subvalvar stenosis, be undertaken to detect and resect structures that cause turbulence.[302] For patients with recurrent obstruction, operation may consist of repeat resection plus creation of an outlet VSD extending up to but not across the aortic valve. This iatrogenic VSD is patched on the right side to further enlarge the subaortic area. For patients in whom the aortic valve cannot be repaired, the Ross pulmonary valve autograft procedure is used.[303]

UNCOMMON FORMS OF SUBAORTIC STENOSIS

COMBINED VALVULAR AND SUBVALVULAR STENOSIS.

In some patients, valvular and subvalvular aortic stenosis coexist with hypoplasia of the aortic valve ring and thickened valve leaflets, producing a tunnel-like narrowing of the left ventricular outflow tract. Additional findings often include a small ascending aorta. The subvalvular fibrous process usually extends onto the aortic valve cusps and almost always makes contact with the ventricular aspect of the anterior mitral leaflet at its base. The presence of "tunnel stenosis" may be suspected echocardiographically or angiographically from the appearance of the outflow tract and the aortic root. Operative treatment often is complicated by the need for an aortoventriculoplasty, consisting of prosthetic or homograft replacement of the aortic valve as well as enlarging the aortic annulus, proximal aorta, and left ventricular outlet tract (the Kono-Rastan operation). The *modified* Kono-Rastan operation preserves the native aortic valve if the annulus is normal or near normal. Alternatively, a conal enlargement technique may be used.[304] [305]

Various anatomical lesions other than a discrete membrane or ridge may produce subaortic stenosis.[306] [307] [308] Among these are abnormal adherence of the anterior leaflet of the mitral valve to the left septal surface, and the presence in the left ventricular outflow tract of accessory endocardial cushion tissue. In some patients with an AV canal, the part of the ventricular septum that contributes to the wall of the left ventricular outflow tract is deficient, and the ventricular aspect of the anterior leaflet of the common AV valve is adherent to the posterior edge of the deficient septum, resulting in a narrow left ventricular outflow tract. Malalignment of the conoventricular septum, resulting in an inferior VSD, produces a leftward superior deviation and insertion of the conal septum, obstructing left ventricular outflow. In patients with a single ventricle and an outflow chamber, the bulboventricular foramen serves as a potential site of aortic outflow obstruction. Additionally, rarer causes of subaortic stenosis include redundant dysplastic left AV valve tissue in patients with congenitally corrected transposition of the great arteries and anomalous muscle bundles of the left ventricular outflow tract.

MUSCULAR SUBAORTIC STENOSIS.

A muscular type of subaortic stenosis may result from a convergence of all the mitral chordae into one or two fused papillary muscles; a "parachute" deformity of the mitral valve is produced, and it is often seen in association with supravalvular stenosis of the left atrium and coarctation of the aorta. In some of these patients, discrete membranous subvalvular aortic obstruction also has been noted.

In patients with VSD, muscular subaortic stenosis has been shown to develop after surgical banding of the pulmonary artery, possibly as a result of hypertrophy of the conal septum or crista supraventricularis encroaching on the left ventricular outflow tract above the septal defect.

Subaortic muscular hypertrophy secondary to diffuse involvement of the myocardium by glycogen storage disease (Pompe's disease) is an extremely rare cause of obstruction to left ventricular outflow. A positive family history, symptoms of muscle weakness, heart failure in infancy, and the characteristic ECG findings of a short PR interval, high-voltage QRS and T waves, and left ventricular hypertrophy warrant skeletal muscle biopsy or fibroblast culture, permitting an antemortem diagnosis.

The last, relatively uncommon form of subaortic stenosis to be mentioned occurs infrequently in patients with congenitally corrected transposition of the great arteries; in these patients, an anomalous muscle bundle in the subaortic area of the arterial ventricle obstructs outflow.

Supravalvular Aortic Stenosis

Supravalvular aortic stenosis is a congenital narrowing of the ascending aorta that may be localized or diffuse, originating at the superior margin of the sinuses of Valsalva just above the levels of the coronary arteries.

The clinical picture of supravalvular obstruction usually differs in major respects from that observed in the other forms of aortic stenosis. Chief among these differences is the association of supravalvular aortic stenosis with idiopathic infantile hypercalcemia, a disease that occurs in the first years of life and may be associated with deranged vitamin D metabolism.[309] [310] [310A] [311] [312]

It is helpful to classify patients according to their clinical presentation into nonfamilial, sporadic cases with normal facies and intelligence; autosomal dominant familial cases with normal facies and intelligence; and the Williams syndrome with abnormal facial appearance and mental retardation (Fig. 43-35) . In contrast to the other forms of aortic stenosis, no gender predilection is noted in any of these three categories.

WILLIAMS SYNDROME.

The designations supravalvular aortic stenosis syndrome or Williams syndrome or Williams-Beuren syndrome[310] [310A] have been applied to the distinctive picture produced by coexistence of the cardiac and multiple-system disorders. Beyond infancy in these patients, a challenge with vitamin D or calcium loading tests unmasks abnormalities in the regulation of circulating 25-hydroxyvitamin D. Unanimity of opinion about the exact relation between Williams syndrome and calcium metabolism does not exist[311] [312] .

Infants with Williams syndrome often exhibit feeding difficulties, failure to thrive, and gastrointestinal problems in the form of vomiting, constipation, and colic. The entire spectrum of clinical manifestations includes auditory hyperacusis, inguinal hernia, a hoarse voice, and a typical personality that is outgoing and engaging. Other manifestations of this syndrome include mental retardation, "eifin facies" (see Fig. 43-32), narrowing of peripheral systemic and pulmonary arteries, strabismus, and abnormalities of dental development consisting of microdontia, enamel hypoplasia, and malocclusion[312A] .

Many medical conditions can complicate the course of Williams syndrome,[312B] including systemic hypertension, gastrointestinal problems, and urinary tract abnormalities. Particularly in an older child or adult, progressive joint limitation and hypertonia may become a problem. Adult patients are usually handicapped by their developmental disabilities.

Williams syndrome was previously considered to be nonfamilial. Interestingly, a number of families in which parent-to-child transmission of WIlliams syndrome has occurred have now been identified. These are not families with autosomal dominant supravalvular aortic stenosis whose members are normal in appearance and intelligence. All of these families show a parent and child to be affected with Williams syndrome, including one instance of male-to-male transmission. This supports autosomal dominant inheritance as the likely pattern, with most cases of Williams syndrome probably occurring as the result of a new mutation. New information indicates that a genetic defect for supravalvular aortic stenosis is located in the same chromosomal subunit as elastin on chromosome 7.[312B] [313] Elastin is an important component of the arterial wall, but precisely how mutations in elastin genes cause the phenotypes of supravalvular aortic stenosis is not known for certain. The various aspects of Williams syndrome may represent a contiguous gene deletion syndrome (see Chap. 56).

FAMILIAL AUTOSOMAL DOMINANT PRESENTATION.

Most commonly, supravalvular aortic stenosis is a feature of the distinctive Williams syndrome described earlier.[312A] [312B] However, the aortic anomaly and peripheral

Figure 43-35 Typical elfin facies in three patients with supravalvular aortic stenosis. *(From Friedman WF, Kirkpatrick SE: Congenital aortic stenosis. In Adams FH, Emmanouilides GC, Riemenschneider TA, et al: [eds]: Moss' Heart Disease in Infants, Children, and Adolescents. 4th ed. Baltimore, © Williams & Wilkins, 1989.)*

pulmonary arterial stenosis are also found in familial and sporadic forms *unassociated* with the other features of the syndrome. Thus, affected patients have normal intelligence and are normal in facial appearance. Genetic studies suggest that when the anomaly is familial, it is transmitted as autosomal dominant with variable expression. Some family members may have peripheral pulmonary stenosis either as an isolated lesion or in combination with the supravalvular aortic anomaly.

Linkage analyses in two unrelated families with autosomal dominant supravalvular aortic stenosis were performed. Linkage was identified between the supravalvular aortic stenosis phenotype and polymorphic markers on the long arm of chromosome 7. These findings indicate that the gene for supravalvular aortic stenosis is located in the same chromosomal subunit as elastin. Further, a family has been identified as having autosomal dominant supravalvular aortic stenosis and a balanced translocation, which disrupts the elastin gene and cosegregates with the disease in this family, also supporting the hypothesis that mutations in the elastin gene may cause supravalvular aortic stenosis.[314] Hemizygosity at the elastin locus is likely responsible for the vascular pathology in Williams syndrome, although it is unlikely that elastin deletions account for all features of the syndrome. Because the deletions responsible for Williams syndrome extend well beyond the elastin locus, it is probable that the syndrome is a contiguous gene disorder.

MORPHOLOGY.

Three anatomical types of supravalvular aortic stenosis are recognized, although some patients may have findings of more than one type. Most common is the hourglass type, in which marked thickening and disorganization of the aortic media produce a constricting annular ridge at the superior margin of the sinuses of Valsalva. The membranous type is the result of a fibrous or fibromuscular semicircular diaphragm with a small central opening stretched across the lumen of the aorta. Uniform hypoplasia of the ascending aorta characterizes the hypoplastic type.[315]

Because the coronary arteries arise proximal to the site of outflow obstruction in supravalvular aortic stenosis, they are subjected to the elevated pressure that exists within the left ventricle. These vessels often are dilated and tortuous, and premature coronary arteriosclerosis has been observed. Moreover, if the free edges of some or all of the aortic cusps adhere to the site of supravalvular stenosis, coronary artery inflow may be reduced. The formation of thoracic aortic aneurysms has been described in several patients.

CLINICAL FEATURES.

Patients with Williams syndrome are mentally retarded and resemble one another in their facial features. The typical appearance is similar to that of the elfin facies observed in the severe form of idiopathic infantile hypercalcemia and is characterized by a high prominent forehead, stellate or lacy iris patterns, epicanthal folds,

underdeveloped bridge of the nose and mandible, overhanging upper lip, strabismus, and anomalies of dentition (see Fig. 43-35). Recognition of this distinctive appearance, even in infancy, should alert the physician to the possibility of underlying multisystem disease. In addition, a positive family history in a patient with a normal appearance and clinical signs suggesting left ventricular outflow obstruction should lead to the suspicion of either supravalvular aortic stenosis or hypertrophic obstructive cardiomyopathy.

Patients with supravalvular aortic obstruction appear to be subject to the same risks of unexpected sudden death [in some of whom myocardial infarction has been found at autopsy[316]] and endocarditis as those with valvular aortic stenosis. Studies of the natural history of the principal vascular lesions in these patients[317] --supravalvular aortic stenosis and peripheral pulmonary artery stenosis--indicate that the aortic lesion is usually progressive, with an increase in the intensity of obstruction related often to poor growth of the ascending aorta. In contrast, the patients with pulmonary branch stenosis, whether or not associated with the aortic lesion, tend to show no change or a reduction in right ventricular pressure with time.

With few exceptions, the major *physical findings* resemble those observed in patients with valvular aortic stenosis. Among these exceptions are accentuation of aortic valve closure due to elevated pressure in the aorta proximal to the stenosis, an infrequent systolic ejection sound, and the especially prominent transmission of a thrill and murmur into the jugular notch and along the carotid vessels. Found uncommonly is an early diastolic, decrescendo, blowing murmur of aortic regurgitation caused by the fusion of one or more cusps to the area of stenosis. The narrowing of the peripheral pulmonary arteries that often coexists in these patients frequently produces a late systolic or continuous murmur that may help to distinguish this anomaly from valvular aortic stenosis. This differentiation is reinforced by the frequent finding of a significant disparity between the arterial pressures in the upper extremities in supravalvular aortic stenosis; the systolic pressure in the right arm tends to be the higher than in the left and occasionally exceeds that in the femoral arteries. The disparity in pulses may relate to the tendency of a jet stream to adhere to a vessel wall (Coanda effect) and selective streaming of blood into the innominate artery.[318] [319]

ECG usually reveals left ventricular hypertrophy when obstruction is severe. Biventricular or even right ventricular hypertrophy may be found if significant narrowing of peripheral pulmonary arteries coexists. Radiographically, in contrast to valvular and discrete subvalvular aortic stenosis, poststenotic dilation of the ascending aorta seldom is seen. The sinuses of Valsalva usually are dilated, and the ascending aorta and aortic arch appear small or of normal size.

Echocardiography is the most valuable technique for localizing the site of obstruction to the supravalvular area (Fig. 43-36) . Most often the sinuses of Valsalva are dilated, and the ascending aorta and arch appear small or of normal size. A useful ratio can be constructed of the measurements of the aortic annulus and the sinotubular junction, in which the latter is always less than the former in patients with supravalvular stenosis, a finding not present in normal persons.[320] Intraluminal ultrasound imaging has also been used to visualize the vascular pathology in Williams syndrome.[321] Doppler examination and retrograde aortic catheterization can determine the degree of hemodynamic abnormality.[322]

Because of the nature of the anatomical defect, we do not think that transcatheter balloon angioplasty,[323] with or without stenting, is an effective treatment option. For several reasons, depending primarily on the anatomical variant of the lesion, supravalvular aortic stenosis may be less amenable to operative treatment than either valvular or discrete subvalvular stenosis. The lumen of the aorta at the supravalvular level may be widened by the insertion of an oval- or diamond-shaped fabric prosthesis or pericardial symmetric aortoplasty in those patients with a normal or near-normal ascending aorta. If the aorta is markedly hypoplastic, however, this operation merely displaces the pressure gradient distally without abolishing the obstruction.

Figure 43-36 Supravalvar aortic stenosis is seen in a parasternal long-axis view. The constriction is distal to the sinuses of Valsalva in the ascending aorta (AAO). RV = right ventricle; LV = left ventricle; LA = left atrium.

Under these circumstances, repair may require replacement or widening of the entire hypoplastic aorta with an appropriate prosthesis.[324] [325] [326] [327]

Hypoplastic Left Heart Syndrome

This designation is used to describe a group of closely related cardiac anomalies characterized by underdevelopment of the left cardiac chambers, atresia or stenosis of the aortic and/or the mitral orifices, and hypoplasia of the aorta.[327] These anomalies are an especially common cause of heart failure in the first week of life. The left atrium and ventricle often exhibit *endocardial fibroelastosis.* Pulmonary venous blood traverses a patent foramen ovale, and a dilated and hypertrophied right ventricle acts as the systemic, as well as pulmonary, ventricle; the systemic circulation receives blood by way of a patent ductus arteriosus (Fig. 43-37) (Figure Not Available) .

The diagnosis should be considered in infants, particularly boys, with the sudden onset of heart failure, systemic hypoperfusion, and nonspecific murmur. *ECG* frequently reveals right-axis deviation, right atrial and ventricular enlargement, and ST and T wave abnormalities in the left precordial leads. Chest roentgenography may show only slight enlargement shortly after birth, but with clinical deterioration there are marked cardiomegaly and increased pulmonary venous and arterial vascular markings. The *echocardiographic* findings usually are diagnostic (Fig. 43-38) . The aortic root is usually diminutive, less than 4 to 5 mm in diameter at the level of the sinuses of Valsalva and narrowed farther above. The left ventricle is frequently absent or is a small slit with a diminutive mitral valve. The endocardium is often thickened, consistent with endocardial fibroelastosis or papillary muscle infarction, features usually more suggestive of aortic stenosis. Indeed, distinction from the latter is pivotal to determine if a biventricular, rather than a Fontan, approach is feasible. Ultrasound study also determines the extent of patency of the interatrial communication; substantial restriction is predictive of

Figure 43-37 (Figure Not Available) Hypoplastic left heart with aortic hypoplasia, aortic valve atresia, and a hypoplastic mitral valve and left ventricle. RA = right atrium; RV = right ventricle; RC = right coronary artery; PA = pulmonary artery; PV = pulmonary vein; LC = left coronary artery; LV = left ventricle; AD = anterior descending coronary artery. *(From Neufeld HN, Adams P Jr, Edwards JE, et al: Diagnosis of aortic atresia by retrograde aortography. Circulation 25:278, 1962.)*

severe pulmonary edema and death. *Retrograde aortography* shows hypoplasia of the ascending aorta.

MANAGEMENT.

Medical therapy directed at cardiac decompensation, hypoxemia, and metabolic acidemia seldom prolongs survival beyond the first days of life.[328] Constriction of the patent ductus arteriosus and limited flow

Figure 43-38 *Left,* Four-chamber view of hypoplastic left heart syndrome demonstrating the right ventricle (RV) anteriorly, considerably larger than the diminutive left ventricle (LV) seen posteriorly. A small mitral valve (MV) separates the left atrium (LA) from the left ventricle. The apex of the heart is formed by the right ventricle. *Right,* Parasternal long-axis view demonstrating the discrepant relative sizes between the right ventricle and the left heart chambers. The aorta (AO) is diminutive and measures approximately 4 mm in diameter. The larger pulmonary valve plate is seen anteriorly. A small platelike mitral valve (MV, dashed arrow) is seen between the left atrium and left ventricle.

through a restrictive patent foramen ovale are the principal factors responsible for early death. Prostaglandin E_1 infusion is effective in maintaining ductal patency.

SURGICAL TREATMENT.

Many centers are attempting staged surgical management in an effort to provide long-term palliation.[329] [330] The first stage, often referred to as *Norwood procedure,* consists of creating an unobstructed communication between the right ventricle and aorta and enlargement of the ascending aorta. The right ventricular-aortic connection has been accomplished with homograft or prosthetic conduits from the right ventricle or pulmonary trunk to the descending aorta, or by direct connection between the proximal pulmonary trunk and ascending aorta, which also enlarges the ascending aorta. Pulmonary blood flow and pressure are controlled by a tubed interposition systemic-pulmonary shunt to the distal pulmonary artery. The patent ductus arteriosus is ligated. A large interatrial communication also must be ensured in stage 1 to allow free access of pulmonary venous blood to the tricuspid valve.

Most surgeons prefer to perform a stage 2 modified superior vena cava-pulmonary artery shunt (bidirectional Glenn operation) or a hemi-Fontan procedure as an

intermediate step before a Fontan correction (stage 3). In some centers, the preferred operation is cardiac transplantation.[331] [332] Stenting of the ductus arteriosus can be used as an ambulatory bridge to transplantation.[333]

Congenital Aortic Regurgitation

Congenital aortic valve regurgitation is a rare isolated congenital cardiac lesion.[334] [345] Aortic regurgitation most often occurs in association with congenital valvular aortic stenosis in which the valve commissures are fused, inhibiting cusp mobility; subvalvular aortic stenosis in which the aortic ring is dilated and the valve cusps are deformed; coarctation of the aorta when the aortic ring is dilated and the aortic valve is bicuspid; VSD; and endocardial fibroelastosis. Aortic valve regurgitation may accompany various complex cardiac anomalies and also may accompany aortic sinus aneurysm or be secondary to dilatation of the ascending aorta in patients with Marfan syndrome, Turner syndrome, cystic medial necrosis, or osteogenesis imperfecta, in which the aortic lesions are manifestations of the underlying connective tissue disorder.

Severe aortic regurgitation also may occur through channels other than the aortic valve.[336] Thus, aortic-left ventricular tunnel is a rare anomaly that must be distinguished from congenital aortic valve regurgitation, because the approach to management of the former usually does not include consideration for prosthetic valve replacement. The aortic-left ventricular tunnel is an abnormal channel beginning in the ascending aorta above the right coronary orifice and ending in the left ventricle below the right aortic cusp. The channel usually passes behind the right ventricular infundibulum and through the ventricular septum.

Echocardiography, Doppler studies, and aortography combine to establish a precise diagnosis. Exercise testing[337] and magnetic resonance velocity mapping[338] are useful to assess the severity of the lesion. In infants and children with congenital aortic regurgitation, the severity of regurgitation increases with time, and valve replacement rather than plication is almost always necessary to correct the lesion. Operation should be deferred until symptoms, signs, and noninvasive assessment dictate its necessity.[339] Conversely, closure of an aortic-left ventricular communication is advisable before progressive dilation of the aortic annulus creates secondary changes in the aortic valve itself, which may necessitate aortic valve replacement.

Pulmonary Vein Atresia and Stenosis

Pulmonary vein atresia is a rare anomaly in which the pulmonary veins do not connect with the heart or with a major systemic vein. The lesion is incompatible with life, but infants may survive for days, probably because communications exist between the pulmonary veins and the bronchial or esophageal veins and allow limited egress for pulmonary venous blood. Pulmonary vein stenosis may occur as a focal stenosis at the atrial junction or generalized hypoplasia of one or more pulmonary veins. The incidence of associated cardiac malformations is extremely high, including atrial septal defect, tetralogy of Fallot, tricuspid and mitral atresia, and endocardial cushion defect. The severe pulmonary vein obstruction imposed by pulmonary vein abnormalities causes severe cyanosis, congestive cardiac failure, and early death. Focal stenosis of one or more pulmonary veins at the atrial junction, recognized by two-dimensional echocardiography, magnetic resonance imaging, or angiography, may be relieved surgically. Results of transcutaneous balloon angioplasty have been disappointing.

Cor Triatriatum

In this malformation, failure of resorption of the common pulmonary vein results in a left atrium divided by an abnormal fibromuscular diaphragm into a posterosuperior chamber receiving the pulmonary veins and an anteroinferior chamber giving rise to the left atrial appendage and leading to the mitral orifice.[340] The communication between the divided atrial chambers may be large, small, or absent, depending on the size of the opening in the subdividing diaphragm, which determines the degree of obstruction to pulmonary venous return. Elevations of both pulmonary venous pressure and pulmonary vascular resistance result in severe pulmonary artery hypertension.

The diagnosis is established by two-dimensional or transesophageal echocardiography[341] [342] ; cardiac catheterization and angiography are necessary only if major associated cardiac anomalies are suspected. The obstructive membrane is visualized in the parasternal long- and short-axis and four-chamber (Fig. 43-39) views and can be distinguished from a supravalvular mitral ring[343] by its position superior to the left atrial appendage, which forms part of the distal chamber. Also present are diastolic fluttering of the mitral leaflets and high-velocity flow detected by Doppler examination in the distal atrial chamber and at the mitral orifice.

The diagnosis should be suspected at cardiac catheterization if the pulmonary arterial wedge pressure is higher than a simultaneous left atrial pressure. The diagnosis also may be established by visualizing the obstructing lesion angiographically. Although rare, the malformation is important to recognize because it may be easily correctable at operation.[344]

Congenital Mitral Stenosis

Anatomical types of mitral stenosis include the parachute deformity of the valve, in which shortened chordae tendineae converge and insert into a single large papillary muscle; thickened leaflets with shortening and fusion of the chordae tendineae; an anomalous arcade of obstructing papillary muscles; accessory mitral valve tissue; and a supravalvular circumferential ridge of connective tissue arising at the base of the atrial aspect of the mitral leaflets.[345] [346] Associated cardiac defects are common, including endocardial fibroelastosis, coarctation of the aorta, patent ductus arteriosus, and left ventricular outflow tract obstruction. Two-dimensional echocardiography, combined with Doppler studies, often provides a complete analysis of the anatomy and function of congenital left ventricular inflow lesions.[346] The clinical and hemodynamic consequences of isolated congenital mitral stenosis are similar to those of acquired mitral obstruction, with modifications imposed by coexisting anomalies.

The prognosis is poor; symptoms attributable to pulmonary vein obstruction usually begin in infancy, and the majority of patients expire before age 1 year unless catheter balloon dilation or operation is successful.[347] [348] Conduit bypass of the mitral valve and prosthetic valve replacement are required if a reparative operation is not possible.[349] [350] The use of a porcine bioprosthesis is contraindicated because of its rapid degeneration in an infant or young child.

Figure 43-39 Echocardiograms demonstrating the membrane (M) of cor triatriatum. The apical four-chamber view *(top panel)* shows the membrane lying within the left atrial chamber. The atrial appendage is distal to the membrane, and the pulmonary veins drain into the proximal portion. The parasternal long-axis view *(center panel)* shows the membrane posterior to the aortic root (Ao) and mitral valve, dividing the left atrium into two chambers. In the parasternal short-axis view *(bottom panel)*, the membrane is within the left atrium close to the posterior aortic root. RA = right atrium; RV = right ventricle; LV = left ventricle.

Congenital Mitral Regurgitation

The syndrome of *mitral valve prolapse* is discussed in Chapter 46 . This condition usually is quite benign in children.[351] [352] However, occasional difficulties exist with infective endocarditis, arrhythmias, atypical chest pain, and sudden death. *Isolated congenital mitral regurgitation* of hemodynamic significance is an unusual lesion in infants and children.

MORPHOLOGY.

Congenital malformations of the mitral valve producing insufficiency most often are encountered in association with endocardial cushion defect, congenitally corrected transposition of the great arteries, endocardial fibroelastosis, anomalous pulmonary origin of the coronary artery, congenital subaortic stenosis, hypertrophic obstructive cardiomyopathy, and coarctation of the aorta. Mitral valve dysfunction also is common in various metabolic disorders (e.g., the mucopolysaccharidoses), primary and secondary cardiomyopathies, connective tissue disease (e.g., rheumatoid arthritis, Marfan's syndrome, Ehlers-Danlos syndrome, pseudoxanthoma elasticum), and rheumatic and nonrheumatic inflammatory diseases of the myocardium.[353]

The various anatomical lesions that result in isolated congenital mitral regurgitation include prolapse of one or both mitral leaflets, cleft or perforated mitral leaflet, inadequate leaflet tissue, double orifice of the mitral valve, anomalous insertion of chordae tendineae (anomalous mitral arcade), redundant leaflet tissue, displacement inferiorly of the ring of the inferior leaflet into the left ventricle, and abnormal length of the chordae tendineae.

CLINICAL FINDINGS.

The clinical, echocardiographic, and hemodynamic findings in patients with isolated congenital mitral incompetence resemble those observed in acquired mitral

regurgitation. Mitral annuloplasty (which is preferred) and prosthetic valve replacement are procedures reserved for infants and children who are at least moderately symptomatic despite comprehensive medical treatment, often with repeated episodes of pulmonary infection or with cardiac failure with anorexia and retarded growth and development.[353] Operative candidates are shown by echocardiographic, Doppler, hemodynamic, and angiographic studies to have pulmonary hypertension, a regurgitant fraction in excess of 50 percent, and a marked increase in left ventricular end-diastolic volume.

Pulmonary Arteriovenous Fistula

Abnormal development of the pulmonary arteries and veins in a common vascular complex is responsible for this rare congenital anomaly (see also Chap. 44). A variable number of pulmonary arteries communicate directly with branches of the pulmonary veins; in some cases, the fistula receives systemic arterial branches.[354] Most patients have an associated Weber-Osler-Rendu syndrome; additional associated problems include bronchiectasis and other malformations of the bronchial tree, as well as absence of the right lower lobe. Venoarterial shunting depends on the extent of the fistulous communications and may result in cyanosis and secondary polycythemia. Paradoxical emboli and brain abscess may cause major neurological deficits.

Patients with hereditary hemorrhagic telangiectasis often are anemic owing to repeated blood loss and may have less obvious cyanosis. Systolic and continuous murmurs are audible over areas of the fistula. Rounded opacities of various sizes in one or both lungs on chest roentgenogram may suggest the presence of the lesion. Pulmonary angiography reveals the site and extent of the abnormal communication. Unless the lesions are widespread throughout both lungs, surgical treatment aimed at removing the lesions with preservation of healthy lung tissue commonly is indicated to avoid the complications of massive hemorrhage, bacterial endocarditis, and rupture of arteriovenous aneurysms. Pulmonary arteriovenous fistulas may also be acquired and the result of surgical creation of cavopulmonary shunts.[355]

Transcatheter balloon or plug or coil occlusion embolotherapy may prove to be the therapeutic procedure of choice.[356]

Peripheral Pulmonary Artery Stenosis

Stenosis of the pulmonary artery may occur as single or numerous lesions located anywhere from the main pulmonary trunk to the smaller peripheral arterial branches.[357] Associated defects are observed in most patients and include pulmonic valvular stenosis, VSD, tetralogy of Fallot, and supravalvular aortic stenosis.

ETIOLOGY.

The most important cause of significant pulmonary artery stenoses producing symptoms in newborns is intrauterine rubella infection.[358] Diagnosis is facilitated in these infants by finding elevations of the IgM fraction and rubella antibody titer. Other cardiovascular malformations commonly found in association with congenital rubella include patent ductus arteriosus, pulmonic valve stenosis, and atrial septal defect. Generalized systemic arterial stenotic lesions also may be a feature of the rubella embryopathy, often involving large and medium-sized vessels such as the aorta and coronary, cerebral, mesenteric, and renal arteries. Cardiovascular lesions are but one manifestation of intrauterine rubella infection because cataracts, microphthalmia, deafness, thrombocytopenia, hepatitis, and blood dyscrasias also are common. Thus, the clinical picture in infants with rubella syndrome depends on the severity of the cardiovascular lesions and the associated abnormalities of other organs and systems.

Peripheral pulmonary stenosis also often is associated with supravalvular aortic stenosis in patients with the familial form of the latter anomaly or in patients with Williams syndrome.

MORPHOLOGY.

Obstruction within the pulmonary arterial tree may be classified into four types: (1) stenosis of the main pulmonary trunk or the main left or right branch; (2) narrowing at the bifurcation of the pulmonary artery, extending into both right and left branches; (3) numerous sites of peripheral branch stenosis; and (4) a combination of main and peripheral stenosis. Pulmonary artery obstruction may be produced by localized narrowing, diffuse constrictions, or, rarely, a membrane or diaphragm. Poststenotic dilatation is usual when the stenosis is localized but may be absent or minimal with elongated constriction. It should be recognized that a physiological branch pulmonary artery stenosis often is present in normal newborns in whom both right and left main pulmonary arteries are small and arise almost perpendicular from a large main pulmonary artery.[359] The branch vessels increase in size with growth and become less angulated in their takeoff from the main pulmonary artery.

CLINICAL FINDINGS.

The degree of obstruction is the principal determinant of clinical severity; the type of obstruction determines the feasibility of direct surgical relief. The clinical features vary; most infants and children are asymptomatic.[360] An ejection systolic murmur heard at the upper left sternal border and well transmitted to the axillae and back is most common. The presence of an ejection sound suggests that pulmonic valve stenosis coexists. The pulmonic component of the second heart sound may be slightly accentuated but occasionally is extremely loud if multiple peripheral stenoses exist. A continuous murmur is audible, especially in patients with main or branch stenosis and particularly if an associated cardiovascular anomaly produces increased pulmonary blood flow. ECG shows right ventricular hypertrophy when obstruction is severe; left-axis deviation with counterclockwise orientation of the frontal QRS vector is common in the rubella syndrome and when the lesion coexists with supravalvular aortic stenosis. Mild or moderate stenosis usually produces normal findings on chest roentgenogram; detectable differences in vascularity between regions of the lungs or dilated pulmonary artery segments are uncommon. When obstruction is bilateral and severe, right atrial and ventricular enlargement may be observed.

Diagnosis.

This is confirmed by observing pressure gradients within the pulmonary arterial system at cardiac catheterization; digital subtraction and/or selective pulmonary angiography defines the exact location, extent, and distribution of the lesion (Fig. 43-40) . Mild to moderate unilateral or bilateral stenosis does not require surgical relief; numerous stenotic areas are not amenable to correction, even with intraoperative balloon angioplasty. Well-localized obstruction of severe degree in the main pulmonary artery or its

Figure 43-40 Right ventricular angiocardiogram showing numerous sites of peripheral pulmonic stenosis and poststenotic dilatation of the peripheral pulmonic arteries.

major branches may be alleviated by percutaneous transcatheter balloon angioplasty (see Chap. 38),[361] often accompanied by endovascular stent implantation[362] [363] or with a patch graft or bypassed with a tubular conduit. The natural history of peripheral pulmonary stenosis is not clear. Obstruction may increase by discrepant growth between a stenotic area and normal portions of the pulmonary artery tree, or as a result of an increase in cardiac output, especially during adolescence. Rarely, hypertrophy of right ventricular infundibular muscle is progressive and results in hypercyanotic spells.

Pulmonic Stenosis with Intact Ventricular Septum (See also p. 1602)

Valvular pulmonic stenosis, resulting from fusion of the valve cusps during mid- to late intrauterine development, is the most common form of isolated right ventricular obstruction and occurs in about 7 percent of patients with congenital heart disease. Hypertrophy of the septal and parietal bands narrowing the right ventricular infundibulum often accompanies the pulmonic valve lesion, especially if it is severe. Fused cusps of varying thickness and rigidity form a fibrous dome in the severest forms. Pulmonic valve dysplasia, especially common in patients with Noonan's syndrome (see Chap. 56), produces obstruction in the absence of adherent leaflets because leaflets are thickened, rigid, and myxomatous and are limited in their lateral movement because of the presence of tissue pads within the pulmonic valve sinuses.[364]

NEONATES AND INFANTS.

The clinical presentation and course of circulation in a newborn with pulmonic stenosis depends on the severity of obstruction and the degree of development of the right ventricle and its outflow tract, the tricuspid valve, and the pulmonary arterial tree. The greater the degree of pulmonic valve stenosis, the more closely the manifestations resemble those observed with pulmonary atresia and intact ventricular septum. Severe pulmonic stenosis is characterized by cyanosis caused by right-to-left shunting through the foramen ovale, cardiomegaly, and diminished pulmonary blood flow in the absence of persistent patency of the ductus arteriosus.

Hypoxemia and metabolic acidemia rather than right ventricular failure are the main clinical disturbances in symptomatic neonates and can be alleviated temporarily by infusion of prostaglandin E_1 to dilate the ductus arteriosus and increase pulmonary blood flow. Distinction of these babies from those with tetralogy of Fallot or tricuspid or pulmonary atresia usually is possible because infants with tetralogy usually do not have roentgenographic evidence of cardiomegaly; infants with tricuspid and pulmonary atresia show a preponderance of left ventricular forces by ECG, in contrast to the right ventricular hypertrophy usually observed with critical pulmonic stenosis in the absence of right ventricular hypoplasia.

Combined two-dimensional echocardiographic and continuous-wave Doppler examination (see Chap. 7) characterizes the anatomical valve abnormality and its severity and has essentially eliminated the requirement for cardiac catheterization and angiographic studies to establish a precise diagnosis (Fig. 43-41) .[365] [366]

Balloon Valvuloplasty.

Balloon dilatation of the pulmonary valve is the therapeutic procedure of choice,[365] [366] [367] [368] [369] [370] but a pulmonary valvotomy and systemic-to-pulmonary arterial shunt may be necessary in infants with underdevelopment of the right ventricular cavity.[371] In this group, success has been achieved by modification of balloon valvuloplasty with predilation initially using a coronary dilatation catheter to facilitate introduction of a definitive balloon catheter. Transcatheter balloon valvuloplasty can be expected to reduce but not abolish the pressure difference in neonates with mobile doming valves. Sustained relief of the severe obstruction is usual, and so is good growth of the right ventricle. This approach is of lesser efficacy in those patients with dysplastic valves and is contraindicated if valve dysplasia is associated with annular hypoplasia.[372]

CHILDREN.

The clinical profile of patients with valvular pulmonic stenosis beyond infancy usually is distinctive.[373] The severity of obstruction is the most important determinant of the clinical course. In the presence of a normal cardiac output, a peak systolic transvalvular pressure gradient between 50 and 80 mm Hg or a peak systolic right ventricular pressure between 75 and 100 mm Hg is considered to be indicative of moderate stenosis; levels below and above that range are classified as mild and severe, respectively. Most patients with mild pulmonic stenosis are asymptomatic, and the condition is discovered during routine examination. In patients with more significant obstruction, the severity of stenosis may increase with time. Progression

Figure 43-41 Right ventriculogram in an infant with critical pulmonic stenosis shows the thickened, nonmobile pulmonic valve (arrow) in the lateral projection *(left)*. Both the lateral and frontal *(right)* projections show regurgitation of contrast material across the tricuspid valve into the right atrium (ra), with subsequent shunting across the foramen ovale to the left atrium (la). rv = right ventricle; pa = pulmonary artery. *(Courtesy of Dr. Norman Talner).*

may be relative and reflect disproportional physical growth of the patient, infundibular narrowing due to progressive hypertrophy of the right ventricular outflow tract, or fibrosis of the valve cusps. Symptoms, when present, vary from mild exertional dyspnea and mild cyanosis to signs and symptoms of heart failure, depending on the degree of obstruction and the level of myocardial compensation. Exertional fatigue, syncope, and chest pain are related to an inability to augment pulmonary blood flow during exercise in some patients with moderate or severe obstruction.

PHYSICAL EXAMINATION.

The severity of obstruction often is suggested by the physical findings. Right ventricular hypertrophy reduces compliance of that chamber, and a forceful right atrial contraction is necessary to augment right ventricular filling. Prominent *a* waves in the jugular venous pulse, a fourth heart sound, and, occasionally, presystolic pulsations of the liver reflect a vigorous atrial contraction and suggest the presence of severe stenosis. Cardiomegaly and a right ventricular parasternal lift accompany moderate or severe obstruction. A systolic thrill is palpable along the upper left sternal border in all but the mildest forms of stenosis. The first heart sound is normal and is followed by a systolic ejection sound at the upper left sternal edge produced by sudden opening of the stenotic valve; an ejection sound is not heard in patients with pulmonic valve dysplasia. The ejection sound typically is louder during expiration; when it is inaudible or occurs less than 0.08 second from the onset of the Q wave on ECG, severe obstruction is suggested. Right ventricular ejection is prolonged in patients with moderate or severe stenosis, and the sound of pulmonic valve closure is delayed and soft. The characteristic feature of valvular pulmonic stenosis on auscultation is a harsh, diamond-shaped systolic ejection murmur heard best at the upper left sternal border. The systolic murmur becomes louder and its crescendo occurs later in systole, obscuring the aortic component of the second sound with more severe degrees of valvular obstruction because these patients have a greater prolongation of right ventricular systole. The holosystolic decrescendo murmur of tricuspid regurgitation may accompany severe pulmonic stenosis, especially in the presence of congestive heart failure. Cyanosis, reflecting venoarterial shunting through a patent foramen ovale, is absent with mild stenosis and infrequent with moderate obstruction. Cyanosis may not be apparent in patients with severe obstruction if the atrial septum is intact.

ELECTROCARDIOGRAPHY.

This technique may be helpful in assessing the degree of obstruction to right ventricular output.[374] In mild cases, the ECG often appears normal, whereas moderate and severe stenoses are associated with right-axis deviation and right ventricular hypertrophy. In the latter patients between ages 2 and 20 years, an estimate of right ventricular pressure can be made by multiplying the height of the R wave in lead V_{4R} or V_1 by 5. A tall QR wave in the right precordial leads with T wave inversion and ST segment suppression (right ventricular "strain") reflects severe stenosis. When an rSR pattern is observed in lead V_1 (20 percent of patients), lower right ventricular pressures are found than in patients with a pure R wave of equal amplitude. High-amplitude P waves in leads II and V_1 indicating right atrial enlargement are associated with severe stenosis.

CHEST ROENTGENOGRAPHY.

In patients with mild or moderate pulmonic stenosis, chest roentgenography often shows a heart of normal size and normal pulmonary vascularity (see Chap. 8). Poststenotic dilatation of the main and left pulmonary arteries often is evident. Right atrial and right ventricular enlargement are observed in patients with severe obstruction and resultant right ventricular failure. The pulmonary vascularity may be reduced in patients with severe stenosis, right ventricular failure, and/or a venoarterial shunt at the atrial level.

ECHOCARDIOGRAPHY.

Reliable localization of the site of obstruction and assessment of its severity are obtained by combined continuous-wave or pulsed-wave Doppler and two-dimensional echocardiography[375] (see Chap. 7 and Fig. 43-42). The latter usually shows prominent pulmonary valve echoes with restricted systolic motion as well as poststenotic dilation of the main pulmonary artery and its branches. In contrast to these findings in classic valvular pulmonic stenosis, patients with a dysplastic valve show thickened and immobile leaflets with hypoplasia of the pulmonary valve annulus and absent poststenotic dilatation of the pulmonary artery. Parasternal and subcostal views are required to detect most accurately maximal pulmonary artery blood flow velocity, which is converted to a pressure difference across the valve using a modified Bernoulli equation (pressure difference [mm Hg] = 4 × the squared peak Doppler velocity [m/sec]) (Fig 43-42). A semiquantitative estimation of pulmonary and tricuspid regurgitation can be

Figure 43-42 *A,* Severe valvular pulmonic stenosis seen from a parasternal short-axis view. The thickened pulmonary valve can be seen lying between the right ventricular outflow tract (RVO) and a dilated pulmonary artery (PA). The arrows are at the annulus of the pulmonary valve; the thickened, domed valve can be identified clearly. LV = left ventricle; AO = aorta; LA = left atrium. *B,* Doppler ultrasound from the subcostal (SC) transducer position. The velocity signal is approximately 3.8 m/sec at its height; predicted peak gradient (PGRAD) is 58 mm Hg, predicted mean gradient (MnGRAD) is 34 mm Hg.

obtained. The peak systolic velocity of the tricuspid regurgitant jet provides a reliable indirect measurement of the severity of obstruction because the reverse gradient between the right ventricle and right atrium allows derivation of the ventricular peak systolic pressure. The constant value of 14 is used for right atrial pressure in the

calculation.

CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY.

These techniques are now used only rarely to establish or preclude other diagnostic possibilities. The usual indication for cardiac catheterization is to provide definitive therapy for the lesion. Cardiac catheterization, however, may also localize the site of obstruction, evaluate its severity, and document the coexistence of additional cardiac malformations. The resting cardiac output usually is normal, even in cases of severe stenosis, and most children show the ability to increase cardiac output with exercise.[376] Right ventricular dysfunction occurs especially when venoarterial shunting is significant and produces systemic arterial desaturation. In patients with critical stenosis, care must be taken during hemodynamic study that the cardiac catheter does not dangerously occlude the stenotic valve opening. The angiographic appearance of a typical valvular pulmonic stenosis differs from that of a dysplastic valve. The former is thickened and domed during systole, returning to normal configuration in diastole. Poststenotic dilatation of the main pulmonary trunk and sometimes of the left pulmonary artery is usual. The leaflets of the dysplastic valve are not fused anatomically but are thickened and immobile, creating little change in the angiographic picture during the cardiac cycle. Moreover, a small annulus and narrow sinuses of Valsalva are common accompaniments of valve dysplasia. With either type of valve, systolic narrowing of the right ventricular infundibulum usually is associated with moderate or severe obstruction.

NATURAL HISTORY.

Mild and moderate pulmonic valve stenoses have a generally favorable course; uncommonly, progression occurs in the severity of obstruction, particularly in infancy.[377] Serial hemodynamic studies reveal unchanged pressure gradients over 4- to 8-year intervals in three-fourths of patients. Equal percentages of the remainder have an increase or a decrease in the severity of obstruction; significant increases in the pressure gradient occur especially in children with a gradient in excess of 50 mm Hg at initial examination.[373]

MANAGEMENT.

Percutaneous transluminal balloon valvuloplasty (see Chap. 38) is the initial procedure of choice in patients with typical pulmonary valve stenosis and moderate to severe degrees of obstruction (Fig. 43-43). [372] This approach provides palliative improvement with the great likelihood that the improvement is permanent. In these same patients, *surgical relief* also can be accomplished at extremely low risk.[378] The valve is approached through an incision in the pulmonary arterial trunk, and resection of infundibular muscle, if necessary, may be accomplished through the pulmonic valve. Reoperation or subsequent balloon valvuloplasty is seldom required. In patients with a dysplastic valve, in whom transcatheter valvuloplasty is ineffective, the thickened valve tissue is removed and a patch often is required to widen the annulus and proximal main pulmonary artery. In children with mild pulmonic valve stenosis, prophylaxis against infective endocarditis is recommended; these patients need not restrict their physical activities. After relief of stenosis, cardiac performance as judged by exercise testing improves in children in whom postoperative resolution of right ventricular hypertrophy is expected. In contrast, myocardial fibrosis can explain a lack of improvement in adults.[379]

Pulmonic Atresia with Intact Ventricular Septum

MORPHOLOGY.

This anomaly is an uncommon and highly lethal cause of neonatal cyanosis that may respond well to aggressive medical and surgical treatment.[380] [381] In almost all infants, the pulmonic valve is atretic; in the majority, both the valve ring and the main pulmonary artery are hypoplastic. The right ventricular infundibulum may occasionally be atretic or extremely narrowed. Right ventricular cavity size and configuration span the spectrum from a diminutive right ventricular chamber, often with tricuspid stenosis, to a large right ventricle, frequently with tricuspid regurgitation (Fig. 43-44) . In most infants, the right ventricle is hypoplastic, and sinusoidal communications

Figure 43-43 Right ventriculogram (RV) in the lateral projection *(top left)* from a patient with valvular pulmonic stenosis. The pulmonary valve (PV) is thickened and domes in systole. Poststenotic dilatation of the pulmonary artery (PA) is seen. At the *top right,* successful balloon valvuloplasty shows almost complete disappearance of the stenotic waist (arrow). The *bottom panel* shows the pre- *(left)* and post- *(right)* valvuloplasty hemodynamics, showing a reduction from moderately severe to mild pulmonic stenosis. AO = aorta. *(Courtesy of Dr. Thomas G. DiSessa.)*

exist in half the patients between the right ventricular cavity and the coronary circulation.[382] [383]

The intramyocardial sinusoids may end blindly or communicate with coronary arteries. Further, these communications may be numerous and may feed both the left and right coronary systems, or they may be fed via a single dilated vessel. The proximal coronary arteries in some patients may be atrophic, proximal to a communication between the sinusoids and the distal coronary artery, particularly

Figure 43-44 Pulmonic atresia with intact ventricular septum. With a competent tricuspid valve, the right ventricular chamber is diminutive *(A)*; significant tricuspid regurgitation is associated with a normal or large right ventricular cavity *(B)*. VC = vena cava; RA = right atrium; RV = right ventricle; PT = pulmonary trunk; PV = pulmonary vein; LA = left atrium; LV = left ventricle; Ductus A. = ductus arteriosus; LPA = left pulmonary artery; RPA = right pulmonary artery; LPV = left pulmonary vein. *(From Edwards JE: Congenital malformations of the heart and great vessels. in hearts with severe hypoplasia of the right ventricle. In these circumstances, the distal coronary vessels are supplied by communications with the right ventricle, and the coronary circulation therefore is right ventricle dependent. In this group, decompression of the right ventricle by a surgical procedure would be associated with a high risk of myocardial ischemia and death.[384] [385]

Because the pulmonic valve is imperforate and completely obstructed, systemic venous blood returning to the heart bypasses the right ventricle through an interatrial communication. Right ventricular output does not contribute to the effective cardiac output and is proportional to the magnitude of tricuspid regurgitation and the size and extent of the sinusoidal communications with the coronary arterial tree. The blood supply to the lungs is derived from the bronchial circulation and from flow through a persistently patent ductus arteriosus. The size and patency of the ductus arteriosus are critical determinants in postnatal survival; ductus closure results in death. Reduced pulmonary blood flow by way of a partially constricted ductus arteriosus results in profound hypoxemia, tissue hypoxia, and metabolic acidemia.

DIAGNOSIS.

The diagnosis is suggested by roentgenographic findings of pulmonary hypoperfusion and the ECG observation of a normal QRS axis, absent or diminished right ventricular forces, and/or dominant left ventricular forces. In the minority of infants with marked tricuspid regurgitation, the right ventricle and right atrium are massively enlarged. The echocardiogram in the usual infant shows a small right ventricular cavity and diminutive or absent pulmonic valve echoes.[386] Doppler examination shows continuous retrograde flow to the pulmonary artery and/or its branches through a patent ductus arteriosus, which usually is narrow and tortuous. Only if tricuspid valve echoes are imaged by ultrasound examination can tricuspid atresia be distinguished from pulmonic atresia.

Although the diagnosis of this entity can be made by echocardiography, angiocardiography is required to assess treatment options because key determinants are the identification and nature of ventriculocoronary connections, which are not well characterized by echocardiography. Cardiac catheterization is usually performed on an emergency basis. Because survival depends on patency of the ductus arteriosus, intravenous infusion of prostaglandin E_1 , (0.05 to 0.1 mug/kg/min) may dramatically reverse clinical deterioration and improve arterial blood gases and pH. The usual hemodynamic findings are right atrial and right ventricular hypertension, with right

ventricular pressure often greater than systemic pressure, and a massive right-to-left interatrial shunt. Selective angiocardiography establishes the diagnosis and allows evaluation of the degree of separation between the right ventricular infundibular and pulmonary trunk, the size of the right ventricular cavity and the pulmonary arteries (Fig. 43-45) , the anatomy and function of the tricuspid valve, and the anatomical and functional details of the coronary circulation.

MANAGEMENT.

Initial stabilization is usually required in infants, necessitating infusion of prostaglandin E_1 to dilate the ductus arteriosus and measures to correct metabolic acidosis. The rare infant with membranous pulmonary atresia may be a candidate for balloon valvotomy. Initial surgical considerations focus on whether the patient is a candidate for a biventricular or univentricular (Fontan) repair (Fig. 43-45) .[384] [387] [388] [389] The angiographic delineation of coronary artery anatomy determines the feasibility of early decompression of the right ventricle, because this approach is contraindicated when there are ventriculocoronary connections with part or all of the coronary circulation right ventricle dependent. Patients in this latter group cannot undergo operation that decompresses the right ventricle and are ultimately candidates for a lateral tunnel Fontan procedure, after initial palliation by balloon atrial septostomy followed by a systemic-pulmonary artery shunt.[390]

At the other end of the spectrum, babies with only mild hypoplasia of the right ventricle and tricuspid valve are candidates for a transventricular closed pulmonary valvotomy, followed later by balloon angioplasty or repeat surgical valvotomy. Ultimately, the size of the tricuspid valve and right ventricle, and occasionally the presence of coronary artery obstructive lesions in association with right ventricle to coronary artery fistulas, will dictate whether patients will be candidates for two-ventricle repair or whether a less corrective procedure such as the Fontan operation will be the most definite surgical option.[387] In infants with moderate right ventricular hypoplasia, a biventricular repair is preferred, often using a homograft valve in the outflow tract. In this group, the smaller the size of the right ventricle and tricuspid valve, the more likely a partial biventricular repair will be necessary, relieving the outflow tract obstruction with insertion of a valve, coupled with a bidirectional cavopulmonary (Glenn) shunt to ensure obligatory pulmonary blood flow.

Intraventricular Right Ventricular Obstruction

Infundibular pulmonic stenosis with an intact ventricular septum and the presence of anomalous muscle bundles are the two principal causes of intraventricular right ventricular obstruction (Fig. 43-46) .[391]

SUBPULMONIC INFUNDIBULAR STENOSIS.

This anomaly usually occurs at the proximal portion of the infundibulum and consists of a fibrous band at the junction of the right ventricular cavity and outflow tract. The clinical manifestations, course, and prognosis of infundibular stenosis are similar to those of valvular stenosis, although the former diagnosis is suggested by the absence of a systolic ejection

Figure 43-46 Intraventricular right ventricular obstruction. The right ventricular inflow (RVI) and outflow (RVO) tracts are separated by bands (arrowheads), creating intraventricular right ventricular obstruction. PA = pulmonary artery.

sound and a systolic murmur lower along the left sternal border. Doppler echocardiography, withdrawal pressure tracings, and selective right ventricular angiocardiography permit localization of the site of obstruction and assessment of its extent and severity. Surgical treatment consists of resection of the fibrotic narrowed area and hypertrophied muscle. It may occasionally be necessary to widen the outflow tract with a pericardial or prosthetic patch.

ANOMALOUS MUSCLE BUNDLES.

A two-chambered right ventricle is formed by right ventricular obstruction due to anomalous muscle bundles; most of the patients have an associated malalignment or perimembranous VSD, and about 5 percent have subaortic stenosis.[392] Aberrant hypertrophied muscle bands, occasionally in association with a VSD, traverse the right ventricular cavity, extending from its anterior wall to the crista supraventricularis and/or the portion of the adjacent interventricular septum. The anomalous pyramid-shaped muscle mass obstructs blood flow through the body of the right ventricle and produces a proximal high-pressure inflow chamber and a distal low-pressure chamber. Thus, this type of obstruction is distinguishable from that in tetralogy of Fallot, in which hypertrophied infundibular muscle protrudes into but does not cross the cavity of the right ventricle.

The clinical, ECG, and chest roentgenographic findings resemble those observed in pulmonic valvular or subvalvular infundibular obstruction, although the systolic thrill and murmur may be displaced lower along the left sternal border. Progressive obstruction occurs in some patients. The diagnosis may be established by two-dimensional echocardiography.[393] Selective right ventricular angiocardiography provides the most accurate diagnosis and reveals a filling defect in the midportion of the right ventricle; this defect often does not change significantly with systole and diastole.

Management.

The treatment for anomalous muscle bundles consists of surgical removal.[394] In the absence of preoperative recognition of the anomaly, the surgeon should be alerted to the correct diagnosis by the presence of a dimple during contraction on the ordinarily smooth anterior surface of the right ventricle and/or the inability to view the tricuspid valve through a longitudinal ventriculotomy because of the presence of the abnormal muscle mass.

Tetralogy of Fallot

DEFINITION.

The overall incidence of this anomaly approaches 10 percent of all forms of congenital heart disease, and it is the most common cardiac malformation responsible for cyanosis after 1 year of age. The four components of this malformation are (1) VSD, (2) obstruction to right ventricular outflow, (3) overriding of the aorta, and (4) right ventricular hypertrophy. The basic anomaly is the result of an anterior deviation of the septal insertion of the infundibular ventricular septum from its usual location in the normal heart between the limbs of the trabecular septum. The interventricular malalignment defect usually is large, approximating the aortic orifice in size, and is located high in the septum just below the right cusp of the aortic valve, separated from the pulmonic valve by the crista supraventricularis. The aortic root may be displaced anteriorly and straddle or override the septal defect, but as in a normal heart, it lies to the right of the origin of the pulmonary artery. In most cases, no dextroposition of the aorta exists; overriding of the aorta is a phenomenon secondary to the subaortic location of the VSD.

HEMODYNAMICS.

The degree of obstruction to pulmonary blood flow is the principal determinant of the clinical presentation.[395] The site of obstruction is variable[396] ; infundibular stenosis is the only major obstruction in about 50 percent of patients and coexists with valvular obstruction in another 20 to 25 percent (Fig. 43-47) . Supravalvular and peripheral pulmonary arterial narrowing may be observed, and unilateral absence of a pulmonary artery (usually the left) is found in a small number of patients. Circulation to the abnormal lung is accomplished by bronchial and other collateral arteries.[397] [398] Atresia of the pulmonic valve, infundibulum, or main pulmonary artery is occasionally referred to as "pseudotruncus arteriosus." True truncus arteriosus with absent pulmonary arteries (type 4) differs from

Figure 43-47 Tetralogy of Fallot with infundibular and valvular pulmonic stenosis. The arrows indicate direction of blood flow. A substantial right-to-left shunt exists across the ventricular septal defect. RA = right atrium; LA = left atrium; RV = right ventricle; LV = left ventricle; Ao = aorta; PA = pulmonary artery.

tetralogy of Fallot, in which pulmonary artery branches are present but are fed by a patent ductus arteriosus and/or bronchial arteries (see Fig. 43-50). A right-sided aortic knob, aortic arch, and descending aorta occur in about 25 percent of patients with tetralogy of Fallot. The coronary arteries may have surgically important variations[399] : The anterior descending artery may originate from the right coronary artery; a single right coronary artery may give off a left branch that courses anterior to the pulmonary trunk; a single left coronary artery may give off a right branch that crosses the infundibulum of the right ventricle. Enlargement of the infundibulum branch of the right coronary artery often presents a problem with respect to a right ventriculotomy.

Associated cardiac anomalies exist in about 40 percent of patients. Major associated cardiac anomalies include patent ductus arteriosus, numerous (usually muscular) VSDs, and complete AV septal defects. Localized single or multiple peripheral pulmonary arterial stenotic lesions are common; rarely, the right or left pulmonary artery may arise anomalously from the ascending aorta. Infrequently, aortic valve regurgitation results from aortic cusp prolapse. Associated extracardiac anomalies are present in 20 to 30 percent of patients.

The relation between the resistance of blood flow from the ventricles into the aorta and into the pulmonary vessels has a major role in determining the hemodynamic and clinical picture.[400] Thus, the severity of obstruction to right ventricular outflow is of fundamental significance. When right ventricular outflow tract obstruction is severe, the pulmonary blood flow is markedly reduced, and a large volume of unsaturated systemic venous blood is shunted from right to left across the VSD. Severe cyanosis and polycythemia occur, and symptoms and sequelae of systemic hypoxemia are prominent. At the opposite end of the spectrum, the term "acyanotic" or "pink" tetralogy of Fallot often is used to describe an interventricular communication and a milder degree of obstruction to right ventricular outflow with little or no venoarterial shunting. In many infants and children, the obstruction to right ventricular outflow is mild but progressive, so that early in life pulmonary exceeds

systemic blood flow and the symptoms resemble those produced by a simple VSD.

CLINICAL MANIFESTATIONS.

Few children with tetralogy of Fallot remain asymptomatic or acyanotic (see Chap. 44). Most are cyanotic from birth or develop cyanosis before age 1 year. In general, the earlier the onset of systemic hypoxemia, the more likely the possibility that severe pulmonary outflow tract stenosis or atresia exists. Dyspnea with exertion, clubbing, and polycythemia is common. When resting after exertion, children with tetralogy characteristically assume a squatting posture. The latter may be obvious even in infancy; many cyanotic infants prefer to lie in a knee-chest position. Spells of intense cyanosis related to a sudden increase in renoarterial shunting and a reduction in pulmonary blood flow most often have their onset between 2 and 9 months of age and constitute an important threat to survival.[401] [402] The attacks are not restricted to patients with severe cyanosis; they are most common in the morning after awakening and are characterized by hyperpnea and increasing cyanosis that progresses to limpness and syncope and occasionally terminates in convulsions, a cerebrovascular accident, and death.

Physical Examination.

This reveals variable degrees of underdevelopment and cyanosis. Clubbing of the terminal digits may be prominent after the first year of life. The heart is not hyperactive or enlarged; a right ventricular impulse and systolic thrill often are palpable along the left sternal border. An early systolic ejection sound that is aortic in origin may be heard at the lower left sternal border and apex; the second heart sound is single, the pulmonic component rarely being audible. A systolic ejection murmur is produced by flow across the narrowed right ventricular infundibulum or pulmonic valve. The intensity and duration of the murmur vary inversely with the severity of obstruction--the opposite of the relation that exists in patients with pulmonic stenosis and an intact ventricular septum. Polycythemia, decreased systemic vascular resistance, and increased obstruction to right ventricular outflow may all be responsible for a decrease in intensity of the murmur; with extreme outflow tract stenosis or pulmonic atresia and during an attack of paroxysmal hypoxemia, no murmur or only a very short, faint murmur may be detected. A continuous murmur faintly audible over the anterior or posterior chest reflects flow through enlarged bronchial collateral vessels. A loud continuous murmur of flow through a patent ductus arteriosus occasionally may be heard at the upper left sternal border.

LABORATORY EXAMINATIONS.

The *ECG* ordinarily shows right ventricular and, less frequently, right atrial hypertrophy. In a patient with acyanotic tetralogy, combined ventricular hypertrophy may be noted initially, progressing to right ventricular hypertrophy as cyanosis develops. *Roentgenographic* examination characteristically reveals a normal-sized boot-shaped heart (coeur en sabot) with prominence of the right ventricle and a concavity in the region of the underdeveloped right ventricular outflow tract and main pulmonary artery. The pulmonary vascular markings are typically diminished, and the aortic arch and knob may be on the right side; the ascending aorta usually is large. A uniform, diffuse, fine reticular pattern of vascular markings is noted in the presence of prominent collateral vessels.

Echocardiography.

Findings include aortic enlargement, aortic-septal discontinuity, and aortic overriding of the ventricular septum.[403] Two-dimensional echocardiography (see Chap. 7) shows the right ventricular outflow tract to be narrowed and in a more horizontal orientation than normal. The main pulmonary artery and its branches are mildly to severely hypoplastic. The usual ventricular septal malalignment defect lies superior to the tricuspid valve and immediately below the aortic valve cusps. These findings are best displayed in views of the long axis of the right ventricular outflow tract, which are the subxiphoid short axis and the high transverse parasternal echo windows. Echo views that show the anteroposterior coordinates best indicate the overriding of the aorta; these are the parasternal long-axis, apical two-chamber, and subxiphoid views (Fig. 43-48) . The echocardiographic examination also reveals the origin of the main pulmonary artery from the right ventricle, as well as continuity of the main pulmonary artery with its right and left branches, and is accurate for diagnosing coronary abnormalities,[404] [405] although the latter are identified best by angiography. Delineation or complex pulmonary vascular abnormalities may require combined angiography and advanced CT[406] (see Chaps. 10 and 11). Combined angiography and three-dimensional CT has been shown to be useful for assessing systemic-to-pulmonary collaterals. The demonstration of mitral-semilunar valve continuity helps to distinguish tetralogy from double-outlet right ventricle with pulmonic stenosis, in which discontinuity of the mitral valve echo and the aortic cusp echo is a critical feature.

Cardiac Catheterization and Angiocardiography (Fig. 43-49) .

Despite the accuracy of noninvasive approaches, many centers still consider invasive study necessary to confirm the diagnosis; assess the magnitude of right-to-left shunting; provide details of additional muscular VSDs, if present; evaluate the architecture of the right ventricular outflow tract, pulmonic valve, and annulus and the morphology and caliber of the main branches of the pulmonary arteries; and analyze the anatomy of the coronary arteries. *Axial cineangiography,* using the sitting-up projection, greatly facilitates evaluation of the pulmonary outflow tract and arteries.[137] Preoperative assessment of tetralogy with pulmonic atresia must include delineation of the arterial supply to both lungs by selective catheterization and visualization of bronchial collateral arteries with late serial filming; pulmonary arteries may be opacified only after the bronchial collateral arteries have cleared of contrast material (Fig. 43-50) . A patient with pulmonic atresia should not be ruled out as a candidate for surgical correction unless an inadequate pulmonary arterial supply to the lungs is clearly demonstrated.[397] Rarely, injection of contrast through a catheter in the pulmonary venous capillary wedge position is required to assess the possibility that anatomical pulmonary arteries are present. CT may visualize central pulmonary arteries when conventional angiography cannot.

MANAGEMENT.

Among the factors that may complicate the management of tetralogy are iron deficiency anemia,

Figure 43-48 Tetralogy of Fallot in a parasternal long-axis (PLAx) view, which demonstrates the aorta overriding the ventricular septum (Sept). RV = right ventricle; RVO = right ventricular outflow tract; LV = left ventricle; LA = left atrium; AO = aorta; AAO = ascending aorta.

Figure 43-49 Lateral view of a right ventriculogram in a child with tetralogy of Fallot showing simultaneous opacification of the pulmonary artery (PA) and aorta (Ao). PV = pulmonic valve; VSD = ventricular septal defect; RV = right ventricle.

infective endocarditis, paradoxical embolism, polycythemia, coagulation disorders, and cerebral infarction or abscess. Paroxysmal hypercyanotic spells may respond quickly to oxygen, placing the child in the knee-chest position, and morphine. If the spell persists, metabolic acidosis develops from prolonged anaerobic metabolism, and infusion of sodium bicarbonate may be necessary to interrupt the attack. Vasopressors, beta-adrenoceptor blockade, or general anesthesia occasionally may be

necessary.[402]

Total Surgical Correction.

This operation is advisable ultimately for almost all patients with tetralogy of Fallot. Early definitive repair, even in infancy, is currently advocated in most centers that are experienced in intracardiac surgery in infants.[407] [408] [409] Successful early correction appears to prevent the consequences of progressive infundibular obstruction and acquired pulmonic atresia, delayed growth and development, and complications secondary to hypoxemia and polycythemia with bleeding tendencies. The anatomy of the right ventricular outflow tract and the size of the pulmonary arteries, rather than the age or size of the infant or child, are the most important determinants in assessing candidacy for primary repair; a transannular patch may be used in infants with severe outflow narrowing.[410] Marked hypoplasia of the pulmonary arteries is a relative contraindication for early corrective operation.

Figure 43-50 Selective systemic collateral bronchial arteriogram demonstrates gull-wing configuration of the hypoplastic right pulmonary artery (rpa) and left pulmonary artery (arrows) in a patient with tetralogy of Fallot and pulmonic atresia. *(Courtesy of Dr. Robert Freedom.)*

Palliative Surgery.

When marked hypoplasia of the pulmonary arteries exists, a palliative operation designed to increase pulmonary blood flow is recommended and usually consists in the smallest infants of a systemic-pulmonary arterial anastomosis.[411] A transventricular infundibulectomy or valvulotomy is an alternative palliative procedure that may be considered. Balloon dilatation of the pulmonary valve may afford palliation in selected infants.[412] Total correction can then be carried out at a lower risk later in childhood. The palliative procedures relieve hypoxemia caused by diminished pulmonary blood flow and reduce the stimulus to polycythemia. Because pulmonary venous return is augmented, the left atrium and ventricle are stimulated to enlarge their capacity in anticipation of total correction. In the most severe forms of tetralogy of Fallot with pulmonic atresia, the goals of operation include establishment of nonstenotic continuity between the right ventricle and pulmonary arteries, closure of the intracardiac shunt, and interruption of surgically created shunts or major collateral arteries to the lungs. Transcatheter coil occlusion of significant aorta-pulmonary collateral vessels as well as of modified Blalock-Taussig shunts and ascending aorta to pulmonary artery interposition grafts can be used before corrective operation.[413] [414] When atresia is confined to the infundibulum or pulmonic valve, repair may be accomplished by infundibular resection and reconstruction of the outflow tract with a pericardial patch. If a long segment of pulmonary arterial atresia exists, a valve-containing conduit is inserted from the right ventricle to the distal pulmonary artery.[415] The presence of a single pulmonary artery in the hilus of either lung is a prerequisite for repair of pulmonic atresia. Prior unifocalization to incorporate several systemic to pulmonary artery collaterals into a neopulmonary artery may be required in selected patients.[416] A conduit also may be necessary in less severe forms of right ventricular outflow tract obstruction when an anomalous coronary artery crosses the right ventricular outflow tract.

Postoperative Complications.

Various complications are common in the postoperative period after palliative or corrective operation. Mild to moderate left ventricular decompensation may be secondary to the sudden increase in pulmonary venous return; various degrees of pulmonic valvular regurgitation increase right ventricular cavity size further. Patients with progressive pulmonary insufficiency and severe right ventricular dilatation are candidates for prosthetic pulmonary valve insertion.[417]

Bleeding problems are common, especially in older polycythemic patients (see Chap. 44). Complete right bundle branch block or the pattern of left anterior hemiblock often is seen, but disabling dysrhythmias are infrequent.[418] [419] Restricted pulmonary arterial flow is the greatest

cause of early and late mortality and poor late results.[420] After convalescence from intracardiac repair, symptoms of hypoxemia and severe exercise intolerance are relieved even in the presence of some residual right ventricular outflow tract obstruction, pulmonic valve incompetence, and/or cardiomegaly. However, cardiovascular performance at rest or during exercise may remain below normal,[421] [422] [423] and major complications, such as trifascicular block, complete heart block, ventricular arrhythmias, and sudden death, may rarely occur many years after surgical treatment.[419]

Late ventricular arrhythmias are rare in patients with successful early correction of the malformation unless complex or numerous operations were performed. Because widespread use of ambulatory ECG monitoring has resulted in greater detection of ventricular arrhythmias, usually isolated ventricular extrasystoles or nonsustained tachycardia, some have suggested that the asymptomatic patients in this category should have pharmacological suppression of their arrhythmias. It would appear that both ventricular depolarization and repolarization abnormalities contribute to the pathogenesis of ventricular arrhythmias after repair of the anomaly (see Chaps. 25 and 44). Most studies, however, do not support the use of potentially dangerous long-term antiarrhythmic treatment for asymptomatic postoperative patients, and a large-scale long-term follow-up study is indicated before prophylactic therapeutic options can be established definitively (see Chap. 23).

Congenital Absence of the Pulmonic Valve

PATHOLOGY AND PATHOGENESIS.

In the majority of cases of this rare malformation, the lesion is associated with a VSD, a narrowed obstructive annulus of the pulmonic valve, and marked aneurysmal dilatation of the pulmonary arteries. The combination of anomalies often is referred to as tetralogy of Fallot with absent pulmonic valve. The obstructing lesion principally consists of underdeveloped, primitive valve tissue within a hypoplastic annulus; infundibular obstruction and the VSD do not differ from classic tetralogy of Fallot. Reports indicate that deletion within chromosome 22 is common in patients with this anomaly.[424]

The massively dilated pulmonary arteries often are the major determinant of the clinical course because they frequently result in upper airway obstruction and severe respiratory distress in infancy.[425] Smaller intrapulmonary bronchi may also be compressed by abnormally branching distal pulmonary arteries, and in some cases the number of bronchial generations or alveolar multiplications is reduced.[426] Poststenotic pulmonary artery aneurysms develop in utero, and their size and location appear to be related to the magnitude of pulmonic regurgitation in fetal life, the orientation of the right ventricular infundibulum to the right or left, and the size of the ductus arteriosus.[427]

CLINICAL AND LABORATORY FINDINGS.

The *clinical* features often are distinctive, with an early onset of severe respiratory distress caused by tracheobronchial compression accompanied by a systolic ejection and a widely transmitted low-pitched, decrescendo diastolic murmur at the upper left sternal border. In the absence of pulmonary complications, cyanosis is commonly mild. *Roentgenographically,* the heart is moderately enlarged; hyperinflated lung fields are observed, with large hilar densities representing the aneurysmally dilated pulmonary arteries. The *echocardiographic* features are similar to those seen in classic tetralogy of Fallot, in addition to massive dilatation of the main pulmonary artery and branch pulmonary arteries. Remnants of pulmonary cusps may be visible. Right ventricular dilatation is produced by significant pulmonary regurgitation; the latter is identified by retrograde diastolic flow in the pulmonary arteries and right ventricle at Doppler examination. These findings may be detected before birth (Fig. 43-51) . Definitive diagnosis is established by cardiac catheterization and selective angiocardiography. Magnetic resonance imaging is a complementary diagnostic modality and is particularly useful for demonstrating bronchial morphology and the severity of bronchial obstruction.[428]

NATURAL HISTORY AND MANAGEMENT.

Prognosis is related to the intensity of upper airway obstruction; pulmonary complications are the usual cause of death in infancy. If survival beyond infancy is accomplished, the respiratory symptoms usually diminish, probably because of maturational changes in the structure of the tracheobronchial tree. The surgical approach in infancy often is unsatisfactory; various procedures have been attempted, ranging from aneurysmorrhaphy to pulmonary artery suspension to transection and reanastomosis of pulmonary artery segments to homograft insertion.[429] Also suggested are ligation of the main pulmonary artery and creation of a systemic-pulmonary shunt, as well as primary repair of the VSD with pulmonary arterial plication. In older patients, the stenotic annulus

Figure 43-51 Two-dimensional *(top panel)* and Doppler *(lower panel)* echocardiogram of a 30-week-gestation fetus with tetralogy of Fallot and an absent pulmonary valve. The pulmonary artery (PA) is aneurysmally dilated, and the right ventricle (RV) is also dilated. The arrow points to the stenotic pulmonary valve annulus. Pulmonary valve leaflets are not detectable. The Doppler study at the level of

the pulmonary valve annulus demonstrates to-and-fro flow with increased forward velocity in systole. LV = left ventricle. *(Courtesy of Dr. James C. Huhta.)*

may be widened with a patch and the VSD closed. It seldom is necessary to replace the pulmonic valve.

Tricuspid Atresia

MORPHOLOGY.

This anomaly is characterized by absence of the tricuspid orifice, an interatrial communication, hypoplasia of the right ventricle, and the presence of a communication between the systemic and pulmonary circulations, usually a VSD.[430] Thus formed is a univentricular AV connection, consisting of a left-sided mitral valve between the morphological left atrium and left ventricle. Unequal division of the AV canal by fusion of the right-sided endocardial cushions has been proposed as the embryological fault. Patients may be subdivided into those with normally related great arteries (70 to 80 percent of cases) and those with dextro- or D-transposition of the great arteries; further classification depends on the presence of pulmonic stenosis or atresia and the absence or size of the VSD (Fig. 43-52) . Additional cardiovascular malformations often are present, especially in patients with D-transposition of the great arteries, and include persistent left superior vena cava, patent ductus arteriosus, coarctation of the aorta, and juxtaposition of the atrial appendages.

PATHOPHYSIOLOGY.

The association with other cardiac malformations determines whether or not pulmonary blood

Figure 43-52 *A,* Tricuspid atresia with normally related great arteries, a small ventricular septal defect, diminutive right ventricular chamber, and narrowed outflow tract. *B,* An example of tricuspid atresia and complete transposition of the great arteries in which the left ventricular chamber is essentially a common ventricle, with the aorta arising from an infundibular component (RV) of the common ventricle. VC = vena cava; RA = right atrium; LA = left atrium; RV = right ventricle; LV = left ventricle; LPV = left pulmonary vein; LPA = left pulmonary artery; PT=pulmonary trunk. *(Modified from Edwards JE, Burchell HB: Congenital tricuspid atresia: Classification. Med Clin North Am 33:1177, 1949.)*

flow is decreased, normal, or increased and therefore the degree of systemic hypoxemia.[431] The clinical picture usually is dominated by symptoms resulting from greatly diminished pulmonary blood flow with severe cyanosis. Cyanosis results from an obligatory admixture of systemic and pulmonary venous blood in the left atrium, and its intensity primarily depends on the magnitude of pulmonary blood flow. Heart failure, rather than cyanosis, is the predominant problem in infants with torrential pulmonary blood flow, which results when D-transposition of the great arteries, a VSD, and an unobstructed pulmonary outflow tract coexist. If these patients survive infancy, they are at risk for pulmonary vascular obstructive disease; a favorable response to pulmonary arterial banding is common early in life.

CLINICAL FEATURES.

The diagnosis is easily established in the vast majority of infants with tricuspid atresia and pulmonary hypoperfusion. The *ECG* findings of left-axis deviation, right atrial enlargement, and left ventricular hypertrophy in a cyanotic infant strongly suggest tricuspid atresia. *Echocardiography* reveals a small or absent right ventricle, large left ventricle, and absent tricuspid valve echoes (Fig. 43-53 ; see also Chap. 7); further, it may demonstrate the relation of the great arteries unless pulmonic atresia is present. Color flow and pulsed Doppler echocardiography reveal the abnormal flow patterns; apical and subxiphoid cross-sectional views best reveal the atretic tricuspid orifice. Seen *roentgenographically* are diminished pulmonary vascular markings and a concavity in the region of the cardiac silhouette usually occupied by the main pulmonary artery. The right atrial shadow may be prominent unless left-sided juxtaposition of the atrial appendages exists, which produces a straight and flattened right heart border.

CARDIAC CATHETERIZATION AND ANGIOGRAPHY.

The right ventricle cannot be entered directly from the right atrium. When the great arteries are related normally, pulmonary blood flow is found to be derived from shunting through a VSD or by way of a patent ductus arteriosus; the latter and the bronchial collaterals are the source of pulmonary flow if the ventricular septum is intact. In complete transposition, the pulmonary artery fills directly from the left ventricle and the aorta indirectly through a VSD and the hypoplastic right ventricle. Because complete admixture exists in the left atrium of pulmonary and systemic venous return, the degree of systemic arterial hypoxemia depends on the pulmonary-systemic flow ratio. Right atrial angiography does not opacify the right ventricle unless by way of a VSD. Selective left ventricular *angiography* permits identification of the hypoplastic right ventricle, the size and location of the VSD, the type of pulmonary obstruction, the relation between the great arteries, and the size of the distal pulmonary arterial tree.

MANAGEMENT.

Balloon atrial septostomy in those infants with a restrictive interatrial communication and palliative operations designed to increase pulmonary blood flow (systemic arterial--or venous--pulmonary artery anastomosis) are capable of producing clinical improvement of significant duration in patients with diminished blood flow.[431]

Functional correction of the anomaly has been accomplished in children older than 12 months by an intraatrial cavopulmonary baffle (lateral tunnel Fontan) (Fig. 43-54) or connection of the left pulmonary artery to the superior vena cava and inferior vena cava to the right pulmonary artery.[432] An adjustable snare around the atrial septal defect or a fenestrated cavocaval baffle with later transcatheter closure appears to prevent acute increases in systemic venous pressure, improve cardiac output, and enhance surgical survival.[433] [434] In patients with tricuspid atresia and complete transposition of the great arteries, subaortic obstruction can be anticipated when the VSD becomes restrictive, also referred to as an obstructive bulboventricular foramen. In most patients, the subaortic tissue must be resected, or preferably, a main pulmonary artery to ascending aorta anastomosis (Damus-Stansel-Kaye procedure) is performed at the time of the Fontan operation.[435] Candidates for these corrective procedures must have normal pulmonary vascular resistance and a mean pulmonary artery pressure less than 15 mm Hg, pulmonary arteries of adequate size, pulmonary vascular resistance less than 3 units/m, and good left ventricular function.[436] The postoperative period usually is characterized transiently by a superior vena cava syndrome with right heart failure, edema, ascites, and hepatomegaly. Long-term results have been generally good, but late management issues after Fontan operation are concerned with ventricular dysfunction,

Figure 43-53 Apical four-chamber views of a patient with tricuspid atresia. In these views, the right atrium (RA) and left atrium (LA) can be seen above, and the small right ventricle (RV) and large left ventricle (LV) can be seen below. *Top,* Diastole with the mitral valve in the open position. Note the intense tissue echoes from the right atrioventricular groove between the right atrium (RA) and right ventricle (RV), indicating absence of the tricuspid valve. The descending aorta (DAO) can be identified posterior to the left atrium (LA). *Bottom,* Doppler color flow map of the same patient taken toward end-systole, showing the passage of blood across the ventricular septal defect (arrow).

atrial ventricular valve regurgitation, atrial arrhythmia, cyanosis, thromboembolism, and protein-losing enteropathy.[437] [438] Late postoperative exercise studies show subnormal exercise tolerance.[439] Late atrial arrhythmias can be a consequence of adverse preoperative hemodynamic function or the type of surgical correction (see Chap. 25).[440]

Ebstein Anomaly of the Tricuspid Valve (See also p. 1603)

This malformation is characterized by a downward displacement of the tricuspid valve into the right ventricle due to anomalous attachment of the tricuspid leaflets (Fig. 43-55 ; see also (Fig. 44-8 (Figure Not Available)).[441] Case-control studies suggest that maternal exposure in the first trimester to lithium carbonate, used in the management of manic-depressive psychosis, is associated with a greatly increased risk of this anomaly in exposed offspring.[442] Tricuspid valve tissue is dysplastic, and a variable portion of the septal and inferior

Figure 43-54 Fontan operation by total cavopulmonary connection. *Top,* The pulmonary trunk has been divided close to the pulmonary valve, and both ends have been closed. The right atrium is opened, and a pump sump sucker is placed across the foramen orale and into the left atrium (not shown). Marking stitches are placed at the proposed site of transection of the superior vena cava (SVC) and at the proposed sites of the two longitudinal incisions on the superior and inferior aspects of the right pulmonary artery (RPA). *Middle,* The anastomosis is made between the distal end of the divided superior vena cava and the incision in the superior aspect of the right pulmonary artery. The cardiac end of the superior vena cava is rarely enlarged; anastomosis is made to an incision in the inferior aspect of the right pulmonary artery. *Bottom,* A tunnel is created from a cylinder of either Dacron, Gore-Tex, or pericardium connecting the inferior vena cava (IVC) to the atrial orifice of the superior vena cava. The right pulmonary veins drain behind the tunnel. Ao=aorta. *(From Kirklin, JW, Barratt-Boyes BG: Cardiac Surgery. 2nd ed. New York, Churchill Livingstone, 1993, p 1068.)*

Figure 43-55 Anatomical specimen of Ebstein's anomaly of the tricuspid valve, cut in the same plane as an apical four-chamber echocardiographic view (see Fig. 43-56). The septal and anterior leaflets of the tricuspid valve (SLTV, ALTV) are displaced into the right ventricle (RV), producing a large atrialized right ventricle (ARV). cusps adheres to the right ventricular wall some distance away from the AV junction. Because of the abnormally situated tricuspid orifice, a portion of the right ventricle lies between the AV ring and the origin of the valve, which is continuous with the right atrial chamber. This proximal segment is "atrialized," and a distal, functionally small ventricular chamber exists. The degree of impairment of right ventricular function depends primarily on the extent to which the right ventricular inflow portion is atrialized and on the magnitude of tricuspid valve regurgitation.

CLINICAL MANIFESTATIONS.

These are variable because the spectrum of pathology varies widely and because of the presence of associated malformations. [443] [444] If the tricuspid valve is severely deformed, neonatal heart failure or even fetal hydrops and intrauterine death may occur.[445] At the other end of the spectrum, patients with a mildly deformed tricuspid valve may remain symptom free well into adulthood. The severity of symptoms also depends on the presence or absence of associated malformations. An interatrial communication consisting of a patent foramen ovale or an ostium secundum atrial septal defect is present in more than half the cases. The most common important associated defect is pulmonic stenosis or atresia. Other coexistent anomalies may include an ostium primum type of atrial septal defect and VSD alone or in combination with other lesions. The Ebstein lesion commonly is observed in association with congenitally corrected transposition of the great arteries, in which the tricuspid valve is in the left AV orifice. The usual manifestations in infancy are cyanosis, a cardiac murmur, and severe congestive heart failure. The magnitude of tricuspid regurgitation in neonates is enhanced because the pulmonary vascular resistance is normally high early in life.[446] In this regard, newborn infants with Ebstein anomaly and massive tricuspid regurgitation must be distinguished by two-dimensional and Doppler echocardiography from those with organic pulmonary atresia and the presence of elevated perinatal pulmonary vascular resistance.

The tricuspid regurgitation in infants with Ebstein anomaly may lessen substantially, and cyanosis may disappear early in life as pulmonary vascular resistance falls, only to occur at a later age when right ventricular dysfunction and/or paroxysmal arrhythmias develop. In some infants with Ebstein malformation, cyanosis is suddenly intensified as the degree of pulmonary hypoperfusion is unmasked by spontaneous closure of a patent ductus arteriosus.[447]

Beyond infancy, the onset of symptoms is insidious; the most common complaints are exertional dyspnea, fatigue, and cyanosis. About 25 percent of patients suffer episodes of paroxysmal atrial tachycardia. A prominent systolic pulsation of the liver and a large *v* wave in the jugular venous pulse accompany the systolic thrill and murmur of tricuspid regurgitation. Wide splitting of the first and second heart sounds and prominent third and fourth heart sounds may produce a characteristically rhythmic auscultatory cadence with a triple, quadruple, and quintuple combination of sounds.

LABORATORY FINDINGS.

The ECG abnormalities commonly fall into two categories--those with a right bundle branch block pattern and those with a Wolff-Parkinson-White (WPW) pattern (see Chap. 25). The ECG presentation in the latter is always from a right-sided accessory pathway, resembling left bundle branch block with predominant S waves in the right pericardial leads. The presence of a WPW pattern increases the risk of supraventricular paroxysmal tachycardia (WPW syndrome).[448] The ECG most often shows giant P waves, a prolonged PR interval (in the absence of WPW), and prolonged terminal QRS depolarization, producing variable degrees of right bundle branch block. These distinctive findings help to distinguish Ebstein's anomaly from other forms of right ventricular dysplasia (see Chaps. 25 and 48), whose presenting problem often is an arrhythmia. *Roentgenographic* studies (see Chap. 8) usually demonstrate an enlarged right atrium, a small right ventricle, and a pulmonary artery with reduced pulsations; the pulmonary vascularity can be reduced if a large right-to-left shunt is present.

Echocardiographic Findings.

Echocardiography clearly defines the features of Ebstein malformation.[449] The apical four-chamber plane shows the downward displacement of the attachment of the septal leaflet of the tricuspid valve, a finding overemphasized in the literature. The most important valvar displacement is that of the posterior or mural leaflet of the tricuspid valve, which is not well seen in the four-chamber view but rather in the subcostal view in infants and smaller children and in the parasternal long-axis or apical two-chamber view in older children and adults (Fig. 43-56) . Subcostal echocardiography also defines the dysplasia of the leaflets of the valve, the right atrial dilatation, and the displacement of the entire tricuspid valve into the right ventricle. An additional challenge posed by the malformation, especially important for operative repair, is to determine whether the valvular attachment of the anterosuperior tricuspid leaflet is attached to the underlying myocardium. Echocardiographic identification of the chordae tendineae informs the surgeon of the need for freeing the valve during annuloplasty.

Doppler color flow imaging defines the degree of tricuspid regurgitation. Mapping determines the magnitude of regurgitation and the site of origin well within the body of the right ventricle. In addition, the presence of valvular stenosis (or nonopening) is determined by Doppler, particularly in neonates in whom patent ductus arteriosus supported systemic pressure may hold the pulmonary valve leaflets shut, simulating pulmonary atresia. The faint detection of pulmonary regurgitation by Doppler flow mapping aids differentiation of these two entities.

Invasive Study.

These are rarely necessary. When *cardiac catheterization* is performed, the intracavitary ECG recorded just proximal to the tricuspid valve shows a right ventricular type of complex, while the pressure recorded is that of the right atrium. A right-to-left atrial shunt is normally present. The hemodynamic findings depend on the degree of tricuspid regurgitation. The cardiac muscle is unusually irritable, and a high incidence of significant arrhythmias during catheterization has been noted. Selective right ventricular *angiocardiography* shows the position of the displaced tricuspid valve, the size of the right ventricle, and the configuration of the outflow portion of the right ventricle.

MANAGEMENT.

Ebstein anomaly may be compatible with a relatively long and active life, with most patients surviving into the third decade of life[450] (see Chap. 44). In

Figure 43-56 Apical four-chamber view of Ebstein's malformation in anatomical orientation. The left atrium (LA) and right atrium (RA) are seen above, and the right ventricle (RV) and left ventricle (LV) are seen below. Arrows point to the anterior leaflet of the tricuspid valve (AL) and septal leaflet (SL). The space between the septal attachment of the tricuspid valve and the mitral valve arrows is enlarged. This area between the true right atrium and the atrioventricular valve indicates the area of atrialized right ventricle.

symptomatic infants with severe cardiomegaly, the initial surgical approach is similar to that in patients with tricuspid atresia, creating a systemic pulmonary shunt, and at a later age the Fontan approach, which necessitates suture or pericardial patch closure of the tricuspid valve. Consideration may be given in some of these patients to creating a bidirectional Glenn shunt from the superior vena cava to the pulmonary arteries, to divert systemic venous return from the right atrium and to increase pulmonary blood flow. In older patients, significant benefit has resulted from reconstruction of the tricuspid valve, closure of the atrial septal defect, plication of the free wall of the right ventricle, posterior tricuspid annuloplasty, and a reduction in right atrial size.[443] [455] Because late results of this latter approach are encouraging, we now recommend operation for all symptomatic patients and even asymptomatic patients if their heart size is increasing significantly.[451] [452] [453] [454] Some surgeons have sought to minimize postoperative tricuspid regurgitation by inserting a bioprosthetic valve if tricuspid valve tissue is inadequate for a good result.[456] In patients with a

preexcitation syndrome (see Chap. 25) that is producing life-threatening rhythm disturbances, the accessory conduction pathways are either catheter ablated or surgically divided (see Chap. 23).[457]

TRANSPOSITION COMPLEXES

The term *transposition* identifies a group of malformations that have in common an abnormal relation between the cardiac chambers and great arteries. In this chapter the term is used to include both anomalous insertion of the pulmonary veins and cardiac malpositions.

Complete Transposition of the Great Arteries (See also p. 1609)

MORPHOLOGY.

This is a common and potentially lethal form of heart disease in newborns and infants.[458] The malformation consists of the origin of the aorta arising from the morphological right ventricle and that of the pulmonary artery from the morphological left ventricle. With rare exceptions, there is no fibrous continuity between the aortic and mitral valves. The origin of the aorta usually is to the right and anterior to the main pulmonary artery but may be lateral to it. Thus, dextro- or D-transposition is a term often used interchangeably with complete transposition. In other classifications, the anomaly is described as concordant AV and discordant ventriculoarterial connections. The embryogenesis of complete transposition of the great arteries is controversial. The consensus is that the ventricular origins of the great arteries are reversed after development of a straight rather than a spiral infundibulotruncal septum. Transposition appears to result from a transfer of the pulmonary artery, instead of the aorta, from the heart tube's outlet zone to the left ventricle.[459] The latter can result from maldevelopment of the infundibulum or from a combination of both infundibulum maldevelopment and truncal malseptation; the former results if the subpulmonary rather than the subaortic infundibulum is absorbed.

The anatomical arrangement results in two separate and parallel circulations. Some communication between the two circulations must exist after birth to sustain life; otherwise, unoxygenated systemic venous blood is directed inappropriately to the systemic circulation and oxygenated pulmonary venous blood is directed to the pulmonary circulation. Almost all patients have an interatrial communication (Fig. 43-57 ; see also Fig. 44-17 (Figure Not Available)). Two-thirds have a patent ductus arteriosus, and about one-third have an associated VSD. Complete transposition occurs more frequently in the offspring of diabetic mothers and more often in males than in females. Without treatment, about 30 per cent of these infants die within the first week of life, 50 percent within the first month, 70 percent within 6 months, and 90 percent

Figure 43-57 Complete transposition of the great arteries. Intercirculatory mixing occurs only at the atrial level. RA = right atrium; LA = left atrium; RV = right ventricle; LV = left ventricle; Ao = aorta; PA = pulmonary artery.

within the first year.[458] Those who live beyond infancy have, as a general rule, either an isolated large atrial septal defect or a single ventricle, or VSD and pulmonic stenosis. Current aggressive medical and surgical approaches to this group of patients have transformed the prognosis for an infant with this malformation from hopeless to very good.

HEMODYNAMICS.

The *clinical course* is determined by the degree of tissue hypoxia, the ability of each ventricle to sustain an increased workload in the presence of reduced coronary arterial oxygenation, the nature of the associated cardiovascular anomalies, and the anatomical and functional status of the pulmonary vascular bed.[460] A bidirectional shunt is always present because continuous unidirectional shunting would result in progressive depletion of the circulating volume in either the pulmonary or the systemic vascular bed.

A major determinant of the systemic arterial oxygen saturation is the amount of blood exchanged between the two circulations by intercirculatory shunts. The net volume of blood passing left to right from the pulmonary to the systemic circulation represents the anatomical left-to-right shunt and is in fact the effective systemic blood flow (i.e., the amount of oxygenated pulmonary venous return reaching the systemic capillary bed). Conversely, the volume of blood passing right to left from the systemic to the pulmonary circulation constitutes the anatomical right-to-left shunt and is in fact the effective pulmonary blood flow (i.e., the net volume of unsaturated systemic venous return perfusing the pulmonary capillary bed).

The net volume exchange between the two circulations per unit time is equal. The magnitude of the intercirculatory mixing volume is modified by the number of intercirculatory communications that exist, the presence of associated obstructive intracardiac and extracardiac anomalies, the extent of the bronchopulmonary circulation, and the relation between pulmonary and systemic vascular resistance. For example, in newborns with an intact ventricular septum and a constricted or closed patent ductus arteriosus, inadequate mixing through a small patent foramen ovale often is the cause of severe hypoxemia. If a large interatrial communication or a VSD exists, systemic arterial oxygen saturation is influenced more importantly by the pulmonary-systemic blood flow relation than by the adequacy of mixing; augmented pulmonary blood flow produces a higher systemic arterial saturation if the left ventricle can sustain a high-output state without the intervention of congestive heart failure and pulmonary edema. The systemic arterial oxygen saturation is low, despite adequate intercirculatory mixing sites, if pulmonary blood flow is reduced by left ventricular outflow tract obstruction or increased pulmonary vascular resistance.

Pulmonary Vascular Changes.

Infants with complete transposition of the great arteries are particularly susceptible to the early development of *pulmonary vascular obstructive disease.*[460] Moderately severe morphological alterations develop in the pulmonary vascular bed by the age of 6 to 12 months in many infants and by 2 years in almost all patients with an associated large VSD or large patent ductus arteriosus in the absence of obstruction to left ventricular outflow. Advanced pulmonary vascular disease is also noted within this same time frame in 15 to 30 percent of patients without a patent ductus arteriosus and with an intact ventricular septum. Systemic arterial hypoxemia, increased pulmonary blood flow, and pulmonary hypertension contribute to the development of pulmonary vascular obstruction in these patients, as they do in other forms of congenital heart disease. Among the additional factors implicated in the accelerated and more widespread pulmonary vascular obstruction found in patients with complete transposition is the presence of extensive bronchopulmonary anastomotic channels, which enter the pulmonary vascular bed proximal to the pulmonary capillary bed; thus, oxygen tension is reduced at the precapillary level, causing pulmonary vasoconstriction.[461]

Beyond the early neonatal period, many patients have an abnormal distribution pattern of pulmonary blood flow, with preferential flow to the right lung. The asymmetrical distribution of pulmonary blood flow in these individuals results from an abnormal rightward inclination of the main pulmonary artery in the transposition malformation that favors flow from the main to the right pulmonary artery. Persistently increased pulmonary blood flow to the right lung would be expected to contribute to pulmonary vascular obstructive changes within the lung; in the left pulmonary vascular bed, thrombotic changes may occur because of the combination of reduced flow and polycythemia. Finally, it should be recognized that a prenatal alteration in pulmonary vascular smooth muscle may exist because blood perfusing the fetal lungs in complete transposition of great arteries has a higher than normal P_{O_2} and may serve to dilate pulmonary vessels in utero. Postnatally, such vessels may have an enhanced capacity to constrict in response to vasoactive stimuli and suffer anatomical, obliterative changes.

CLINICAL FINDINGS.

Average birth weight and size of infants born with complete transposition of the great arteries are greater than normal. The usual clinical manifestations are dyspnea and cyanosis from birth, progressive hypoxemia, and congestive heart failure. Early in postnatal life, the clinical manifestations and course are influenced principally by the magnitude of intercirculatory mixing. The most severe cyanosis and hypoxemia are observed in infants who have only a small patent foramen ovale or ductus arteriosus and an intact ventricular septum and in whom mixing is inadequate, or in those infants with relatively reduced pulmonary blood flow because of left ventricular outflow tract obstruction.[462] With a large persistent patent ductus arteriosus or a large VSD, cyanosis may be minimal and heart failure is the usual dominant problem after the first few weeks of life.[458] It should be recognized that a patent ductus arteriosus is present in about half of newborn infants with transposition, although it closes functionally and anatomically soon after birth in almost all cases. If the ductus arteriosus remains open, better mixing of the venous and arterial circulations usually is at the expense of pulmonary artery hypertension.[463]

Cardiac murmurs are of little diagnostic significance and are absent or insignificant in about 30 to 50 percent of infants with complete transposition of the great arteries and an intact ventricular septum. In infants with a large persistent patent ductus arteriosus, fewer than half exhibit physical signs typical of ductus arteriosus, such as continuous murmur, bounding pulses, or a prominent mid-diastolic rumble. Moreover, *differential cyanosis* caused by reversed pulmonary-to-systemic shunting across

the ductus arteriosus is difficult to detect because of generalized arterial desaturation. In those infants with a large VSD, a pansystolic murmur usually emerges within the first 7 to 10 days of life. In newborns with transposition and severe pulmonic stenosis or atresia, the clinical findings are similar to those in infants with tetralogy of Fallot.

ELECTROCARDIOGRAPHY AND ROENTGENOGRAPHY.

The most usual *ECG findings* include right-axis deviation, right atrial enlargement, and right ventricular hypertrophy, reflecting that the right ventricle is the systemic pumping chamber. Combined ventricular hypertrophy may be present in those patients with a large VSD and elevated pulmonary blood flow. Isolated left ventricular hypertrophy is encountered rarely in patients with a VSD and a hypoplastic right ventricle, in many of whom the tricuspid valve is displaced abnormally and straddles a VSD. In the first days of life, the chest radiograph may appear normal, particularly

---

in infants with an intact ventricular septum. Thereafter, roentgenographic findings often are highly suggestive of the diagnosis,[464] and consist of (1) progressive cardiac enlargement in early infancy; (2) a characteristic oval or egg-shaped cardiac configuration in the anteroposterior view, and a narrow vascular pedicle created by superimposition of the aortic and pulmonary artery segments; and (3) increased pulmonary vascular markings (Fig. 43-58) . A right aortic arch is seen in about 4 percent of infants with an intact ventricular septum and 11 percent of infants with VSD.

CT scanning and magnetic resonance imaging (see Chap. 10) are also capable of establishing the diagnosis.

ECHOCARDIOGRAPHY.

Two-dimensional echocardiography is the procedure of choice in the diagnosis of complete transposition of the great arteries and the detection of significant associated cardiac anomalies[465] (Figs. 43-59 and 43-60 ; see also Fig. 44-21). Indeed, prenatal detection, leading to early management, favorably modifies neonatal morbidity and mortality.[465] Postnatally, in sagittal cross sections, the aorta is observed to ascend retrosternally, in contrast to the normal posterior sweep of the pulmonary artery. With transverse short-axis cross-sectional imaging, the diagnosis is confirmed by demonstrating that the anterior great artery (the aorta) is to the right of the posterior great artery (pulmonary) or that the two arteries are visualized side by side (see Fig. 43-59). Moreover, from subcostal views (see Fig. 43-60), the course of the two great arteries may be traced to delineate their ventricle of origin, demonstrating that the anterior rightward vessel (aorta) originates from the right ventricle and the posterior leftward vessel (pulmonary artery) originates from the left ventricle (see Fig. 43-60). In addition, echocardiography allows sensitive demonstration of the proximal coronary artery position, branching, and course. The intramural proximal course of a coronary artery has also been recognized.[467] [468] Echocardiography also readily identifies associated defects. VSDs may be localized to the membranous, AV, and trabecular muscular septa, and malalignment types of VSDs may be identified if the infundibular septum is shifted either anteriorly or posteriorly.[469] A subaortic obstruction may be created by anterior shifting of the infundibular septum, whereas a posterior shift may narrow the subpulmonary area. The nature of left ventricular outflow tract obstruction may be further identified as a fixed obstruction caused by a fibromuscular ridge or as a dynamic obstruction caused by deviation of the interventricular

Figure 43-58 Chest roentgenogram in a 4-day-old infant with complete transposition of the great arteries showing an oval-shaped heart with a narrow base and increased pulmonary vascular markings.

Figure 43-59 *Top,* A two-dimensional echocardiographic short-axis scan demonstrates normal great artery relations. The right ventricular outflow tract (RVO) wraps around the aorta (AO) in a clockwise direction. The pulmonic valve (PV) is to the left of the aortic valve. *Bottom,* Parasternal short-axis (P S AX) view showing the aorta (AO) anteriorly and the pulmonary artery (PA) posteriorly bifurcating into its left and right branches (arrow). LA = left atrium; RA = right atrium; TV = tricuspid valve.

septum toward the left ventricular cavity and the apposition between a thickened interventricular septum and systolic anterior motion of the mitral valve.

Ultrasound imaging has become a standard procedure to guide catheter placement and manipulation during balloon atrial septostomy[470] and to assess the anatomical adequacy of the septostomy. Because echocardiography so clearly delineates the arterial transposition, the coronary arteries, and associated anomalies, many infants may proceed to surgery without prior cardiac catheterization.

CARDIAC CATHETERIZATION.

The major abnormal hemodynamic findings include right ventricular pressure at systemic levels and either a high or low left ventricular pressure, depending on pulmonary blood flow, pulmonary vascular resistance, and the presence or absence of left ventricular outflow tract obstructive lesions. Oxygen saturation in the aorta is lower than that in the pulmonary artery. Application of the Fick principle to the calculation of pulmonary and systemic blood flow rates in these patients is an important source of error. Assumed values of oxygen consumption are unreliable in severely hypoxemic infants.

Figure 43-60 Composite subcostal views of transposition of the great arteries. *Top,* Subcostal coronal view showing the main pulmonary artery (MPA) arising directly from the left ventricle (LV) and dividing into the right (R) and left (L) pulmonary arteries. The right atrium (RA) and right ventricle (RV) lie adjacent in this view to the liver. *Middle,* The scan plane has been rotated 90 degrees clockwise (note the change in spatial orientation and the position of the spine). The thymus (TH) is seen anteriorly, and the innominate vein (IV) lies anterior to the aortic arch (indicated by arrows, respectively). The right ventricle (RV) lies anteriorly above the diaphragm and behind the thymus and gives rise to the aorta (AO), its arch, and the descending aorta (DAO). The main pulmonary artery (PA) lies in the crux of the aortic arch. *Bottom,* An intermediate subcostal view, lying oblique in a plane between the top two panels. The entire ventriculoarterial connection is imaged in this plane, showing the right ventricle connecting to the aortic arch, a small ventricular septal defect indicated by the small arrow, and the pulmonary artery (PA) arising from the left ventricle (LV). The left atrium (LA) can be seen below the pulmonary artery.

Moreover, because systemic and particularly pulmonary arteriovenous oxygen differences may be quite reduced, small errors in oxygen saturation values result in large errors in flow calculations. Furthermore, because bronchial collaterals enter the pulmonary circuit at the precapillary level, a true mixed pulmonary artery saturation cannot be sampled; pulmonary blood flow is therefore overestimated when one uses a sample from the central pulmonary artery, and pulmonary vascular resistance values often are underestimated.

Infants who have simple, complete transposition of the great arteries and who present in the first few weeks of life to a center prepared to correct the anomaly by the arterial switch operation (discussed later) often are taken to the operating room shortly after two-dimensional echocardiography and Doppler examination are performed.[21] In these cases, transcatheter balloon atrial septostomy is not performed unless a delay is expected in taking the patient to the operating room. In essentially all other patients, under echocardiographic or fluoroscopic guidance at cardiac catheterization, balloon septostomy is the initial approach to the patient.

The diagnostic portion of the cardiac catheterization allows confirmation of the anatomical derangement of the great arteries and establishes the presence of associated lesions; in newborns, unless prompt arterial switch repair is planned, it should always be accompanied by a palliative balloon atrial septostomy, which serves to enlarge the interatrial communication and improve oxygenation. In older neonates, usually beyond age 3 weeks, thickening of the atrial septum may preclude satisfactory balloon septostomy. In those instances, transcatheter blade septostomy is the preferred approach to palliation. Two-dimensional echocardiography, with or without fluoroscopy, may be used as the imaging mode for both balloon and blade creation of an atrial septal defect.[471] Subcostal four-chamber and sagittal views image cardiac anatomy and catheter position during the procedure, substantially reducing radiation dose.

Both the diagnostic and the palliative procedures can be performed by percutaneous entry into the femoral vein, umbilical vein catheterization, or direct cutdown into the femoral or saphenous vein. The catheter passes easily across the foramen ovale into the left atrium and left ventricle and may be manipulated into the pulmonary artery by means of a flow-directed balloon-guided catheter or by manipulation of a standard catheter bent in the form of a J loop within the left ventricle, with the tip pointed posteriorly to the pulmonary artery. When a large VSD is present, the catheter can often be manipulated directly across it from the right ventricle into the pulmonary artery.

ANGIOGRAPHY.

This is diagnostic and demonstrates that the anteriorly placed aorta arises from the right ventricle and that the posteriorly placed pulmonary artery in continuity with the mitral valve arises from the left ventricle. The status of the ductus arteriosus and the site and size of a VSD can be well visualized by angiography. Interventricular defects posterior and inferior to the crista supraventricularis occur in about half of these patients; less often, the defects are anterior and superior to the crista supraventricularis or are of the AV septal type.[472] Various lesions may be

identified as the cause of left ventricular outflow tract obstruction, including ventricular septal hypertrophy with systolic anterior movement of the mitral valve, discrete or tunnel fibromuscular subpulmonic stenosis, valvular and supravalvular stenosis, and, rarely, an aneurysm of the membranous ventricular septum or redundant tricuspid valve tissue protruding through a VSD.

Both angiographic and echocardiographic imaging may be required to detect the coronary arterial patterns seen in patients with complete transposition of the great arteries.[467] [468] [473] [474] In the majority, the left coronary artery originates in the left sinus and the right coronary artery originates in the posterior sinus, with a single ostium above both the left and the posterior sinus. In almost 20 percent of patients, the left circumflex artery arises as a branch of the right coronary artery; a single coronary artery is present in about 6 percent; in 3 to 4 percent of patients, either the right coronary and anterior descending arteries originate in the left sinus, with the left circumflex originating in the posterior sinus, or two ostia are present above one sinus, one giving rise to the right and the other to the left coronary artery. To avoid the danger of excision during transfer of the coronary arteries as part of the arterial switch corrective operation, the intramural course of the left coronary artery or the left anterior descending coronary artery should be identified, a finding in up to 5 percent of patients. An intramural course should be assumed when the vessel has an aberrant origin from the right sinus or when it is in intimate relationship with the commissure between the right and left sinuses and courses between the great arteries.

MANAGEMENT

Medical Treatment.

This often is of limited help but should be vigorous because both functional and anatomical corrections of the malformation achieve good results. Conservative measures include the use of oxygen, digitalis, diuretics, iron (if an associated iron-deficiency anemia is present), and intravenous sodium bicarbonate for severe hypoxemic metabolic acidosis. Dilatation of the ductus arteriosus by prostaglandin E_1 in the early neonatal period both augments pulmonary blood flow and enhances intercirculatory mixing.

Atrial Septostomy.

Creation or enlargement of an interatrial communication is the simplest procedure for providing increased intracardiac mixing of systemic and pulmonary venous blood; this is preferably achieved by rupturing the valve of the foramen ovale by balloon catheter during transseptal catheterization of the left side of the heart (Rashkind procedure) or by blade septostomy. Surgical atrial septectomy seldom is required. The balloon should be inflated to a diameter of about 15 mm before pull-back to the right atrium. Salutary results consist of a fall in left atrial pressure, equalization of mean left and right atrial pressures, and an increase in the systemic arterial oxygen saturation. When the foramen ovale is stretched by the balloon without accomplishing rupture of the septum primum valve of the fossa ovalis, the improvement in oxygenation is short lived. Infusion or reinfusion intravenously of prostaglandin E_1 (0.05 to 0.1 mg/kg/min) has been shown to improve systemic oxygenation temporarily in the latter situation by dilating the ductus arteriosus and thereby facilitating intercirculatory mixing. Although balloon atrial septostomy usually is successful in stabilizing the infant's condition and allowing survival in the neonatal period, the initial rise in systemic arterial oxygen saturation to 65 to 75 percent often is not sustained beyond 6 to 9 months of age.

SURGICAL TREATMENT

The development of *corrective operations* for infants born with transposition of the great arteries has greatly improved prognosis.[475] It has also been suggested that prenatal detection of the anomaly reduces neonatal morbidity and mortality.

ARTERIAL SWITCH OPERATION.

A one-stage anatomical correction is the approach of choice in major centers that care for infants with congenital heart disease.[475] [476] [477] [478] [479] In this operation, both coronary arteries are transposed to the posterior artery; the aorta and pulmonary arteries are transected, contraposed, and anastomosed (Jatene operation) (Fig. 43-61 ; see also Fig. 44-18 (Figure Not Available)). The arterial switch anatomical correction may be complicated by coronary ostial stenosis, acquired supravalvular aortic and/or pulmonary stenosis, and pulmonic and/or aortic incompetence. The major advantages of the arterial switch procedure, when compared with the atrial switch procedure, are restoration of the left ventricle as the systemic pump and the potential for long-term maintenance of sinus rhythm.[480]

Within the first month of life or rarely two,[477] the arterial switch operation may be performed as a single-stage repair. In such patients, the origin and branching patterns of the coronary arteries are reliably defined preoperatively by two-dimensional echocardiography. One of the main limiting factors for success in the arterial switch procedure is proper relocation of the coronary arteries. Thus, it is particularly important to know the precise variations in coronary arterial anatomy. In approximately 5 percent of the patients, the arteries follow an intramural course, requiring reroofing to allow coronary transfer.[458] Most centers consider that in infants beyond age 1 month it is necessary to prepare the left ventricle to withstand the systemic pressure that is produced after switching the great arteries, because if the ventricular septum is intact, left ventricular pressure and left ventricular wall thickness diminish normally in relation to the postnatal reduction in pulmonary artery pressure. In these infants, a two-stage approach is used, the first of which consists of banding the pulmonary artery; the arterial switch is performed soon thereafter, in some centers as early as 1 to 2 weeks later.[481]

In the unusual infant with an intact ventricular septum and a significant patent ductus arteriosus, an early neonatal arterial switch corrective operation with closure of the ductus is indicated. The optimal management of a large VSD is a one-stage intraarterial switch anatomical correction as early in life as possible.

In some patients, after early arterial repair of transposition of the great arteries, abnormally enlarged bronchial arteries are identified at postoperative catheterization, and they explain continuous murmurs or persistent cardiomegaly. When these vessels are large enough to produce a volume load to the systemic ventricle, catheter-directed coli embolization is indicated.[482] Follow-up studies after the arterial switch operation have demonstrated good left ventricular function

Figure 43-61 Complete transposition of the great arteries, corrected by a modified arterial switch operation *(a)*. The aorta and pulmonary artery are transected, and the orifices of the coronary arteries are excised with a rim of adjacent aortic wall *(b)*. The aorta is brought under the bifurcation of the pulmonary artery, and the proximal pulmonary artery and the aorta are anastomosed without necessitating graft interposition. The coronary arteries are transferred to the pulmonary artery *(c)*. The mobilized pulmonary artery is directly anastomosed to the proximal aortic stump *(d)*. *(From Stark J, deLaval M: Surgery for Congenital Heart Defects. New York, Grune & Stratton, 1983, p 379.)*

and normal exercise capacity.[483] [484] Potential sequelae of the operation include supravalvular pulmonary stenosis (which may be treated by either reoperation or balloon angioplasty), supravalvular aortic stenosis, and neoaortic regurgitation, usually mild. Long-term patency and growth of the coronary arteries appear satisfactory.[485] [486] [487] Infants with transposition of the great arteries plus a VSD and left ventricular outflow tract obstruction may require a systemic-pulmonary artery anastomosis when a pronounced diminution in pulmonary blood flow exists. A later corrective procedure for these patients bypasses the left ventricular outflow obstruction and uses an intracardiac ventricular baffle connecting the left ventricle to the aorta and an extracardiac prosthetic conduit between the right ventricle and the distal end of a divided pulmonary artery (Rastelli procedure).[488] An alternative approach (Lecompte procedure) couples an intraventricular tunnel and the arterial switch operation, avoiding the use of an extracardiac conduit.[489]

ATRIAL (VENOUS) SWITCH OPERATION.

This correction, by either the Mustard or Senning techniques, diverts systemic venous return into the left ventricle through the mitral valve and thence through the left ventricle and pulmonary artery, while the pulmonary venous blood is diverted through the tricuspid and right ventricle to the aorta. Because midterm results of atrial switch procedures disclosed numerous problems involving late right ventricular failure, tricuspid insufficiency, and arrhythmias, most centers have abandoned the use of the atrial switch approach in favor of the more anatomical arterial switch operation.[490] [491] [492] [493] [494] [495] [496]

After physiological correction by atrial switch, postoperative complications are directly related to the intraatrial repair (shunts across the intraatrial patch and obstruction to either systemic or pulmonary venous return or both). There is a high incidence of early and late postoperative dysrhythmias that are more likely to have their basis in injury to the sinoatrial node and/or its arterial supply than in disruption of internodal tracts or damage to the AV node.[491] Tricuspid regurgitation is a less common complication of operation and may in some patients be related to a preexisting abnormality of the tricuspid valve, whereas in most it is related to right ventricular dysfunction. Although assessment of right ventricular contractility is difficult, the right ventricular pump function appears to be impaired before Mustard operation and does not return to normal after successful surgery.[496] It seems likely that the right ventricle can perform as a systemic pumping chamber for the duration of a normal life span.[492]

In patients with significant pulmonary vascular obstructive disease, the risk associated with definitive repair (anatomical correction or intraatrial baffle and closure of the ventricular septal defect) is great. In this group of patients, a "palliative" Mustard or Senning procedure leaving the ventricular septal defect open often provides good, short-term, symptomatic improvement by increasing arterial oxygen tension and reducing the stimulus to progressive polycythemia.[497]

Congenitally Corrected Transposition of the Great Arteries (See also p. 1612)

This term is applied to two distinctly different anomalies: anatomically corrected transposition or malposition of the great arteries and physiologically corrected levo- or L-transposition of the great arteries.

DEFINITION.

Invariably, the term *congenitally corrected l*-transposition is applied to the heart in which a functional correction of the circulation exists by virtue of the relation between the ventricles and great arteries.[499] [500] Corrected or L-transposition occurs when the primitive cardiac tube loops to the left instead of to the right during embryogenesis. The anatomical right ventricle comes to lie on the left and receives oxygenated blood from the left atrium; this blood is ejected into an anteriorly placed, left-sided aorta. The anatomical left ventricle lies to the right and connects the right atrium to a posteriorly placed pulmonary artery. Thus, there are both ventriculoarterial and AV discordant connections, with ventricular inversion. This arrangement of the great arteries and ventricles (in contrast to the uncorrected, complete, or D-transposition) permits functional correction, so that systemic venous blood passes into the pulmonary trunk while arterialized pulmonary venous blood flows into the aorta. In a heart with congenitally corrected transposition, the venae cavae and coronary sinus drain into a right atrium that is normal in position and structure.

MORPHOLOGY.

Anatomically corrected malposition of the great arteries is a rare form of congenital heart disease in which the great arteries are abnormally related to each other and to the ventricles but arise, nonetheless, above the anatomically correct ventricles.[498] Because of this, the term *malposition* rather than *transposition* is preferable. The anomaly results from either leftward looping of the ventricular segment of the embryonic heart tube in the situs solitus heart or from rightward looping in the situs inversus heart. In this unusual malformation, the aorta is anterior and to the left (levo- or L-malposition) and the pulmonary artery is posteromedial and to the right, presumably because of a subaortic conus that causes mitral-aortic discontinuity.

When no other defect exists, the circulation proceeds normally. When an associated lesion prompts ochocardiographic examination, the diagnosis is indicated by the finding of AV concordance in association with wide mitral-aortic discontinuity with an anteriorly placed aorta. At cardiac catheterization, the diagnosis of the abnormal relation between the great arteries may be made by biplane angiocardiography. Anomalies commonly associated with anatomically corrected malposition of the great arteries include VSD, left juxtaposition of the atrial appendages, tricuspid atresia or stenosis, and valvular and subvalvular pulmonic stenosis.

PHYSIOLOGY.

Venous blood flows from the right atrium, designated as the "venous atrium," across an AV valve that has the structure of a normal mitral valve and into the right-sided "venous ventricle" (Fig. 44-22) (Figure Not Available) . The venous ventricle, however, has the morphological characteristics of a normal left ventricle; i.e., its interior lining is trabeculated, it has no crista supraventricularis, and the AV valve is in continuity with the posteriorly placed semilunar valve. It ejects blood into the pulmonary trunk, which arises posterior to the ascending aorta. Oxygenated blood returns from the lungs to the left atrium, which is normal in position and structure; from there it flows into the left-sided "arterial ventricle" across an AV valve that has the structure of a normal tricuspid valve. The interior lining of the arterial ventricle has the morphological characteristics of a normal right ventricle (i.e., it has coarse trabeculations and a crista supraventricularis), and the tricuspid AV valve is not in continuity with the anteriorly placed semilunar valve. The arterial ventricle ejects blood into the aorta, which arises anterior to the pulmonary trunk. In addition to inversion of the cardiac ventricles, there is inversion of the conduction system and coronary arteries. Commonly associated anatomical lesions include atrial and ventricular septal defects, often accompanied by valvular or subvalvular pulmonary stenosis; single ventricle with an outlet chamber with or without pulmonic stenosis; left AV valve regurgitation, usually because of an Ebstein's malformation of the left-sided tricuspid valve; and abnormalities of visceral and atrial situs.[499]

CLINICAL MANIFESTATIONS.

The clinical presentation, course, and prognosis of patients with congenital functionally corrected transposition vary, depending on the nature and severity of the complicating intracardiac anomalies. [500] Patients in whom corrected transposition exists as an isolated anomaly present no functional alterations and have no symptoms.[501] Asymptomatic children with an increase in the size of the systemic ventricle, due to significant left-to-right shunting or tricuspid regurgitation, usually develop symptoms of systemic ventricular dysfunction by the third or fourth decade.[500] [501] [502] [503] The natural history of the anomaly and the ability of the right ventricle to perform systemic work are determined primarily by the nature and severity of the associated cardiac defects.[502]

The *physical findings* in congenitally corrected transposition are those of the associated lesions with two exceptions: (1) a single accentuated second heart sound usually is present in the second left intercostal space, representing closure of the aortic valve lying lateral and anterior to the pulmonic valve; and (2) there is a high incidence of cardiac dysrhythmias.

LABORATORY EXAMINATION.

Because of the inversion of the heart's conduction system, the *ECG* can provide important clues in the diagnosis. An abnormal direction of initial (septal) depolarization from right to left causes leftward, anterior, and superior orientation of the initial QRS forces and reversal of the precordial Q wave pattern (Q waves are present in the right precordial leads and absent in the left). Two AV nodes, one posterior and one anterior, are present in some patients.[504] In addition to inversion of the conduction system, the His bundle is elongated because of the greater distance between the AV node and the base of the ventricular septum. The His bundle is located beneath

the pulmonic valve in the position of mitral pulmonary continuity; thus, it is subject to significant excursions during mitral valve closure. The anterior "accessory" AV node may be connected directly with an aberrantly located penetrating portion of the His bundle. This arrangement may be a causal factor in the arrhythmias and AV conduction disturbances commonly observed in these patients. First-degree AV block occurs in about 50 percent and complete AV block occurs in 10 to 15 percent of patients. Other degrees of AV dissociation may be observed, as well as paroxysmal supraventricular tachycardia and ventricular extrasystoles. In some patients, Kent bundle connections provide the anatomical substrate for preexcitation.[504]

Roentgenographic examination characteristically reveals absence of the normal pulmonary artery segment and a smooth convexity of the left supracardiac border produced by the displaced ascending aorta (see Chap. 8). The latter may be visualized by radionuclide scintillation scans of the central circulation. The main pulmonary trunk is medially displaced and absent from the cardiac silhouette; the right pulmonary hilus often is prominent and elevated compared with the left, producing a right-sided waterfall appearance.

Two-dimensional echocardiography seeks to identify the morphology of each ventricle by defining the characteristics of the inflow and outflow tracts and papillary and trabecular muscle morphology, ventricular shape, and great artery position.[505] By tracing the great arteries back to their ventricles of origin in subxiphoid and parasternal short-axis planes, one would find that the anterior leftward great artery (the aorta) arises from the left-sided ventricle and is not in continuity with the

left-sided AV valve. The great arteries exit the heart in parallel fashion; the position, origin, and branching pattern of the great arteries are observed in subxiphoid and suprasternal views, and the anteroposterior and right-left positions of the great arteries can be seen from the parasternal short-axis view. Because the ventricular septum lies in the anteroposterior plane parallel to the echo beam, it may not be visualized from a left parasternal view. In apical-basal or subxiphoid four-chamber echocardiographic views, the right and left ventricular morphology and the inverted position of the AV valves may be ascertained correctly. The latter views also demonstrate the level of attachment of the AV valves and allow detection of inferior displacement of the left-sided tricuspid valve when Ebstein's anomaly coexists.

At *cardiac catheterization,* the diagnosis should be suspected when the venous catheter enters a posterior and midline main pulmonary trunk. Retrograde arterial catheter passage establishes the typical position of the ascending aorta at the upper left cardiac border. Hemodynamic abnormalities depend on the lesions associated with corrected transposition. Selective *angiocardiography* allows visualization of the transposed great arteries and morphological differentiation of the two ventricles (Fig. 43-62) . The ventricles usually lie side by side, with the ventricular septum oriented in an anteroposterior direction. Selective aortography demonstrates the inverted coronary arterial pattern that is invariably present in corrected transposition. The competence of the left AV valve may be determined by injection of contrast material into the arterial ventricle.[506] When a left-sided Ebstein's malformation exists, the leaflets are displaced distal to the true valve annulus. The level of the annulus may be determined by visualization of the circumflex branch of the left coronary artery, which courses posteriorly in the AV groove.

Specific problems have attended operative repair of the lesions associated with congenitally corrected transposition, owing primarily to the course of the conduction AV system and the coronary arterial pattern.[507] [508] The inversion of the coronary arterial system occasionally may limit and preclude an incision into the venous ventricle, thereby interfering with exposure of intracardiac defects in the usual manner. The disadvantage in approaching intracardiac anomalies using an incision in the morphological right ventricle is that this is the systemic ventricle. When significant pulmonary stenosis exists within a VSD, a valved extracardiac conduit often is a required part of the surgical repair. Surgical risks are especially high in patients in whom significant regurgitation exists from the arterial ventricle to the arterial atrium. In these patients, annuloplasty or, more usually, valve replacement is required. In all operative approaches, if complete heart block has been present intermittently or permanently preoperatively or intraoperatively, permanent epicardial atrial and ventricular pacemaker leads are implanted.

The disappointing results with traditional techniques of repair have led to more anatomical forms of surgical correction in which the morphological left ventricle supports the systemic circulation, rather than leaving the morphological right ventricle and tricuspid valve in the systemic circulation. Thus, the so-called double-switch procedure promises to decrease the development and significance of tricuspid valve regurgitation as well as the incidence of surgical complete heart block. In this procedure, an arterial switch operation establishes ventriculoarterial concordance and the systemic and pulmonary venous returns are rerouted by either the Mustard or Senning technique. If a VSD is present, it can be closed in the usual manner. When pulmonary stenosis is present in association with a ventricular defect, the performance of an arterial switch procedure is precluded, but the left ventricle can be routed to the aorta via a prosthetic baffle within the right ventricle to channel the VSD to the aortic valve. The outflow tract of the right ventricle can then be reconstructed by placement of a conduit from the right ventricle to the pulmonary artery bifurcation, and a venous switch procedure completes the operation.

Double-Outlet Right Ventricle

MORPHOLOGY.

Other designations applied to this lesion include origin of both great arteries from the right ventricle, partial transposition, complete transposition of the aorta and levoposition of the pulmonary artery, complete dextroposition of the aorta, and the Taussig-Bing complex. This is an extremely heterogeneous category of malformations in which an abnormal relation exists between the aorta and the pulmonary trunk, which arise wholly or in large part from the right ventricle.[509]

DEFINITIONS.

A uniform definition or classification of double-outlet right ventricle does not exist. To some, double-outlet right ventricle means origin of one great artery and at least 50 percent of the other over the right ventricle; others require the presence of bilateral conus muscle between both great arteries and the AV annulus. One or both great arteries may arise from an infundibular chamber; there may be considerable variability in the amount of subarterial conus muscle. Thus, the semilunar valves may lie side by side, or with the pulmonary valve more anterior and superior, or with a more anterior and superior aortic valve. Commonly, neither semilunar valve is in fibrous continuity with either AV valve, and a VSD is usually present and represents the only outlet from the left ventricle. The VSD is of the malalignment type because the infundibular septum is positioned abnormally.

When the amount of conus muscle beneath the two great arteries varies, the VSD commonly is positioned beneath the more posterior semilunar valve, which in fact usually overrides the interventricular septum through this VSD. The amount of conus muscle underneath the valve determines the position of the semilunar root in relation to the ventricles below. Thus, double-outlet right ventricle resides within the spectrum of conotruncal abnormalities ranging from tetralogy of Fallot to transposition of the great arteries. The VSD occasionally extends beneath both great arteries and is referred to as doubly committed. In some instances, the VSD is remote from both great arteries, or is considered uncommitted, in which case the defect often lies in the inlet or muscular portion of the interventricular septum.

ASSOCIATED LESIONS.

More than half of patients with double-outlet right ventricle have associated anomalies of the right AV valves.[509] [510] Mitral atresia associated with a hypoplastic left ventricle is common; less often observed are tricuspid stenosis, Ebstein's anomaly of the tricuspid valve, complete AV septal defect, and overriding or straddling of either AV valve. Aortic coarctation may be associated with double-outlet right ventricle, particularly when the subaortic area is narrowed by malalignment of the infundibular septum. Double-outlet right ventricle also may be a component of the many cardiovascular anomalies of the splenic dysgenesis or heterotaxy syndromes. An increased incidence of the anomaly occurs in infants with the trisomy 18 syndrome.

The pathological features in most patients include side-by-side pulmonic and aortic valves and discontinuity between the mitral and aortic valves. The latter exists because muscular infundibulum is usual beneath both semilunar valves. The VSD may be remote from or closely related to one or both semilunar valves (Fig. 43-63) . When the interventricular defect is subpulmonic, with or without a straddling pulmonary trunk, the complex is designated Taussig-Bing. In most patients, the interventricular septal defect is below the crista supraventricularis and is subaortic in location. Least often, the defect either

Figure 43-62 Congenitally corrected (levo-)transposition of the great arteries in a 4-year-old boy. *A,* Anteroposterior ventriculogram in left-sided ventricle with mesocardia. The morphological right ventricle (RV) is left sided, indicating an L-ventricular loop (inverted ventricles in situs solitus). The aorta (AO) originates above the morphological right ventricle and is thus transposed and in classic levo-transposition. *B,* Lateral ventriculogram in left-sided ventricle (same frame as *A)*. The aorta originates anteriorly above the morphological right ventricle (RV). *C,* Anteroposterior ventriculogram in right-sided morphological left ventricle (LV). The transposed pulmonary artery (PA) arises from this ventricle, and the ventricular septum appears intact. Pulmonic valve thickening is also evident. The aorta *(A)* is to the left of the pulmonary artery. Note that the ventricular septum in the L-ventricular loop is visualized best in the anteroposterior views. *D,* Lateral ventriculogram in right-sided ventricle (same frame as *C)*. The pulmonary artery is posterior to the aorta, and supravalvular pulmonic narrowing is seen. *(From Freedom RM, Harrington DP, White RI Jr, et al: The differential diagnosis of levo-transposed or malposed aorta: An angiocardiographic study. Circulation 50:1040, 1974.)*

is remote from both semilunar valves (uncommitted) or underlies both (doubly committed).

CLINICAL MANIFESTATIONS.

The clinical and physiological picture is determined by the size and location of the VSD and the presence or absence of pulmonic stenosis. In the Taussig-Bing form of double-outlet right ventricle, the malformation resembles physiologically and clinically complete transposition with VSD and pulmonary hypertension. When the VSD is subaortic, the stream of blood from the left

Figure 43-63 Double-outlet right ventricle with side-by-side relation of great arteries is illustrated in both panels. *A,* A subaortic ventricular septal defect below the crista supraventricularis favors delivery of left ventricular blood to the aorta. *B,* Subpulmonary location of the ventricular septal defect above the crista favors streaming to the pulmonary trunk. *(From Castaneda A, Jonas RA, Mayer*

JE Jr, et al: Cardiac Surgery of the Neonate and Infant. Philadelphia, WB Saunders, 1994, p 446.)

ventricle is directed preferentially to the aorta. Thus, there may be little or no detectable cyanosis, and these patients usually clinically resemble those with an isolated large VSD and pulmonary hypertension.

The most important determinant of the natural history in both these types of double-outlet right ventricle is the progression of pulmonary vascular obstruction. In contrast, when there is pulmonary outflow tract obstruction, which often is severe and found commonly in these patients in whom the VSD is subaortic, clinical findings are similar to those of cyanotic tetralogy of Fallot. In some patients, especially without pulmonic stenosis, the ECG shows a superiorly oriented counterclockwise frontal plane QRS loop in addition to right ventricular hypertrophy.[511] The pattern appears to result from relative hypoplasia of the anterosuperior left bundle and preferential activation of the posteroinferior left ventricular wall. The presence of the latter ECG pattern in patients with double-outlet right ventricle should alert one to the possibility of a coexistent AV septal defect or abnormality of the mitral valve.

DIAGNOSIS.

Two-dimensional *echocardiography* may reliably distinguish double-outlet right ventricle from other lesions causing cyanosis, such as tetralogy of Fallot and transposition of the great arteries.[512] [513] The three key imaging features are origin of both great arteries from the anterior right ventricle, mitral-semilunar valve discontinuity, and absence of left ventricular outflow other than the VSD. The relative anteroposterior positions of the great arteries can be determined from the parasternal short-axis view. The parasternal long-axis view shows the position of the more posterior semilunar root relative to the interventricular septum and anterior mitral leaflet and is the best view for demonstrating the presence of subarterial conus muscle. Subxiphoid views best demonstrate the position of both great arteries over the ventricles. Each great artery is displayed on long- and short-axis subxiphoid sweeps.

In reporting echocardiographic results, it is imperative to state each component's anatomical feature, i.e., the position of both great arteries, the presence and amount of infundibulum under each semilunar valve, the anatomy of both subpulmonary and subaortic outflow tracts, the position and size of the associated VSD, and the presence of all other associated lesions, particularly AV valve anomalies and coarctation of the aorta.

In each of the different types of double-outlet right ventricle, precise delineation of the malformation also depends on careful angiocardiographic analysis. The diagnosis can be established with confidence when the angiographic findings include simultaneous opacification of both great vessels from the right ventricle, aortic and pulmonic valves at the same transverse level, and separation of the aortic valve from the aortic leaflet of the mitral valve by the crista supraventricularis (Fig. 43-64) . The position of the VSD and the relation between the great arteries must be defined to plan surgical procedures appropriately.

Experience is growing with the application of transesophageal echocardiograpy in analyzing the complex anatomical and spatial relationships encountered in double-outlet right ventricle, requiring a biplane or multiplane format for adequate assessment.

SURGICAL TREATMENT.

The goals of operative treatment are to establish left ventricle-to-aorta continuity, create adequate right ventricle-to-pulmonary continuity, and repair associated lesions.[510] Because of the complexity of intracardiac repair of these anomalies, many centers prefer to give palliation to infants, attempting reparative surgery after the age of 1 to 2 years. In double-outlet right ventricle with subaortic VSD, repair is accomplished by creating an intraventricular baffle that conducts left ventricular blood to the aorta. When the VSD is subpulmonic, repair is accomplished by closure of the VSD and arterial switch.[510] [514] When the VSD is doubly committed, i.e., both subaortic and subpulmonic, operation consists of creating an intraventricular baffle that conducts left ventricular blood to the aorta. The type of double-outlet right ventricle in which the VSD is remote and uncommitted to either semilunar orifice may be approached by a venous switch operation, permitting the right ventricle to eject into the aorta, followed by placement of a conduit between the left ventricle and the pulmonary trunk. Alternatively, some patients may be candidates for a cavopulmonary shunt or a modified Fontan procedure, particularly if additional findings include a common AV orifice, hypoplastic ventricles, a straddling tricuspid valve, or a straddling mitral valve.[515]

Double-Outlet Left Ventricle

One of the rarest cardiac anomalies consists of the origin of both great arteries from the morphological left ventricle. Conal musculature or an infundibulum usually is absent or deficient beneath the orifices of both semilunar valves.[516] The spectrum of associated malformations is broad. VSD and valvular or subvalvular pulmonic stenosis has been present in most patients. Supportive diagnostic information is provided by magnetic resonance imaging. Echocardiographic[517] and angiocardiographic assessment of the spatial relations of the origins of the great arteries are essential to an accurate diagnosis and to evaluating the possibility of operative repair. In most patients, the latter consists of closure of the VSD and placement of a right ventricle-pulmonary artery conduit.

Figure 43-64 Simultaneous opacification of both great arteries from a right ventricular injection of contrast material in a patient with double-outlet right ventricle (RV). The aortic and pulmonic valves are at the same transverse level. AO = aorta; PA = pulmonary artery. *(Courtesy of Dr. Robert White.)*

Total Anomalous Pulmonary Venous Connection

This anomaly has been estimated to account for 1 to 3 percent of all cases of congenital heart disease and 2 percent of deaths therefrom in the first year of life.[518] The anomaly is the result of persistence during embryogenesis of communications between the pulmonary portion of the foregut plexus and the cardinal or umbilicovitelline system of veins, resulting in the connection of all the pulmonary veins either to the right atrium directly or to the systemic veins and their tributaries. Because all venous blood returns to the right atrium, an interatrial communication is an integral part of this malformation. Additional major cardiac malformations occur in about 30 percent of patients. Among these are common atrium, atrial isomerism, single ventricle, truncus arteriosus, and anomalies of the systemic veins. Extracardiac malformations, particularly of the alimentary, endocrine, and genitourinary systems, are present in 25 to 30 percent of cases.

MORPHOLOGY.

The anatomical varieties of total anomalous pulmonary venous connection may be subdivided, depending on the level of the abnormal drainage (Fig. 43-65). Table 43-10 provides average figures of the distribution of the sites of anomalous connection.[578] The anomalous connection usually is supradiaphragmatic and to the left brachiocephalic vein, right atrium, coronary sinus, or superior vena cava. In about 13 percent, particularly in males, the distal site of connection is below the diaphragm. In this situation, a common trunk originates from the confluence of pulmonary veins and descends in front of the esophagus, penetrating the diaphragm through the esophageal hiatus. The anomalous trunk then connects into the portal vein or one of its tributaries, the ductus venosus, or, rarely, to one

Figure 43-65 Anatomical types of total anomalous pulmonary venous return: supracardiac, in which the pulmonary veins drain either via the vertical vein to the anomalous vein *(A)* or directly to the superior vena cava with the orifice close to the orifice of the azygos vein *(B)*. *C,* Drainage directly into the right atrium or into the coronary sinus. *D,* Infracardiac drainage via a vertical vein into the portal vein or the inferior vena cava. *(From Stark I, deLeval M: Surgery for Congenital Heart Defects. 2nd ed. Philadelphia, WB Saunders, 1994, p 330.)*

TABLE 43-10 -- SITE OF CONNECTION IN TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION

Connection to right atrium	15%
Connection to common cardinal system	
(Right) superior vena cava	11%
Azygos vein	1%
Connection to left common cardinal system	
Left innominate vein	36%
Coronary sinus	16%

Connection to umbilicovitelline system	
Portal vein	6%
Ductus venosus	4%
Inferior vena cava	2%
Hepatic vein	1%
Multiple sites	7%
Unknown	1%

of the hepatic veins. In rare cases, various combinations of anomalous connection occur, with drainage to several levels.

HEMODYNAMICS.

The physiological consequences and, accordingly, the clinical picture depend on the size of the interatrial communication and on the magnitude of the pulmonary vascular resistance. When the interatrial communication is small, systemic blood flow is markedly limited.[519] Right atrial and systemic venous pressures are elevated, and hepatic enlargement and peripheral edema are present. The size of the interatrial communication also is an important determinant in the development in utero and postnatally of the left atrium and left ventricle. Left atrial cavity size usually is somewhat reduced, whereas left ventricular volumes may be reduced or normal. The magnitude of pulmonary blood flow and therefore the ratio of oxygenated to unoxygenated blood that returns to the right atrium are a function of pulmonary vascular resistance. The arterial oxygen saturation, which ranges from markedly reduced to normal values, is inversely related to the pulmonary vascular resistance. In this regard, in most patients, the principal determinant of pulmonary pressures and resistance is related less to augmented pulmonary blood flow and pulmonary arteriolar vascular obstruction than to the presence and intensity of pulmonary venous obstruction.[520] [521]

Obstruction to pulmonary venous return and pulmonary venous hypertension are invariably present in patients with infradiaphragmatic anomalous pulmonary venous connection and in many with a subdiaphragmatic pathway. In the former type, pulmonary venous obstruction results from the length and narrowness of the common pulmonary venous trunk, compression at the esophageal hiatus of the diaphragm, constriction at the subdiaphragmatic site of insertion, or pulmonary venous return that must pass first through the portal-hepatic circulation before returning to the right atrium. When venous obstruction occurs in supradiaphragmatic types of drainage, constriction may exist at the entrance site of the anomalous veins into the systemic venous circulation, and/or the anomalous venous channel may be kinked or situated abnormally and compressed between the left pulmonary artery and left bronchus.[520] The presence of a small, restrictive patent foramen ovale occasionally results in pulmonary venous obstruction. Pulmonary vascular obstructive disease is rare during infancy, although exceptions have been reported. In patients without pulmonary venous obstruction, the risk of developing Eisenmenger reaction is comparable with that in patients with an atrial septal defect.

CLINICAL MANIFESTATIONS.

The majority of patients with total anomalous pulmonary venous connection have symptoms during the first year of life, and 80 percent die before age 1 year if left untreated.[518] The few who remain asymptomatic have a relatively good prognosis; once the condition is detected, operation may be elected later in

childhood. Symptomatic infants with total anomalous pulmonary venous connection present with signs of heart failure and/or cyanosis. Infants with pulmonary venous obstruction present with the early onset of severe dyspnea, pulmonary edema, cyanosis, and right heart failure. Cardiac murmurs often are not prominent. In the unobstructed forms of total anomalous pulmonary venous connection, the characteristic physical findings include right ventricular precordial overactivity and minimal cyanosis unless congestive heart failure intervenes. Multiple heart sounds often are audible, consisting of a first heart sound followed by an ejection sound; a fixed, widely split second heart sound with an accentuated pulmonic component; and a third and often a fourth heart sound. A soft systolic ejection murmur is usual along the left sternal border, and a mid-diastolic murmur of flow across the tricuspid valve commonly is audible at the lower left sternal border.

LABORATORY FINDINGS.

The *ECG* shows right-axis deviation and right atrial and right ventricular hypertrophy. *Roentgenograms* of the chest reveal increased pulmonary blood flow; the right atrium and ventricle are dilated and hypertrophied, and the pulmonary artery segment is enlarged (Fig. 43-66) . In addition, the specific site of anomalous connection may cause a characteristic appearance of the cardiac silhouette. Thus, in patients with total anomalous pulmonary venous connection to the left brachiocephalic vein, the superior vena cava on the right, left brachiocephalic vein superiorly, and vertical vein on the left produce a cardiac shadow that resembles a snowman or figure eight. The upper right cardiac border may be prominent when the anomalous connection is to the right superior vena cava.

Echocardiography demonstrates marked enlargement of the right ventricle and a small left atrium.[522] The objective of ultrasound imaging in these patients is to confirm the clinical diagnosis and to locate the site of connection of the common pulmonary vein. Doppler flow and color mapping enhance the capability of identifying all the pulmonary veins and their drainage sites and help to assess the presence of obstruction within individual pulmonary veins and along the vertical vein.[523] [524] An echo-free space representing the common pulmonary venous chamber may occasionally be seen to lie behind the left atrium on ultrasound examination. The use of echocardiography has supplanted cardiac catheterization in preoperative diagnosis in patients without atrial isomerism or single-ventricle hearts. Diagnostic echocardiographic findings include an absence of pulmonary

Figure 43-66 Chest roentgenogram in an infant with total anomalous pulmonary venous connection below the diaphragm shows normal overall heart size but a diffuse pattern of pulmonary venous hypertension in both lung fields.

vein connections and a small left atrium in the presence of right-to-left bulging of the septum primum at the foramen ovale. Positive diagnosis is made by identifying pulmonary venous connection to the systemic veins, coronary sinus, or right atrium rather than to the left atrium. All four pulmonary veins and their connections must be identified to diagnose mixed types accurately. There is no standard echocardiographic method for tracing pulmonary venous pathways because of their diverse anatomical positions, although transesophageal studies can importantly assist in this regard.[524]

An infradiaphragmatic total anomalous pulmonary venous connection usually connects to the portal venous system but can connect to the hepatic veins. Doppler is used to distinguish between the abdominal vessels. Thus, the flow pattern in the inferior vena cava is phasic, nearly continuous, and toward the heart, in contrast to flow in the descending aorta, which has a laminar profile in systole in a direction away from the heart. Flow in the common pulmonary vein resembles that of the inferior vena cava except that its direction is away from the heart. Although not often used, especially in infants, magnetic resonance imaging may also delineate the site of connections of the various types of total anomalous pulmonary venous return.

At *cardiac catheterization,* those patients found to have systemic arterial saturations below 70 percent and pulmonary artery pressure at or above systemic levels are likely to have pulmonary venous obstruction. Variations in oxygen saturation in the systemic venous circulation may be helpful. In the subdiaphragmatic type, a step-up may not be apparent in inferior vena caval oxygen saturations obtained by way of femoral vein cannulation because of the contribution of highly oxygenated renal venous blood to the caval stream. In contrast, sampling of the hepatic or portal vein by way of a catheter inserted through the umbilical vein yields diagnostically higher oxygen saturations, indicating anomalous return to those vessels. If the cardiac catheter can be manipulated directly into the anomalous trunk through its site of connection, selective injection of contrast material into the common channel provides anatomical definition of the pulmonary venous tree. If the pulmonary veins cannot be entered directly, selective right and left main pulmonary artery injection of contrast material often is more helpful than is injection into a main pulmonary artery because many infants have a persistent patent ductus arteriosus through which the contrast agent flows right to left. Moreover, the drainage from both lungs must be outlined clearly to preclude a mixed type of anomalous venous drainage. Pulmonary venous obstruction may be detected by noting a pressure difference between the pulmonary artery wedge pressure and the right atrium.

MANAGEMENT.

Corrective surgery for sick infants should be performed as soon as possible, usually on the basis of two-dimensional and Doppler echocardiography, avoiding the additional stress of invasive diagnostic study. Before age 1 month, survival greater than 75 percent is anticipated. Infants with the worst prognosis are those in whom individual pulmonary vein sizes are smallest, which are measurements that can be made preoperatively by echocardiogram. Unless a child has pulmonary vascular disease, results of operation for total anomalous pulmonary venous connection in patients beyond infancy are generally good.[525] [526] The procedure consists of creating

an anastomosis between the common pulmonary venous channel and left atrium and closing the atrial defect and the anomalous venous pathway. Improved results of operation in infancy require that postoperative pulmonary venous hypertension be averted by construction of a generally large anastomosis with or without enlargement of the left atrium. Normal hemodynamics and cardiac function have been demonstrated after surgical correction.

Partial Anomalous Pulmonary Venous Connection

In this condition, one or more of the pulmonary veins, but not all, are connected to the right atrium or to one or more of its venous tributaries. An atrial septal defect, particularly one of the sinus venosus type, commonly accompanies this anomaly; the usual connection involves the veins of the right upper and middle lobes and the superior vena cava.[518] Exclusive of atrial septal defects, major additional cardiac malformations occur in about 20 percent of patients: these include VSD, tetralogy of Fallot, and various complex anomalies.

In the absence of associated anomalies, the physiological disturbance is determined by the number of anomalous veins and their site of connection, the presence and size of an atrial septal defect, and the state of the pulmonary vascular bed.[527] In the usual patient with isolated partial pulmonary venous connection, the hemodynamic state and physical findings are similar to those in atrial septal defect. Rarely, venous drainage of the right lung is into the inferior vena cava. This condition often is associated with hypoplasia of the right lung, dextroposition of the heart, pulmonary parenchymal abnormalities, and anomalous system supply to the lower lobe of the right lung from the abdominal aorta or its main branches. This complex has been designated the *scimitar syndrome* because of the characteristic roentgenographic finding of a crescent-like shadow in the right lower lung field that is produced by the anomalous venous channel.[528]

Transesophageal echocardiography is highly diagnostic of partial anomalous pulmonary venous connection and can obviate catheterization and angiography.[524] At *cardiac catheterization,* partial anomalous pulmonary venous connection to the coronary sinus, azygos vein, or superior vena cava may be identified by careful and frequent oximetry sampling. Oximetry is of limited value when the anomalous connection is to the inferior vena cava because of both reduced flow through the right lung and the contribution to the vena caval stream of highly oxygenated blood from the renal veins. Selective angiography is most helpful in cases in which the anomalous veins connect far away from the right atrium. Surgical repair offers definitive therapy at low risk if pulmonary vascular obliterative disease has not yet developed.

Malpositions of the Heart and Cardiac Apex

Positional anomalies of the heart are conditions in which the cardiac apex is located in the right side of the chest (dextrocardia) or is centrally located (mesocardia), or in which the heart is in its normal location in the left side of the chest but the position of the viscera is abnormal (isolated levocardia). Such hearts commonly are abnormal with respect to chamber localization and great artery attachments: associated complex intracardiac and extracardiac lesions are common.

Problems of terminology abound in the literature describing these complex cardiac anomalies, although sensible and uniform systems of classification are available.[529] [530]

ANATOMICAL FEATURES.

Defining the cardiac anatomy in instances of cardiac malposition requires a description of three cardiac segments--the visceroatrial situs, the ventricular loop, and the conotruncus (the atria, ventricles, and great arteries, respectively). In addition to defining positional interrelation, the description of the malposed heart also must include the connections of the ventricles to the atria and great arteries as well as chamber identification, both morphologically and functionally.

DIAGNOSIS.

To accomplish accurate diagnosis may require a synthesis of findings from noninvasive tests such as two-dimensional echocardiography, CT, and magnetic resonance imaging,[531] as well as hemodynamic and cineangiographic findings obtained at cardiac catheterization. Expert echocardiographers analyze, separately and independently of adjacent segments, each cardiac segment (atria, AV canal, ventricles, infundibulum, and great arteries) in terms of both situs and alignments.[532] [533]

In general, the determination of the body situs indicates the position of the atria. The visceral situs usually can be determined by the location of the stomach bubble and liver on a routine roentgenogram and of the inferior vena cava by means of echocardiography or the position of a cardiac catheter or by means of a CT or venous or radioisotope angiocardiogram. Atrial anatomy is best investigated noninvasively by using subxiphoid long- and short-axis and apical four-chamber echocardiographic views. Venous contrast injections may be useful to define systemic venous connections.

Situs solitus is the normal arrangement of viscera and atria, with the right atrium right sided and the left atrium left sided. Situs solitus is further characterized by a trilobed right lung and eparterial bronchus (i.e., the right upper lobe bronchus passes above the right pulmonary artery), a bilobed left lung and hyparterial bronchus (i.e., the left bronchus passes below the left pulmonary artery), the major lobe of the liver on the right, a left-sided stomach and spleen, and right-sided venae cavae. *Situs inversus* is a mirror image of normal. *Situs ambiguus* or visceral heterotaxy refers to an anatomically uncertain or indeterminate body configuration. The latter often is seen in association with congenital asplenia, which resembles bilateral right-sidedness (right isomerism), and congenital polysplenia, which resembles bilateral left-sidedness (left isomerism).[530] [531] [532] [533] [534] [535]

ASPLENIA (RIGHT ISOMERISM).

Cardiac anomalies commonly associated with asplenia include anomalous systemic venous connection, atrial septal or complete endocardial cushion defect, common ventricle, transposition of the great arteries, severe pulmonic stenosis or atresia, and anomalous pulmonary venous connection usually infradiaphragmatic or to the superior vena cava-atrium junction. Polysplenia (left isomerism) commonly is associated with absence of the hepatic portion of the inferior vena cava with azygos continuation, bilateral superior venae cavae, anomalous pulmonary venous connection, and atrial septal defect (either ostium secundum or endocardial cushion). Pulmonic stenosis and double-outlet right ventricle are each observed in about 25 percent of cases. It is important to recognize these complex syndromes to distinguish them from forms of cyanotic heart disease that may be more amenable to corrective surgical therapy. In many of these patients, improvement results from palliation by modifications of the Fontan procedure, despite anomalies of systemic and pulmonary venous return in association with single ventricle anatomy.[536] [537] Diagnosis is suggested by a symmetrical liver shadow roentgenographically and, in asplenia, by the presence of Howell-Jolly and Heinz bodies in red blood cells demonstrated on blood smear, and it is confirmed by a negative or abnormal radioactive spleen scan.

Once the type of visceral situs is defined, it is necessary to describe the bulboventricular loop. The primitive cardiac tube normally bends to the right (D-loop), and thus the anatomical right ventricle is brought to the right of the anatomical left ventricle. An L-loop brings the morphological right ventricle left-sided relative to the morphological left ventricle. The L-loop is normal in the presence of situs inversus, but in situs solitus it is synonymous with inverted ventricles.

VENTRICULAR MORPHOLOGY.

The number, morphology, and size of the ventricles can be ascertained by using various echocardiographic views. The morphological features of each ventricle also can be identified angiographically. The anatomical right ventricle is equipped with a tricuspid valve, is highly trabeculated, and contains the septal band of the single papillary muscle; its infundibulum lies anterior to and superiorly beyond the outlet of the left ventricle. The anatomical right ventricle usually connects with whichever of the two great arteries is the more anterior. The anatomical left ventricle is smooth walled and contains an outlet that lies posterior to the right ventricular infundibulum; its entrance is guarded by a bicuspid mitral valve, the anterior leaflet of which is normally in continuity with elements of the semilunar valve at its outlet. On echocardiographic examination, the insertion of the AV valves assists identification of the ventricle. The tricuspid valve is more apically situated than the mitral valve and is attached to the ventricular septum by papillary muscles, whereas the mitral valve is not. The right ventricular apical musculature is coarse and contains a moderator band of muscle.

GREAT ARTERIES.

The great arteries are described in terms of their positional interrelations and their ventricular connections. Each outflow tract and semilunar valve should be examined in both long- and short-axis echocardiographic views.[533] The ventriculoarterial alignments may be determined by direct visualization from the subxiphoid window. The relation between the great arteries can best be demonstrated noninvasively using parasternal short-axis echocardiographic views, which display the semilunar roots. The aortic arch and brachiocephalic arteries are seen well using suprasternal notch views. The pulmonary artery is seen from high parasternal or suprasternal notch short-axis sections. The ventricular attachments may be normal or may form the anomalies of double-outlet right or left ventricle or transposition. The arterial

interrelations are described as D(dextro), in which the ascending aorta sweeps toward the right and lies to the right of the main pulmonary artery; L(levo), in which the ascending aorta sweeps toward the left and lies to the left of the main pulmonary artery; or A(antero), which is the rare situation in which the aorta lies directly in front of the pulmonary artery. The D, L, and Adescriptions of the aorticopulmonary artery interrelations should not be confused with the D- or L-loop designation of the ventricular interrelations.[530]

Using segmental sets composed of descriptive units of visceroatrial situs/ventricular loop/great artery relations greatly simplifies expression of the type of cardiac anatomy present in cardiac malposition. For example, the normal heart in a patient with situs inversus and dextrocardia is referred to as inversus/Lloop/Lnormal; complete transposition of the great arteries in a patient with situs inversus is referred to as inversus/Lloop/Ltransposition; functionally corrected transposition in a patient with situs solitus is referred to as solitus/Lloop/Ltransposition; dextrocardia and functionally corrected transposition is designated solitus/Dloop/Dtransposition with dextrocardia.

After the cardiac chambers are diagnosed functionally (arterial and venous), the positional and morphological relations are understood, and the presence of associated anomalies is established, the principles of medical and surgical treatment apply to these cardiac malpositions as they do to normally located hearts.[536]

OTHER CONDITIONS

Congenital Pericardial Defects

Isolated pericardial defects (see Chap. 50) are rare. They most commonly occur in males and usually are left sided, although they may be right sided, diaphragmatic, or total.[538] The anomaly is produced by deficient formation of the pleuropericardial membrane or, if diaphragmatic, defective formations of the septum transversum. Associated congenital anomalies of the heart and lungs occur in about 30 percent of cases. Most patients with the isolated defect are asymptomatic. Nonspecific anterior chest pain may be the result of torsion of the great arteries due to absence of the stabilizing forces of the left pericardium.

With complete absence of the left pericardium, a conspicuous apical impulse may be noted to be shifted leftward to the anterior or midaxillary line. ECG changes may be related to levoposition of the heart; a leftward displacement of the QRS transition in the precordial leads and vertical or right-axis deviation are usual. The diagnosis may be suggested by chest roentgenograms. With complete left pericardial absence, the heart is levo-posed, and the aortic knob, pulmonary artery, and ventricles form three prominent left heart border convexities.

A partial left pericardial defect may be suspected on the basis of various degrees of prominence of the pulmonary artery and/or the left atrial appendage. Echocardiographic findings often mimic those observed in patients with right ventricular volume overload (enlarged right ventricle and abnormal ventricular septal motion), probably owing to the altered cardiac position and motion with the thorax.[539] Other echocardiographic clues include lateral extension of the left atrial appendage as it herniates through the pericardial defect; this is best seen in short-axis views. The anomaly can be definitively diagnosed by CT or magnetic resonance imaging.[540] Cardiac catheterization is of little diagnostic value.

Complete absence of the left pericardium requires no treatment. Partial defects, however, may impose serious risks, including herniation and strangulation of the ventricles or left atrial appendage with left-sided defects or the possibility of a superior vena cava obstructive syndrome with right-sided defects.[541] In the diaphragmatic type, cardiac compression by abdominal contents requires surgical repair. Partial left or right defects may be closed with a patch of mediastinal pleura.

Single Atrium

Single or common atrium is a rare, isolated defect. The anomaly consists of an absent atrial septum, usually with a cleft in the anteromedial leaflet of the mitral valve and, occasionally, with a cleft tricuspid valve as well. The lesion may be one component of the Ellis-van Creveld syndrome (see Table 43-2 (Table Not Available)) or of the complex cardiac anomalies in patients with asplenia or polysplenia.

Single atrium may be suspected clinically by the presence of cardiac murmurs of an atrial septal defect and mitral regurgitation associated with mild cyanosis, roentgenographic evidence of cardiac enlargement and increased pulmonary blood flow, and ECG features of AV septal defect. An absence of echoes from any part of the atrial septum is the essential feature of two-dimensional echocardiographic examination, which also may show a cleft anterior mitral leaflet, increased right ventricular end-diastolic dimension, paradoxical ventricular septal motion, and a dilated, pulsatile pulmonary trunk. Angiographically, the absence of the atrial septum produces a large, globe-shaped single atrial structure. Selective left ventricular angiocardiography shows the characteristic gooseneck appearance seen in the various forms of AV septal defect. In the absence of pulmonary vascular obstructive disease, surgical correction is indicated by means of a prosthetic patch.

Single Ventricle (Univentricular Atrioventricular Connection)

Hearts with univentricular AV connection constitute a family of complex lesions in which both AV valves or a common AV valve open into a single ventricular chamber.[542] Terminology is varied, and the anomaly often is referred to as a double-inlet, single, or common ventricle, which is imprecise but useful shorthand for the entity. The definition excludes examples of tricuspid or mitral atresia. Single ventricle is almost always accompanied by abnormal great artery positional relations; the incidence of L-malposition of the great arteries is about equal to that of D-malposition. Associated anomalies are common and include, in particular, pulmonic valvular or subvalvular stenosis, subaortic stenosis, total or partial anomalous pulmonary venous connection, and coarctation of the aorta.

MORPHOLOGY.

In about 80 percent of patients, the single ventricle morphologically resembles a left ventricular chamber that is separated from an infundibular outlet chamber by a bulboventricular septum.[543] The opening is variously called the bulboventricular foramen and VSD. The infundibular chamber is considered to represent developmentally the outflow tract of the right ventricle. The usual AV connection is transposition; when the heart is left sided, the connection is usually L-transposition, whereas it is usually D-transposition when the heart is right sided. When the great arteries are malposed, the infundibulum lying anteriorly at the basal position of the single ventricle communicates with the aorta and may be in one of two positions: noninverted (D-malposition), when it is situated at the right basal aspect of the heart, or inverted (L-malposition), when it is located at the left base of the heart. In the unusual situation in which the great arteries are normally related, the infundibulum communicates with the pulmonary trunk.[542] *Double-inlet left ventricle* is a term used synonymously to describe the most frequently encountered single ventricular chamber that has the anatomical characteristics of the left ventricle. Less commonly, the single ventricular chamber resembles a right ventricle (double-inlet right ventricle) or contains features suggestive of both ventricles or neither one; the latter two situations occasionally have been designated common ventricle and single ventricle of the primitive type, respectively.

CLINICAL FINDINGS.

Depending on the associated anomalies, the clinical presentation of single ventricle mimics other conditions in which cyanosis and decreased or increased pulmonary blood flow coexist, e.g., tetralogy of Fallot or tricuspid atresia in the former instance or complete transposition of the great arteries and double-outlet right ventricle in the latter. The *ECG* in double-inlet left ventricle without inversion of the infundibulum (D-malposition) usually shows features of left ventricular hypertrophy. with infundibular inversion (L-malposition) the electrical forces are directed anteriorly and rightward, as they are in ventricular inversion without associated defects. In patients with the more primitive types of common or single ventricle, a repetitious rS pattern is seen in all the precordial ECG leads. *Chest roentgenographic* findings resemble those observed in patients with complete (dextro-) transposition of the great arteries or functionally corrected (levo-) transposition of the great arteries without features distinctive of single ventricle.

ECHOCARDIOGRAPHY.

Two-dimensional and Doppler echocardiography are extremely important to demonstrate ventricular anatomy and to recognize associated intra- and extracardiac anomalies (Fig. 43-67) . A segmental approach should be used for accurate and complete echocardiographic evaluation. Thus, precise details are required of the basic anatomy of atrial and visceral situs, location of the cardiac apex, the extracardiac course of the great arteries, and systemic and pulmonary venous connections.

In those patients in whom two separate AV valves communicate with the single ventricular chamber, *echocardiography* (see Chap. 7) suggests the correct diagnosis when echoes are visualized from the two valves without an intervening interventricular septum. In the absence of ventricular septal echoes when the two valves are not visualized simultaneously, they may be identified separately with a careful long-axis sweep of the ventricle. It is possible to detect the presence of a small outflow

chamber anterior to the AV valves by using subcostal or parasternal short-axis views and a plane orthogonal to the long-axis plane (see Fig. 43-63).

The single ventricle with a single AV valve is suspected when the excursion of echoes from the single valve located posteriorly in the

Figure 43-67 Echo images of a double-inlet left ventricle type of univentricular heart. *Top,* Subcostal coronal view shows the right atrium (RA) giving rise to a tricuspid valve guarding entry into a main chamber (M CH) of left ventricular morphology from which the pulmonary artery (PA) arises. The arrow indicates the small ventricular septal defect (bulboventricular foramen) entering into an outflow chamber (O CH), which gives rise to the aorta (AO). *Middle,* Orthogonal subcostal sagittal equivalent to the top frame. The left atrium (LA) is seen above the main chamber of left ventricular morphology (V). The arrows indicate the origin of the left and right atrioventricular valves within the same ventricular chamber. The pulmonary artery (PA) arises from the main chamber, and the long narrow bulboventric ular foramen is shown to enter the outlet chamber (O Ch.), with its connection to the aorta. *Bottom,* Apical four-chamber view shows the right atrium (RA) and the left atrium (LA) with their corresponding valves (arrows) entering into the common large ventricle (V).

ventricular chamber is of large amplitude. Enhanced assessment of the AV valve in patients with single ventricle is provided by Doppler echocardiography.[544] Magnetic resonance imaging provides valuable information complementary to echocardiographic study. Selective ventriculography is necessary to delineate with certainty the anatomical type of single ventricle and to diagnose the associated great artery interrelations and the presence or absence of additional lesions.

SURGICAL TREATMENT.

Modifications of Fontan approach are generally applied to patients with all types of anatomical and functional single ventricle.[545] [546] [547] Surgical outcome is related to the creation of an unobstructed pathway from the systemic veins to the pulmonary arteries, low pulmonary vascular resistance, and a compliant, well-functioning ventricle. In most centers, Fontan procedure is divided into two stages, an initial superior vena cava-pulmonary artery anastomosis (bidirectional Glenn shunt or hemi-Fontan procedure: Fig. 43-68), followed later by completion of the Fontan procedure directing flow from the inferior vena cava to the amalgamation of the superior vena cava and the branch pulmonary arteries. At first-stage operation, prior systemic-pulmonary shunts are eliminated and any areas of distortion or narrowing of the pulmonary arteries are repaired, particularly if a prior pulmonary artery banding was performed to limit pulmonary blood flow.

At our center, the complete Fontan procedure is accompanied by placement of a snare around the atrial septal defect to control its size postoperatively,[548] whereas in other centers, fenestrations in the atrial baffle may be used.[549] [550] [551] [552] These procedures appear to reduce significantly postoperative morbidity from pericardial effusions and significantly improve survival. Results of early bidirectional cavopulmonary shunting in young infants are encouraging. The objective of this approach early in life is to yield a more suitable Fontan candidate while reducing ventricular volume overload and repeated palliative procedures. Subaortic stenosis, a common occurrence in patients with univentricular heart and malposed great arteries, occurs as a result of a restrictive bulboventricular foramen (VSD) or as a consequence of ventricular hypertrophy from a previous pulmonary banding operation.

The *Damus-Kaye-Stansel operation,* consisting of anastomosis of the pulmonary artery to the ascending aorta, is a generally successful approach to this problem.[552] After operation, all patients need continued close surveillance.[553] [554] [555] [556] Complications include thromboembolic phenomena and atrial arrhythmias. Survivors generally lead active lives with exercise levels less than normal but relevant to ordinary daily life.

VASCULAR RINGS

MORPHOLOGY.

The normal development of the aortic arch system is described earlier (see Fig. 43-3). The term *vascular ring* is used for those aortic arch or pulmonary artery malformations that exhibit an abnormal relation with the esophagus and trachea, causing compression, dysphagia, and/or respiratory symptoms.[557] The most common and serious vascular ring is produced by a double aortic arch in which both the right and left fourth embryonic aortic arches persist. In the most common type of double aortic arch, there is a left ligamentum arteriosum or ductus arteriosus and both arches are patent, the right being larger than the left. A right aortic arch with a left ductus or ligamentum arteriosum connecting the left pulmonary artery and the upper part of the descending aorta and with an anomalous right subclavian artery arising from the left descending aorta are additional important vascular ring arrangements.

Figure 43-68 A bidirectional cavopulmonary artery shunt with patch occlusion of the superior vena cava right atrial junction (hemi-Fontan procedure) using direct cannulation of the superior and inferior venae cavae and a single arterial cannula. The main pulmonary artery is shown divided and oversewn, but in some cases it may be allowed to remain patent. Connections are made between both ends of the divided superior vena cava and the pulmonary artery. A subsequent Fontan operation involves only removal of the patch at the junction of the superior vena cava and the right atrium and placement of the intraatrial baffle to divert the inferior vena caval blood up to the superior vena cava orifice. *(From Castaneda A, Jonas RA, Mayer JE Jr, et al: Cardiac Surgery of the Neonate and Infant. Philadelphia, WB Saunders, 1994, p 263.)*

The latter anomaly frequently exists in cases of tetralogy of Fallot and otherwise uncomplicated coarctation of the aorta. An unusual cause of tracheal compression is the vascular sling created by an anomalous left pulmonary artery that arises from a rightward, elongated pulmonary trunk and courses between the trachea and esophagus before it branches normally within the left lung.[558] This arrangement commonly is associated with other cardiac and extracardiac anomalies.

CLINICAL FINDINGS.

The symptoms produced by vascular rings depend on the tightness of anatomical constriction of the trachea and esophagus and consist principally of respiratory difficulties, cyanosis (associated especially with feeding), stridor, and dysphagia. The ECG appears normal unless associated cardiovascular anomalies are present. The barium esophagogram is a useful screening procedure. Prominent posterior indentation of the esophagus is observed in the common vascular ring arrangements, although the pulmonary artery vascular sling produces an anterior indentation. Unusual and rare aortic arch anomalies may create rings that impinge on the trachea but do not compress the esophagus and are detected not by this simple radiographic procedure but rather by bronchoscopy. Selective contrast angiography delineates the anatomy of the aorta and its branches or the course of the main pulmonary arteries. CT and magnetic resonance imaging offer excellent imaging alternatives.[559]

MANAGEMENT.

The severity of symptoms and the anatomy of the malformation are the most important factors in determining treatment. Patients, particularly infants, with respiratory obstruction require prompt surgical intervention. Operative repair of the double aortic arch requires division of the minor arch (usually the left).[560] A reported 10 to 20 percent operative mortality is related, in part, to problems in postoperative respiratory care, especially when there is coexistent residual anatomical tracheal narrowing. Patients with a right aortic arch and a left ductus or ligamentum arteriosum require division of the ductus or ligamentum and/or ligation and division of the left subclavian artery, which is the posterior component of the ring. Video-assisted thoracoscopy holds promise as an alternative to open thoracotomy for management.[561] Operation seldom is indicated for patients with an aberrant right subclavian artery derived from a left aortic arch and left descending aorta. In patients with a pulmonary artery vascular sling, operation consists of detachment of the left pulmonary artery at its origin and anastomosis to the main pulmonary artery directly or by way of a conduit of its proximal end brought anterior to the trachea.[560] Some patients with persistent respiratory symptoms require postoperative evaluation of residual anatomical obstruction, tests of pulmonary function, and bronchodilator therapy.[562]

CONGENITAL ARRHYTHMIAS

This classification refers to arrhythmias that are present in infancy, whose causes, when known, relate to a structural malformation or defect of the conduction system or to an acquired prenatal condition such as myocarditis, hypoxia acidosis, or transplacental passage of a drug or substance from mother to fetus. In these latter examples, the substrate for the postnatal expression of the rhythm disturbance existed before birth and the arrhythmia is therefore designated congenital. Complete heart block and supraventricular and ventricular tachycardias are the most common important congenital arrhythmias.[563] The electrophysiological and ECG features of these arrhythmias are discussed elsewhere (see Chaps. 23 and 25).

Congenital Complete Heart Block

The AV node and the His bundle originate during fetal development as separate structures and later join together. Anatomical studies have shown the basic lesion in congenital complete heart block to consist of discontinuity between the atrial musculature and the AV node or the His bundle, if the AV node is absent. The anatomical interruption occasionally can be situated between the AV node and the main His bundle or within the bundle itself.[564] No cause is known for the vast majority of cases of congenital heart block in infants, who usually have otherwise anatomically normal hearts. However, fetal myocarditis, idiopathic hemorrhage and necrosis involving conduction tissue, and degeneration and fibrosis related in some instances to the transplacental passage of anti-SSA/Ro-SSB/La antibodies and other immune complexes from mothers with systemic lupus erythematosus all are entities capable of causing congenital heart block.[565] It is not clear if medical treatment in high-risk pregnancies aimed at reducing antibody titers will modify immunopathologic damage to the fetus. Less often, congenital heart block can be associated with various forms of congenital heart disease, the most common malformation being congenitally corrected transposition of the great arteries.[566]

Detection of consistent fetal bradycardia (heart rate 40 to 80 beats/min) by auscultation, fetal echocardiography (Fig. 43-69) , or electronic monitoring allows anticipation of the correct diagnosis. A newborn, especially with a ventricular

Figure 43-69 M-mode recording taken from the four-chamber fetal reference image shown in the lower right corner. The image is inverted, with the M-mode reference from fetal left ventricle (LV) through to the right atrium. In the M-mode, the ventricle is seen above (V) and the atrium (A) is seen below. The ventricular rate is approximately 48 beats/min, whereas the atrial rate is approximately 150 beats/min. There were no structural cardiac abnormalities. The mother had lupus erythematosus.

rate less than 50 beats/min and atrial rate in excess of 150 beats/min, is at highest risk; the presence of an associated cardiovascular anomaly greatly lessens the chances of survival. Treatment is not required for asymptomatic infants. Digitalization is recommended for infants in congestive heart failure, irrespective of complete heart block. Isoproterenol and other sympathomimetic drugs and atropine do not have permanent or beneficial effect. Congestive heart failure and Stokes-Adams attacks require pacemaker treatment at any age, including transvenous or transatrial placement of endocardial leads in older children or permanent epicardial pacemaker insertion in infants and small children.[567] [568] Various problems can be anticipated after pacemaker implantation related to growth of the patient, which stresses the electrical lead system; the fragility of the lead system in a physically active young patient; and the limited life span of the pulse generator. Patients who have congenital complete heart block and who survive infancy usually remain asymptomatic until late in childhood or adolescence.[569]

Supraventricular Tachycardia

Paroxysmal tachycardia of supraventricular origin can have its origin in utero or in the immediate postnatal period. The most frequent arrhythmias producing symptoms are paroxysmal supraventricular tachycardia with or without ventricular preexcitation, atrial flutter, and junctional tachycardia. The arrhythmia can cause intrauterine cardiac failure and hydrops fetalis[570] [571] ; its detection and persistence prenatally should prompt consideration of administration of digitalis or, if that fails, of propranolol, quinidine, flecainide, or amiodarone to the mother if amniocentesis indicates surfactant deficiency and fetal lung immaturity, because early delivery is not indicated if the baby will have hyaline membrane disease. Experience with antiarrhythmic drugs, delivered by umbilical venous infusion, is limited.[96] Cesarean delivery or induced labor may be indicated if the fetus is close to term. No cause is recognized for the disorder in the majority of infants. Transplacental passage of long-acting thyroid stimulators (LATSs) and immune gamma-2-globulin from hyperthyroid mothers, hypoglycemia, and Ebstein's anomaly of the tricuspid valve occasionally are causative. WPW syndrome (see Chaps. 23 and 25) is present in 10 to 50 percent of infants with supraventricular tachycardia.[572] Symptoms produced by the tachyarrhythmia after birth are subtle and often remain undetected until signs of heart failure have been present for 24 to 36 hours. Conversion to normal sinus rhythm usually is accomplished by administration of digitalis or adenosine, direct-current cardioversion, transesophageal atrial pacing, or a diving reflex elicited by covering the face with an ice-cold wet washcloth for 4 to 5 seconds.[573] [574] [575] [576] [577] Conversion should be followed by digitalization on a prophylactic basis. Common practice consists of digitalis treatment for 9 to 12 recurrence-free months followed by its abrupt cessation.[578] Recurrence of tachycardia, particularly in those infants with ventricular preexcitation, is not uncommon; maintenance of normal rhythm may require administration, alone or in combination, of digitalis, phenytoin sodium, flecainide, sotalol, and amiodarone.[573] The rate of recurrence falls substantially between ages 2 and 10 years, with a slight rise during adolescence. In general, the prognosis is excellent.

ELECTROPHYSIOLOGICAL STUDIES.

Beyond infancy, patients whose condition is refractory to medical treatment are candidates for electrophysiological catheter evaluation, which facilitates differentiation of a causative ectopic anatomical focus within the atria from accessory conduction pathways (see Chap. 23).[579] [580] If the tachyarrhythmia is refractory to pharmacological therapy, it should be treated definitively by radiofrequency catheter ablation of accessory pathways (see Chaps. 23 and 25). This procedure has become the primary treatment modality for most symptomatic rhythm disturbances in children. The results are excellent, with success exceeding 90% and very low complication rates.[576] [580] [581] Among the advantages of this approach is that successful ablation represents a cure; the heart is left structurally normal, and the cause of the arrhythmia is eliminated. Further, the need for antiarrhythmic agents with the concomitant risk of side effects or proarrhythmia is eliminated.

ATRIAL FLUTTER (see Chaps. 23 and 25).

Uncommonly, atrial flutter is the cause of supraventricular tachycardia,[582] especially in newborn infants with hydrops fetalis, whose intrauterine tachyarrhythmia

is an alternation between supraventricular tachycardia with WPW syndrome and atrial flutter. Another common clinical setting for atrial flutter is in infants younger than 6 months with an otherwise normal heart, who show frequent premature atrial complexes. In infants, classic flutter waves may not be present on a surface ECG or rhythm strip; detection may require recordings of transesophageal atrial electrograms. Acute treatment with electrical conversion or transesophageal overdrive pacing effectively terminates the rhythm disturbance.[583] If synchronized direct-current electrocardioversion is used, standby pacing should be available; if overdrive pacing is used, the same pacing catheter can be used to pace the heart in the event of asystole. Long-term drug treatment with digitalis, digitalis plus quinidine, or amiodarone may uncommonly be required.

Junctional automatic tachycardia is characterized by a narrow QRS complex and AV dissociation, with the ventricular rate faster than the normal atrial rate. Ventricular dysfunction and congestive heart failure occur early, and the rhythm disturbance usually is not convertible to sinus rhythm by any medical treatment. When the latter falls and because sudden death is a risk, catheter ablation can be used to eliminate the tachycardia focus. Pacemaker implantation may be necessary if heart block results (see Chap. 25).

VENTRICULAR TACHYCARDIA.

Ventricular tachycardia is defined as three or more consecutive premature ventricular complexes (see Chap. 25). The definition, however, falls to identify a high-risk group. Infants or children who meet this criterion but seldom require treatment and seem to be at little risk have no symptoms and no evidence of anatomical heart disease. Potentially serious ventricular tachycardia in the newborn is associated with QT prolongation, mitral valve prolapse, and Marfan's syndrome. In these settings, the tachycardia is potentially life threatening and always merits treatment.[563]

Numerous genes causing long QT syndrome have been identified, confirming that the defects occurs in a transmembrane ion channel in most patients (see Chaps. 23 and 25).[584] The two most effective treatments are beta blockade and high thoracic left sympathectomy, which reduce the incidence of syncope and sudden death without affecting the QT interval. Trials of gene-specific therapy directed at the involved ion channel may be anticipated in the future.[584] Implantable defibrillators can be life saving in patients at risk for torsades de pointes and ventricular fibrillation.

The treatment of ventricular tachycardia (see Chap. 23) consists of intravenous administration of lidocaine, followed by direct-current electrical cardioversion. In the absence of QT prolongation but in the presence of mitral prolapse or other cardiac abnormalities, long-term treatment should be undertaken of multiform premature ventricular complexes, couplets, or ventricular tachycardia. In infants and children unresponsive to conventional or investigational antiarrhythmic drugs, consideration should be given to pacemaker implantation, cardiac sympathetic denervation, and perhaps implantation of a defibrilator.[585]
